ABSTRACT

The world is facing a climate crisis as a result of greenhouse gas (GHG)-driven warming. Many geothermal operators and researchers are actively implementing and finding new solutions to the challenge of abating GHG emissions from geothermal plants to ensure a sustainable future.

In geothermal power operations, non-condensable gases (NCG) are brought to the surface dissolved in / with the geothermal fluids. The most abundant geothermal gases are carbon dioxide (CO_2 - the most dominant NCG), hydrogen sulfide (H_2S) and methane (CH_4), with other gases considered trace gases. Their inability to condense (i.e., be turned into a liquid) by the cooling which occurs in geothermal power stations at the surface means NCGs are most often released to atmosphere during the power generation process. Decarbonization drivers for industry means reinjection of NCGs back into reservoirs is increasingly becoming standard practice at many locations globally, to close the emissions loop.

There is a need, and an opportunity, to find different uses and ways to abate the NCG emissions from geothermal plants that can be beneficial to operations, lower costs and potentially add value. In this paper, we examine several avenues of abatement through gas capture and re-use, into applications including horticulture, green fuels and chemicals production, and industrial uses, as an added benefit of geothermal energy production. Several pathways for utilization are illustrated that may have been overlooked.

1. Introduction

Geothermal power plants have high availability factors and, in most cases, produce significantly less GHG emissions than fossil-fuel driven plants, whilst having the constant output that other renewables do not have due to their reliance on daylight and weather conditions. However, geothermal plants can make contributions to decarbonization by addressing their GHG emissions profile.

Reinjection of GHG's back into reservoirs is increasingly becoming common practice. However, there are still challenges in this approach. For example, reservoirs may have limited ability to uptake reinjected gases without negative effects on production or scaling in the immediate vicinity. Additionally, flash-plant technology may have the challenge of oxygen introduced into the process

where direct contact condensers are used, which can increase the reactivity and corrosivity of the NCG stream.

Meanwhile, carbon dioxide, the most abundant NCG, is an essential processing gas in the modern world. Packaging, beverage production, agriculture, industrial processes, and several other industries rely on carbon dioxide gas as an essential input. There is an opportunity to capture and re-purpose NCGs for value-added uses, replacing fossil equivalents.

This paper summarizes the current challenges and opportunities for NCG abatement pathways. References are cited where data and experiences have been shared in the public domain, in many instances, the observations and recommendations stem from the authors' own experiences.

2. Non-Condensable Gas Emissions from Geothermal Power Plants

Produced geothermal fluids carry gases that are emitted in the process of extracting heat and power. These emissions challenge the notion that geothermal is an explicit 'green' source of energy. Geothermal power plants harness the heat stored in the Earth's crust to generate electricity from the fluids that permeate the subsurface. Geothermal fluid extracted from the underground reservoirs contains not only water, but also various dissolved gases, such as carbon dioxide (CO_2), hydrogen sulfide (H_2S), methane (CH_4), ammonia (NH_3) and nitrogen (N_2). During the geothermal production cycle, these gases must be processed using specialized gas trains as they do not stay condensed in the liquid phase at the operating conditions of the power plant. The NCGs are separated from geothermal steam in the condenser or binary heat exchanger and are usually vented to the atmosphere as byproducts, sometimes causing damage to site infrastructure and acting as environmental irritants.

Mclean and Richardson (2020) overview geothermal emissions from the New Zealand generation fleet, quantified in terms of CO_2e (CO_2 + methane equivalent), illustrating that overall, nearly 531 kilotonnes of CO_2e is emitted related to geothermal power generation. This highlights a significant emission profile for the nation's electricity production but also highlights an opportunity for finding innovative ways of repurposing these emissions since domestic CO_2 supply in New Zealand has become increasingly expensive (Olley, 2023).

2.1 Drivers to Reduce NCG & GHG Emissions

NCG emissions pose environmental and economic challenges for geothermal power generation as their emissions are closely regulated and, in New Zealand, bear the costs of emissions taxation, through the Emissions Trading Scheme (ETS). The New Zealand model taxes emissions similar to other jurisdictions where carbon taxation follows trading mechanisms and other cap-and-trade type initiatives (see Flues, 2020). Some financial benefits to consider in addressing GHG abatement for geothermal plants include:

- *Financial benefits of reducing carbon tax liability*: Reducing emissions from geothermal plants can save money by avoiding the costs of surrendering emission units under the emission trading schemes (where applicable), where costs are expected to increase over time.

- *Environmental benefits of reducing greenhouse gas emissions*: Reducing emissions from geothermal plants can help achieve climate change goals and demonstrate a commitment to sustainability and decarbonization.
- *Environmental benefits of reducing H_2S emissions*: Reducing H_2S emissions from geothermal plants can improve the local air quality and reduce the health and safety risks associated with exposure to toxic gas as well as ill-effects on plant infrastructure due to exposure to corrosive H_2S gas.

Even without financial incentives, operators may prefer to implement more sustainable solutions, such as reinjection or purification and sale of NCGs or derivatives, to boost their environmental performance and reputation. These actions show a commitment to corporate social responsibility, green energy, and earn the support of stakeholders. It also helps fight climate change and foster a low-carbon economy. However, operators of these plants are challenged to retrofit and repurpose the emissions in ways that will not affect plant operation and the sustainability and producibility of subsurface reservoirs.

3. Reinjection of NCGs into Reservoirs

Many locations around the world, including Iceland (Aradottir, *et al.*, 2020+1), New Zealand (Ruiz *et al.*, 2021) and Turkey (Layman, 2017; Yücetaş *et al.*, 2018), are now adopting the practice of sending GHG's back into reservoirs to close the emissions loop. The key advantage is the opportunity to dispose of GHGs, hydrogen sulfide and mercury emissions, which are often closely monitored and regulated.

Binary-cycle plants can usually capture NCGs and reinject them more easily than direct-contact condensing flash plants that use cooling circuits open to atmosphere that introduce air into the system. Geothermal flash plants can compress NCGs and inject them into brine handling systems, but there are challenges with methane, oxygen and nitrogen components that will not easily dissolve back into the brine and the increased corrosivity due to oxygen. Other challenges we believe need to be understood to achieve successful abatement through injection include:

- *Site Variability*: The uncertainty and variability of the NCG composition and flow rate at different sites and over time, which depend on the location, depth, and age of the reservoir, as well as the operational conditions of the power plant.
- *Chemistry & Geology*: The possible negative effects on the reservoir chemistry and geology, such as changing the pH, mineralogy, permeability, and fracture network of the rock formation, which could reduce the productivity and longevity of the reservoir.
- *Equipment*: The need for additional equipment, such as compressors, pipelines, and injection wells, increasing the capital and operational costs of the power plant.
- *Scaling & Corrosion*: The presence of oxygen from the condensing cycle introduces a major corrosion risk in brines, particularly those at high temperature and modified to reduce pH to control silica scale.
- *Energy consumption*: Energy intensity of gas abatement equipment and the parasitic loads on achieving economic success for geothermal power installations must be well understood and sensitivities tested.
- *Dissolved gases*: Keeping gases dissolved during transport to the well is critical for avoiding operational challenges, such as gas-locking of wellheads due to build-up of

pressure, as well as corrosion considerations from high gas concentrations in site infrastructure.
- *Containment failure*: There is a risk of releasing a gas cloud as a result of a containment failure in compressed gas lines or vessels.

Reinjection of NCGs into geothermal reservoirs requires careful evaluation of the technical, economic, and environmental feasibility of each case, as well as monitoring and modelling the reservoir behavior and performance (e.g. Figure 1). Considerations include:

- *Tracer test results*: Tracer tests can help indicate (e.g. Nyawir *et al.,* 2023; Kristjánsson *et al.*, 2016) what proportion of the injected fluid that returns to the production area. Operators can use this information to understand how much gas may find its way back to production areas (noting that mobility of gas-laden liquids may change compared with pre-injection results), which may increase both gas production from wells and possibly increase scaling risk.
- *Production and reinjection*: The production fluid is composed of a mixture of reservoir fluid unaffected by injection plus returns from reinjection. The reinjected fluid often has a higher gas concentration than that produced, due to evaporation.
- *Risks for the reservoir*: The main risks for the reservoir are scaling and plugging over widespread areas, and changes in gas concentrations that may affect the power output and injection capabilities (e.g., Byrne *et al.,* 2023; Kaya and Zarrouk, 2017). Concentration of gas may already be somewhat depleted if the plant has already been operating prior.
- *Concentration mechanism and model*: A concentration mechanism exists if all gases are forced into the reinjection stream and then return to the production area as demonstrated through modeling performed by Sevindik et al., 2023. The concentration changes expected due to returns can be estimated through models and validated during operation.
- *Best approach and learnings*: In our opinion, the best approach will be to slowly ramp up reinjection rates and monitor the system response over time as demonstrated by Abd Ghafar *et al.* (2022) at New Zealand's Ngatamariki field. The results at operations conducting gas injection are encouraging at locations like Ngatamariki, Ngāwha, Te Huka, and Hellisheidi (White, 2023, Abd Ghafar *et al.,* 2022, Ruiz *et al.,* 2021, Aradottir *et al.,* 2020), but are not directly applicable to all fields due to the different geologic setting and degrees of connectivity.

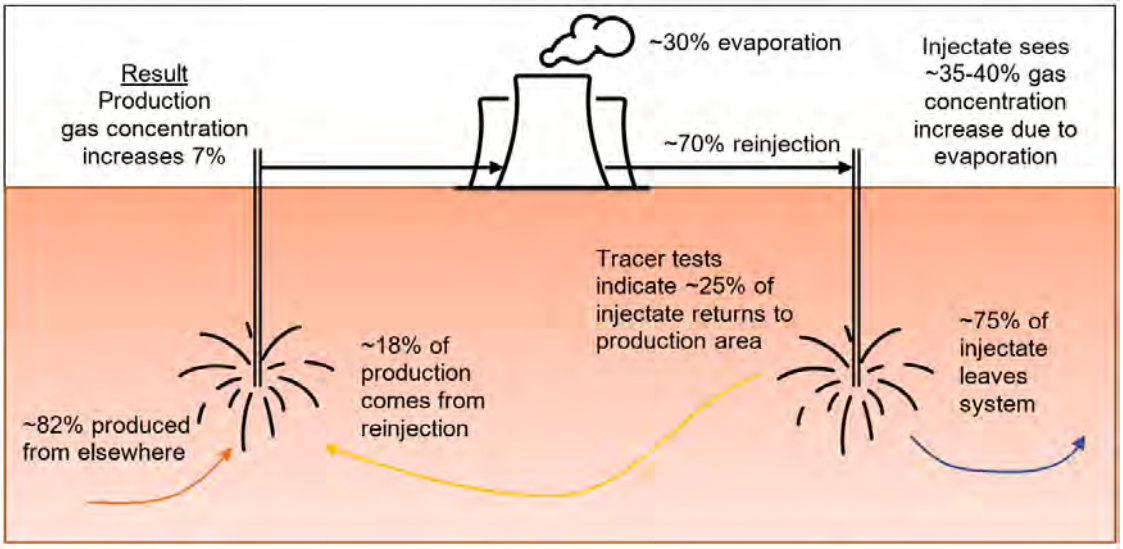

Figure 1: Conceptual model of Flash-Plant NCG reinjection. The pathway of NCGs reinjected into the reservoir will likely follow those seen in tracer testing but may also find new ways back to production areas particularly where gas or two-phase fluid zones exist.

4. Alternative Uses for CO_2 Emissions

Renewable energy sources such as geothermal, wind and hydro are anticipated to support the emergence of new low-carbon industries driven by electricity. Intermittency and market-driven electricity prices will favor technologies capable of flexible generation. Notably, there is potential in the concept of 'flexible geothermal' (Marsh *et al.*, 2023; Aljubran & Horne, 2023), particularly when aligned with the appropriate load or value-adding product. The flexible geothermal approach allows for large scale production and efficient storage when buffering electricity-heavy inputs during periods of low electricity prices, particularly where the storage duration is limited such as a daily oversupply cycle for electricity.

Likewise, a flexible approach to emissions management could realize economic and environmental benefits for operators. The examples below focus on CO_2, the most abundant NCG. While a known and vilified GHG, CO_2 is also an essential component of many industrial processes and is often produced as a byproduct of fossil fuels. By purifying and selling/using CO_2 from geothermal plants, new industries and supply vectors can be formed. This could create new revenue streams and support the development of low-carbon products and services, as well as displacing the need to produce CO_2 through traditional means.

4.1 Industrial Use of CO_2

There is the possibility of purifying and selling CO_2 from the geothermal NCG stream to a wholesaler or a direct user. This could reduce emissions, generate revenue, and provide a financial benefit from the avoided emissions taxation costs (where they exist). Liquid CO_2 is used in a variety of applications, including beverage carbonation, refrigeration, packaging, and fermentation. Gaseous CO_2 is used in a variety of applications, including packaging, fermentation, and animal stunning. An industrial user of gas would likely require specific levels of purification adapted from CO_2Meter (2019):

- Medical-grade CO_2 should be at least 99.5% pure and free of impurities, such as hydrocarbons, oxygen, and water.
- Food-grade CO_2 should be at least 99.9% pure and free of impurities, such as heavy metals, pesticides, and microbiological contaminants.
- Industrial-grade CO_2 should be at least 99% pure and free of impurities that could contaminate the product or process.

To meet the requirements of the food and beverage industry, the CO_2 would need to undergo purification and then be transported in liquid tanks or as bottled gas to customer/consumer markets (Brownsort *et al.*, 2019).

Direct collaboration with a new or established local industry is also possible. This approach offers several advantages, including enhanced certainty of supply volume and transport efficiencies (by piping directly) that can lead to competitive pricing. Moreover, partnering with an industrial entity nearby a geothermal site means access for the industry partner to renewable electricity, low-grade heat, fresh water, minerals, industrial-zoned land, and perhaps existing permits. There could be synergies with other local industries, such as in the New Zealand example at Kawerau or Wairakei/Tauhara where forestry offers a suitable feedstock for fuels production amongst other industrial outputs (McClintock *et al.*, 2020; Stephenson and Goodwin, 2019).

For horticulture, supplementation of CO_2 is a common practice in greenhouses. This is necessary because atmospheric CO_2 levels are typically low, and plants within closed greenhouse systems can rapidly deplete the available CO_2. By augmenting CO_2 levels, growers can enhance both the yield and quality of their crops (Nederhoff, 2021). Utilizing all the CO_2 from one power plant could support tens of hectares of glasshouse infrastructure by following the standard convention that 150 kg/Ha/hour of CO_2 is an optimal supply rate for closed greenhouse growing conditions (Nederhoff, 2022). For example, a 20-hectare glasshouse would require ~32,000 tons/annum of CO_2 to supplement growing, which would consume a significant portion of the ~37,578 tons/CO_2 per annum emitted at the Ngatamariki power station (Mclean & Richardson, 2020).

4.2 Geothermal CO_2 for Fuel & Chemical Production

Many efforts are being made globally to leverage CO_2 in the production of chemicals and fuels production (Grim *et al.*, 2022). This pathway offers several advantages: Firstly, it aids in mitigating overall greenhouse gas emissions by displacing more emissions-intensive production methods. Secondly, it promotes local production, reducing reliance on other countries and creates jobs for communities typically in need of employment opportunities. Some of the most common applications of CO_2 use in chemical and fuel production include:

- *Methanol*: A versatile chemical that can be used in a variety of applications, including as a fuel, a solvent, and as a raw material for other chemicals. Methanol can be produced from CO_2 by reacting it with hydrogen in the presence of a catalyst.
- *Urea*: A fertilizer that is used to improve crop yields. Urea can be produced from CO_2 by reacting it with ammonia.
- *Polycarbonates*: A type of plastic used in a variety of applications, including food packaging, electronics and construction. Polycarbonates can be produced from CO_2 by reacting it with epoxides.

- *Fuels*: CO_2 can be used to produce a range of fuels, including synthetic gasoline, diesel and jet fuel. These fuels can be produced by reacting CO_2 with hydrogen in the presence of a catalyst. Geothermal could potentially provide CO_2 through both NCG capture and direct-air capture (DAC) on-site, making for a circular fuel system (Figure 2).

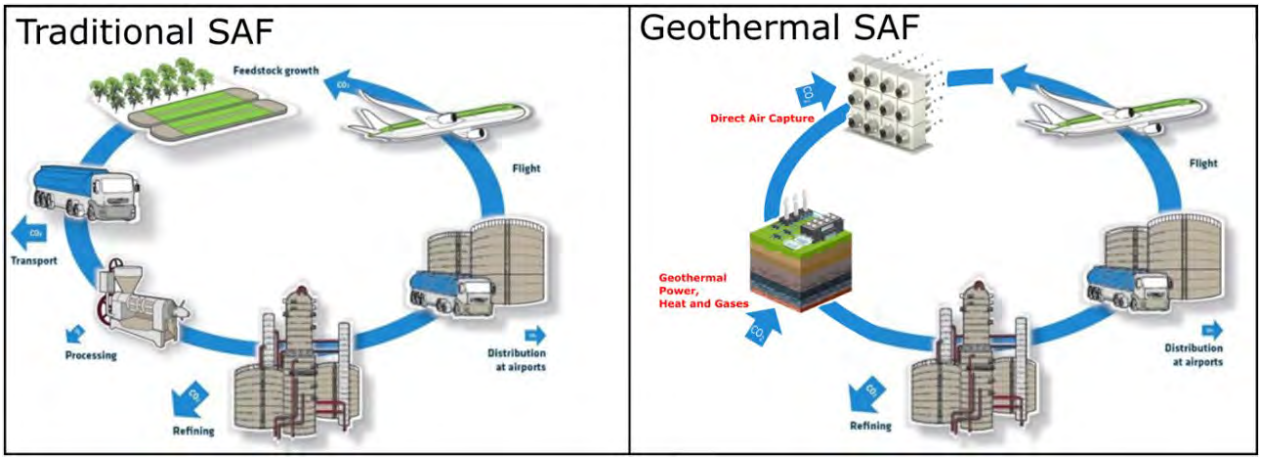

Figure 2: Traditional Sustainable Aviation Fuel (SAF) pathway versus a potential Geothermal SAF pathway. The need for external carbon feedstock is replaced by geothermal plant emissions and supplemented by direct-air capture (DAC) of CO_2 (Modified from Earth.org/sustainable-aviation-fuel-companies).

A compelling case study is that of Carbon Recycling International (Iceland) where an e-methanol pilot plant was developed using carbon emissions from a geothermal power plant in 2012. The George Olah Renewable Methanol plant is located within 1 km of the Svartsengi plant (IEA, 2019). In 2015, annual e-methanol production was 4,000 metric tons (1.1 million gallons) from this facility. The company is now focused on large scale international deployment of their technology into non-geothermal domains. This represents an example of how to meet the environmental goals of CO_2 reduction through repurposing of waste NCG streams.

5. Abatement Pathways

Whilst reinjection of CO_2 into geothermal reservoirs has recently increased, it is likely that a combination of abatement strategies will be needed to address the NCG emissions issue in its entirety. This paper has explored several avenues of abatement through both reinjection and via gas capture and re-use into non-geothermal commercial applications.

It is recommended that solutions be phased in a way to tackle the easiest to convert first, layering in more complex, and potentially more beneficial options as the technologies develop and mature. It is also likely that the economics will improve over time as fossil alternatives are gradually phased out. Table 1 shows a possible combination of pathways operators can consider in mitigating geothermal emissions.

Table 1: CO_2 abatement pathways for geothermal power-plants. Wholesale refers to selling CO_2 to a distributor; direct use refers to a model which the CO_2 is sold and utilized immediately adjacent to the existing geothermal production facility.

<table>
<tr><td colspan="3">No abatement
Some level of abatement will be possible at all plants, doing nothing should be avoided.</td></tr>
<tr><td>Reinject
Some reinjection will be possible, even beneficial, but stand-alone injection of all CO_2 will often be too risky.</td><td>Wholesale
Sale of all produced CO_2 may be possible but, depending on commercial terms, there are risks of varying returns and leaving significant value on the table long-term.</td><td>Direct Use
There may, eventually, be a direct use for all of the CO_2 in site adjacent new facilities (e.g. e-fuels), but this may take too long to build and secure.</td></tr>
<tr><td>Reinject + Wholesale
This option is best if there is some flexibility in the amount of CO_2 that can be injected to balance supply/demand changes in the wholesale market through a combined injection/sales strategy.</td><td>Wholesale + Direct Use
This option may be underpinned by strong demand for CO_2 where direct use and wholesalers compete for volume.</td><td>Reinject + Direct Use
Where there is strong and cheap CO_2 wholesale supply from that diminishes a need for geothermal CO_2, an industrial direct use would be needed to abate the balance not reinjected to the reservoir.</td></tr>
<tr><td colspan="3">Reinject + Wholesale + Direct Use
To achieve full abatement, it may be necessary to combine all three options in some proportion.</td></tr>
</table>

A significant effort would be required to decarbonize the global geothermal fleet in all locales and circumstances. The following list outlines recommended priorities for the geothermal industry to advance its knowledge base and, whilst not exclusive, gives a view as to what can be done to create a step-change in abatement of geothermal NCG emissions.

Advances in several fields of research are needed to provide solutions to geothermal emissions. These include:

- *Process Modeling* – Improved solubility and chemistry modeling, supported by laboratory testing of fluid mixtures. Widespread availability of gas process modeling tools to support projects and operations.
- *Carbon Measurement & Accounting* – Establish clear responsibilities within businesses. Design of new methods, and improvement to these methods, over time. Implement physical upgrades, such as better instrumentation.
- *Understanding Scaling / Corrosion* – Testing chemical reactions in the lab for each circumstance. Testing of plant side-streams, at pilot scale and full scale, and reporting these results. Corrosion product predictions and forecasting abilities for scaling. Improved data for corrosion rates in common geothermal steels for a wide range of dissolved gas chemistries.
- *Reinjection effects* – Results from different fields to build a picture of risk. Extensive tracer testing, repeated over time to understand return volumes times. Simulations to determine maximum injectable CO_2.

- *Overall Financial Evaluation* – Further developing financial models supports costs and benefits of emissions projects. Carbon credit price forecasting (with uncertainty) and investment triggers.
- *Plant Design and Estimation* – Short-listed plant design options and optioneering studies. Detailed estimates and equipment package development with pricing available. CAPEX and OPEX estimates for financial models.
- *State-of-the-art technology* – Forum for active developers and operators. Technology transfer from other industries. Further and wider strategy development.
- *Gas markets* – Conversation with existing gas suppliers. Negotiated commercial terms for sales. Evaluate sites and investments for CO_2 purification.
- *New Carbon Economies* – Strategize further how to engage and support new opportunities. Survey options and project the potential. Develop the commercial framework to capitalize, and triggers for investment. Monitor / ongoing support.
- *Regulatory Development* – Engage through geothermal associations to implement enabling policy statements and settings to support emissions abatement, particularly the re-use of gases.

6. Summary

The global geothermal industry can further contribute to reducing GHG emissions by reducing its own emissions profile. NCG emissions, containing GHGs such as CO_2 and CH_4, require dedicated thinking and consideration of how operators, in their particular circumstance, want to address these environmental degradants. As the world moves away from fossil-fueled industries, geothermal operators could add value through creative use of what has previously been regarded as waste byproduct. Solutions and potential uses for NCGs will be situation dependent. Whilst binary plants and flash plants with surface condensers have a marginally easier task to inject NCGs, they still face the issue of understanding how much NCG can be safely and sustainably injected back into the subsurface without harming the reservoir or wells. A combination of reinjection and gas off-take at the surface offers opportunities for gases to be utilized or repurposed as an industrial commodity and an enabler to extend the reach and positive impact of geothermal resources.

ABSTRACT

Geothermal power generation typically (but not always) results in greenhouse gas emissions as a result of these gases being naturally present in geothermal fluids. Globally, there is an increasing focus on reducing naturally occurring emissions from geothermal electricity generation to contribute to wider decarbonization goals and efforts. Several countries have already implemented carbon emissions pricing, generally as a carbon-dioxide equivalent (CO_2e) value, or are in the process of considering doing so. Three major factors will increase the focus of operators in reducing emissions: (1) increased direct costs due to carbon pricing, (2) societal pressure from the general public, and (3) investment funds or funding institutions with ESG targets that influence the pricing and availability of funding for both new and existing projects.

This paper attempts to catalog details of global geothermal power plants that have meaningful greenhouse gas emissions reduction technologies in place, with details on the methods employed. The authors intend to republish this paper with an updated catalog regularly, and we encourage feedback from readers to ensure this catalog is updated accurately.

1. Introduction

Geothermal power generation is typically a low-emission, reliable and renewable source of electricity that is powered by earth's natural heat. Most geothermal power plants release a small amount (relative to fossil-fueled power plants) of greenhouse gases – primarily carbon dioxide (CO_2) and methane (CH_4). These gases are not created in the geothermal power generation

process. Still, they are contained naturally in the fluid from the geothermal reservoir and are then often released as a part of the power generation process. When pressure is reduced, the fluid from the reservoir boils, and due to Henry's law, these gases preferentially move into the steam phase, with minimal amounts retained within the separated geothermal water (also known as brine). The release of the gases from the power generation process is a result of the gases being non-condensable – such that when geothermal steam is condensed in a plant heat exchanger (typically a condenser in a flash plant and a vaporizer or pre-heater in a binary plant) the non-condensable gases remain as gases. In contrast, the steam is condensed into water. These non-condensable gases can interfere with the power generation process by restricting steam flow due to pressure build-up, so they must be removed from the process, and this typically results in them being released to the atmosphere (via a gas extraction system if the gases are at a pressure below atmospheric) and vented above a cooling tower or air cooled condenser to disperse the gases safely.

Several technologies are in use today to reduce gaseous emissions from geothermal power plants, and several drivers for emissions reduction from these power plants are described below.

2. Drivers for emissions reduction

Reducing geothermal emissions to the atmosphere can have multiple benefits, and as a result there are multiple drivers for reducing emissions, including some where emissions reduction is a secondary benefit to a different primary objective.

2.1 Odor nuisance and compliance

Odor nuisance and strict environmental limits on hydrogen sulfide emissions in some jurisdictions have resulted in several geothermal power plants undertaking non-condensable gas (NCG) reinjection where all of the geothermal gases exsolving from the production fluid are reinjected into the reservoir, including carbon dioxide and methane as an alternative to hydrogen sulfide scrubbing systems. The Puna geothermal plant in Hawaii, USA, has been reinjecting all of the non-condensable gases produced at the plant to meet environmental requirements (Richard, 1990) since the plant came online in 1993, whilst the Coso geothermal power plant in California operated with the NCG reinjected for a time to manage hydrogen sulfide emissions before changing to hydrogen sulfide abatement technology in lieu of NCG reinjection (Layman, 2017). The Hellisheidi geothermal plant in Iceland commenced injection of a concentrated hydrogen sulfide stream from its NCGs to meet air emissions requirements, which was known as SulFix, and has grown to also include the injection of carbon dioxide under the CarbFix program (Gunnarsson et al., 2015; Juliusson et al., 2015) with approximately 75% of hydrogen sulfide injected and 30% of carbon dioxide injected (Ragnarsson et al., 2023).

2.2 Greenhouse gas reduction

Given the typically low greenhouse gas emissions associated with geothermal power generation, employing additional technology to further reduce greenhouse emissions is not always seen as the best use of limited resources or is seen to apply risk or costs to the process. However, in jurisdictions with a direct cost of greenhouse gas emissions, such as New Zealand, the installation of greenhouse gas abatement technology has increased significantly over the past few years as emissions prices have increased. In the United States of America, whilst there is no direct cost of greenhouse gas emissions as seen in New Zealand (McLean, 2023; Carmichael and Zarrouk,

2023), there are increasing off-taker requirements observed in power purchase agreements in particular markets such as California which will likely drive continued pricing premiums for new zero carbon emissions geothermal electricity (Ormat, 2024) due to geothermal baseload reliability compared to other renewable zero carbon emission generation technologies such as wind or solar. Future production tax credits (PTCs) or similar appear to be requiring zero carbon emissions geothermal electricity to be eligible (Ormat, 2024).

Risks associated with reducing gas emissions that need to be managed to enable gas emission reductions to occur include, but are not limited to:

- Lower pH in the injected fluid stream whereby gas has been dissolved into, resulting in the increased likelihood of corrosion and, a reduction in the lifespan of the pipeline or well assets and an increased likelihood of reliability concerns. This is often managed through the application of a suitable chemical corrosion inhibitor or in some instances, an increase in the steel quality through the use of more corrosion-resistant alloys.
- The mixing of geothermal gases that include H_2S can result in an increase in the deposition and scaling of mineral deposits in reinjection systems, particularly in the mixing zone itself. Saturation of heavy metal sulfides such as antimony sulfides is common in geothermal reinjection systems where H_2S is dissolved in the reinjection fluid due to the increased sulfide concentration and decreased pH.
- Possibility of building up gas pockets within the injection line or wells, in particular for wells with high injectivity where the pressure of the injected fluid stream can reduce and cause flashing of what was a single-phase fluid stream. These gas pockets can cause challenges with flow dynamics, especially during plant upsets or plant start-ups. Condensation of the gases also poses a risk of low-pH conditions that can cause corrosion, and this is a risk, in particular in wellhead infrastructure for high permeability wells. The risk of gas pockets is often managed by having venting setups at appropriate locations through the pipework to support plant start-up processes.
- Reservoir feedback, particularly if gases are reinjected close to a production area and/or near a steam cap, there is a possibility that gas concentrations in the total production can increase, increasing the potential for calcite scaling in the production well and decreasing power plant efficiency due to the higher NCG content of the production fluid. The quantity of gas can overwhelm the power plant cycle by causing gas concentrations outside the design range of the plant.
- Safety considerations are essential for many emissions reduction systems where concentrated gas mixtures are conveyed at elevated pressure, with geothermal gas mixtures often containing significant concentrations of hydrogen sulfide, which is toxic even at low concentrations. Where gases are separated or purified, the potential of forming flammable gas mixtures also needs to be considered where the concentration of flammable species such as hydrogen and methane are high (Piggot et al., 2021; Olafsdottir et al., 2023)

2.3 Commercial use of carbon dioxide

Processing geothermal non-condensable gases to produce a commercial carbon dioxide product has been undertaken to provide both food and industrial-grade carbon dioxide (Simsek, 2003; Layman, 2017) and also carbon dioxide for greenhouse use (Ngethe and Jalilinasrabady, 2021). While this process may not reduce geothermal greenhouse gas emissions in a strict sense

depending on how the captured carbon dioxide is used. The use of geothermal-sourced carbon dioxide may offset the carbon dioxide produced by other means, such as the combustion or production of fossil fuels. Preparing commercial-grade gases from geothermal NCGs requires the removal of the unwanted components of the gas mixture – typically hydrogen sulfide, ammonia, mercury and hydrocarbons – although other unwanted species may also be present. Where the amounts of these unwanted species are low adsorbents may be used to remove them from the bulk gas flow. However, for higher concentrations more complex equipment may be required, such as a complex iron-sulfur recovery system for H_2S, while elevated levels of hydrocarbons may require the use of a catalytic oxidizer (Catox) or Regenerative Thermal Oxidizer (RTO). The removal of gases such as oxygen and nitrogen is likely to require liquefaction and reboiler systems in the purification of carbon dioxide to a high standard.

2.4 Reservoir support

The presence of dissolved gases in geothermal fluid results in a lower boiling point for depth than would otherwise be the case. This typically results in geothermal production wells being easier to flow than if the fluid did not contain dissolved gases (for wells producing 2-phase fluid – a mixture of water and steam) through a lighter column within the wellbore. In lower enthalpy systems, the gas content of the geothermal fluid can be critical in keeping production wells flowing without the need for pumps through the decreased fluid density and lower boiling point for depth that results from the presence of dissolved gases in the reservoir fluid.

2.5 Silica scale prevention (pH modification)

Carbon dioxide has the potential to be used in geothermal brine pH modification systems to reduce silica polymerization and scaling in geothermal reinjection systems. This is often seen in binary-type geothermal power plants where fluid outlet temperatures can be run at a relatively low level without the need for acid addition for pH modification – in this case, the condensate from the binary plant is typically acidic due to the presence of carbon dioxide and hydrogen sulfide, which when mixed with the brine reduced the pH sufficiently to inhibit silica polymerization long enough to return the reinjection fluid to the geothermal reservoir. While this is a benefit of NCG reinjection for both Binary and flash-type power plants, the authors are unaware of any power plants currently operating an NCG reinjection system for the sole purpose of inhibiting silica polymerization in the geothermal brine, however it is noted that this can be a factor in the technology selection process (Addison and Brown, 2012) and NCG reinjection was retained for a time at the Coso geothermal power plant for the purpose brine pH modification after an alternative H_2S abatement system was in service (Layman, 2017).

3. Technologies

There are three main technologies currently in use to reduce greenhouse gas emissions from geothermal power generation. (1) NCG Reinjection, where the gases are redirected into the geothermal reservoir – often dissolved in water but in some cases in a gaseous or supercritical state. (2) Pumped Binary technology – where the greenhouse gases remain dissolved in the geothermal liquid through the production, utilization and reinjection stages, and hence are not released to the atmosphere. (3) Gas purification involves preparing the geothermal gases (typically carbon dioxide) for commercial and industrial uses, such as in greenhouses or the food and beverage industry. Each of these technological approaches is discussed below.

3.1 NCG Reinjection

Non-condensable gas reinjection is a process that redirects the non-condensable gases that have been separated from the geothermal steam and condensate and directs the gas into the reinjection system, where the gas is returned to the geothermal reservoir. This technology can be used at both binary and flash-type geothermal power plants, although it is typically easier and simpler to employ at binary power plants due to more favorable operating conditions. These conditions include the exclusion of oxygen from the gas mixture to minimize corrosion, higher gas pressure that reduces or eliminates the need for gas compression, and often lower reinjection temperatures, which improves the solubility of the gases in the reinjection liquid. When used at binary plants, it is typical to route the NCGs from the vaporizer (or other heat exchanger where the gases would otherwise accumulate) to the reinjection fluid downstream of the preheaters – where the fluid is coldest. If the vaporizer pressure is high enough the NCGs can flow to the reinjection piping without the need for gas compression. For the purposes of this paper, NCG reinjection refers to deliberately routing the NCGs into the reinjection system (active reinjection) and does not refer to NCGs that dissolve in the condensate within the vaporizer (passive reinjection - Ruiz et al., 2021)

NCG reinjection can be applied to flash plants utilizing condensing steam turbines, however some extra design considerations are required. These include ensuring the presence of oxygen in the NCGs is minimized. This would typically require a surface condenser and well-designed and operated turbine gland steam system to minimize air ingress in the systems that operate under vacuum conditions. If a direct contact condenser is used, a system to remove oxygen and nitrogen from the NCG mixture will likely be required to minimize corrosion and breakout pressure issues, respectively. With both surface and direct contact condensing systems, a gas compression system will also be required to increase the NCG pressure to a suitable level for reinjection.

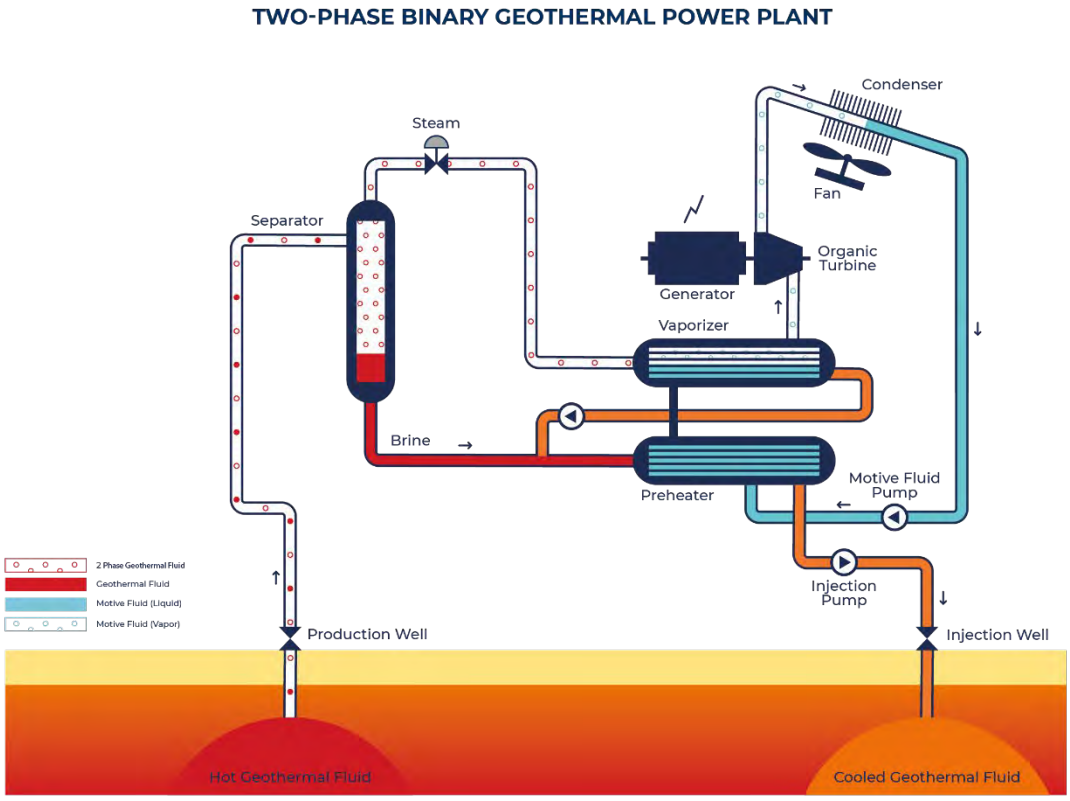

Figure 1: Two-phase Binary schematic

3.2 Pumped Binary

Pumped binary geothermal power plants are often the choice of plant design for low enthalpy and some medium enthalpy geothermal fields. The use of production pumps enables the development of non-artesian resources and can boost production in fields with low production pressures. Pumped binary systems can be temperature and depth limited, with these limitations dependent on pump and well designs as well as field conditions. While pumped binary geothermal power plants are typically zero emission (as described below), emissions may still occur if the geothermal fluid pressure is not maintained. This has been the case where the fluid has been exposed to atmosphere prior to reinjection (Bliem and Walrath), and when artesian systems have been converted to a pumped system while retaining the flash system (separator and steam systems) without implementing NCG reinjection.

Two major technological advancements have occurred throughout time to enable pumped Binary to be the leading technology employed for geothermal greenhouse gas reductions, with numerous power plants utilizing this combination of technology in low-medium enthalpy geothermal fields. The first is the development and evolution of binary power plant technology, with increases in efficiency and unit sizes. The other has been that well pump technology has evolved and become more reliable with the application of pumps increasing over time. Recently, in the United States

a number of original power plants on low-medium enthalpy geothermal fields have been repowered with new binary plants and making use of well pump technology, with more to come into the future with a repowered Beowawe facility coming online in 2024 (Ormat, 2023). Through the installation of pumps, the fluid does not flash in the wellbore or pipeline process, and therefore, any dissolved gases are kept in solution. This process is shown in the schematic in Figure 2. Pressures throughout the cycle are maintained at a suitably high level, and after energy extraction occurs through heat exchangers, the solubility of the gases increases as the temperature of the fluid is decreased, providing the ability to reduce pressures in the injection system without gas breakout occurring.

Lifecycle costs of the pumps tend to generally result in the installation of line-shaft pumps (LSPs) rather than electrical submersible pumps (ESPs). Cases where ESPs are utilized over LSPs are rare, except for where the well was deviated at a shallow depth and therefore LSPs cannot be utilized, or, where the depth required for the pump is extremely deep due to limited permeability in the wells formation or a deep water table. The primary reason for the lifecycle costs of LSPs being generally lower than ESPs is the operational lifespan between pump failures, with the main driver of this being that LSPs have electronic infrastructure on the surface rather than downhole.

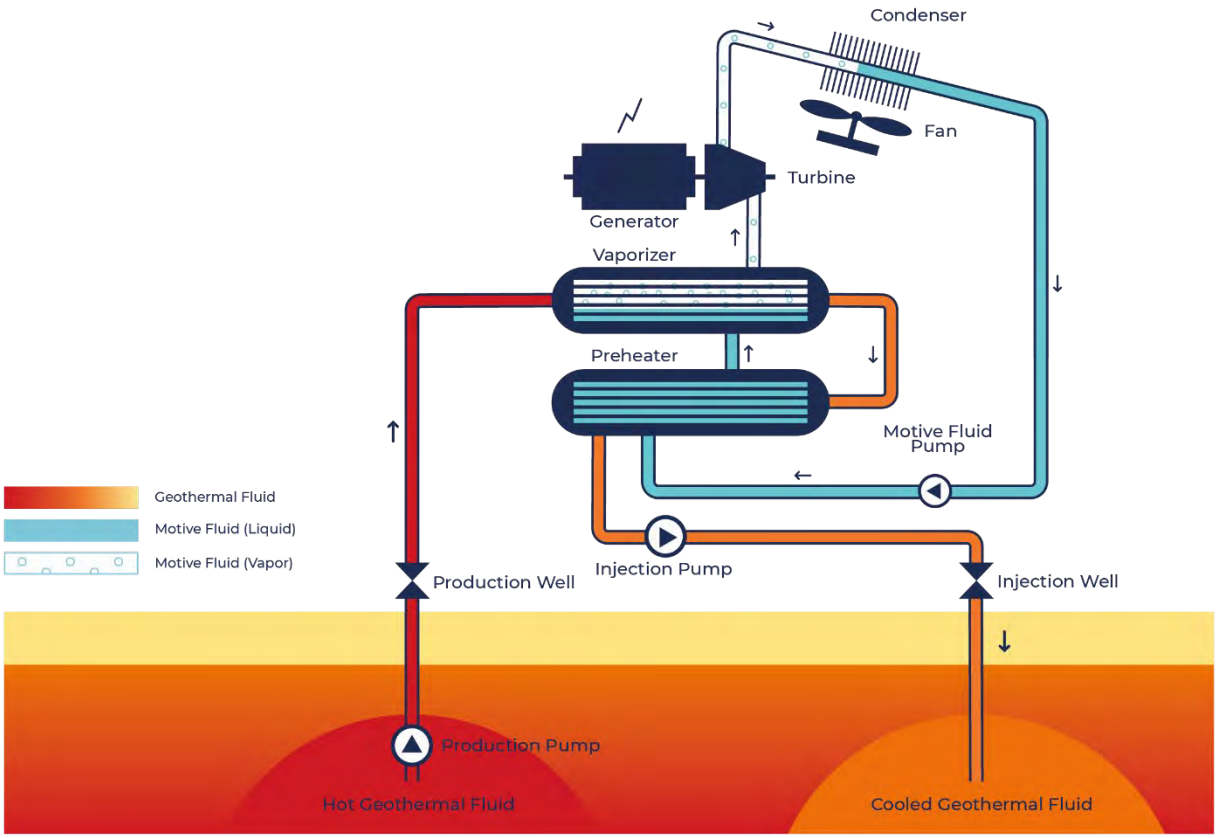

Figure 2: Pumped Binary schematic

3.3 Gas purification and reuse

Gas purification and reuse involves using one or more of the gases in the non-condensable gas mixture (typically carbon dioxide, although methane can also be captured for later use) for commercial or industrial use. The composition of a given NCG mixture and the intended downstream use will determine the various processing steps required to produce a gas that is commercially useful. Production of carbon dioxide suitable for industrial or food-grade use from geothermal sources may require significant processing, with removal materials found in geothermal such as hydrogen sulfide, ammonia, mercury, methane, non-methane hydrocarbons, nitrogen, hydrogen and argon (as well as oxygen if air ingress there is air ingress into the gas system) all having to be removed to a very high standard. It may often be the case that very high concentrations and volumes of carbon dioxide are required for a purification plant to be financially viable in addition to being located close to potential customers. For horticultural use, the required treatment may be reduced, especially where the presence of nitrogen and oxygen are of little consequence.

4. Examples

4.1 NCG Reinjection

4.1.1 Puna, Hawaii USA

The Puna geothermal power plant was commissioned in 1993 and is located on the Big Island in Hawai'i, USA. The stringent permitting conditions for the Puna power plant require that no hydrogen sulfide geothermal emissions are released from the power plant to alleviate concerns about impacts from nearby residents (Richard et al., 1989; Richard, 1990). This resulted in the design and installation of a 100% NCG reinjection system. The system involves collecting the NCGs from the vaporizers of the binary plants that receive the exhaust steam from the steam turbines. A gas compressor is used to increase the pressure of the gases such that they can be mixed with the geothermal brine and condensate that is also used in the power plant. This results in a 100% reinjection system, where all the geothermal brine, condensate and gases are returned to the reservoir. This system has been operating successfully since the plant was originally commissioned.

4.1.2 Carbfix, Hellisheidi, Iceland

The Carbfix project in Iceland is perhaps one of the best-known examples of NCG reinjection and greenhouse gas emissions reduction in the geothermal industry and is well reported in the literature. The Carbfix project aims to reduce greenhouse gas emissions by the reinjection of carbon dioxide into reactive rock formations where it can react and form stable minerals, thus avoiding emissions to the atmosphere. Commissioned at scale in 2014 at the Hellisheidi geothermal power plant (Aradottir et al., 2021), the Carbfix process has several key differences from most other geothermal NCG reinjection projects, including the use of either ground water (Carbfix 1) to dissolve the geothermal gases (although geothermal fluid can be used if there is a sufficient quantity available as was the case at Hellisheidi for Carbfix 2), and the use of a gas absorber - although this aspect is also used at Verkhne-Mutnovsky (Povarov and Nikolskyi, 2005) to promote dissolution of highly soluble gases (carbon dioxide and hydrogen sulfide) while

allowing for the venting of poorly soluble gases (such as methane and hydrogen). The use of non-geothermal water sources also allows for the geothermal gases to be reinjected outside of the geothermal reservoir, as long as the geology is suitable for the mineralization of the gases.

The Carbfix process, while more complex than some other NCG reinjection systems, enables more flexibility in the composition of NCG mixtures that can be used, and the type of geothermal plants that the process can be used with (potentially plants with direct contact condensers) as a result of the ability to largely remove poorly soluble gases from the gas stream.

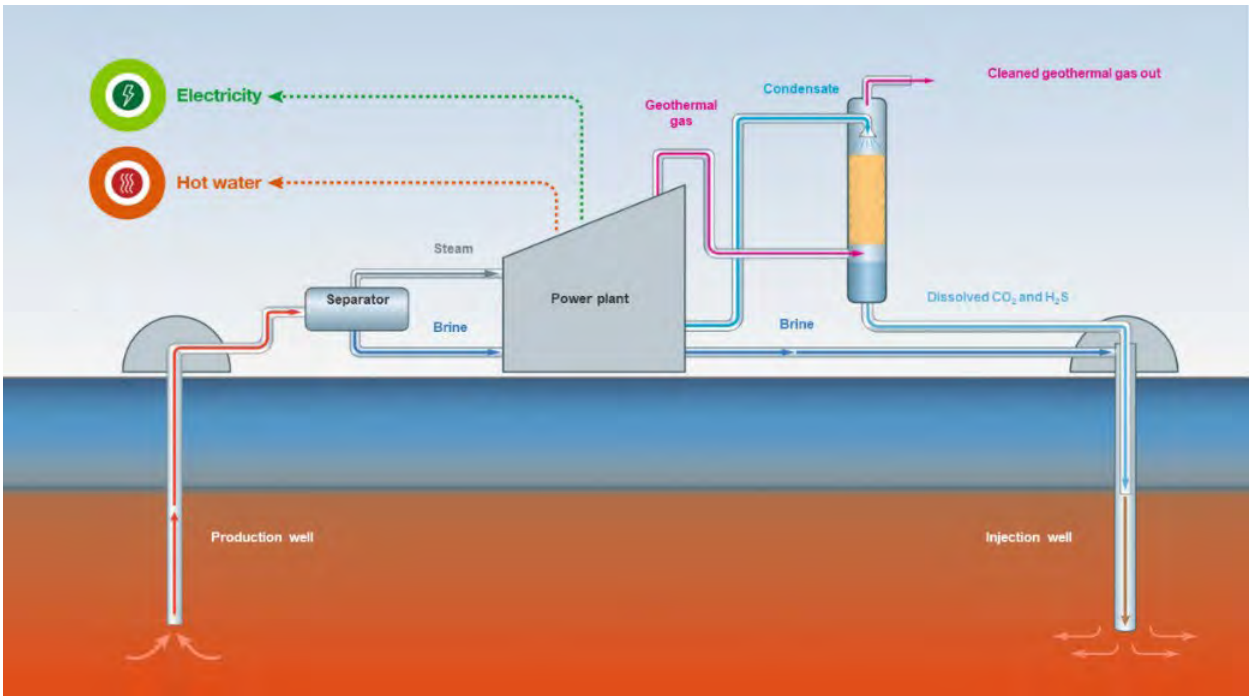

Figure 3: Basic Schematic of the Carbfix 2 process at Hellisheidi (from Aradottir et al., 2021)

4.1.3 Te Huka, Tauhara, New Zealand

The Te Huka geothermal power plant was commissioned in 2012 and is located in New Zealand and consists of two binary units utilizing geothermal brine and steam from the Tauhara geothermal field to produce a total of 25 MWe net. Under normal operating conditions the Te Huka plant released ~9,200t CO_2e per year as NCGs that did not naturally dissolve on the steam condensate under vaporizer conditions were vented to the atmosphere. In 2020, a project was commenced to reduce greenhouse gas emissions from geothermal generation by the plant's operator Contact Energy, which resulted in a redesign of the NCG venting system. Commissioning in 2022 this system resulted in a new NCG handling system to redirect the NCG flow from the atmosphere to the liquid reinjection system for the plant, where the NCGs are mixed with, dissolved into the reinjection liquid, and reinjected back into the geothermal reservoir. This enabled all of the gaseous emissions from the power plant to be reinjected as the plant conditions allowed for all of the gases to be dissolved in the surface equipment prior to reinjection, eliminating gas (and greenhouse gas) emissions from the power plant. The original design of the binary plant made these modifications relatively simple, with no gas treatment or compression required (Richardson et al., 2023).

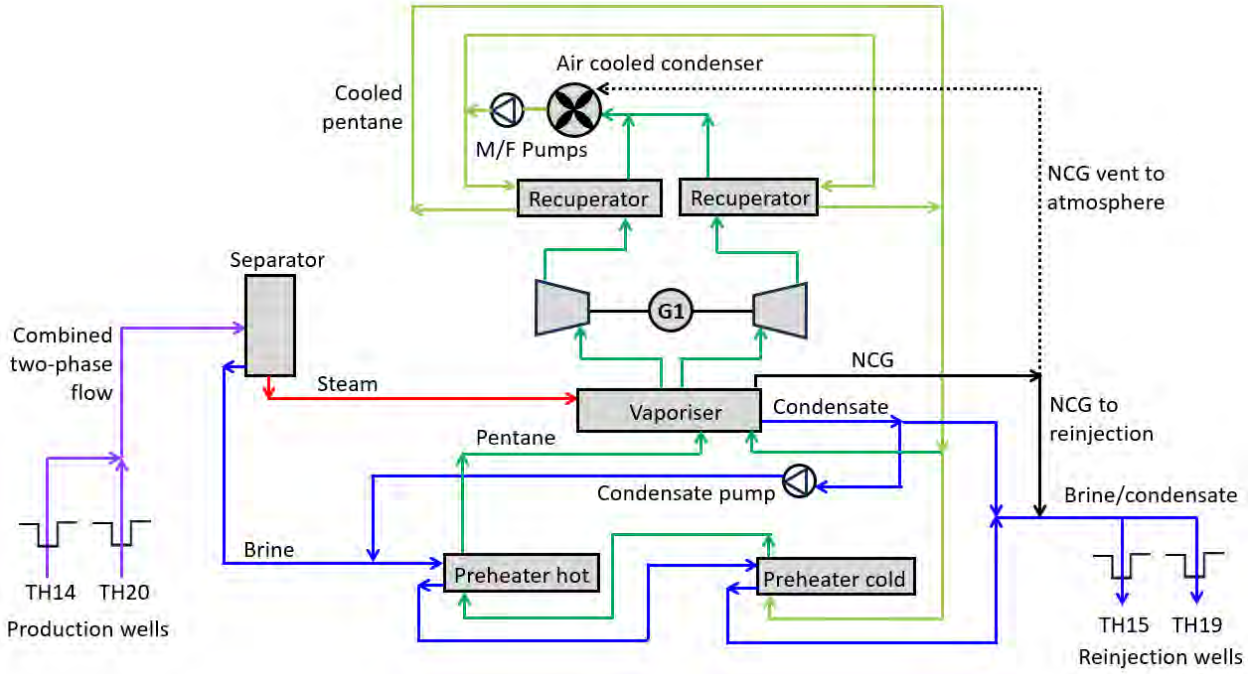

Figure 4: Te Huka flow schematic with NCG Reinjection (from Richardson et al., 2023)

4.2 Pumped Binary

4.2.1 McGinness Hills, Nevada USA

The McGinness Hills Geothermal Complex commenced generation in 2012, with three separate geothermal power plants in operation. The second plant came online in 2014, and the third in 2018. As of 2024 fields total capacity was 146 MW. All production wells make use of line-shaft pumps, which maintains pressure and prevents flashing. Therefore, the power plant has no separation equipment and throughout the whole process all gases are kept in solution.

4.2.2 Steamboat, Nevada USA

The Steamboat Geothermal Complex commenced its generation in 1986, with Steamboat 1 as a pilot project, and Steamboats 2 and 3 coming online in 1992. Significant development occurred over time on the field, with Ormat's subsequent consolidation of ownership. There are now 5 geothermal power plants operating as of the start of 2024 with a nameplate capacity of 79 MW, all featuring zero greenhouse gas emissions technology using binary power plants. The final major change in the field occurred in 2020 with the repower of the Steamboat Hills power plant with the binary Steamboat Hills Repower (Ormat, 2021).

Over time, numerous wells have been modified to pumped wells, with most of the Steamboat Hills section of the field having previously been all artesian wells historically, and these were almost all converted to pumped wells as part of the Steamboat Hills Repower (Akerley et al., 2021). Where good permeability was proven and economics allowed for it, new wells were drilled to enable the installation of line-shaft pumps. Where this was not the case and wells had a shallow kick-off

point or smaller casing, electric submersible pumps were installed. As of the start of 2024 only one artesian well remains on the field, well 24-5, and this feeds the Galena 2 plant then has infrastructure is designed to prevent any emissions from this well with a downhill pipe run to increase pressure by the time the fluid reaches the power plant and mixing with numerous pumped wells.

Figure 3: The original Steamboat Hills powerplant that was replaced with the new binary Steamboat Hills Repower in 2020.

4.3 Carbon Dioxide Reuse

Carbon dioxide reuse is a way to generate value from what would otherwise be a waste product from geothermal power generation. Perhaps the largest reuse of geothermal carbon dioxide can be found in Türkiye at the Kizildere facility operated by Zorlu Energy. The Kizildere 1 geothermal power plant was commissioned in 1984 and generated 18 MW of electricity. However, power generation in the field has increased substantially with the commissioning of Kizildere 2 and Kizildere 3. Kizildere delivers a part of its non-condensable gas flow to an adjacently located Linde gas processing plant, which uses the carbon dioxide contained in the NCG flow to produce high-purity carbon dioxide for commercial and industrial use. The high concentration and volume of carbon dioxide produced in the Kizildere geothermal plant (up to 99% of the non-condensable gas) results in a simpler, and more efficient processing system than would likely be required in many other geothermal fields to produce high-purity carbon dioxide.

Similar carbon dioxide recover plants were also in use at the Dora geothermal facilities in Türkiye. However, these were removed when the volume of gas from the power plants decreased to the point recovery was uneconomic, at which point gas reinjection was commenced (Asnük, 2024).

At the Svartsengi geothermal field in Iceland CO_2 from the NCG stream from the Svartsengi power plant is utilized to produce methanol (Ragnarsson 2023), at Carbon Recycling International's George Olah facility. While geothermally sourced carbon dioxide has been used for horticulture in Kenya, where the Oserian flower farm used carbon dioxide from the Olkaria geothermal system to support plant growth and increase output in its greenhouse operations (Ngethe and Jalilnasrabady, 2021).

5. Table of Power Plants with Greenhouse gas emissions abatement technology

This table is published with ownership and generation details as of 1 January 2024. This table excludes: temporary trials such as Umurlu, (Yucetas et al., 2018); plants that have ceased greenhouse gas abatement processes (e.g. Coso); plants smaller than 5 Mwe net in size; plants that are bottoming units or brine-only units; and, facilities that utilize geothermal CO_2 but do not generate electrical power (eg Haedarendi). This table is focused on greenhouse gas emissions abatement; for general emissions abatement from geothermal power plants Lenzi et al. (2021) provides a comprehensive overview.

6. Conclusions

While there are currently a significant number of geothermal power plants with greenhouse gas emissions reduction technology, this is dominated by pumped binary systems where the greenhouse gases remain in solution within the geothermal fluid throughout the power generation process. There are far fewer power plants where gases that have separated from the geothermal fluid are actively redirected into the reinjection process and examples of these plants are currently favored in binary plants due to the simplicity of adapting this process to typical binary plant designs. NCG reinjection in flash plants is more challenging both technically and economically. However as demonstrated in Iceland and Russia this technology is viable and likely to grow, particularly in jurisdictions where there is a significant benefit to greenhouse gas emissions reduction through a carbon price or other incentives. There are also plans for more commercial use of geothermally sourced carbon dioxide among geothermal plant operators as this is seen as an opportunity in some markets, and a potential requirement in others.

The use of carbon pricing, such as direct pricing in New Zealand, or indirectly through power purchase agreements like in California in the US, is driving more action towards zero greenhouse emission geothermal power plants. As other markets create either direct or indirect incentives, we expect significant increases to occur over time in the amount of geothermal power plants reducing their greenhouse gas emissions. The rapid pace of development of zero greenhouse emission geothermal power plants in New Zealand is an example where a market pricing incentive has resulted in outweighing risks associated with the activity, resulting in a significant deployment in a relatively short period time, generally as a function of a significant carbon price increase.

Enhanced / Engineered Geothermal Systems

Experimental Investigation of the Flow Behavior of Ionic Liquids for use as Working Fluids in Enhanced Geothermal Systems

Christian Akhilome, Sushobhan Pradhan, and Prem Kumar Bikkina

Oklahoma State University

Keywords: *Enhanced geothermal systems, Ionic liquids, microfluidics, thermal short-circuiting*

Abstract

The heat recovery efficiency of an enhanced geothermal system (EGS) relies on the flow dynamics of the circulated working fluid in the natural and engineered fractures within the reservoir. The use of Ionic liquids (ILs) as geothermal working fluids is a promising alternative to conventional working fluids such as water due to their favorable properties including wide liquid range, high thermal stability, and shear thinning behavior. ILs are expected to offer enhanced flow hydraulics and address thermal short-circuiting, a potential issue in EGS operations. ILs dynamically adjust their rheological properties in response to localized temperature changes, enabling them to selectively traverse higher temperature flow paths with minimal resistance. Consequently, ILs can potentially eliminate flow shortcuts, thereby improving the overall heat recovery from the EGS.

This study investigates the flow behavior of ILs and their performance in EGS. Specifically, it examines correlations between flowrates and pressure drops of two ILs, viz., 1-butyl-3-methyl-imidazolium bromide ([bmim][Br]), and 1-hexylpyridinium bromide ([hPy][Br]), within idealized micro fractures. Experimental evaluations were conducted using a microfluidic set-up to simulate flow through micro channels in EGS, utilizing a variety of fluid samples, including De-ionized (DI) water, and 5%, 10%, and 25% solutions of [bmim][Br] and [hPy][Br]. Furthermore, the study also investigated the high-temperature flow behavior of [bmim][Br] at 18 ^{o}C, 50 ^{o}C, and 80 ^{o}C, comparing it to the performance of DI water under the same conditions. The reduction in the frictional pressure drops of the IL is compared to that of DI water, revealing significant hydrodynamic improvements with the IL. Particularly, as temperature increased, the IL showed better performance over DI water in terms of reduction in frictional pressure loss within the microchannels with an average reduction approximating four times larger than that of DI water. This research enhances our understanding of IL flow behavior in microchannels, which is crucial for optimizing heat recovery from EGS and advancing sustainable and cost-effective geothermal operations.

1. Introduction

The vast thermal energy resources found in the Earth's subsurface offer considerable potential for green and sustainable power generation. This thermal energy is mainly generated from heat conduction and convection from the Earth's core and exothermic decay of radioactive elements (Emujakporue, 2017). Bertani (2016) estimates that harnessing 1% of the Earth's crust heat could power the world for about three millennia, underscoring its enormity. Furthermore, the replenishment rate exceeds depletion, emphasizing the sustainability of geothermal energy. However, most high geothermal gradient areas are located within igneous rocks with very low permeabilities which makes harnessing this energy very challenging. Thus, the concept of enhanced geothermal systems (EGS) was developed to exploit these vast resources by creating flow paths that permit heat extraction from these reservoirs. EGS involves artificially stimulating hot dry rock (HDR) reservoirs to create a subsurface fracture network that allows circulation of a working fluid, traditionally water, between an injection well and a production well. Heat is exchanged from the HDR to the working fluid which is produced to the surface through the production well. Depending on the temperature of the produced fluids, they can be used for different purposes such as space heating for geothermal fluid temperatures as low as 80 ^{o}C and about 180 ^{o}C for economical electricity generation (Smith et al., 1975).

The efficiency of EGS is dependent on the temperature of the extracted fluid. Higher temperatures indicate better performance (Asai et al., 2019). The properties of the circulated working fluid are crucial for optimizing heat recovery from geothermal reservoirs. Various working fluids have been explored to improve the performance of EGS, with water and CO_2 being the most commonly used. Although water is relatively cheaper than other working fluids, its use in EGS is limited by issues related to mineral dissolution and precipitation. However, water does have higher thermal conductivity and specific heat capacity compared to CO_2 (André et al., 2006; Brown, 2000). Supercritical CO_2 ($ScCO_2$ – occurs when CO_2 is held above its critical temperature and pressure), prevents the silica precipitation and mineral dissolution challenges associated with water-based EGS projects. Furthermore, $ScCO_2$ yields a higher mass flow rate and net heat extraction for a given injection rate in EGS due to the existence of thermal siphoning between injection and production wells (T. Guo et al., 2019; Lei, 2022; Olasolo et al., 2016; Sun et al., 2018). In addition, unlike water, fluid losses in geothermal reservoirs may be beneficial when CO_2 is used as the working fluid due to the possibility of carbon sequestration, depending on suitable site conditions. A prevalent issue with both CO_2 and water geothermal working fluids is the possibility of flow channeling which can lead to early thermal breakthrough. Formation heterogeneities often lead to the creation of fractures with non-uniform properties when geothermal reservoirs are stimulated. This often leads to the creation of preferential flow paths in EGS due to the uneven hydraulic conductivities of the induced fractures (Gischig & Preisig, 2015; T. Li et al., 2016). Since preferential flow paths allow more flow compared to other fractures, the temperature of the surrounding rock decreases more rapidly. This cooling causes an increase in the fracture aperture due to thermal destressing, which in turn leads to even more channelized flow (Fu et al., 2016; B. Guo et al., 2016). This phenomenon, called thermal short-circuiting, can result in insufficient heat exchange and early thermal breakthroughs, leaving a large volume of reservoir rock untouched (S. Li et al., 2022). As a result, the temperature of the produced fluids reduces, thereby compromising the economic viability of the EGS project. Numerous field studies have documented evidence of thermal short-circuiting in EGS. For instance, Lu (2018) reviewed prominent EGS sites worldwide and noted that thermal short-circuiting contributed to the inability of projects like Rosemanowes

in the UK and Hijiori in Japan to achieve their target heat production over time, ultimately leading to the termination of operations at both sites. Different approaches have been suggested to mitigate thermal short-circuiting in literature including the use of temperature-sensitive proppants to modify fracture conductivity (Al Balushi et al., 2023; Hu et al., 2021), periodic shut-ins of injectors and producers (Fan et al., 2020), and the use of chemicals to plug highly conductive fractures (Zhang & Dahi Taleghani, 2023). However, there has been insufficient evidence to support the applicability of these remedies in practical terms.

Recently, ionic liquids (ILs) have been garnering significant attention in various fields, including thermal energy storage and EGS. ILs are salts composed entirely of ions and are generally liquids below 100 ^{o}C. ILs have emerged as promising alternatives to water and CO_2 due to their unique properties such as high thermal and chemical stability, low melting point, low vapor pressure, and shearing thinning which are favorable for EGS applications. Unlike water and $ScCO_2$, ILs significantly vary their rheological properties in response to temperature changes in the fractures which can potentially eliminate flow shortcuts. The underlying concept is that the viscosity of the ILs increases significantly when the temperature of the bounding rock matrix in channelized flow paths reduces. This increases the hydraulic resistance to flow in the preferential flow paths which leads to a redistribution of the working fluid into other regions in the EGS, thus, eliminating thermal shortcuts (Atashnezhad et al., 2023; Momoh et al., 2023). Despite this enormous potential, there is a relative scarcity of studies investigating the use of ILs as geothermal working fluids.

In this study, we investigated the performance of two ILs: 1-butyl-3-methyl-imidazolium bromide ([bmim][Br]) and 1-hexylpyridinium bromide ([hPy][Br]) as potential working fluids for EGS applications. We conducted a series of flowrate vs. pressure drop experiments using a microfluidic setup to mimic flow through a geothermal reservoir. Various fluid samples, including deionized (DI) water, and 5%, 10%, and 25% solutions of [bmim][Br] and [hPy][Br], were tested. Additionally, the study explored the high-temperature flow behaviors of [bmim][Br] at 18 °C, 50 °C, and 80 °C, comparing them to the performance of DI water under the same conditions. Our findings enhance the understanding of the flow behavior of ILs in microchannels, which is crucial for optimizing heat recovery from EGS and advancing sustainable and cost-effective geothermal operations. This research aims to contribute to the optimization of EGS by providing valuable insights into the flow dynamics of ILs as working fluids, potentially leading to more efficient and sustainable geothermal energy extraction methods.

2. Materials And Methods

2.1 Microchip

In this work, a 45 x 15 mm borosilicate glass microchip with three flow channels of varying widths was utilized. The microchip was designed and fabricated by Micronit Microtechnologies B.V., Netherlands. A Micronit Fluidic Connect Pro chip holder houses the microchip to ensure proper confinement and prevent fluid leaks during flow tests. Table 1 shows the dimensions of the microchannels in the chip while Figure 1 shows the chip holder and a detailed description of the microchip.

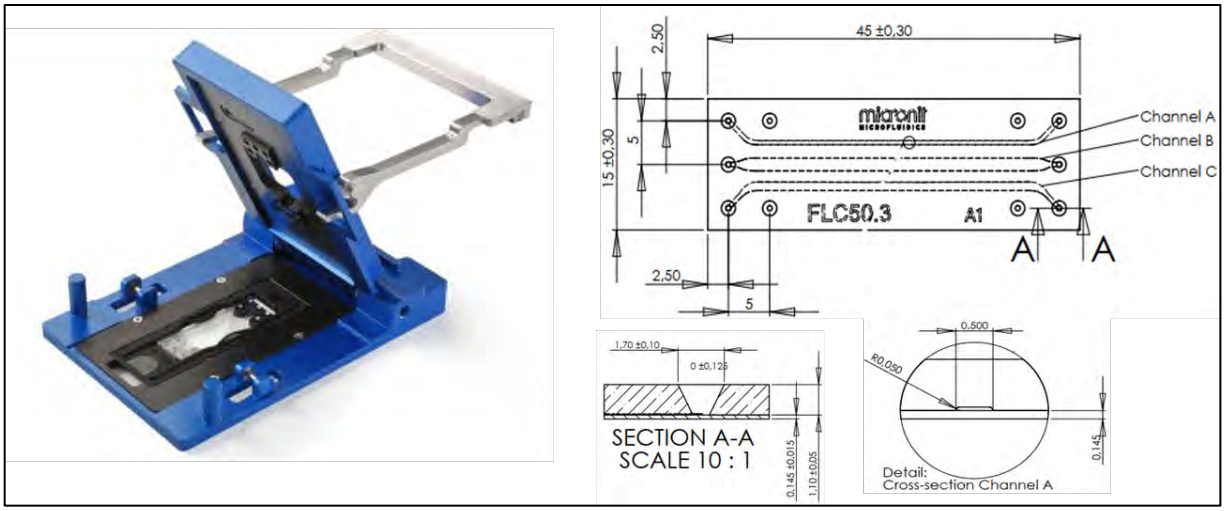

Figure 1: Pictorial description of the Fluidic Connect Pro chip holder (left) and the Microchip (right) (www.micronit.com)

Table 1: Dimensions of Microchannels.

Channel	Width (mm)	Length (mm)	Depth (mm)	Volume (µl)
A	0.5	42	0.05	1
B	1.5	40	0.05	2.8
C	1	42	0.05	1.9

2.2 Test Fluids

Two (ILs), 1-butyl-3-methyl-imidazolium bromide ([bmim][Br]) and 1-hexylpyridinium bromide ([hPy][Br]), were used to conduct the flow tests. The results obtained from the ILs were compared against those from deionized (DI) water). In addition, aqueous solutions of [bmim][Br] and [hPy][Br] were tested at three different concentrations of the ILs. The properties of the ILs, determined by Atashnezhad et al., (2023), are presented in Table 2 below.

Table 2: Properties of test fluids (Atashnezhad et al., 2023).

Fluids	Viscosity @ SR = 25-100 1/s & P = ~ 101.5 psi (cP)	Density (g/cc)	Thermal Stability (ºC)
[bmim][Br]	199-364	0.94	280
[hPy][Br]	697-715	1.105	380
DI Water	1	1.000	---

The viscosities of the aqueous test fluids were determined using a RheoSense microVISC viscometer. The viscometer uses an array of pressure sensors to measure the force required to pump fluids through a rectangular microfluidic channel which is indicative of the fluid's resistance to flow. Analytical solutions, such as the Hagen-Poiseuille equation, are then applied to estimate the shear stress and viscosity from the measured pressure drop. The densities of the aqueous samples were measured using a densitometer (Mettler Toledo DA-100M). The densitometer uses

the vibration frequency of a liquid-filled U-tube to determine the density of the liquid. Table 3 shows the viscosity and density of aqueous solutions of the ILs at 18 ^{o}C.

Table 3: Properties of test fluids continued.

	Viscosity @ 18 ^{o}C (cP)	**Density (g/cc)**
5% [bmim][Br]	1.402	1.0070
10% [bmim][Br]	1.528	1.0140
25% [bmim][Br]	2.007	1.0437
5% [hPy][Br]	1.258	1.0100
10% [hPy][Br]	1.340	1.0200
25% [hPy][Br]	1.791	1.0507

2.3 Experimental Facility

The microfluidic facility used to evaluate the reversibility of the ILs consists of several key components: i) constant pressure and constant rate syringe pumps for injecting and withdrawing the liquids into and from the chip; ii) a microchip and chip holders to simulate flow through fractures in EGS; iii) control valves; iv) differential pressure sensors to measure the pressure difference between the inlet and outlet of the microchip; v) a data acquisition device (DAQ) for real-time data gathering and performance analysis; vi) a workstation to monitor flow through the microchannels; vii) various fittings and PEEK tubings to facilitate fluid flow across the microchip. Figure 2 illustrates the process flow diagram of the experimental setup. For multichannel experiments, the Tee connectors at the inlet and outlet of the microchip are replaced by a union cross. The microchip features three idealized microfractures of varying widths but roughly the same length and depth.

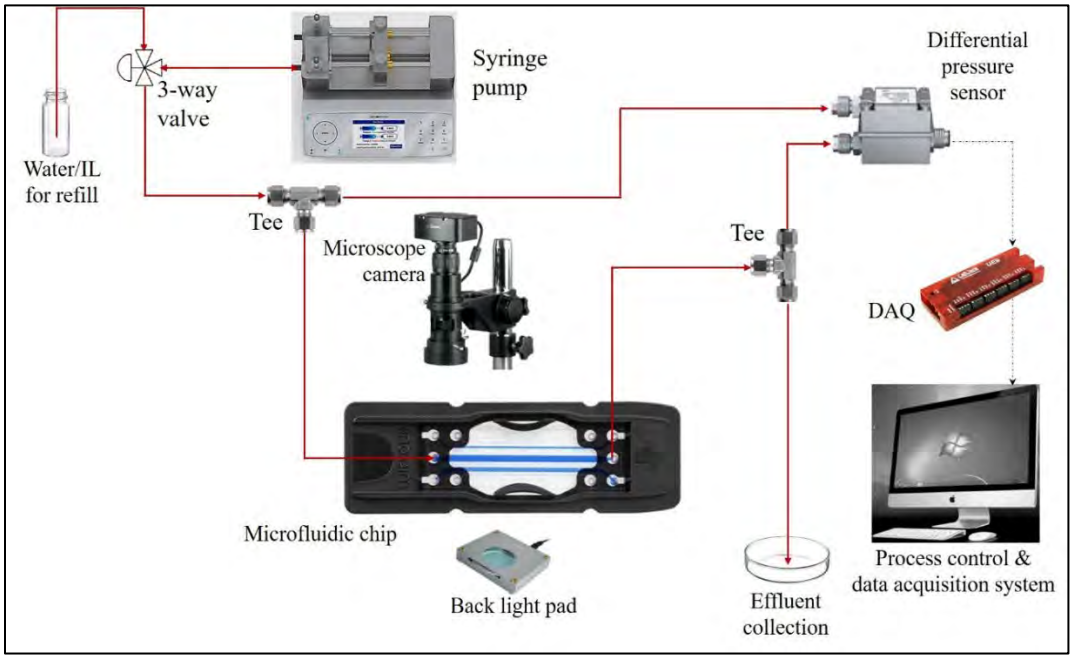

Figure 2: Process flow diagram for the experimental setup to conduct flow tests across the microchannel(s)

2.4 Pressure Drop across the Microfluidic Channels

A TDK minicell pressure sensor was used to measure the differential pressure across the microchannel(s). The pressure sensor records the voltage difference between the inlet and the outlet of a microchannel based on the piezoelectric effect. The measured voltage is transmitted through a LabJack UE9pro data acquisition device to a computer monitor. To convert the recorded voltage values to differential pressure (ΔP), the pressure sensor was calibrated to obtain a relation between voltage (V) and pressure drop (psi). The calibration was performed using a constant pressure injection pump (make: Teledyne ISCO; model: 260 D), yielding a linear relationship between the differential pressure and the voltage ($\Delta P = 35.711V - 17.162$, $R^2 = 0.9999$), as shown in Figure 3. This linear model was used to estimate ΔP from the voltage values recorded during the different flow experiments. By maintaining a constant flow rate through the microchannels, we recorded voltage values and applied the linear model to estimate ΔP which provided insights into the behavior of ILs in EGS.

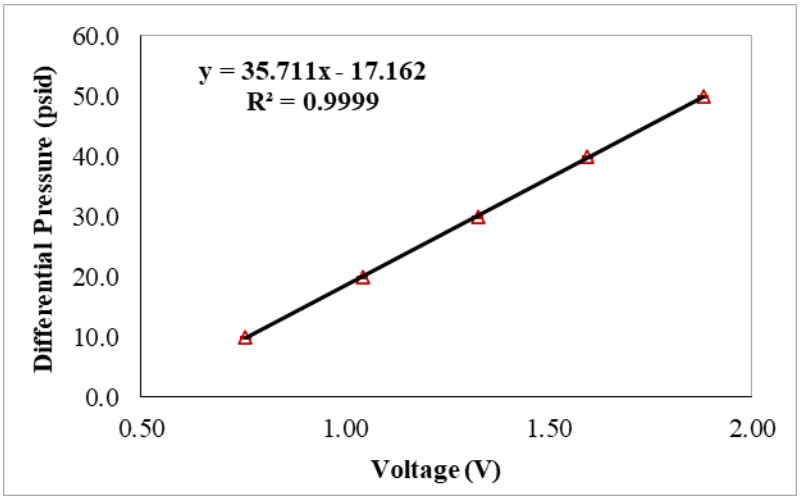

Figure 3: Calibration curve for the differential pressure sensor.

2.5 Procedures for Determining the Pressure Drop across the Microchannel(s)

2.5.1 Low Temperature Experiments

A Havard PHD Ultra syringe pump was used to conduct low-temperature experiments. Test fluids are withdrawn from the fluid reservoir into the syringe pump. They are then injected into the microchannel at a constant flow rate at room temperature (18 ^{o}C). The ΔPs across single microchannels are estimated using stabilized voltage readings i.e., when steady state flow exists in the microchannels. The flow rate is initially increased in steps until a predetermined rate is attained with the stabilized voltage values recorded at each flow rate. Next, the flow rate is reduced from the maximum to the minimum rate in the previous cycle while maintaining the same flow rate intervals. Finally, the flow rate is increased again from the lowest to the highest rate using the same step intervals in the first two cycles. This sequence is repeated for each test fluid, and the average of all three voltage values is used to estimate the pressure drop across the microchannel(s).

To minimize contamination of the test liquids, the microchannels and the pump's syringe are thoroughly cleaned with DI water and isopropyl alcohol (IPA) between experiments. This entire procedure is repeated for each test fluid and for both single- and two-channels.

2.5.2 High Temperature Experiments

For high-temperature experiments, a Chemyx Fusion 6000X syringe pump was used. Chemyx Fusion 6000X pump was used to pre-heat, regulate, and maintain the temperature of fluids in its syringe. The test fluids were preheated in a water bath to the desired temperature before withdrawing the liquids into the pump's syringe. The pump is then used to preheat the fluid again before injecting it into the microchannel. A thermal insulation tape was used to wrap the components of the setup, including the syringe, tubings, and fittings, to minimize heat losses. The procedures utilized to determine the pressure drop at the room temperature experiments were also adopted for the high-temperature experiments.

3. Results And Discussion

3.1 Aqueous Solutions

ILs may be diluted by water when utilized as geothermal working fluids, especially in hot wet rocks (HWR). It is therefore necessary to understand the flow behavior of aqueous solutions of the ILs utilized in this study. Flow behavior of 5%, 10%, and 25% solutions of [bmim][Br] and [hPy][Br] in the microchannels were examined in this work. The pressure drop vs. flowrate curves for these solutions are presented in the following sections.

3.1.1 Results for [bmim][Br]

The flow of fluid from one point to another in a system generally leads to a reduction in pressure due to three main factors: kinetic losses, potential losses, and frictional losses. The microfluidic setup consists of horizontally positioned and uniformly sized microchannels, thus eliminating potential and kinetic losses respectively. Frictional loss is a measure of a fluid's resistance to flow and is dependent on the fluid and system properties. Analytical solutions describing flow through microfluidic channels have shown that the pressure drop across microfluidic channels is dependent on the flowrate, fluid properties, and dimensions of the channel(s) (Estarki et al., 2023; Joseph et al., 2013). The viscosity of the fluid is the main fluid property that affects pressure drop, it describes the internal resistance of the fluid to flow. Thus, the more viscous the IL/aqueous solution, the higher its internal resistance and the consequent differential pressure across the channel/multichannel. Figure 4 shows the variation of pressure drop with flowrate for aqueous solutions of [bmim][Br] in single- and two-channels. It can be observed that the recorded ΔP increased with flowrate in all the cases considered. In addition, for a fixed flow rate, the pressure drop increased with increasing concentration of the [bmim][Br]. The increased pressure drop can be attributed to an increase in viscosity as the concentration of the IL increased from 5% to 25%. Readers are referred to Table 3 for the viscosities of the test fluids. Similarly, the differential pressure reduced with increase in the width of the channels because shear rate and flow resistance decreases as the width of the channels increases. This behavior was also noted in the two-channel experiments where the pressure drop derived from flowing through the single channel was always higher than the pressure drop recorded when a second channel was combined. The error bars on each data point in the plots represent the standard deviations of the mean ΔP value from three ΔP data points recorded in distinct experiments.

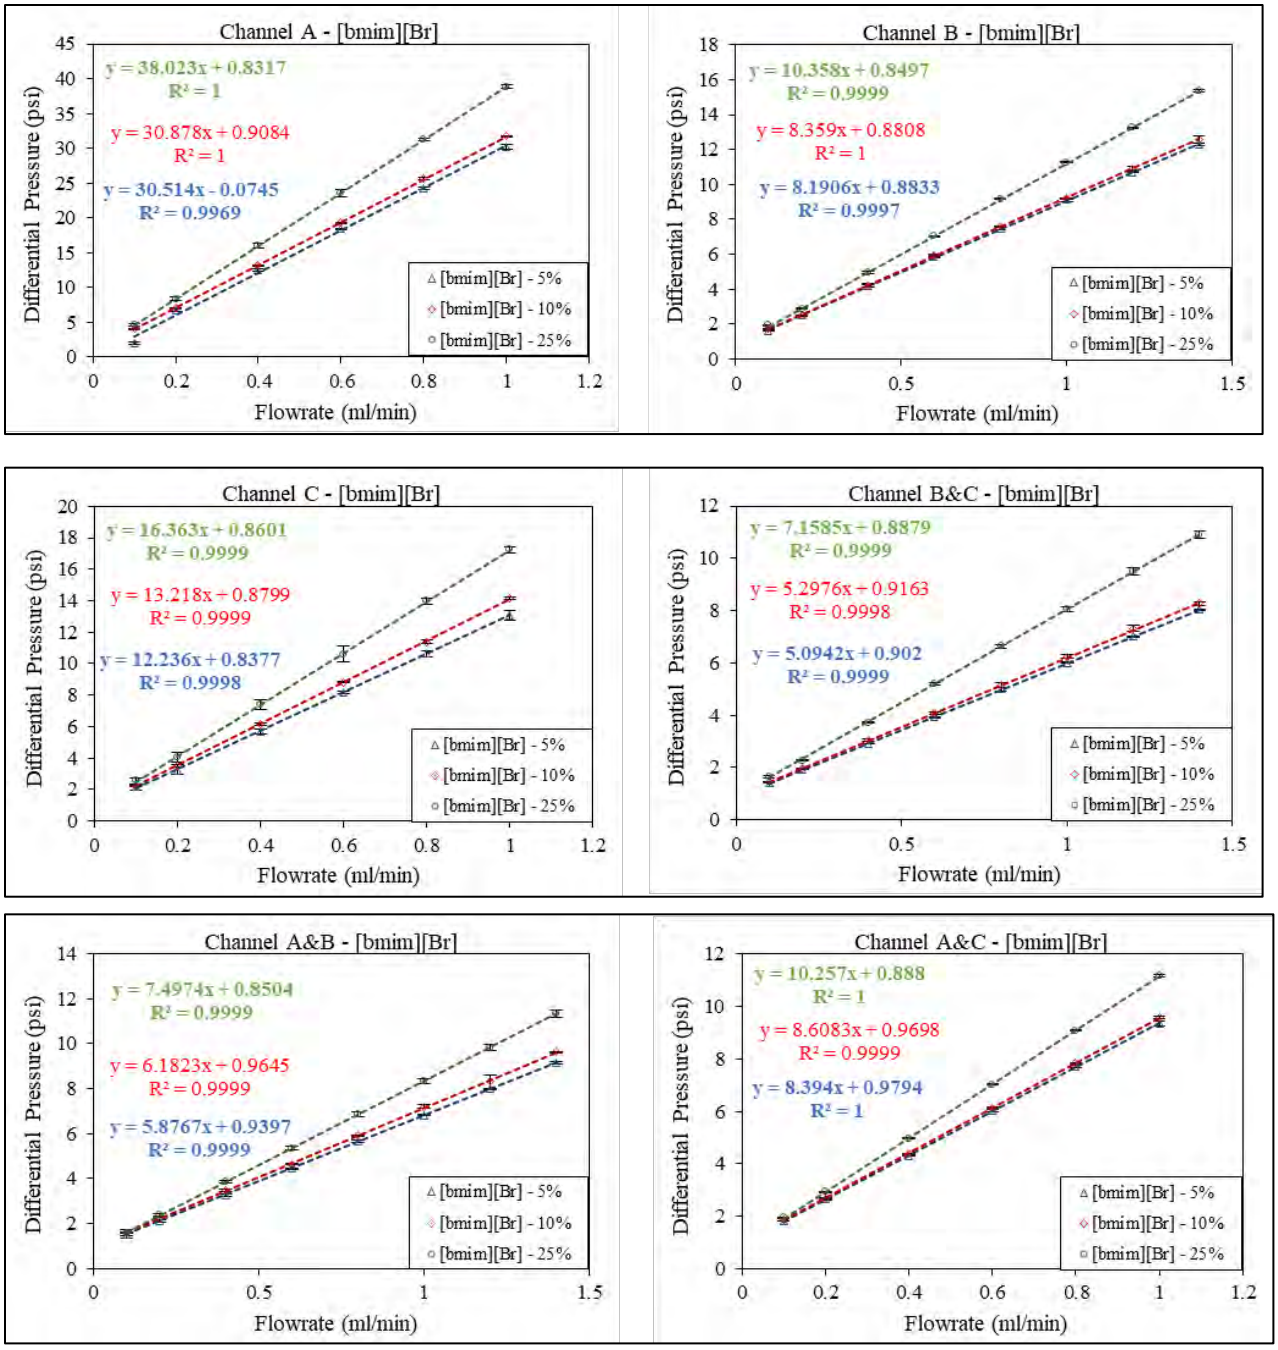

Figure 4: Variation of pressure drop (ΔP) with flow rate of [bmim][Br] in the microchannels

3.1.2 Results for [hPy][Br]

Similar trends were observed in the [hPy][Br] solutions as with the aqueous [bmim][Br] solutions. The pressure drop increased with both flowrate and concentration of the ILs, while it decreased with increasing channel width. It is important to note that the viscosity of 5% and 10% samples are closer compared to that of 10% and 25% concentrations which could explain the comparable ΔP-Q trends for 5% and 10% in all the cases.

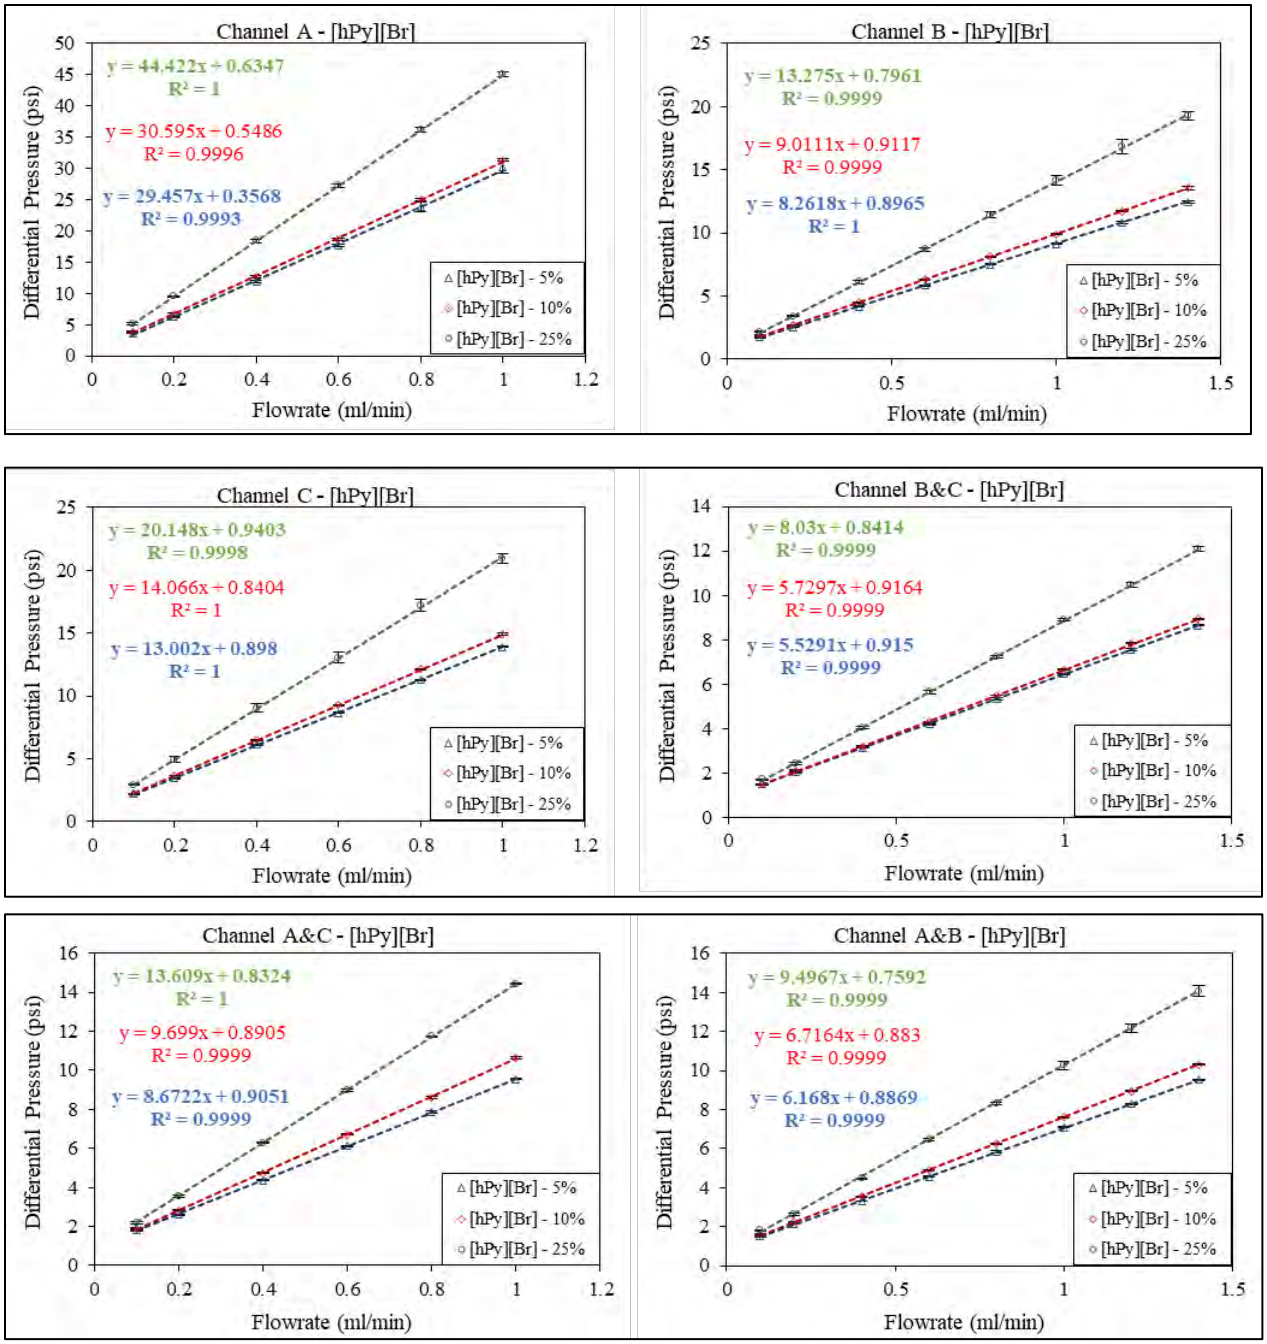

Figure 5: Variation of pressure drop (ΔP) with flow rate of [hPy][Br] in the microchannels

3.2 Results for [bmim][Br] and DI Water at High Temperature

Figures 6 and 7 show the effect of increasing the temperature of the DI water and [bmim][Br] on the pressure drop across a microchannel. As stated in previous sections, the pressure drop across each channel results from the frictional losses in the system which are mainly dependent on the viscosity of the flowing liquid and the internal conditions of the channel such as roughness, and channel dimensions. Temperature dependence of viscosity varies from fluid to fluid. The viscosity of [bmim][Br] reduces significantly when the temperature is increased. Thus, the measured pressure

drop across the channel at a constant rate reduces as the temperature of the IL increases. DI water, on the other hand, does not experience much viscosity reduction with increasing temperatures. For example, Korson et al., in 1969 estimated the viscosity of DI water at a temperature range of 0-100 ^{o}C. The viscosities of DI water at 18 ^{o}C, 50 ^{o}C, and 80 ^{o}C are approximately 1 cP, 0.55 cP, and 0.35 cP, respectively. As shown in Figure 6, the pressure drop across the channels did not change much when the temperature of DI water was increased from 18^{o}C to 50^{o}C and 80^{o}C.

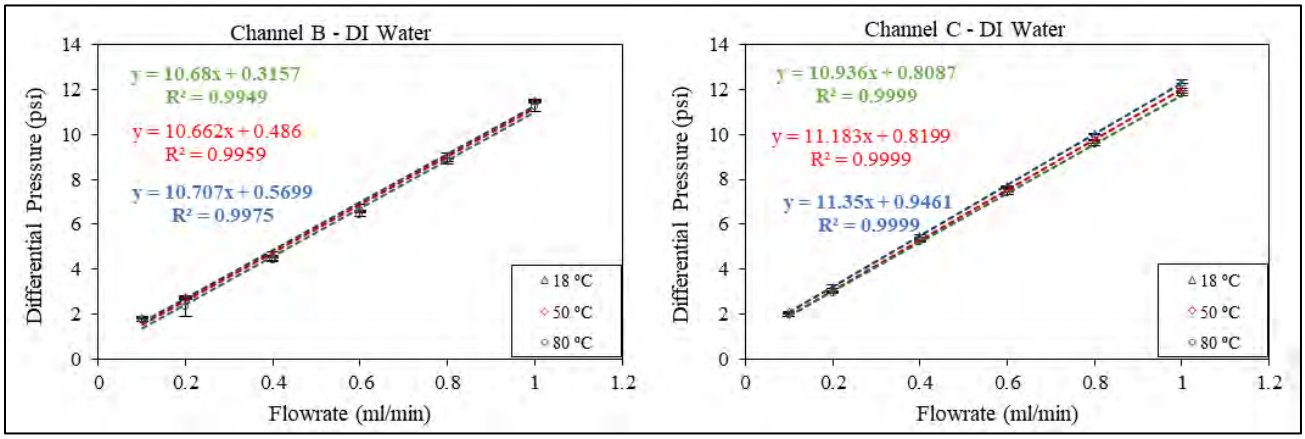

Figure 6: Variation of pressure drop (ΔP) with flow rate of DI water at 18 °C, 50 °C, and 80 °C in channel B and channel C

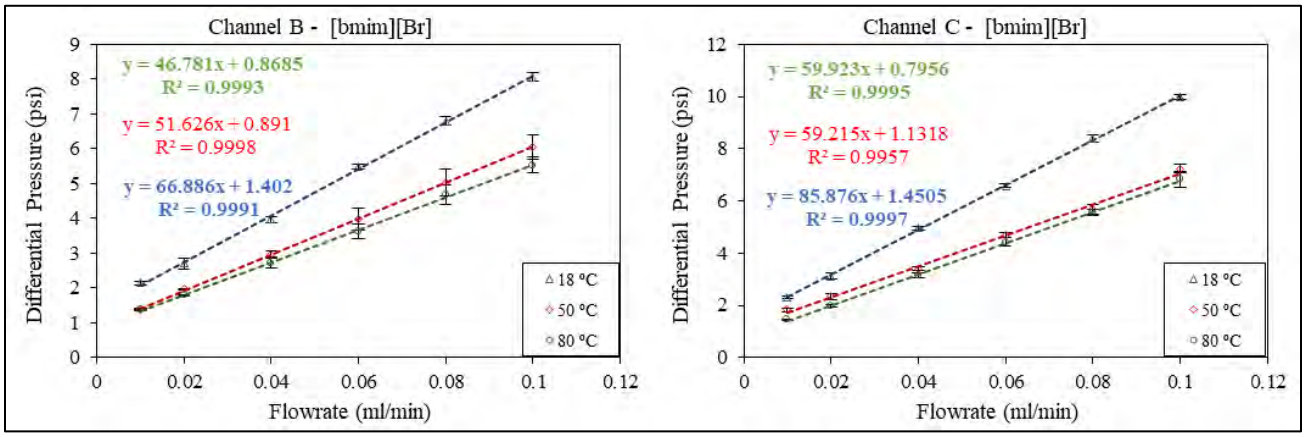

Figure 7: Variation of pressure drop (ΔP) with flow rate of [bmim][Br] at 18 °C, 50 °C, and 80 °C in channel B and channel C

Figure 6 and 7 demonstrates that [bmim][Br] exhibits enhanced hydrodynamic properties with increasing temperature compared to DI water at the microscale. This is further illustrated in Table 4 which shows the percentage reduction in pressure drop for both DI water and [bmim][Br], when a constant flow rate of 0.1 ml/min was maintained for both liquids.

Table 4: Recorded ΔP values and percent change of ΔP with temperature increase from 18°C to 80°C for DI water and [bmim][Br] in Channel B and Channel C.

Test fluid	Channel B						Channel C					
	DI Water			[bmim][Br]			DI Water			[bmim][Br]		
Temperature (°C)	18	50	80	18	50	80	18	50	80	20	50	80
ΔP (psi)	1.84	1.76	1.75	8.06	6.05	5.53	2.11	1.94	1.94	9.99	7.24	6.82
Percent reduction in ΔP	--	3.89	4.54	--	24.95	31.38	--	7.9	7.9	--	27.52	31.69

The frictional pressure loss reduction ratio, derived by comparing the percent reduction in ΔP of [bmim][Br] with that of DI water, is shown in Table 5.

Table 5: Frictional pressure loss reduction ratio of [bmim][Br] with respect to DI water.

Channel	Channel B		Channel C	
Temperature (°C)	50	80	50	80
Frictional pressure loss reduction ratio	6.4	6.9	3.5	4

Tables 4 and 5 show that the percent reduction in differential pressure with increasing temperature for DI water is much lower than the reduction experienced with [bmim][Br]. [bmim][Br] outperforms DI water in terms of the reduction in the frictional pressure loss in microchannels with increasing temperature. In channel B, [bmim][Br] exhibited a frictional pressure loss reduction seven times greater than that of DI water, while in channel C, it showed a four-fold reduction compared to DI water.

3.3 EGS Implications

As stated earlier, flow channeling can lead to thermal short-circuiting which can negatively impact the overall heat recovery efficiency of an EGS project. Unlike water, ILs have temperature-dependent viscosities, which can prevent thermal short-circuiting. As the viscosity of ILs increases in highly conductive, low-temperature flow paths, flow resistance increases, redirecting the ILs to lower conductivity, higher temperature paths. This redistribution into smaller, hotter fractures enhances the recovery efficiency of an EGS and can extend the project's lifespan. We can infer from the results that the use of [bmim][Br] (and similar ILs) as geothermal working fluids leads to greater frictional pressure loss which could cause more fluid flow in low-conductivity fractures. It is important to note that these experiments were conducted at a maximum temperature of 80°C due to the limitations of our experimental facility. In reality, higher temperatures exceeding 180°C have been recorded in EGS (Lu, 2018). Therefore, the frictional pressure loss ratio is expected to increase under actual EGS conditions, leading to improved flow hydraulics. However, drawing definitive conclusions from these findings requires further study to verify the flow behavior of ILs in fracture networks at the elevated temperatures typical of geothermal reservoirs.

4.0 Conclusions

The flow behaviors of [bmim][Br] and [hPy][Br] within idealized microfractures were evaluated using a microfluidic setup, and their potential as geothermal working fluids was discussed. The main findings from this study are:

- The ILs demonstrated pressure drops across single and multichannel proportional to the flowrate, viscosity of the ILs, and the dimensions of the single- and two-channels. [bmim][Br] showed a significant reduction in the frictional loss compared to DI water. The frictional pressure loss reduction of [bmim][Br] at 80^{o}C was about seven times that of DI water in channel B and four times greater than DI water in channel C.
- In EGS reservoir conditions, we expect a much higher viscosity increase ratio for the ionic liquids when temperature declines which can potentially eliminate short circuits.
- The use of ILs presents a dynamic solution to fracture tuning, enhancing the overall heat recovery and performance of EGS.

5.0 Acknowledgement

The research is based on work funded by the Department of Energy Office of Energy Efficiency and Renewable Energy (EERE) under the Geothermal Program Office Award Number DE-EE0009788.

We also thank our research collaborators Dr Al Dushaishi M., and Dr Atashnezhad A., for their work on the synthesis and characterization of the ILs.

ABSTRACT

Cornell University is pursuing development of an enhanced geothermal system (EGS) for providing heating to its main campus in Upstate New York. A ~3 km deep vertical observation well ("CUBO") was drilled in 2022 to characterize the subsurface using wellbore logging, borehole imaging, fluid sampling, mini-frac tests, coring, and drill cutting analysis. Down-hole temperatures measured at 3 km depth are about 80°C, sufficiently high for direct-use heating. The well drilled through generally low porosity and low permeability Paleozoic sedimentary formations and into metamorphic basement rock, encountered at about 2.8 km depth.

Leveraging subsurface data obtained through CUBO, we investigated technical feasibility and design requirements of a doublet well system with horizontal laterals connected to a fracture network created through hydraulic fracturing. The EGS reservoir is sized to provide a nominal heat output in the range 5 to 10 MW_{th} of continuous heating over a 15-year lifetime with limited thermal drawdown. We applied the Gringarten multiple parallel fractures model, the Cornell Discrete Fracture Simulator FOXFEM, and the commercial simulator ResFrac to estimate required heat transfer area and design a potential hydraulic stimulation treatment. Reservoir simulations indicate that, depending on fluid flow rate and injection temperature, 2 to 3 km^2 of effective fracture heat transfer area is required to supply the target heat output of 5 to 10 MW_{th} over 15 years.

1. Introduction

Cornell University aspires to become a carbon-neutral university by 2035 through its Climate Action Plan. A key pillar of this plan is decarbonizing the bulk of the heating load of the university's main campus in Ithaca, New York, with deep geothermal energy or "Earth Source Heat" (Tester et al., 2023). Over the past decade, various studies have been conducted to characterize the subsurface, investigate designs to integrate the geothermal system with the

existing campus energy infrastructure, and assess the overall technical and economic feasibility. In the summer of 2022, a 9,791 ft (2,984 m) deep exploratory well, named CUBO (Cornell University Borehole Observatory) was drilled to provide insights on the mechanical, thermal and hydrologic subsurface conditions using data collected through logging, coring, borehole imaging, mini-frac tests, assessing drill cuttings, and fluid sampling (Fulton et al., 2024). CUBO was drilled through about 9,400 ft (2,865 m) of Paleozoic sedimentary formations overlaying low-grade metamorphic basement rocks. Bottom-hole subsurface temperatures (after correcting for cooling due to drilling fluid circulation) are around 80°C, corresponding to a geothermal gradient of about 23°C/km. Analysis of mini hydraulic fracture testing combined with density logging suggests a strike-slip stress regime, i.e., the maximum and minimum principal stresses are horizontal and the intermediate principal stress is vertical.

Given the recent advances in EGS technology (e.g., by Fervo Energy and FORGE), this study explored developing a doublet system with long horizontal laterals at about 3 km vertical depth intersected by a large number of parallel vertical fractures created using multi-stage hydraulic stimulation (Figure 1). We leveraged three subsurface simulation models to explore potential reservoir designs capable of producing 5 to 10 MW_{th} of heat with limited thermal decline over a 15-year lifetime. Study objectives were (1) estimating the required number of fractures and required fracture area to sustain long-term heat production, (2) designing a potential hydraulic stimulation treatment program, and (3) comparing predicted reservoir performance across reservoir simulators.

2. Methodology

The three models applied to explore EGS reservoir performance are (1) the multiple parallel vertical fractures model by Gringarten et al. (1975) (Section 3), (2) the FOXFEM finite element simulator for heat transfer in fractures developed by Cornell (Fox, 2016; Hawkins, 2017; Section 4), and the commercial simulator ResFrac, allowing for simulating both hydraulic simulation and long-term fluid circulation (Section 5). The analytical Gringarten heat transfer model considers uniform flow through multiple parallel fractures. It does not calculate the pressure field, only the temperature field of the fluid. We applied the model as implemented in Python in GEOPHIRES (Beckers and McCabe, 2019; Ross and Beckers, 2023) and available on GitHub (NREL, 2024.). The model is easy to apply and provides a quick solution but assumes a simplified flow field with the fluid sweeping the entire area of the fracture with identical velocity.

The thermal-hydraulic FOXFEM simulator calculates the velocity field and corresponding pressure distribution of the fluid within the fracture, in addition to the fluid temperature field, thereby more accurately capturing the heat sweep with flow through a fracture. It can account for a variable aperture distribution but does not account for gravity (i.e., buoyancy effects due to difference in fluid density) and simulates only a single, discrete fracture. The tool is implemented in MATLAB and applies Green's functions in the Laplace domain to rapidly calculate the heat transfer between the fluid and the rock.

The thermal-hydraulic-mechanical simulator ResFrac is an advanced, commercial simulator that simulates both hydraulic stimulation to create fractures and long-term fluid circulation to estimate heat extraction. It is the most advanced simulator of the three applied, capable to simulate all relevant physics at play but has a steeper learning curve and simulations take a longer time (hours vs. seconds with the Gringarten model and minutes with the FOXFEM model).

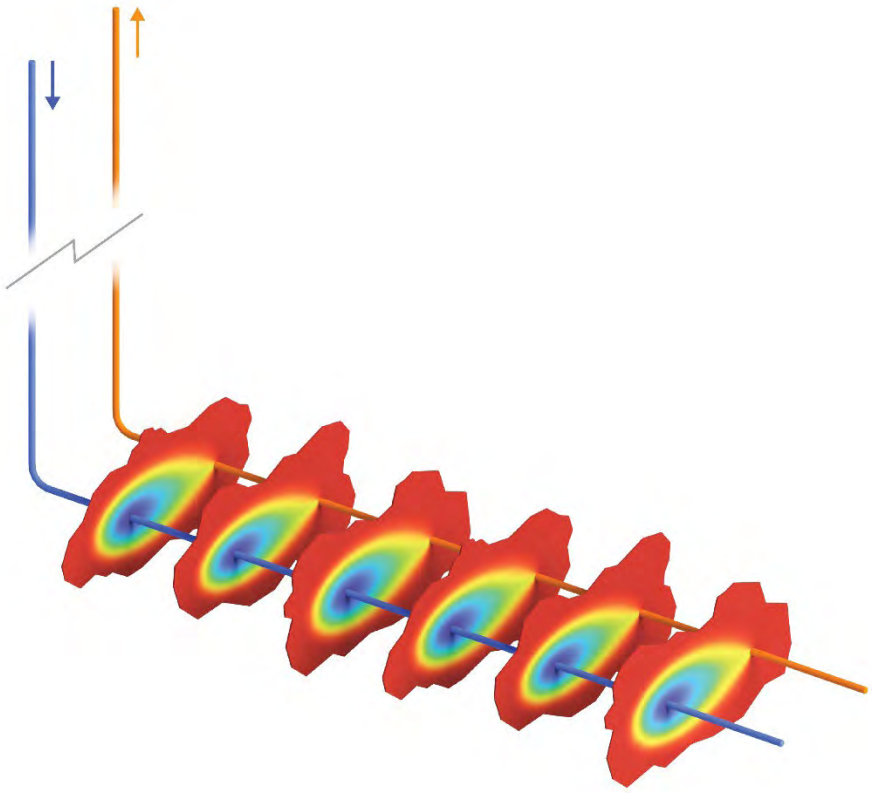

Figure 1: Simplified diagram of doublet EGS reservoir with multiple parallel vertical fractures connecting long horizontal laterals.

3. Thermal Simulations using Gringarten Multiple Parallel Fractures Model

We applied the analytical Gringarten et al. (1975) multiple parallel fractures model to investigate the required fracture heat transfer area to sustain heat production over a ~15-year lifetime. We considered four scenarios, exploring two different flow rates (30 and 50 kg/s) and two different injection temperatures (20° and 40°C). The design assumes two horizontal laterals spaced relatively close together at 150 m and with a fracture height of 150 m. The fracture spacing is set to 15 m. For comparison, Project Red in Nevada had a lateral well spacing of about 110 m (Norbeck and Latimer, 2023). For each scenario, we calculated the required number of fractures and corresponding lateral length to limit the temperature decline to 20°C after 20 years. The initial rock temperature is set to 80°C. All input parameters are listed in Table 1.

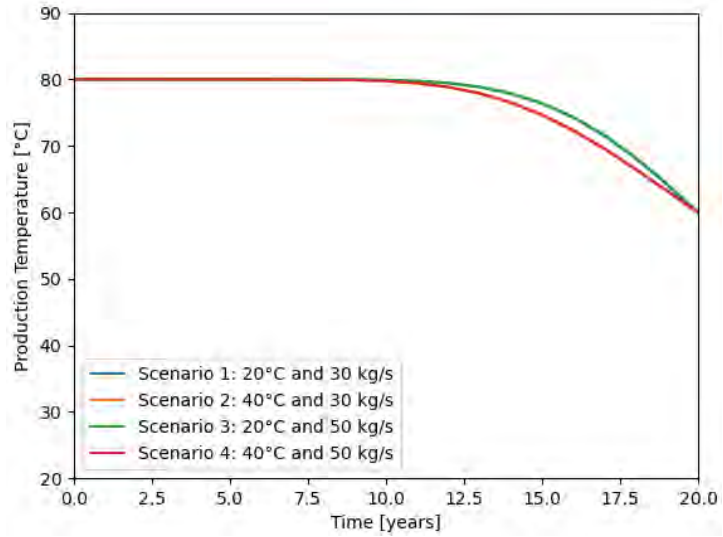
The required number of fractures (and corresponding lateral length and total heat transfer area) and initial and final thermal output for each scenario are presented in Table 1. All four scenarios have a similar production temperature profile (Figure 2a) but show a wide range in thermal output, with the initial thermal output ranging from 5 to over 12 MW_{th}, depending on the injection temperature and flow rate (Figure 2b). The lateral length required falls in the range of 1,200 to 2,300 m, and the number of fractures lies in the range of 85 to 157. For comparison, Project Red had a lateral length of about 1 km and about 100 perforation clusters in total (over 16 stages) (Norbeck and Latimer, 2023). The high thermal output scenario (Scenario 3) required the longest lateral length and highest number of fractures with a total fracture area of about 3.5 km^2. When flowing at only 30 kg/s instead of 50 kg/s (Scenario 1), a fracture heat transfer area of 2.1 km^2 is

sufficient to maintain a production temperature above 60°C. However, decreasing the flow rate also decreases the thermal output (initial thermal output drops from 12.5 to 7.5 MW_{th}).

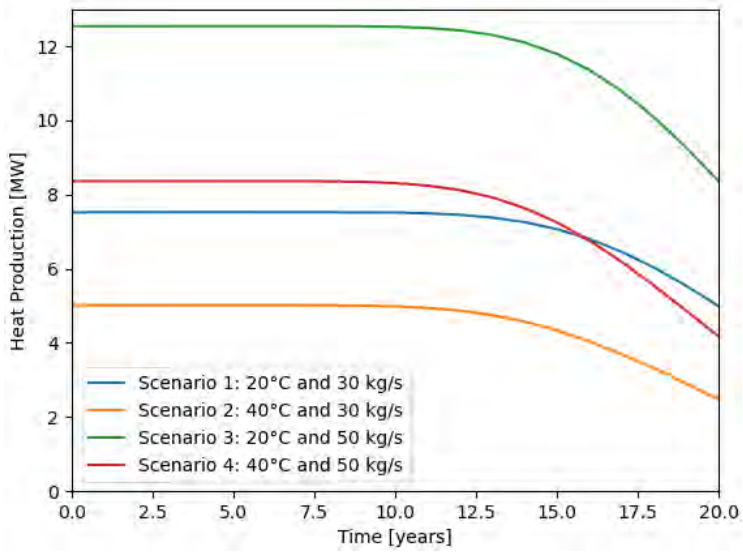
Table 1: Input parameter and simulation results using Gringarten multiple parallel fractures model.

	Scenario 1	**Scenario 2**	**Scenario 3**	**Scenario 4**
Simulation Input Parameters				
Rock initial temperature	80°C			
Fluid injection temperature	20°C	40°C	20°C	40°C
Fluid flow rate	30 kg/s		50 kg/s	
Fluid density	1,000 kg/m3			
Fluid specific heat capacity	4,180 J/kg/K			
Rock thermal conductivity	2.8 W/m/K			
Rock density	2,800 kg/m^3			
Rock specific heat capacity	1,000 J/kg/K			
Fracture length = lateral spacing	150 m			
Fracture height	150 m			
Fracture spacing	15 m			
Number of fractures	94	85	157	142
Simulation Results				
Initial heat production	7.5 MW_{th}	5.0 MW_{th}	12.5 MW_{th}	8.4 MW_{th}
Heat production at 20 years	5.0 MW_{th}	2.5 MW_{th}	8.4 MW_{th}	4.2 MW_{th}
Production temp. at 20 years	59.8°C	59.8°C	60.0°C	60.0°C
Lateral length	1,380 m	1,245 m	2,325 m	2,100 m
Total heat transfer area	2.1 km^2	1.9 km^2	3.5 km^2	3.2 km^2

The required fracture geometry, and temperature and heat production results provided in Table 1 and Figure 2 are high-level estimates, given the simplifications in the Gringarten model. In Section 4, a more advanced simulator (FOXFEM) is applied, which calculates both the fluid velocity field and corresponding pressure distribution, in addition to the fluid temperature field.



(a)



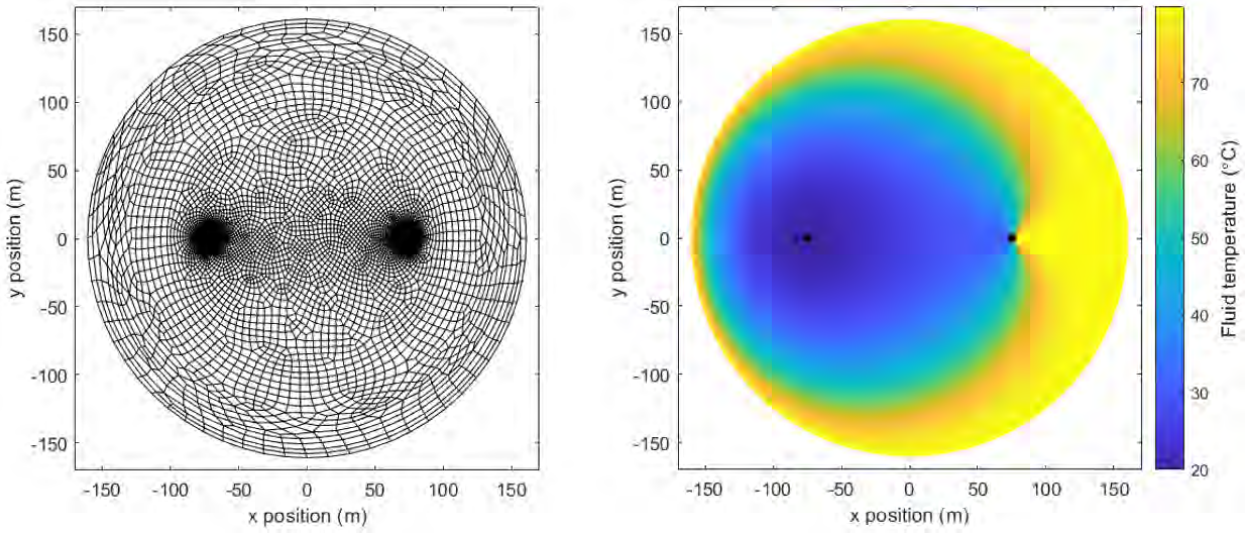
(b)

Figure 2: Production temperature (a) and corresponding heat production (b) for the four scenarios listed in Table 1. In all four scenarios, the number of fractures (and lateral length) was set to limit the production temperature decline to 20°C after 20 years of continuous operation. The heat production scales with the flow rate and difference between production and injection temperature, causing the wide range in heat production among the four scenarios. In (a), scenarios 1 and 3, and 2 and 4 overlap.

4. FOXFEM Thermal-Hydraulic Simulations

We applied the FOXFEM simulator, developed at Cornell, to estimate more accurately the heat extraction with fluid flow through a fracture located in a conduction-only medium. The tool only simulates a single fracture but simulates both the temperature and velocity field of the fluid, and can account for a variable aperture distribution.

We ran a simulation for a single fracture with FOXFEM to compare the heat sweep and effective heat transfer area with the Gringarten model, which for a single fracture simplifies to an error function. The fracture modeled is a circular fracture with a 160-m radius, with injection and production points spaced 150 m apart (Figure 3a). Rock and water properties are listed in Table 1, with water flow rate through the fracture set to 3 kg/s and injection temperature set to 20°C. The fluid temperature field after 20 years of operation is characteristic for a dipole flow field and indicates regions of the fracture with limited heat extraction from the rock (Figure 3b: yellow-colored regions). The production temperature for this case is shown in Figure 4 with the blue line, showing a temperature decline of about 30°C after 20 years. The same fracture area (0.081 km^2) with a uniform flow field as simulated with a modified Gringarten model for a single fracture shows a temperature drop of only 18°C after 20 years (red curve in Figure 4). The equivalent area with uniform flow to obtain the same temperature decline as with a dipole model is 0.054 m^2 (yellow line in Figure 4). This translates to roughly 66% heat sweep efficiency for a dipole model compared to the idealized uniform flow fracture model (assumed in Gringarten model). The heat sweep efficiency value can be different for different fracture geometries, flow rates, etc.



(a) (b)

Figure 3: Mesh (a) and fluid temperature field after 20 years of operation (b) for single fracture flow simulated with the FOXFEM simulator. Fracture has radius of 160 m with injection (left black dot) and production (right black dot) spaced 150 m apart.

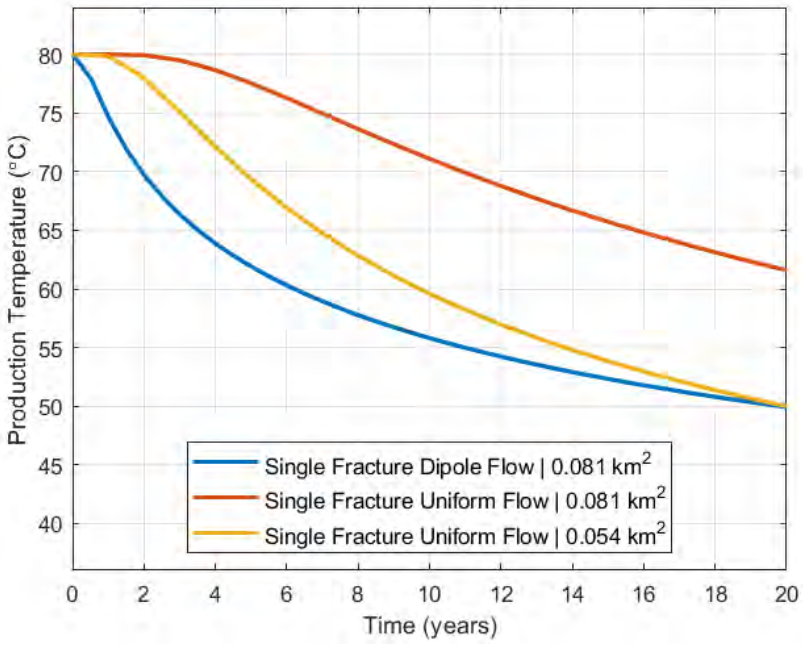


Figure 4: Production temperature profile for three scenarios: (1) single fracture dipole flow simulated with FOXFEM (as in Figure 3), (2) uniform flow in rectangular fracture for same fracture area, and (3) uniform flow in rectangular fracture with 34% reduction in fracture area.

The results shown in Figure 4 assume a uniform aperture field. Next, we explored the impact of the aperture distribution on the temperature field and production temperature. We considered three additional scenarios: a random aperture distribution between 0.5 and 2 mm (case 2), a high aperture flow path representing a "short-circuit" (case 3), and a low aperture blockage positioned in between the injection and production point (case 4). The aperture field and temperature field after 20 years for these three cases are shown in Figure 5. The production temperature profiles are presented in Figure 6. This analysis indicates the aperture field can have significant impact on the production temperature, particularly in the case of a channeled flow path, which concentrates the heat extraction along the flow path resulting in a low sweep efficiency. In real EGS reservoirs, proppants can be used to keep fractures open to facilitate obtaining high sweep efficiencies. Tracer testing can help with characterizing the effective heat transfer area. Techniques are currently being developed to mitigate high aperture flow paths, e.g., using temperature-dependent swelling particles.

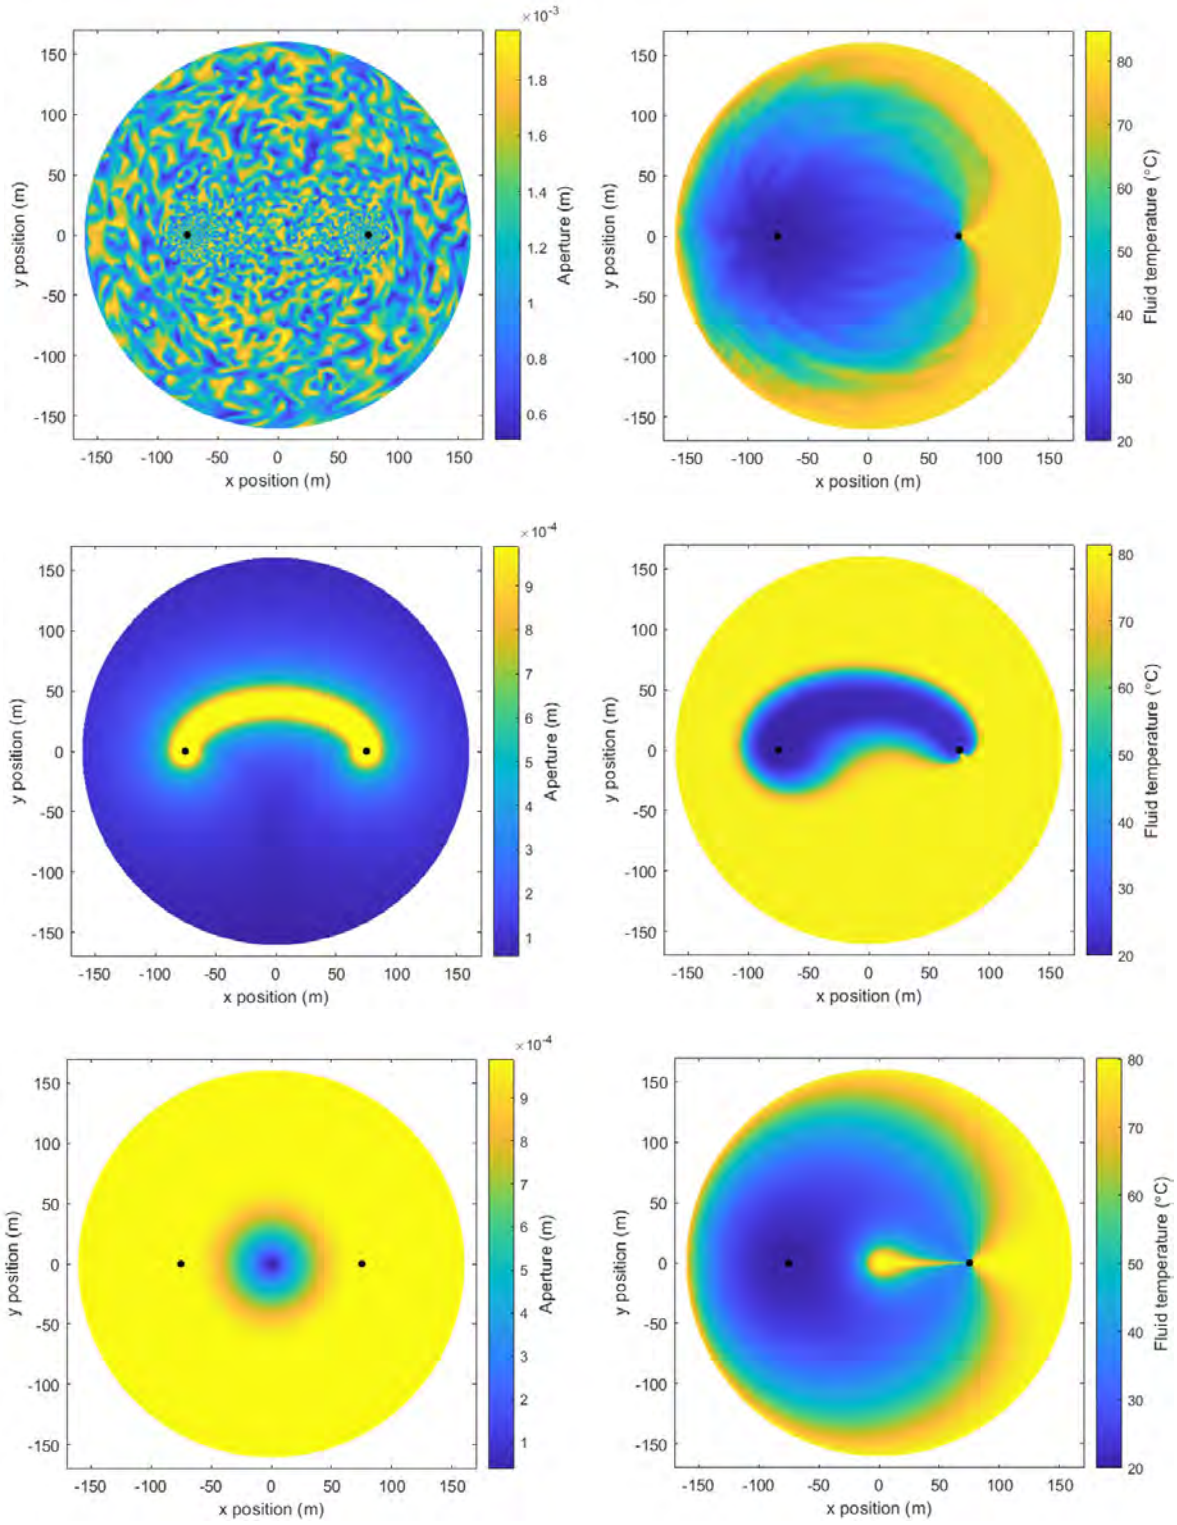

Figure 5: Fluid temperature field after 20 years (right column) for three additional aperture fields (left column): (case 2) random aperture (top), (case 3) high aperture flow path (middle), and (case 4) low aperture center blockage (bottom).

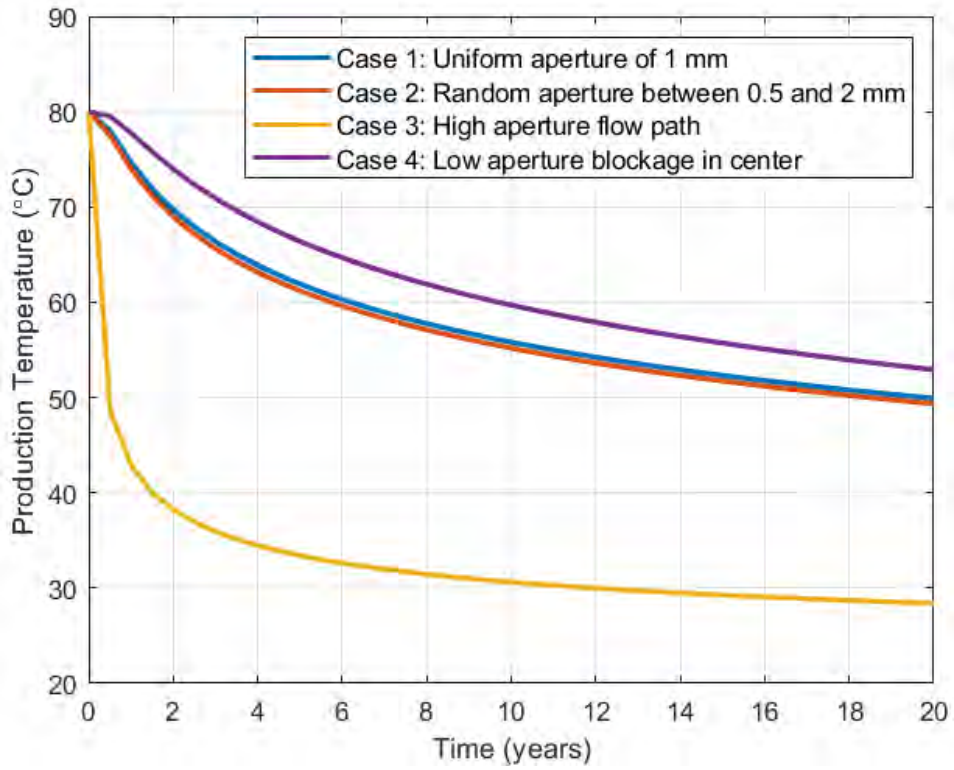

Figure 6: Production temperature profile for four aperture fields: (case 1) uniform aperture field (Figure 2), (case 2) random aperture field, (case 3) high aperture flow path, and (case 4) low aperture block in center. Corresponding aperture and temperature fields for cases 2, 3, and 4 are shown in Figure 5.

5. ResFrac Thermal-Hydraulic-Mechanical Simulations

5.1 LAS Data Processing

We utilized the commercial simulator ResFrac to explore hydraulic stimulation treatments and analyzed the corresponding thermal performance with long-term fluid circulation. We leveraged collected logging data from CUBO stored in a LAS file, provided as input to ResFrac. Figure 7 presents various logged properties with the entire profile shown on the left and the zoomed in profile for the bedrock shown on the right. The average values for the bedrock are provided as input to ResFrac, i.e., porosity of 3.9%, Young's modulus of 31 GPa, Poisson's Ratio of 0.32, and Biot coefficient of 0.58. A hydrostatic column is assumed for pore pressure with pressure gradient of 10.8 MPa/km.

5.2 ResFrac Simulations

ResFrac simulations were conducted to design a potential hydraulic stimulation treatment and further explore the necessary number of fractures and fracture area to obtain long-term heat production with commercially acceptable thermal decline. Dozens of simulations were run considering different wellbore and stimulation designs. For this paper, we selected a promising case study with design parameters listed in Table 2 and simulation results presented in Figure 8. In this design, we considered 20 stages where each stage has five clusters, for a total of 100 fracture clusters. To save on computational time, only one stage was simulated using a no-flux condition as a domain boundary condition in between the stages. The injection and production lateral were spaced 150 m apart, the clusters were spaced 20 m apart, and we stimulated both laterals. The lateral length for each well is about 2 km. Stress field (with linear gradient) and uniform rock properties were specified using data from the wellbore logging (as stored in the LAS file; Section

5.1) and documented in Fulton et al. (2024). We limited the number of perforations per cluster to four and the perforation diameter to 0.01 m to enforce a sufficiently large pressure drop across the perforations, facilitating uniform fracture creation and uniform inflow across all fractures. The wellbore diameter was set to 0.18 m and the wellbore heat transfer coefficient to 50 $W/m^2/K$. We specified a matrix permeability multiplier of 10 when the pore pressure is 20 MPa above initial pore pressure in the matrix to account for effects such as small existing natural fractures opening at high pressures, causing increased leak-off. We used pure water instead of slickwater during stimulation and 100 mesh particles as proppants.

The production temperature for this design (Figure 8a) initially increases (due to diminishing wellbore heat losses) before dropping by about 5°C after 20 years. The production flow rate (Figure 8b) gradually increases to over 95% of the injection flow rate. Different designs such as a large wellbore field with alternating injection and production laterals may yield a smaller water loss rate. The injected proppant in all five fractures mostly settled in the bottom section of the fractures (Figure 8d), resulting in heat sweep of the hottest region of the fracture but also preventing fluid from accessing the entire fracture heat transfer area. Other treatments are currently being explored such as using proppants with smaller density or using slickwater instead of clean water during stimulation, which may result in a more uniform proppant distribution within the fractures. When simulating the same design with only 16 stages instead of 20 stages (i.e., 80 fractures instead of 100 fractures), the production temperature drops to 66°C after 20 years.

Table 2: Input parameters for preliminary base case design simulated with ResFrac.

Parameter	Value
Vertical depth of laterals	3 km
Lateral spacing	150 m
Fracture spacing	20 m
Rock density	2,800 kg/m^3
Rock specific heat capacity	1,000 J/kg/K
Rock thermal conductivity	2.8 W/m/K
Rock porosity	3.9%
Rock permeability	10^{-19} m^2
Rock initial temperature	81°C at 3 km depth
Minimum horizontal principal stress $S_{h,min}$	72 MPa at 3 km depth
Maximum horizontal principal stress $S_{h,max}$	108 MPa at 3 km depth
Vertical stress S_v	80 MPa at 3 km depth
Initial pore pressure	32 MPa at 3 km depth
Young's modulus	31 GPa
Biot coefficient	0.58
Poisson's ratio	0.32
Horizontal fracture toughness	2.2 MPa-m$^{1/2}$
Vertical fracture toughness	3.3 MPa-m$^{1/2}$
Rock thermal expansion coefficient	0.00001 1/°C
$E_{0,max}$	0.00027 m
90% closure stress	17 MPa
$E_{res,max}$	0.000001 m
Total number of fracture clusters	100
Stimulation treatment	Both injection and production well stimulated with 4 clusters per stage and 4 perforations per cluster. Injection sequence: 1. 10 min at 0.1 m^3/s (no proppant) 2. 80 min at 0.25 m^3/s with proppant (90 kg/m^3) 3. 80 min at 0.25 m^3/s with proppant (150 kg/m^3) 4. 10 min at 0.05 m^3/s (no proppant).

6. Conclusions

In support of the Earth-Source Heat project at Cornell University, we conducted reservoir simulations to explore technical feasibility and design requirements of an EGS reservoir supplying 5 to 10 MW_{th} of heating to the university's district heating system. We applied three different simulators: (1) the thermal (T) Gringarten model, (2) the thermal-hydraulic (TH) FOXFEM simulator, and (3) the thermal-hydraulic-mechanical (THM) ResFrac simulator. We leveraged subsurface data obtained from the 3 km deep CUBO well drilled in 2022, including reservoir temperature, stress field, and thermo-physical properties.

Inspired by the recent EGS advancements, the EGS reservoir considered consists of an injection-production doublet at ~3 km vertical depth and ~2 km long horizontal laterals. The wells are spaced

about 100 to 150 m apart and connected with a network of ~100 vertical parallel fracture clusters. The initial rock temperature is 80°C, and water as heat transfer fluid is injected at 20° to 40°C and 30 to 50 L/s. Lower injection temperatures would require utilizing a heat pump for integrating with the existing district energy infrastructure.

The key study outcome, supported by all three simulators, is that, depending on injection temperature and flow rate, an *effective* heat transfer area on the order of 2 to 3 km^2 is required to provide 5 to 10 MW_{th} of heating continuously over 15 years with limited thermal decline. This total heat transfer area can be obtained with ~100 to ~150 fracture clusters where each fracture has an effective heat transfer area on the order of 20,000 m^2. ResFrac simulations indicate that stimulating both wells that are spaced 100 to 150 m apart with injecting proppants is a potential stimulation treatment to obtain a sufficiently large effective fracture heat transfer area. Previous work has shown that with today's drilling costs, integrating this doublet system with a heat pump into the existing district heating network has a cost-competitive levelized cost of heat on the order of $40/MWh (assuming 4.25% nominal discount rate).

Simulations with FOXFEM and ResFrac allowed quantification of the difference between fracture dimensions and effective fracture heat transfer area, as certain zones of the fracture may not be accessed by the circulating fluid. Reasons include flow not reaching the outer edges of the fracture, and preferential pathways within the fracture due to large aperture regions (e.g., proppants settling in the lower zone of the fracture.

Planned future modeling work includes conducting additional reservoir simulations to further explore sensitivity to subsurface conditions, including considering reservoir heterogeneity, different reservoir depths, and different wellbore designs. Further in-situ subsurface characterization is planned by deepening the CUBO well, installing permanent fiber, and running additional logs, stress field tests and flow tests. Finally, planning and design of a first doublet with horizontal laterals combined with multi-zone stimulation to provide heating to the campus is ongoing.

ABSTRACT

The thermal performance of an enhanced geothermal energy production system is analyzed. The system consists of a network of multilateral conduits which can be either drilled cylindrical holes or notionally rectangular ones generated by fractures. The steady state energy equation is coupled to that in the formation using a pseudo transient approach based on the Fourier Number. Expressions for the interface flux and penetration depth of the cold thermal front into the formation are developed for both drilled and fractured configurations. It is shown that the thermal performance of any multilateral or fracture-connected system can be characterized by a single parameter defined as the Number of Transfer Units (NTU), which is commonly used in heat exchanger analysis. The NTU in turn is proportional to the ratio of the Biot to Peclet numbers, and to the ratio of contact area to conduit area. Several examples are provided illustrating the approach. The results indicate that while the surface flux decays more rapidly in a planar (fractured) configuration, the significantly greater thermal contact area results in far superior thermal performance even after extended production times as large as 5 years.

1. Introduction

In recent years, a number of innovative concepts have been proposed to extract geothermal energy from hot dry resources. These include connecting multilaterals between injector and producer (Holmes, et al., 2021), thermal reach enhancement (Moncarz and Suryanarayana, 2022), closed loop geothermal (Beckers, et al., 2022), down-borehole exchange (all of which are increasingly referred to as Advanced Geothermal Systems, or AGS), and the classical Enhanced Geothermal Systems (EGS) that connect two (or more) wells through some form of fracturing or stimulation. The EGS approach has historically received the most attention and funding, since its beginnings in 1970s in Fenton Hill (Brown et al., 2012). The recent successes of Fervo (Norbeck, et al, 2023) and Utah FORGE (Allis and Moore, 2019) have brought EGS closer to reality. Both these demonstration projects were at temperatures around 200°C. More recently, the idea of using EGS in superhot rock (with resource temperatures greater than 375°C) has emerged as a viable and

scalable technique for the production of geothermal energy (US Department of Energy, 2024). Moncarz and Suryanarayana (2022) describe a novel AGS technique for exploiting superhot rock. The US DOE has recently increased its focus in this area by awarding a grant to Mazama Energy, to create EGS reservoirs in superhot rock.

All these methods involve the circulation of a working fluid through the fracture network in the resource to extract heat from the resource, which is then converted into electric power using an appropriate power cycle. The most commonly used working fluid is water.

Regardless of the concepts being proposed and tested, they all scale according to the parameters and properties governing heat transfer behavior in the resource. In this paper, we illustrate the heat transfer behavior of these systems using scaling parameters that govern the problem. It is shown that at pseudo-steady state, the non-dimensional temperature of the working fluid scales with the Biot number and a suitably defined Peclet number, as well as the ratio of the contact area to conduit area, thus encompassing all the parameters that govern heat transfer. The scaling curves provide a useful basis for comparing different heat extraction concepts, and for identifying improvements. It is shown that a single unified parameter known as the Number of Transfer Units, common in Heat Exchanger Analysis, can describe the thermal performance of practically any EGS or AGS.

One of the objectives of this study is to generalize the approach of the nearly 50-year-old study of Gringarten et al. (1975) who considered a network of very large (1 km^2) infinite planar fractures, and define a non-dimensional time parameter. While perhaps not practical at the time of their study, their results indicate the potential for substantial power generation with a properly constructed network of fractures in a hot dry resource.

Further, when extracting heat from hot, dry resources, depending upon the technique being used, the thermal penetration depth, and therefore, rate of thermal decline, vary. The thermal penetration depth is analogous to the drainage radius in oil and gas production. In this paper, we present a semi-analytical approach to determine the non-dimensional penetration depth, as a function of non-dimensional time (the Fourier number). Combining this with the scaling analysis above, we then investigate the expected thermal decline rate and the pseudo-steady state energy recovery for a number of examples. The notion of thermal recovery efficiency (analogous to the recovery factor in hydrocarbon reservoirs) is discussed in the context of these examples.

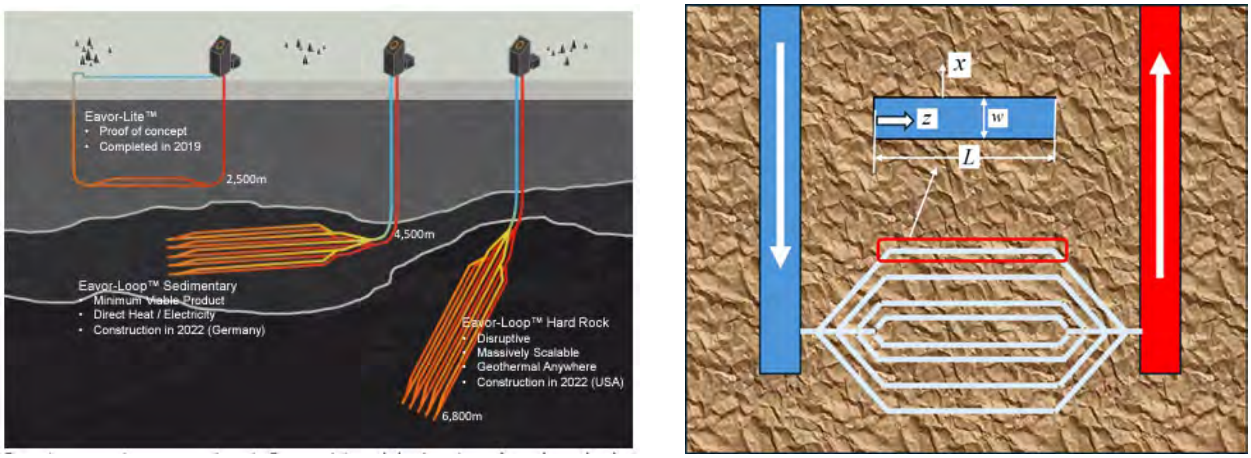
The authors believe that this work serves as a useful, generalized basis for quickly evaluating different thermal recovery concepts, and examining the impact of different modifications or improvements to heat recovery and recovery efficiency. This work complements the more sophisticated, but time-consuming, numerical simulations that are often used in literature to model heat recovery assurance. While it does not replace these numerical methods, it provides valuable insight into the thermal performance of different AGS and EGS systems.

2. Mathematical Model

Without loss of generality, an engineered “heat exchanger” created in a geothermal resource can be represented by two wellbores in the resource connected by one to several lateral conduits. The conduits can represent a single closed loop (as in a Closed Loop Geothermal System, or CLGS), a connected multilateral system, or a pair of wells connected by fractures. Figure 1 (left panel) shows a notional closed loop geothermal well with two vertical wellbores connected by a multilateral

system consisting of several widely spaced horizontal conduits of specified length and diameter, as indicated in the figure. An example of this concept is presented by Holmes et al. (2021).

The network can also consist of several fractures connecting the two vertical wells, as shown in the right panel of Figure 1. In this case, the fractures are assumed to be notionally rectangular with specified thickness (typically 3—5 mm), length, and height (breadth) of the planar fracture. Length and breadth are usually of the order of 100 m. Although the figure shows two vertical wells connected by planar fractures, the orientation of the wellbores and fractures can be arbitrary, as long as the fractures have constant width.



(a) Drilled Multilaterals **(b) Fractured Multilaterals**

Figure 1: Multilateral Configurations connecting two Vertical Wellbores.

The key geometrical parameters of the two types of connectivity are shown in Figure 2. Since the width b of the fractured multilaterals is generally several orders of magnitude larger than the thickness w, the hydraulic diameter can be approximated as $D_h \approx 2w$.

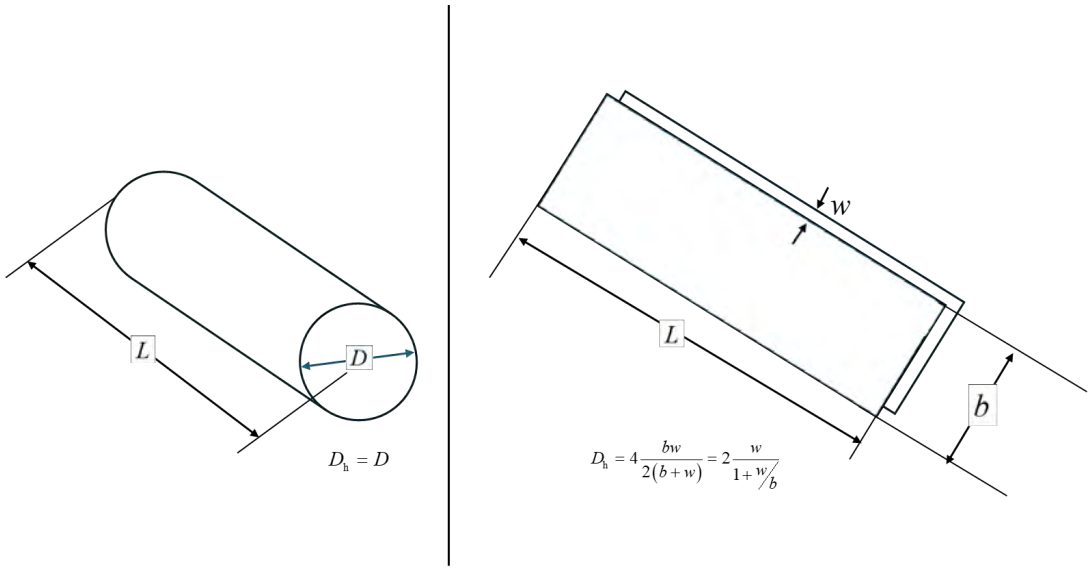


Figure 2: Geometry of a single Cylindrical (Drilled, Left) and Planar (Fractured, right) Conduit.

2.1 Governing Equations

Consider hydrodynamically fully developed flow in each horizontal conduit segment in Figure 1, under which the following assumptions are valid:

1. The resource is homogeneous, with constant thermophysical properties,
2. The flow is one-dimensional, with no thermophysical property variations or phase change in transverse directions (the implications of property variations or phase change on the scaling are discussed in the appendix),
3. The diameter of each conduit, or the width (aperture) of each fracture, is constant,
4. The sensible heat approach allows the enthalpy gradient to be represented by temperature and pressure gradients,
5. Transients are relegated to the formation and hence only to the conduit-formation interface flux, and
6. There is no thermal interference between individual conduits or fractures.

With the above assumptions, the quasi-steady (or pseudo-steady) non-conservative form of the transport equations of mass, momentum (Navier-Stokes), and energy in cylindrical coordinates reduce to

$$\frac{\mathrm{d}\dot{m}_\mathrm{c}}{\mathrm{d}z} = \frac{\mathrm{d}\dot{m}}{\mathrm{d}t}0 \Rightarrow V = \frac{\dot{m}}{\rho A_\mathrm{f}} \tag{1}$$

$$\frac{\mathrm{d}P}{\mathrm{d}z} = -\frac{1}{2} f \rho \frac{V^2}{D_\mathrm{h}} \tag{2}$$

and

$$\rho c_{\mathrm{p}} V \frac{\mathrm{d}T}{\mathrm{d}z} - \rho c_{\mathrm{p}} c_{\mathrm{JT}} V \frac{\mathrm{d}P}{\mathrm{d}z} = \frac{\dot{Q}(\bar{t})}{A_{\mathrm{f}}} \tag{3}$$

where the mass flow rate in each lateral conduit is the global mass flow rate divided by the number of conduits i.e., $\dot{m} = \dot{m}_{\mathrm{G}} \big/ N_{\mathrm{c}}$, and A_f is the conduit flow area. The heat flux $\dot{Q}(\bar{t})$ at the wellbore-formation evaluated at some snapshot $\bar{t}$ is obtained from the solution of the transient transverse formation heat diffusion problem. The friction factor can be evaluated in terms of the flow Reynolds number and the conduit relative roughness as

$$f = f\left(\mathrm{Re}, \frac{\varepsilon}{d}\right) = f\left(\frac{\rho V D_{\mathrm{h}}}{\mu}, \frac{\varepsilon}{d}\right) \tag{4}$$

from one of the many explicit forms of the Colebrook-White equation. The heat flux term $\dot{Q}(\bar{t})$ can also be expressed in terms of the instantaneous formation temperature gradient for drilled cylindrical multilaterals as

$$\dot{Q}(\bar{t}) = 2\pi h \frac{D}{2}\left(T_{\mathrm{W}} - T\right) = 2\pi R k_{\infty} \left.\frac{\partial T}{\partial r}\right|_{r=R} (z, \bar{t}) = 2\pi \bar{U}(\bar{t})\left(T_{\infty} - T\right) \tag{5}$$

and in the case of rectangular fractures, as

$$\dot{Q}(\bar{t}) = 2hb\left(T_{\mathrm{W}} - T\right) = 2bk_{\infty} \left.\frac{\partial T}{\partial x}\right|_{x=w} (z, \bar{t}) = 2\bar{U}(\bar{t})\left(T_{\infty} - T\right) \tag{6}$$

where the factor of 2 arises from the flux on each side of the rectangular conduit. In each case, the overall heat transfer conductance $\bar{U}$ relates the instantaneous heat flux at any axial location to the temperature difference between the undisturbed formation (T_∞) and the flowing stream (T).

The energy equation above is subject to the horizontal conduit inlet boundary condition

$$T(0) = T_{\mathrm{in}} \tag{7}$$

A set of dimensionless entities can be defined as

$$\xi = \frac{z}{L} \qquad\qquad \theta = \frac{T_{\infty} - T}{T_{\infty} - T_{\mathrm{in}}} \tag{8}$$

Accordingly, the energy equation can be expressed in non-dimensional form as

$$\frac{\mathrm{d}\theta}{\mathrm{d}\xi} = \Lambda - \Gamma\theta \tag{9}$$

where the frictional heating parameter (also known as the pressure gradient parameter) is

$$\Lambda = \frac{c_{\mathrm{JT}} L}{\left(T_{\infty} - T_{\mathrm{in}}\right)} \frac{\mathrm{d}P}{\mathrm{d}z}, \tag{10}$$

and

$$\Gamma = 2\pi^n \frac{\bar{U}L}{\dot{m}c_{\mathrm{p}}} = 2\pi^n \frac{\bar{U}}{k} \frac{kL}{\dot{m}c_{\mathrm{p}}} \tag{11}$$

The parameter Γ will be apparent to those familiar with heat exchanger analysis as the *Number of Transfer Units.* The index n is equal to 1 and 0 for cylindrical and planar geometries. The importance of this parameter is discussed in a later section.

With the above nondimensionalization, the boundary condition is

$$\theta(0) = 1 \tag{12}$$

In Appendix 1, it is shown how the *Number of Transfer Units* is also the governing parameter for the general case with variable thermophysical properties in an enthalpy-based formulation of the transport equation that is valid across trans-critical, supercritical and two-phase regimes.

2.2 Conduit Surface Flux

At any snapshot in time, the conduit surface flux represents the thermal interaction between the flowing stream, the conduit and the formation. Appendix 2 shows the mathematical details of the estimation of this flux, in terms of a dimensionless flux multiplier. For cylindrical geometry, the flux multiplier is given by

$$F(\tau) = \mathrm{L}^{-1}\left[\frac{1}{\sqrt{s}}\frac{K_1\left(\sqrt{s}\right)}{K_o\left(\sqrt{s}\right)}\right]\begin{cases} = \dfrac{1}{\sqrt{\pi\tau}}, & \tau \le 0.001, \\ \approx 10^{\sum_{k=0}^{5} p_k (\log_{10}\tau)^k}, & \tau > 0.001 \end{cases} \tag{13}$$

And for the planar geometry, the flux multiplier is

$$F(\bar{\tau}) = \left(\sqrt{\pi\tau}\right)^{-1} \tag{14}$$

These flux multipliers are pseudo-transient, in that they are functions of the nondimensional time

$$\tau = \left[\frac{4n}{D^2} + \frac{(1-n)}{w^2}\right]\alpha_\infty t \tag{15}$$

where n = 0 is for planar geometry, and n = 1 is for cylindrical geometry. but are evaluated at a snapshot in time.

The flux multiplier is useful when streamwise temperature variation at different time snapshots (elapsed time) is of interest. For each time snapshot, the flux multipliers can be evaluated, from which the conduit surface heat flux can be estimated. As a result, depending upon the case, a decay in outlet temperature can be seen as time progresses. This decay is an important result in determining the long-term performance of the system.

2.3 Thermal Penetration Depth

As the working fluid extracts thermal energy from the resource, the resource rock cools in the vicinity of the conduit. The thermal penetration depth is the normal distance from the conduit

centerline at which the resource temperature recovers to its undisturbed initial temperature. Thermal penetration depth affects heat extraction by the flowing fluid and decay in exit temperature with time. In Appendix 3, we describe how thermal penetration depth is calculated in this work, for both the cylindrical and planar geometries.

Figure 3 shows the normalized penetration depth as a function of the Fourier number, for the two geometries. It is seen that at large Fourier numbers (large times), the penetration depth in a planar configuration is larger. This suggests a more rapidly diminishing surface heat flux in a planar configuration, as compared with a cylindrical configuration. It also implies that a larger volume of the resource rock participates in the heat transfer, leading to higher cumulative thermal energy extraction. In both cases, the rate of increase of the penetration depth decreases logarithmically with time, suggesting that a pseudo-steady state approximation for the penetration depth is appropriate. Nevertheless, it should be noted that thermal penetration continues to evolve with time, and a true steady state is not achieved within the typical timeframes of interest (20-50 years).

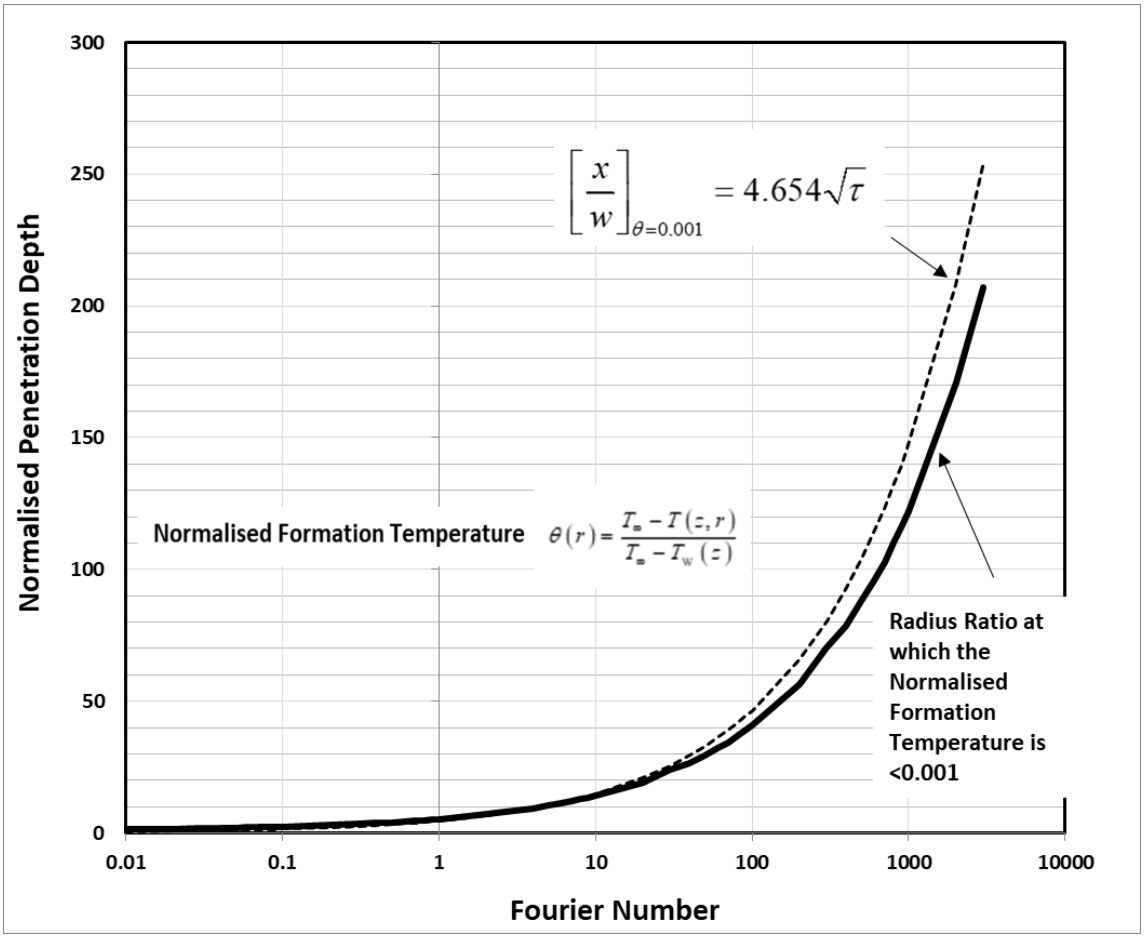

Figure 3: Thermal Penetration Depth as a function of the Fourier Number.

2.4 Temperature Field

Integration of Eq. (9) subject to the boundary condition in Eq. (12) leads to

$$\theta(\xi) = e^{-\Gamma\xi} - \frac{\Lambda}{\Gamma}\left(1 - e^{-\Gamma\xi}\right) \tag{16}$$

A plot of the dimensionless exit temperature θ (i.e., at $\xi = 1$) versus the Number of Transfer Units Γ is shown in Figure 4 for various values of the pressure gradient parameter Λ. Note that in order to facilitate an intuitive understanding of an increasing exit temperature with Γ, what is plotted in the figure is actually $1 - \theta_{\xi=1}$. It is seen that except for very large values of Λ (greater than 0.1) the exit temperature can be very accurately approximated as

$$\theta_{\xi=1} = e^{-\Gamma} \tag{17}$$

The negative Joule-Thomson effect is in evidence at Λ = 0.1, as a result of which the exit temperature is slightly higher than the undisturbed geothermal. This is similar to the phenomenon seen in prolific high pressure, high temperature hydrocarbon producer wells in which the arrival temperatures are often higher than the static bottom hole temperature. In the present context, this is purely academic, since the actual pressure gradients are substantially lower, rendering Λ values typically << 0.1.

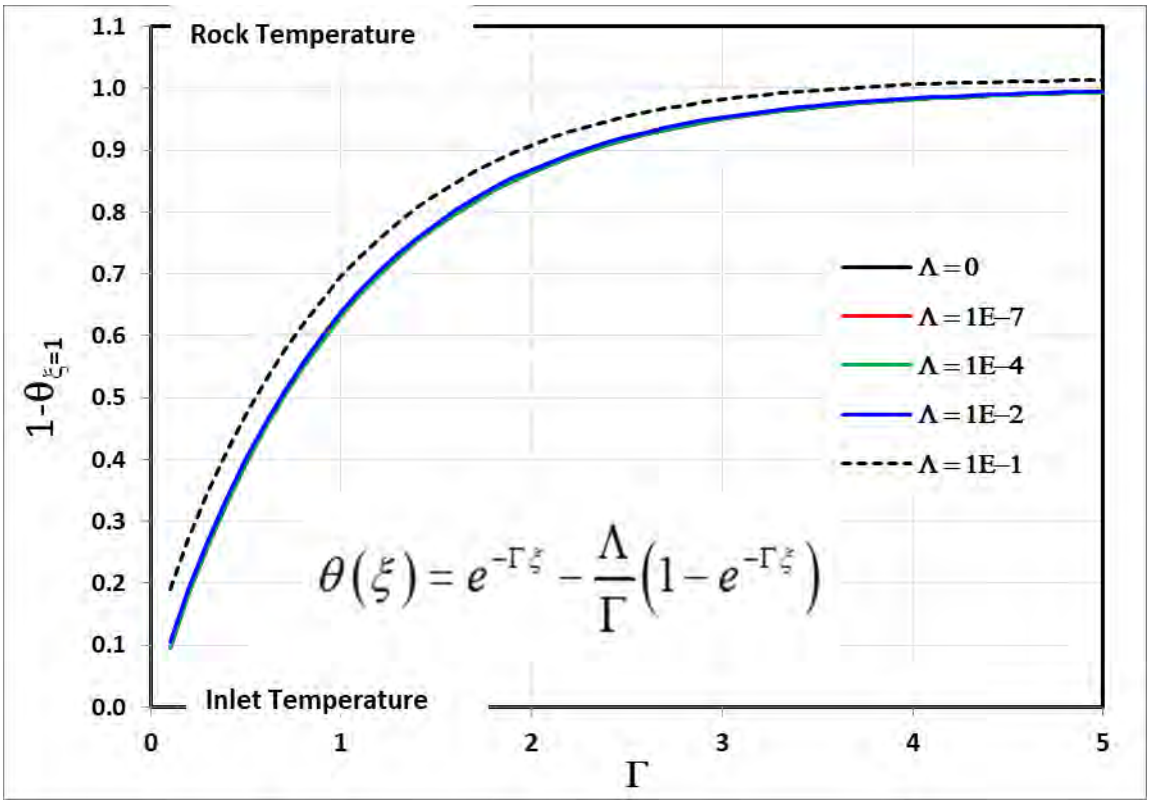

Figure 4: Dimensionless Exit Temperature as a function of the Number of Transfer Units (Γ) and the Pressure Gradient Parameter (Λ.)

2.5 Characterization of the Number of Transfer Units

An important result from this work is that the Number of Transfer Units (NTU) emerges as the key scaling parameter. It is therefore instructive to examine the Number of Transfer Units in the context of the operating parameters. We note that Eq. (11) can be written as

$$\Gamma = 2\pi^n \frac{k}{\rho V P c_p} \frac{\bar{U}}{k_\infty} \frac{k_\infty}{k} \frac{LP}{A_f} = 2\pi^n \frac{k}{\rho V P c_p} \frac{\bar{U}}{k_\infty} \frac{k_\infty}{k} \frac{A_c}{A_f} = 2\pi^n \frac{\mathrm{Bi}}{\overline{\mathrm{Pe}}} \frac{k_\infty}{k} \frac{A_c}{A_f} \tag{18}$$

where the Peclet and Biot numbers are

$$\overline{\mathrm{Pe}} = \frac{\rho V P c_p}{k} \tag{19}$$

and

$$\mathrm{Bi} = \frac{\bar{U}}{k_\infty} \tag{20}$$

and the product A_c of the conduit length and perimeter is the thermal contact area. It is more convenient to describe the Peclet number in terms of the key conduit dimension rather than the perimeter. Accordingly for the planar geometry, we have

$$\overline{\mathrm{Pe}} = 2\frac{\rho V w c_p}{k}\left(1+\frac{b}{w}\right) = \left[2\left(1+\frac{b}{w}\right)\right]\mathrm{Pe}_w \tag{21}$$

and for the cylindrical geometry,

$$\overline{\mathrm{Pe}} = \pi\frac{\rho V D c_p}{k} = \pi\mathrm{Pe}_D \tag{22}$$

Substitution into Eq. (18) results in

$$\Gamma = \gamma\frac{\mathrm{Bi}}{\mathrm{Pe}}\frac{k_\infty}{k}\frac{A_c}{A_f} \tag{23}$$

where

$$\gamma = \begin{cases} \dfrac{w}{w+b}, & \text{Planar Geometry} \\ 2, & \text{Cylindrical Geometry} \end{cases} \tag{24}$$

We see three important nondimensional groupings in the above equation: the ratio of the Biot number (*Bi*) to the Peclet number (*Pe*), the ratio of the formation conductivity to fluid conductivity, and the ratio of the thermal contact area (A_c) to the fluid flow area (A_f). The Number of Transfer Units (Γ) is *directly* proportional to the Biot number, the ratio of the areas, and the ratio of the conductivities. It is *inversely* proportional to the Peclet number (*Pe*). Since the higher the Γ, the more effective the thermal recovery (the higher the return temperatures), any strategy to improve

thermal recovery has to necessarily increase Γ. This can be achieved by increasing the area ratio (for example, increasing the contact area while reducing flow area), the conductivity ratio (for example, enhancing effective formation thermal conductivity), or *Bi*, or by reducing *Pe* (for example, by increasing the number of connecting conduits or fractures). In a previous work (Suryanarayana, et al, 2023), the authors have noted the importance of reducing *Pe* to increase the nondimensional exit temperature. This work expands upon this notion, and shows that NTU (Γ) is the fundamental governing nondimensional parameter for EGS and AGS.

2.6 Relationship to the nondimensional time parameter of Gringarten et al (1975)

It is interesting to note that the nondimensional time parameter t'_D defined by Gringarten et al (1975) is related to the NTU (Γ) of this work. In terms of the nomenclature of this study, their t'_D can be written as

$$t'_{\mathrm{D}} = \frac{\left(\rho c_{\mathrm{p}}\right)^2}{k_\infty \rho_\infty c_{\mathrm{p}_\infty}} \left(\frac{\dot{q}}{bz}\right)^2 t \tag{25}$$

setting $z = L$ at the conduit exit, and noting that $\dot{m} = \rho \dot{q}$ leads to

$$t'_{\mathrm{D}} = \left[\frac{k_\infty}{\rho_\infty c_{\mathrm{p}_\infty}} \frac{c_{\mathrm{p}}}{k_\infty} \frac{\dot{m}}{Lb^2} t\right] \frac{\dot{m} c_{\mathrm{p}}}{k_\infty L} = \left[\tau \frac{w^2}{b^2}\right] \left(\frac{\dot{m} c_{\mathrm{p}}}{k_\infty L}\right)^2 \tag{26}$$

Substitution of the definition

$$\frac{\bar{U}}{k_\infty} = \frac{b}{w} \frac{1}{\sqrt{\tau}} \tag{27}$$

into Eq.(26) results in

$$t'_{\mathrm{D}} = \left(\frac{\dot{m} c_{\mathrm{p}}}{\bar{U} L}\right)^2 = \Gamma^{-2} \tag{28}$$

leading to the key observation that the dimensionless time in the study of Gringarten et al. (1975) is effectively the inverse square of the NTU as defined in this study ($t'_D = 1/\Gamma^2$). Furthermore, if as Gringarten et al. (1975) did, internal thermal resistance is neglected at the conduit/formation interface (effectively Nu → ∞), then Eq. (27) is identical to Eq. (47) with the exception of the multiplier $\pi^{-1/2}$ of τ. The significance of this term however disappears at the large times considered in this study.

It is more intuitive to present the results in terms of NTU, as done in this work, as the different nondimensional groupings that control the thermal behavior are readily apparent, and make physical sense. Further, as we shall see, for a given system, NTU changes with time, which is important to observe when evaluating a given system.

Figure 4 is a useful representation of thermal recovery from EGS and AGS systems, and allows quick comparison of different systems. The basic approach is to calculate the NTU corresponding

to any given system, and read off the corresponding nondimensional temperature from Figure 4. In this manner, different concepts or modifications to concepts can be quickly evaluated.

3. Results and Discussion

We now examine a few EGS and AGS concepts using the above theory. In what follows, we present the results first in dimensional terms to provide physical context, and finally present them in nondimensional terms (Figure 4) to enable comparative assessment.

3.1 Cylindrical Drilled Multilaterals

Table 1 indicates a configuration with a 6000 m total lateral length. This mimics the connected multilateral system described in Holmes et al, (2021). A total of 5 laterals each with a diameter of 8.5 in are considered. With the assumed geothermal gradient of 0.08°C/m, the static rock temperature at the resource depth of 4500 m is 360°C. All thermophysical properties are evaluated at a reference temperature taken to be the average of the rock temperature and the specified inlet temperature of 100°C. The reference pressure is merely the hydrostatic pressure of pure water at the resource depth. For a specified mass flow rate of 20 kg/s, the estimation of all of the parameters leading to the pressure gradient parameter Λ and the Number of Transfer Units Γ are also shown. The pressure gradient parameter is several orders of magnitude lower than the Number of Transfer Units thereby justifying the use of the solid curve in Figure 4.

Table 1 Parameter Estimation with Drilled Multilaterals

Wellbore Parameters		Diameter (m)	0.2159		
# Laterals	5	Hydraulic Diam (m)	0.2159	Relative Roughness	9.41E-03
Length (m)	6,000	Flow Area (m^2)	3.66E-2	Aspect Ratio	27,790
Diameter (in.)	8.500	Perimeter (m)	0.6783	Prandtl Number	0.826
Resource Depth (m)	4500	Thermal Contact Area (m^2)	4,070		
		Reference Pressure (MPa)	44	Reynolds Number	1.87E+5
		Resource Temperature (°C)	360	Friction Factor	0.0375
Operational Parameters		Reference Temperature (°C)	230	Nusselt Number	356
Mass Flow Rate (kg/s)	20.0			Biot Number	0.231
Inlet Temperature (°C)	100	**Thermophysical Properties**		k-Ratio	2.967
Flow Duration (hrs)	10000	Density (kg/m^3)	861	Area ratio	1.11E+05
		Viscosity ($Pa.s^{-1}$)	1.26E-4	Geometry factor	2.000
Formation Properties		Specific Heat (J/kg-K)	4,409	τ	2.47E+03
Thermal Conductivity (W/m-K)	2.00	Thermal Conductivity (W/m-K)	0.674	F(τ)	0.23205
Thermal Diffusivity (m^2/sec)	8.00E-07	Joule-Thomson Coefft (m^2K/N)	-8.90E-8	U/k	0.686
Geothermal Gradient (°C/m)	0.08	Thermal Diffusivity (m2/s)	1.78E-7	Pe	1.54E+05
Roughness (in.)	0.08			Ac/Af.U/k	24,266
		Time Constant (s)	1.46E+4		
		Velocity (m/s)	0.127	Γ	**0.988** (NTU)
		Pressure Gradient (N/m^3)	-1.2	Λ	**2.47E-6**

The temperature variation along the conduit length is plotted in Figure 5 for different operating times. For each of these times, the Fourier number can be calculated from Eq. (48) from which the pseudo-transient conduit surface flux is approximated. There is decay with time, which appears to be stabilizing as physical time approaches 1 year, with the exit temperature dropping by about

25%. Figure 6 shows similar exit temperature curves, this time for a single lateral, as in classical closed-loop systems. Compared to Figure 5, the decay is more pronounced.

Figure 7 compares the decay of the exit temperature for a classical single-lateral closed-loop system with the five multilateral system discussed above. The figure starkly demonstrates the rapid decay of the single-lateral system, log scale of time notwithstanding, and underlines the need for long single laterals, or multiple laterals to obtain reasonable declines. This rapid decay of a single-lateral system was also remarked upon by Beckers, et al. (2022).

It is worth noting that the NTU reduces with time in both cases, and will approach a near-constant value at long times. More importantly, note that the NTU for the five-lateral system is an order magnitude higher than the single-lateral case, implying better thermal recovery.

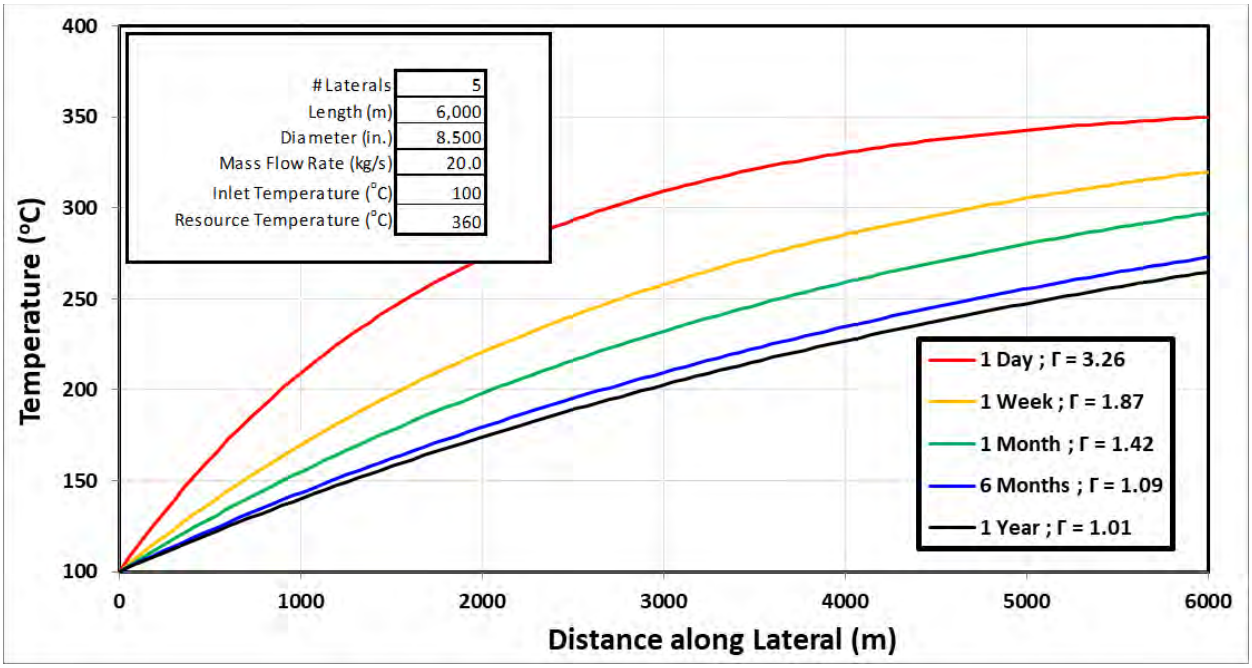

Figure 5: Streamwise Temperature Profiles at various operating times – 5 Drilled Multilaterals.

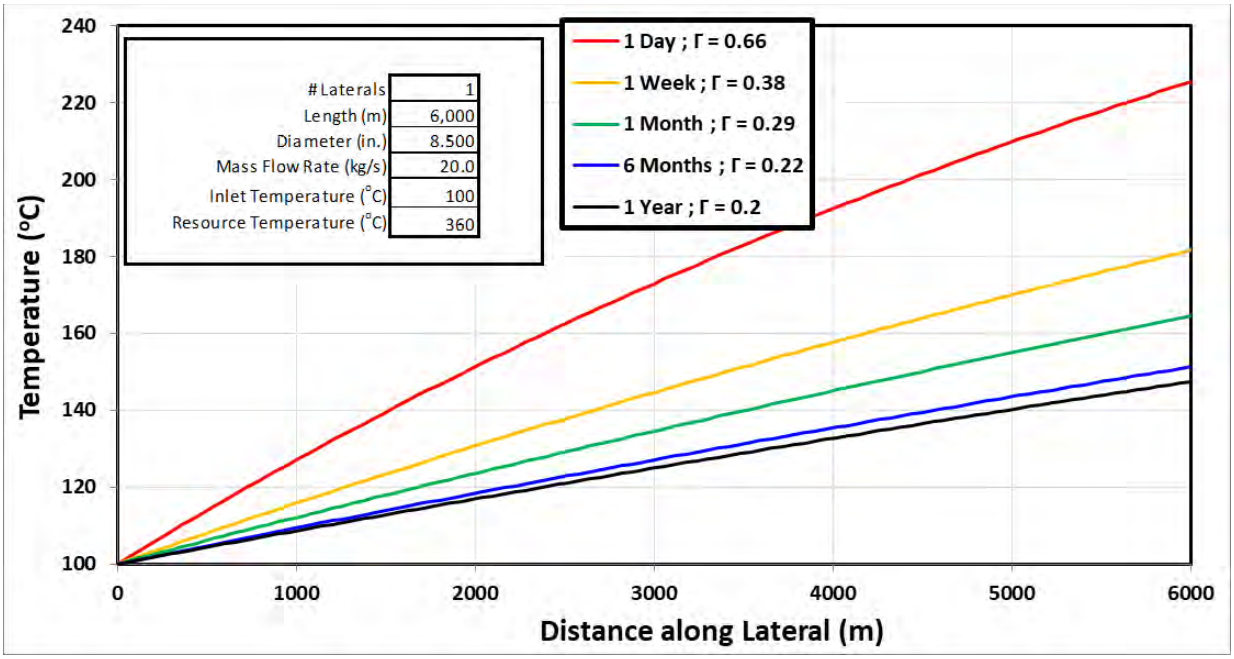

Figure 6: Streamwise Temperature Profiles at various operating times – 1 Drilled Multilateral.

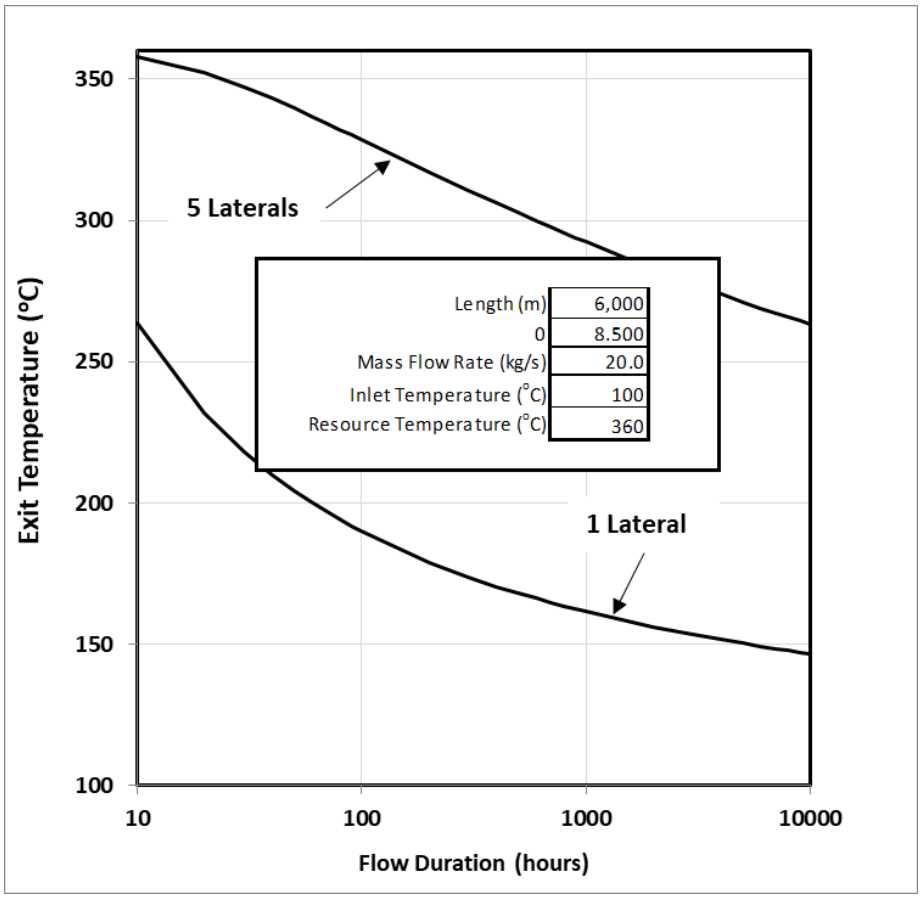

Figure 7: Decline of Exit Temperature with Time – 20 kg/s through 1 and 5 laterals.

3.2 Multiple Planar Fractures

In a planar configuration where several planar conduits caused by fracturing connect two vertical wellbores, the distance between wellbores is limited from practical considerations to 100 m. A total of 100 fractures, each of width 3 mm is assumed. The other parameters are exactly as in the case of cylindrical drilled multilaterals.

The temperature decay with time in the case of planar fractures is much lower than in the case of drilled multilaterals as evidenced in Figure 8. What is clear is that the greater contact area in the case of fractured multilaterals more than adequately compensates for the higher decay rate of the flux with time. Even after a 5-year producing period, the exit temperature at the given flowrate is still at the initial resource temperature. We also see that increasing the inter-wellbore distance is beneficial, with 70 m being a minimum in the case shown to avoid decline after 5 years. Also note the much higher values of NTU.

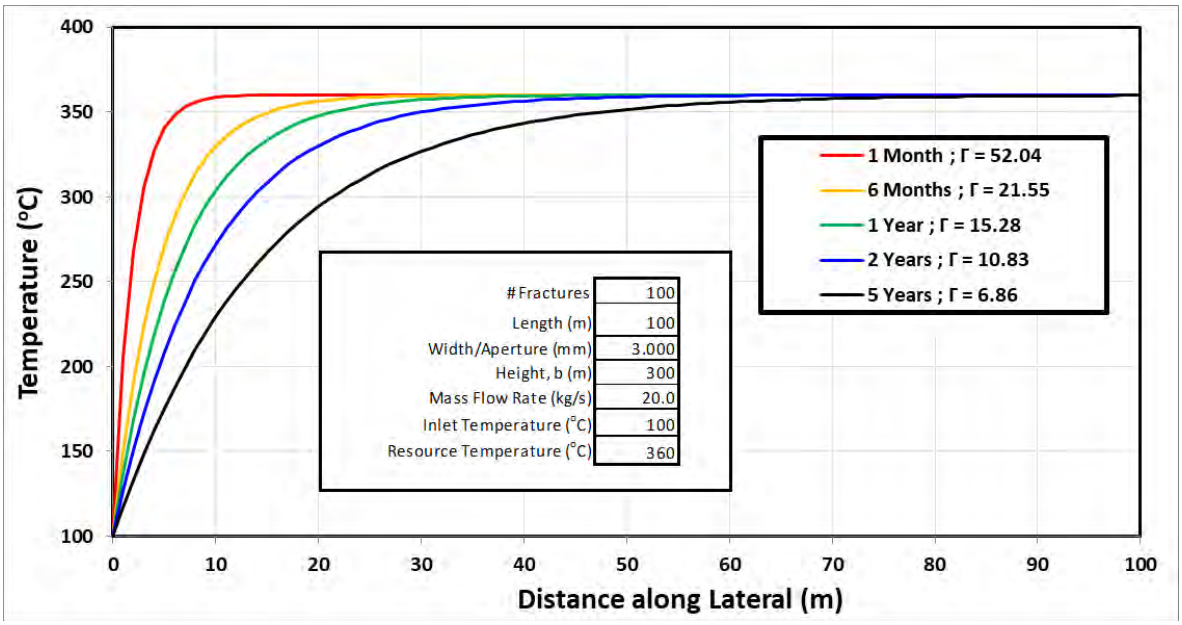

Figure 8: Streamwise Temperature Profiles at various operating times – 100 Planar Fractures at a Resource Temperature of 360 °C.

Figure 9 shows that with fewer planar fractures (in this case, five), thermal decay is more pronounced, implying that higher number of connected fractures is more beneficial to thermal recovery with lower rate of decline. This is in line with the conclusions of Gringarten, et al (1975).

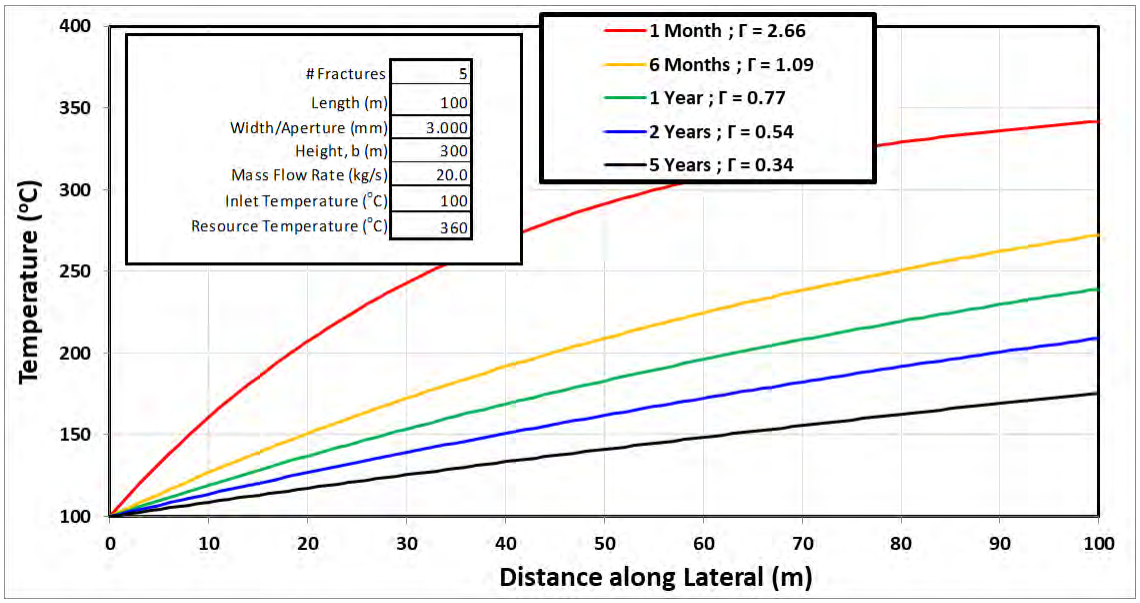

Figure 9: Streamwise Temperature Profiles at various operating times – 5 Planar Fractures at a Resource Temperature of 360 °C.

The effect of global mass flow rate - i.e., the total mass flow rate through all of the fractures is shown in Figure 10 at the end of an operating period of 5 years. This is for the 100 fractures case. Only for mass flow rates greater than 50 kg/s does the exit temperature drop substantially below undisturbed geothermal (resource temperature), indicating a respectable power generation capability. Further, the figure suggests that mass flow rates can be managed with time according to exit temperature or exit enthalpy constraints in practical systems.

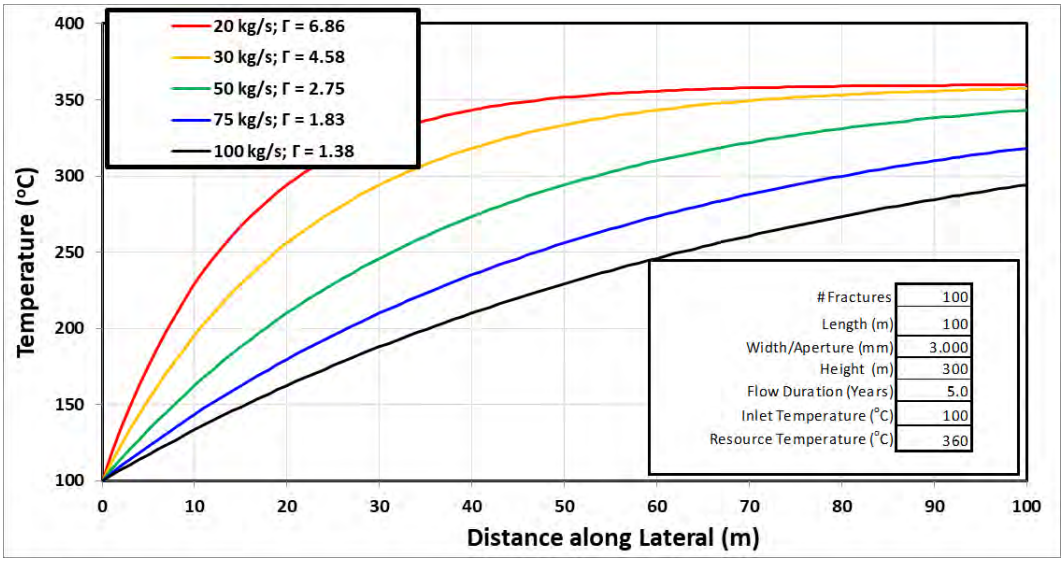

Figure 10: Streamwise Temperature Profiles at various Mass Flow Rates after 5 years – 100 Planar Fractures at a Resource Temperature of 360 °C.

Returning our attention to the scaling curve, the different operating scenarios evaluated in this work, corresponding to both cylindrical conduits and planar fractures, are indicated on the universal exit temperature vs NTU curve as shown in Figure 11. It should be noted that the mass flow rate has been kept constant in this illustration. In actual applications, the mass flow rate can be optimized for different extraction methods.

Any EGS or AGS concept not covered in this limited study can be similarly placed on this graph to assess its thermal performance. Likewise, the impact of modifications in flow rates, geometries, or thermal properties can be examined by calculating the NTU and using the graph to estimate the exit temperature.

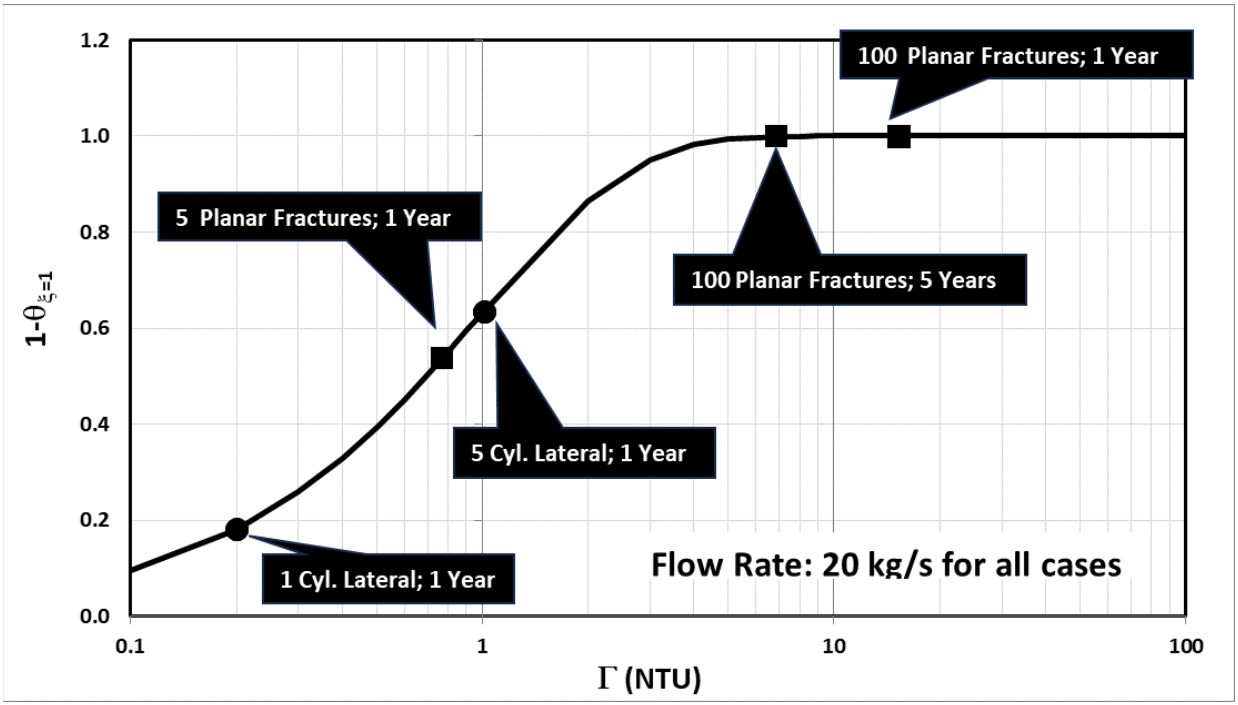

Figure 11: Various Operating Scenarios Superimposed on the Universal Exit Temperature vs Number of Transfer Units Curve.

3.3 Superhot Rock EGS – Illustrative Example

As noted in the introduction, there is increasing interest in the creation of EGS reservoirs within superhot rock (SHR, > 375°C) resources. In order to examine the thermal recovery from such systems, we look at an illustrative example. In this example, the following assumptions are made:

- Resource Temperature = 400 C
- Inlet temperature into the fracture network = 100 C
- Working Fluid is water
- Total Mass Rate = 50 kg/s
- Duration of Interest = 20 years
- Number of planar connecting fractures = 10 and 100
- Distance between Wells (Fracture Length) = 100 m
- Fracture height = 300 m
- Fracture width (aperture) = 3 mm
- Pressure gradient parameter is much less than 0.1

The streamwise thermal performance of this hypothetical system is shown in Figure 12 (10 fractures) and Figure 13 (100 fractures), in physical units, as a function of time. The transient surface flux term is calculated from the Fourier number corresponding to these times. With only

10 fractures (Figure 12), rapid decline is evident even after just a year. This is primarily because of the short distance between wellbores. The available contact area with ten fractures is not adequate to compensate for this. In order to arrest the decline, either the mass flow rate has to be reduced, or the distance (fracture length) has to be increased. However, with 100 fractures, for a significant length of time (2-5 years), we can see that the exit temperature is practically the same as the resource temperature (ignoring any production well heat loss). Clearly, the higher the number of connected fractures, the greater the thermal recovery. For completeness, we note that in order to create a large number of connected fractures, multi-stage fracturing of long deviated or horizontal wells may be required.

Even for the 100-fractures case, the exit temperature decays with time for long time, implying that the exit enthalpy will reduce with time. The reduction after 20 years (compared to the resource temperature) is not as drastic as in the drilled multilateral systems discussed earlier, and is about 20%. Still, it is not negligible, and should be considered in specific applications. Field development plans and operational strategies may need to manage either the number of wells or flow rates to maintain either a constant exit temperature or constant exit enthalpy over time, depending upon the design of the surface power facilities. Increasing the distance between the wellbores (fracture lengths) will also improve thermal performance. While detailed assessment of development strategies and operational management is beyond the scope of the current work, it serves to illustrate the need for more detailed analyses to support these activities.

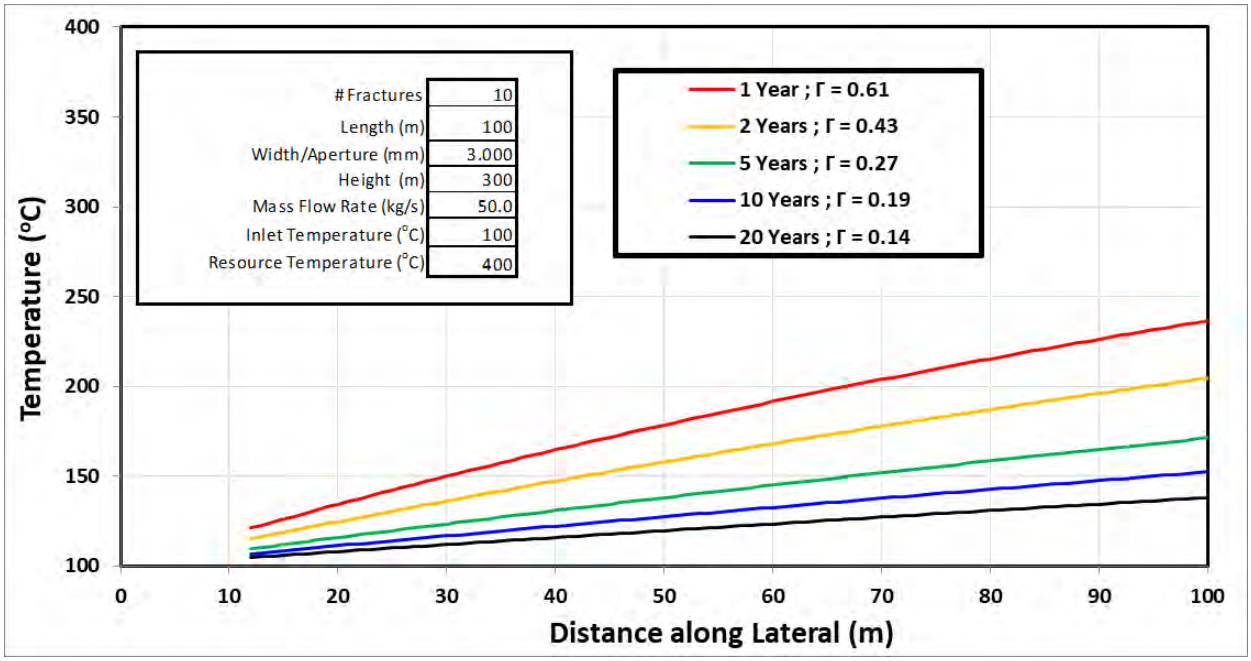

Figure 12: Streamwise Temperature Profiles at various operating times – 10 Planar Fractures at a Flow Rate of 50 kg/s and a Resource Temperature of 400°C.

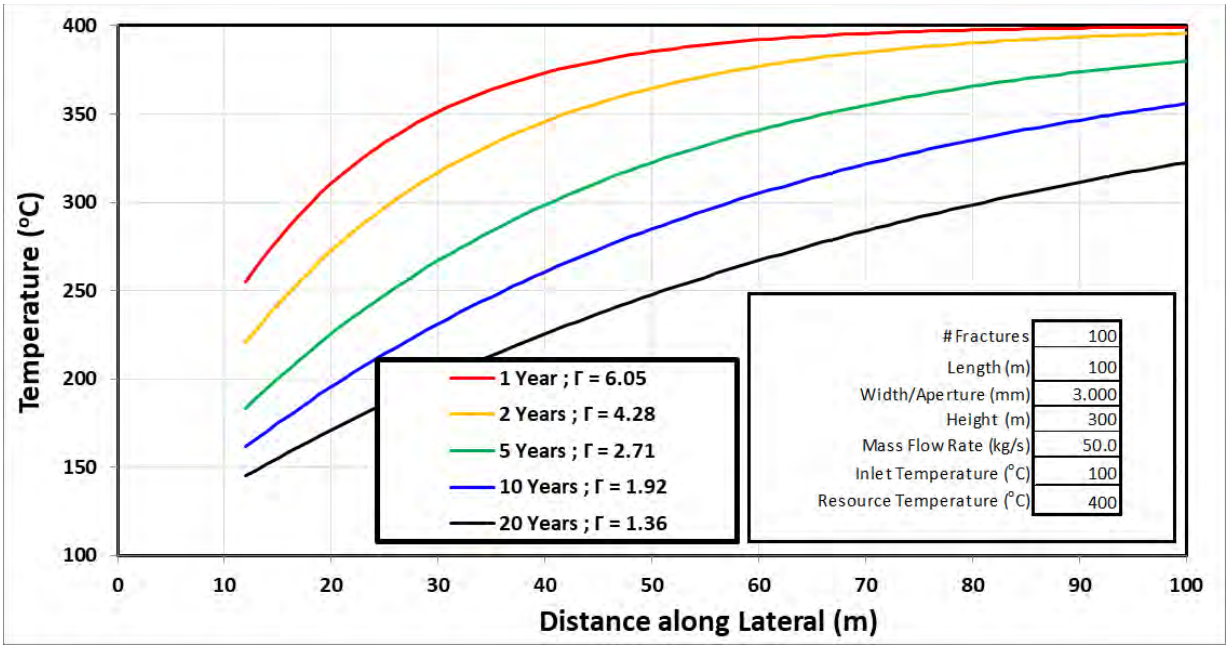

Figure 13: Streamwise Temperature Profiles at various various operating times – 100 Planar Fractures at a Flow Rate of 50 kg/s and a Resource Temperature of 400°C.

4. Conclusions

The thermal performance of enhanced (or engineered) geothermal energy production systems is analyzed in this study using a scaling approach. The system consists of a network of multilateral conduits which can be either drilled cylindrical holes or notionally rectangular planar fractures. The steady state energy equation is coupled to that in the formation using a pseudo transient approach based on the Fourier Number. Expressions for the interface flux and penetration depth of the cold thermal front into the formation are developed for both drilled and fractured configurations. It is shown that the thermal performance of any multilateral or fractured system can be characterized by a single parameter Γ, the Number of Transfer Units (NTU). NTU is a parameter that is commonly used in heat exchanger analysis. Therefore, it is not surprising that it emerges as the key scaling parameter here, as in essence, extraction of heat from hot, dry rock requires the creation of a heat exchanger in the resource.

The NTU is proportional to a) the ratio of the Biot to Peclet numbers; b) the ratio of the formation thermal conductivity to the fluid conductivity; and c) the ratio of the thermal contact area to flow area. In order to improve thermal recovery, NTU has to be maximized over the intended service life of a project. This can be achieved by designing and operating the extraction systems such that the above ratios are maximized.

Several examples of AGS and EGS concepts are provided to illustrate the main points of this work. Results indicate that while the surface flux decays more rapidly in a planar (fractured) configuration, the significantly greater thermal contact area results in far superior thermal performance even after extended production times as large as 5 years, particularly in superhot rock resources. Finally, it is shown that superior thermal performance and lower decline is possible with superhot rock EGS, especially when a large number of connected fractures can be created.

The scaling analysis and curves presented here are universal, and can be used to evaluate different concepts for heat extraction from hot dry rock resources. The authors hope that this work will be useful to quickly evaluate different heat extraction concepts, and to assess the impact of any modifications or improvements to the design or operation of such systems.

Acknowledgement

The authors thank the management of Mazama Energy for funding the work leading to this paper, and for allowing its publication. The authors are also grateful to Dr Ismail Ceyhan for his detailed review of the paper and his comments for improvement.

APPENDIX 1

The quasi-steady state energy equation can also be cast in terms of the enthalpy derivative as

$$\rho V \frac{\mathrm{d}h}{\mathrm{d}z} = \frac{2\pi \bar{U}}{A_\mathrm{f}} \left(T_\infty - T \right) \tag{29}$$

subject to the boundary condition

$$h(0) = h\left(P_\mathrm{in}, T_\mathrm{in} \right) \tag{30}$$

where P_in and T_in are the inlet pressure and temperature. The momentum equation remains

$$\frac{\mathrm{d}P}{\mathrm{d}z} = -\frac{1}{2} f \rho \frac{V^2}{D_\mathrm{h}} \tag{31}$$

subject to its boundary condition

$$P(0) = P_\mathrm{in} \tag{32}$$

Temperature is extracted from enthalpy and pressure according to

$$T = T\left(P, h \right) \tag{33}$$

and the constitutive models for the overall heat transfer conductance and friction factor are as previously described in the body of the paper. If we define a reference conductance in terms of inlet properties as

$$\bar{U}_* = k_* \left[\frac{2}{\mathrm{Nu}_*} + \frac{1}{F(\tau)} \frac{k_*}{k_\infty} \right]^{-1} \tag{34}$$

and introduce the following set of dimensionless variables

$$\begin{aligned} \omega &= \frac{h - h(0)}{c_{\mathrm{p}_*} \left(T_\infty - T_\mathrm{in} \right)} \\ \xi &= \frac{z}{L} \\ \theta &= \frac{T_\infty - T\left(P, h \right)}{T_\infty - T_\mathrm{in}} \\ \phi &= \frac{\bar{U}}{\bar{U}_*} \end{aligned} \tag{35}$$

then the energy equation and its boundary condition are transformed to

$$\frac{\mathrm{d}\omega}{\mathrm{d}\xi} = \left[\frac{2\pi\bar{U}_{*}L}{\dot{m}c_{\mathrm{p}_{*}}}\right]\phi\theta = \Gamma_{*}\phi\theta$$
$$\omega(0) = 0 \tag{36}$$

The term Γ_{*} is the Number of Transfer Units defined in terms of inlet properties. As in the sensible heat formulation, the terms ω, θ, and ϕ are all of Order One. While Eq. (36) is not amenable to a closed form solution, it can be integrated numerically along the conduit in conjunction with a thermophysical property database[1] to yield profiles of enthalpy and hence temperature along the conduit. The velocity at any streamwise location is determined in accordance with mass conservation from

$$V = \frac{\dot{m}}{\rho A_{\mathrm{f}}} \tag{37}$$

For a flow that remains in the subcritical regime, which is typical of most operating scenarios, Figure 14 shows that despite the substantial thermophysical property variation along the conduit, the temperature profiles predicted by both the sensible-heat and enthalpy formulations are practically identical.

In a trans-critical flow scenario, with the operating pressure (and temperature) close to the critical pressure (and temperature), the differences in the predicted temperature profiles are more significant as shown in Figure 15.

[1] like NIST's REFPROP

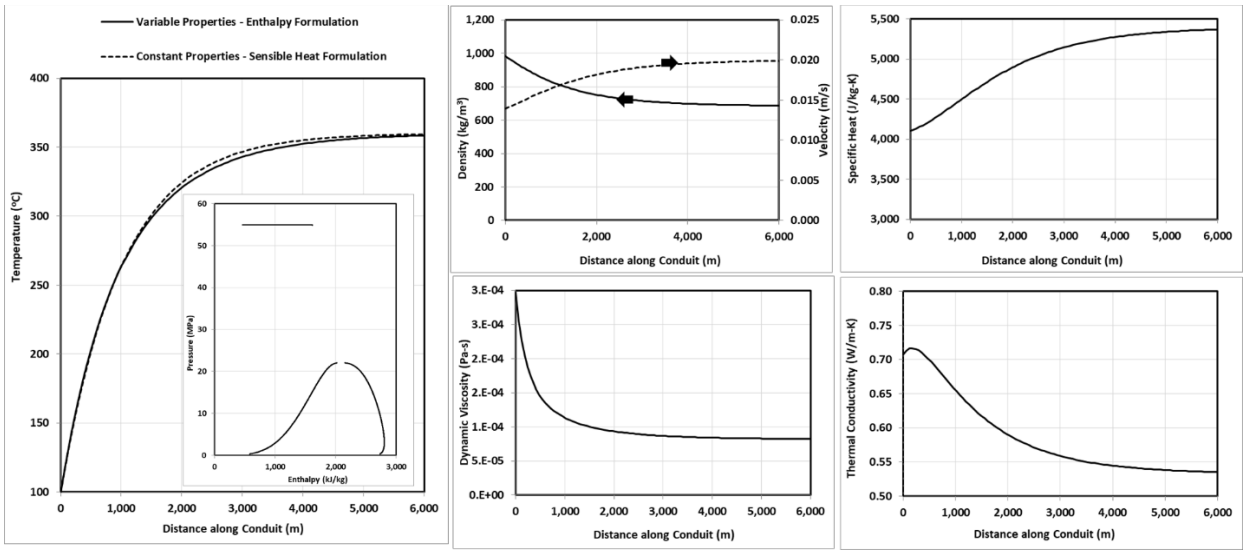

Figure 14: Temperature and Thermophysical Property Profiles for a Subcritical Flow Scenario (Resource Temperature 360°C and Inlet Pressure 55 MPa).

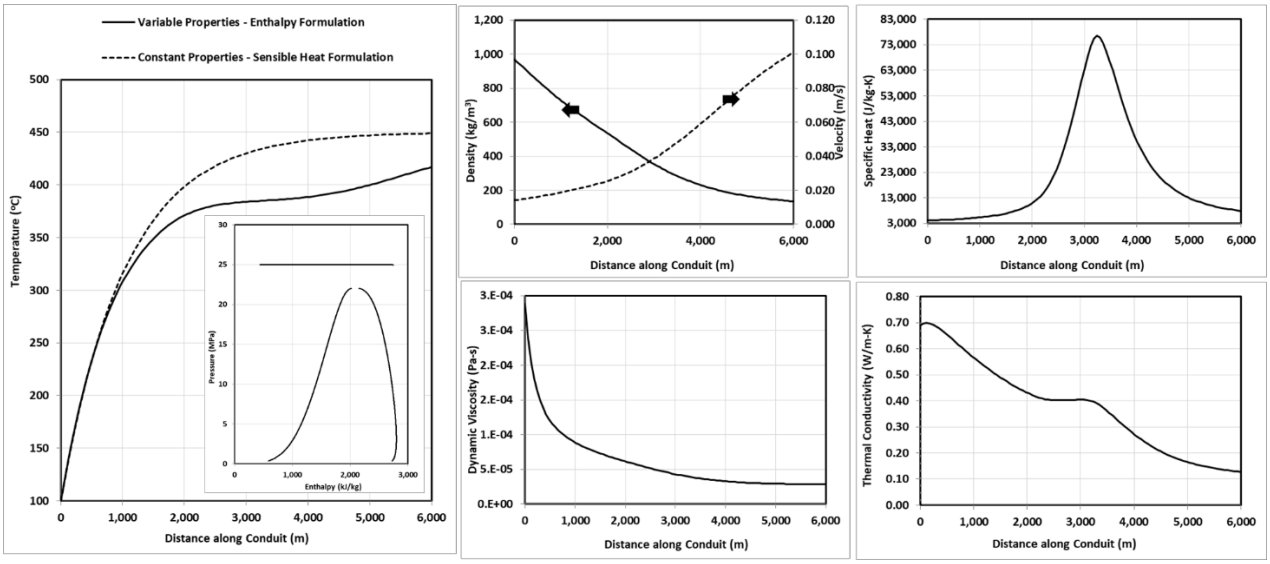

Figure 15: Temperature and Thermophysical Property Profiles for a Trans-Critical Flow Scenario (Resource Temperature 450°C and Inlet Pressure 25 MPa).

APPENDIX 2

Cylindrical Geometry (Drilled Multilaterals)

The flux at the interface of a cylindrical conduit and the formation is

$$\frac{\dot{Q}(t)}{2\pi} = Rk_{\infty}\left.\frac{\partial T}{\partial r}\right|_{r=R}(z,t) = k_{\infty}\left(T_{\infty}-T_{\text{in}}\right)\left.\frac{\partial \theta}{\partial \eta}\right|_{\eta=1}(\tau) = F(\tau)k_{\infty}\left(T_{\infty}-T_{\text{in}}\right) \tag{38}$$

where the dimensionless time is essentially a Fourier Number corresponding to the snapshot in time in question, and defined as

$$\tau = 4\frac{\alpha_\infty t}{D^2}, \tag{39}$$

where α_∞ is the formation thermal diffusivity. The pseudo-transient flux multiplier can be represented by the curve fit to solution of the one-dimensional radial diffusion problem of a cylinder embedded in a semi-infinite medium.

$$F(\tau) = \mathrm{L}^{-1}\left[\frac{1}{\sqrt{s}}\frac{K_1(\sqrt{s})}{K_o(\sqrt{s})}\right]\begin{cases} = \dfrac{1}{\sqrt{\pi\tau}}, & \tau \le 0.001, \\ \\ \approx 10^{\sum_{k=0}^{5} p_k (\log_{10}\tau)^k}, & \tau > 0.001 \end{cases} \tag{40}$$

In Eq. (40), $K_0(s)$ and $K_1(s)$ are the Modified Bessel Functions of the Second Kind, of Orders 0 and 1, respectively. For $\tau > 0.001$, the inverse Laplace Transform by contour integration – vide Carslaw and Jaeger (1959) – can be approximated by a polynomial as indicated in Eq. (40). The reader is referred to Chandrasekhar (2020) for details. Ramey (1962) approximated the cylindrical conduit as a line source in a semi-infinite medium and presented the approximation to the exponential integral solution as

$$F(\tau) = \ln\left(\frac{1}{2\sqrt{\tau}}\right) + 0.29 \tag{41}$$

The function $F(\tau)$ as given by both expressions is plotted in Figure 16, which also shows the coefficients in Eq. (40). It is seen that the simplified expression of Eq. (41) breaks down for very short times from the startup.

Following some algebra, we have

$$\frac{\bar{U}}{k} = \left[\frac{2}{\mathrm{Nu}} + \frac{1}{F(\tau)}\frac{k}{k_\infty}\right]^{-1} \tag{42}$$

where the Nusselt number is given by the Dittus-Boelter correlation according to

$$\mathrm{Nu} = \frac{hD}{k} = 0.023\,\mathrm{Re}^{0.8}\,\mathrm{Pr}^{0.3} \tag{43}$$

where the Reynolds and Prandtl numbers are

$$\mathrm{Re} = \frac{\rho V D}{\mu} \tag{44}$$

and

$$\mathrm{Pr} = \frac{\mu c_\mathrm{p}}{k} \tag{45}$$

Planar Geometry (Multiple Fractures)

For a planar geometry, the temperature profile in the transverse direction is given by Ozisik (1993). Differentiation with respect to the transverse coordinate yields

$$\left.\frac{\partial T}{\partial x}\right|_{x=w}(t)=\frac{\left(T_{\infty}-T_{\mathrm{w}}\right)}{\sqrt{\pi\alpha_{\infty}t}} \tag{46}$$

Substitution in Eq. (6), rearranging terms, and noting that in the limit $b/w \to \infty$ the hydraulic radius $R_{\mathrm{h}} \approx w$, yields

$$\frac{\bar{U}(t)}{k}=\left[\frac{1}{\mathrm{Nu}}\left(\frac{w}{b}\right)+\frac{w}{b}\frac{\sqrt{\pi\alpha_{\infty}t}}{w}\frac{k}{k_{\infty}}\right]^{-1} \approx \frac{b}{w}\left[\frac{1}{\mathrm{Nu}}+\sqrt{\pi\tau}\,\frac{k}{k_{\infty}}\right]^{-1} \tag{47}$$

where in this case the Fourier number is defined in terms of the fracture hydraulic diameter as

$$\tau=\frac{\alpha_{\infty}t}{R_{\mathrm{h}}^2}=\frac{\alpha_{\infty}t}{w^2} \tag{48}$$

and the pseudo-transient flux multiplier is

$$F\left(\bar{\tau}\right)=\left(\sqrt{\pi\tau}\right)^{-1} \tag{49}$$

suggesting that at very short times, the heat flux from a cylindrical body is similar to that from a plane. The Nusselt number in Eq. (47) is based on the conduit thickness, but the Reynolds number – also used to evaluate the friction factor – is based on the hydraulic diameter D_{h}.

The Fourier Number, which depending on the geometry (planar or cylindrical) can be defined in terms of the geometry index ($n=1$ for a cylindrical geometry and $n=0$ for a planar geometry), can be compactly expressed as

$$\tau=\left[\frac{4n}{D^2}+\frac{(1-n)}{w^2}\right]\alpha_{\infty}t \tag{50}$$

and a composite expression for the ratio $\bar{U}/k$ can be written as

$$\frac{\bar{U}}{k}=\left(\frac{w}{b}\right)^{1-n}\left[\frac{2^n}{\mathrm{Nu}}+\frac{1}{F(\tau)}\frac{k}{k_{\infty}}\right]^{-1} \tag{51}$$

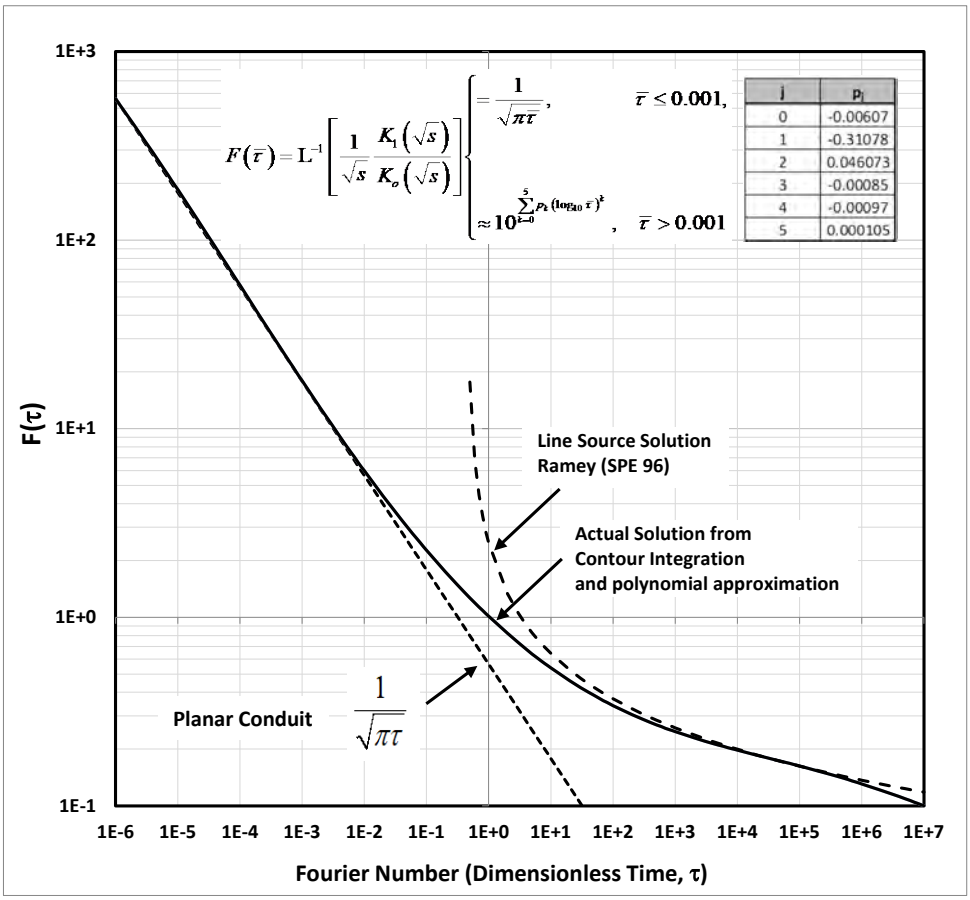

Figure 16: Decay of the Dimensionless Interface Flux from a cylinder embedded in a semi-infinite medium.

Appendix 3

Cylindrical Geometry (Drilled Multilaterals)

The normalized temperature in the formation at any streamwise location in a cylindrical conduit can be defined as

$$\theta(r) = \frac{T_\infty - T(z,r)}{T_\infty - T_{\mathrm{W}}(z)} \tag{52}$$

which is different from that in Eq. (8), as the normalizing temperature scale is the difference between the undisturbed geothermal and the instantaneous conduit surface temperature –as opposed to the conduit inlet temperature. If the radial position from the conduit is normalized with respect to the wellbore radius $R = D/2$ so that $\eta = r/R$, the radial temperature distribution is given by the inverse Laplace Transform

$$\theta(\eta) = \mathrm{L}^{-1}\left[\frac{\mathrm{K}_0\left(\sqrt{s}\eta\right)}{s\mathrm{K}_0\left(\sqrt{s}\right)}\right] \tag{53}$$

which can be evaluated following Carslaw and Jaeger (1959) using contour integration with a branch cut about the origin in the complex plane.

If the penetration depth is defined as the radial position at which the temperature decays to 0.001, this depth can be estimated by inverting Eq. (53). This is shown in Figure 3.

Planar Geometry (Multiple Fractures)

For planar geometries, the temperature variation with time and distance from the surface has been shown by Özisik (1993) to be

$$\theta = \mathrm{erf}\left(\frac{x}{2\sqrt{\alpha_\infty t}}\right) \tag{54}$$

which decays to 0.001 at

$$\left[\frac{x}{2\sqrt{\alpha_\infty t}}\right]_{\theta=0.001} = 2.327 \tag{55}$$

from which the distance normalized by the conduit width w can be determined as

$$\left[\frac{x}{w}\right]_{\theta=0.001} = 4.654\sqrt{\tau} \tag{56}$$

in terms of the same Fourier number definition as in (48).

Interpretation of Stimulated Permeability by Model Calibration with Data from Circulation Program at FORGE

ABSTRACT

In April of 2022, three stimulation stages were carried out near the toe of well 16A(78)-32 at the Utah FORGE site. Based on the extent of the recorded microseismicity and modeling results, well 16B(78)-32 was drilled 100 m above well 16A(78)-32. In July of 2023, a circulation program was conducted between two wells. The aim was to implement low-rate injection to interrogate the reservoir between the injection and the production wells, 16A(78)-32 and 16B(78)-32, respectively, and to assess the effect of reservoir stimulation in April 2022. The circulation testing was designed to use low injection rates to prevent hydraulic fractures from being initialized or propagated. Back analysis of the circulation test was carried out using a coupled hydro-mechanical (HM) numerical model based on the distinct element method (DEM). The objective of the modeling was to interpret the state of the reservoir by matching the recorded injection pressures and rates at both wells. The model includes an explicit representation of the DFN. Some DFN fractures were generated to match the observed microseismic event locations, while most were generated stochastically. The model indicates that the stimulated reservoir permeability is a function of distance from the injection well. Although seismicity recorded during stimulation extended 100 m above the injection well, and the circulation test confirmed connectivity between the two wells, the back analysis indicated that the domain of increased permeability did not connect the two wells. Also, the circulation at rates of 5 bpm resulted in additional fracture propagation, which is evident from the injection pressure history and microseismicity recorded during circulation. The coupled thermo-hydro-mechanical (THM) model was subsequently used to simulate 80 days of water circulation between two wells by injection in three stages at the toe of well 16A (78)-32 to evaluate temperature decay with time.

1. Introduction

Utah Frontier Observatory for Research in Geothermal Energy (FORGE) is an Enhanced Geothermal System (EGS) project supported by the U.S. Department of Energy. The injection well 16A(78)-32 drilling was completed in December 2020. In April of 2022, three stages of reservoir

stimulation by fluid injection were conducted at the toe of well 16A(78)-32 (McLennan et al., 2023). In June of 2023, production well 16B(78)-32 was drilled within the extent of the microseismic cloud recorded during the stimulation, 100 m above 16A(78)-32. In July of 2023, after drilling the production well, circulation tests were conducted to assess the connectivity between wells 16A(78)-32 (injection) and 16B(78)-32 (production). The injection pressures recorded during the tests were analyzed by different teams using different methods, including analytical and numerical modeling approaches. In this article, we present the back-analysis of injection pressures recorded during Day 1 (on July 4, 2023) Circulation Test 1 (two tests were carried out on Day 1) using *XSite* (Itasca, 2020) with a hydro-mechanically (HM) coupled model based on the discrete element method (DEM) and lattice method. The objective of the back-analysis was to use the calibrated model (by matching the injection pressure history) to interpret the state of the reservoir near the toe of well 16A(78)-32 when the circulation tests commenced. The coupled thermo-hydro-mechanical (THM) model was subsequently used to predict the temperature decay of produced water in well 16B(78)-32 during 80 days of circulation between two wells.

2. Circulation Test Data

The circulation tests (including analysis of well connectivity) are discussed in detail by Xing et al. (2024). Only details of Day 1 of Circulation Test 1 relevant to the analysis described here are repeated. The geometry of the two wells and their completions at the time of Circulation Test 1 are illustrated in Figure 1. Three stages were stimulated near the toe of well 16A(78)-32. Stage 1 of stimulation was conducted in the openhole section of the well, while Stages 2 and 3 were carried out through perforated sections in the well casing.

Water was injected in all three stages along well 16A(78)-32 during the circulation tests. Recorded wellhead pressures for wells and injection rates in 16A(78)-3 are shown in Figure 2. The injection started at 0.5 bpm, increased to 2.5 bpm, and finally to a maximum rate of 5 bpm. The single pumping unit could not achieve 5 bpm at the wellhead pressure encountered, and a second (standby) unit was rigged up and brought online. Consequently, there were interruptions and oscillations in pumping rate and wellhead pressure.

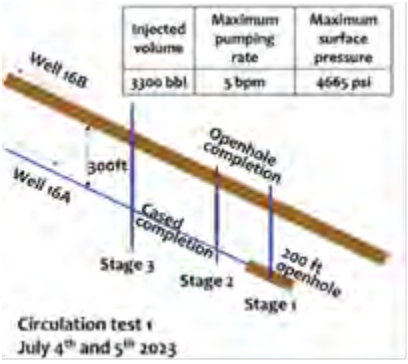

Figure 1 Illustration in vertical cross-section of the well toe geometries and completions during Circulation Test 1 (after Xing et al. 2024).

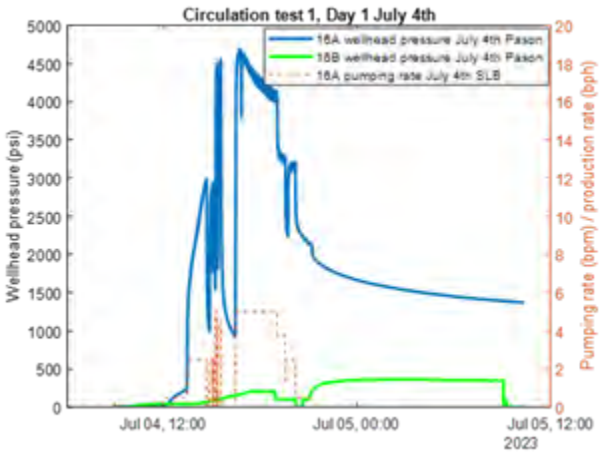

Figure 2 Wellhead pressure, injection, and production rates during Day 1 of Circulation Test 1 (after Xing et al. 2024).

Well 16B(78)-32 produced fluid and recorded a pressure response (Figure 2) during the first circulation test. About 40 minutes after injection initiation, the pressure increased (relative to the initial value) in well 16B(78)-32. The wellhead pressure in well 16B(78)-32 built up slowly with the flow line closed (i.e., the well was shut in at the surface, and the throttling valve to the pit from the production well was closed). When the wellhead pressure in 16B(78)-32 reached 200 psi, the throttling valve in the flow line was opened to maintain 200 psi as back pressure by flowing to the pit. Later, the back pressure was reduced to 100 psi during the pumping. After the injection stopped, the injection well and the production well were shut in. The pressure in well 16B(78)-32 built up to a maximum of 362 psi.

3. Discrete Fracture Network

Both the pre-existing natural fractures and new hydraulic fractures created during reservoir stimulation were explicitly represented in the model. Discrete stochastic fractures provided in the discrete fracture network (DFN) model have radii in the 10 to 150 m range and orientations matching the mean values of the four fracture sets identified from FMI logs (Finnila et al., 2021). The DFN was amended by adding fifteen fractures (Figure 3) inferred by interpreting the microseismic data recorded during the stimulation in 2022 (Finnila et al., 2023). Uncertainty in locations of the events recorded during stimulation of Stages 1 and 2 (and consequently in the geometry of the inferred fractures) is much greater than that for Stage 3 because, during Stages 1 and 2, fewer, more distant geophones were used to record microseismicity.

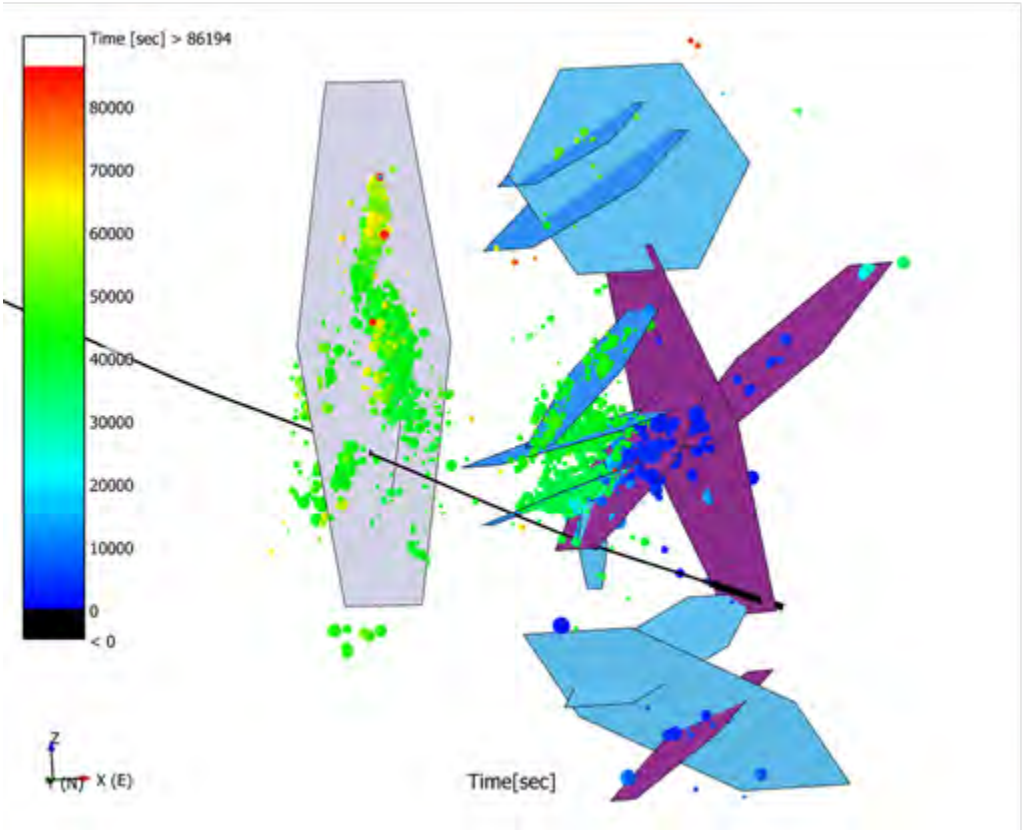

Figure 3 The geometry of the added fractures and the recorded microseismicity during reservoir stimulation in 2022. (The color scale indicates the timing of the microseismic events relative to the beginning of the injection.)

4. Numerical Models

The models were simulated using the numerical code *XSite*, which implements the synthetic rock mass (SRM) approach using the DEM and the lattice method (Damjanac et al., 2016). The model is fully coupled thermo-hydro-mechanically, and deformation and damage of the reservoir rock mass include the effects of deformation and damage of the intact rock (including hydraulic fracturing) and slip and opening of the pre-existing joints.

4.1 Short-Term Circulation

The thermal processes were not simulated in the short-term circulation models because of the relatively short duration of the tests. Modeling of the circulation test using *XSite*, with the capability to approximate hydro-mechanical coupling, is essential, particularly during injection at higher rates (e.g., 2.5 and 5 bpm) when the fluid pressures are expected to be sufficiently large to cause significant deformation of the fractures and change in their hydraulic apertures (i.e., permeability).

The material properties and initial stress conditions used by the models are listed in Table 1. It was assumed that all DFN, including the fractures created during stimulation, have a friction angle of 37°. After the excess pore pressures dissipated following the stimulation in 2022, it is assumed that the pore pressures returned to the initial hydrostatic state. The fractures closed if hydro-

shearing and placed proppant volume were negligible. Although the fractures have closed, it is assumed that there is a residual hydraulic aperture. The DFN residual aperture, a function of distance from the injection well, and the extent of the DFN that lost cohesive strength due to stimulation were calibration parameters used in this study.

The planned pumping schedule for Day 1 of Circulation Test 1 is shown in Figure 4. The rate oscillations that took place in the field were not reproduced in the model, in which fluid was injected at the (injection) points at the intersections between well 16A(78)-32 and the fractures. No perforation pressure drop was considered for any of the injection points. The fluid is injected in all three stages simultaneously, and the code resolves the rate distribution between the stages and injection points as a part of the model solution.

Table 1 Material properties and initial conditions for the circulation model with injection from well 16A(78)-32 (TVD 8490 ft, 2587.8 m).

Variable	**Value**
Young's modulus	55 GPa (8.0×10^6 psi)
Poisson's ratio	0.26
Fracture toughness	3 MPa×$m^{1/2}$ (2740 psi×$in^{1/2}$)
Fluid viscosity	Newtonian fluid, 2 cp
Pore pressure	0.0093 MPa/m (0.41 psi/ft), 24.0 MPa (3481 psi)
Minimum horizontal stress	0.0174 MPa/m (0.73 psi/ft), 42.68 MPa (6190 psi)
Maximum horizontal stress	0.0189 MPa/m (0.84 psi/ft), 48.80 MPa (7078 psi)
Vertical stress	0.0243 MPa/m (1.07 ft/ft), 62.80 MPa (9108 psi)

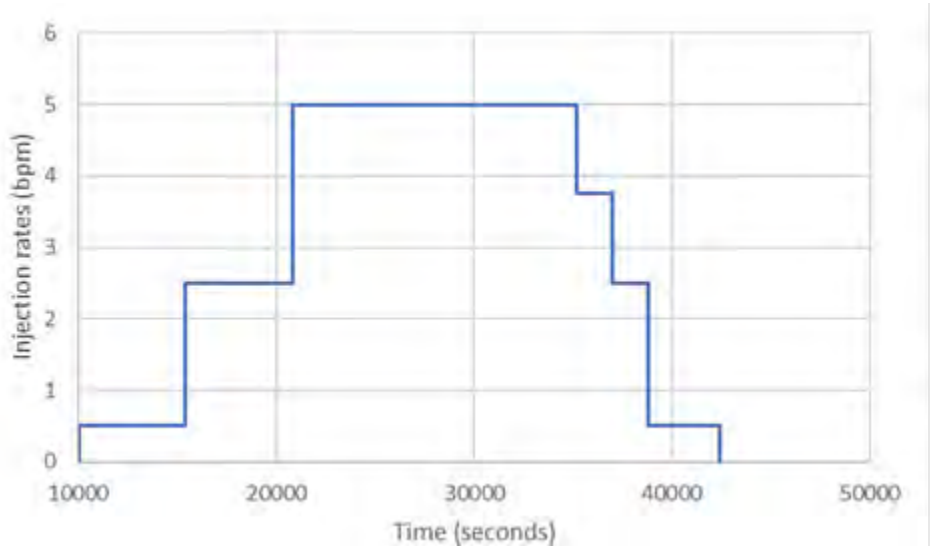

Figure 4 Simulated pumping schedule.

4.2 Long-Term Circulation

Water circulation between wells 16A(78)-32 and 16B(78)-32, when water is injected in three stages at the toe of 16A(78)-32, was simulated using a coupled THM model (Detournay et al., 2022). This model simulates heat advection with flowing fluid in fractures, convective heat transfer between fluid and rock, and heat conduction in the rock coupled with fluid flow in discrete fractures and a mechanical model of rock deformation. For computational efficiency, it is assumed that the flow model is continuously in a steady state and the mechanical model is continuously in equilibrium. Those assumptions are reasonable, considering that the characteristic time scales of the fracture flow and mechanical models are much smaller than the characteristic time scale of heat conduction (which is a relatively slow process). The model is advanced in time using heat transport processes, heat advection by flowing fluid, and heat conduction. The model is re-equilibrated mechanically at sufficiently small time intervals (i.e., sufficiently small thermally induced stress changes). Subsequently, the flow model is simulated to achieve a new steady state corresponding to changed apertures (i.e., permeability). The flow rates from the steady-state flow model are used in the advection model in the next thermal step.

The model simulates water circulation from well 16A(78)-32 to well 16B(78)-32. It is assumed that fluid percolation takes place only in stimulated pre-existing fractures and created hydraulic fracture (in Zone 3) as identified by interpreting the microseismic data shown in Figure 3. Water is injected at 5 bpm into all three stimulated zones at the toe of well 16A(78)-32.

5. Results

5.1 Model Calibration with Short-Term Circulation Data

The extent of the permeable DFN and contours of the hydraulic aperture calibrated to the field results are shown in Figure 5 (following preliminary results by Radakovic-Guzina et al. 2024). It includes the initially permeable (stimulated) DFN within the 50-m radius around 16A(78)-32. Outside that radius, the DFN is assumed to be impermeable with cohesion and tensile strength of

5 MPa. The permeability and hydraulic apertures within the permeable part of the DFN are considered to be variable depending on the distance from well 16A(78)-32. An initial hydraulic aperture of 0.4 mm is assumed within a radius of 25 m from well 16A(78)-32. The rest of the DFN within the permeable (stimulated) region (50 m radius) is assumed to have hydraulic apertures of 0.2 mm.

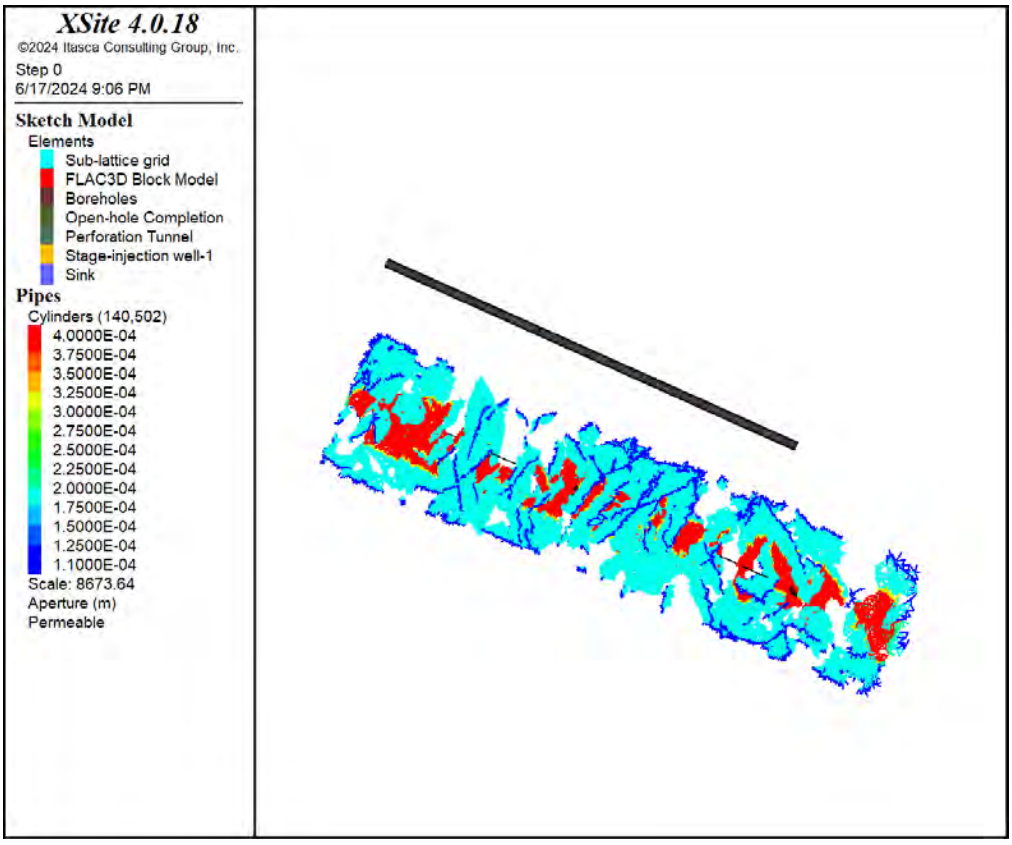

Figure 5 Initial hydraulic aperture (m) contours within the extent of initially permeable DFN (extending within a 50 m radius from well 16A(78)-32) are shown in a vertical cross-section along the sub-horizontal sections along two wells. The remaining DFN is impermeable and not shown in this plot. The wells are shown as inclined line segments (well 16A(78)-32 is shown as a thin line, and well 16B(78)-32 is shown as a cylindrical volume).

The contours of fracture fluid pressures and induced microcracks after 4.7 hours of injection, obtained by the calibrated model, are shown in Figure 6. The model indicates the response at 0.5 bpm injection rate governed by fluid pressure diffusion into a well-connected and stimulated DFN at pressures smaller than the minimum stress (i.e., through closed but permeable DFN, including fractures created during the 2022 stimulation). Hydro-mechanical coupling becomes important when injection rates increase to 2.5 and 5 bpm, resulting in additional stimulation of DFN and propagation of hydraulic fracture created in Stage 3 (indicated by new microcracks in Figure 6). The permeability of the reservoir at that stage of the circulation test is governed by the induced hydraulic aperture changes, not by the initial hydraulic apertures.

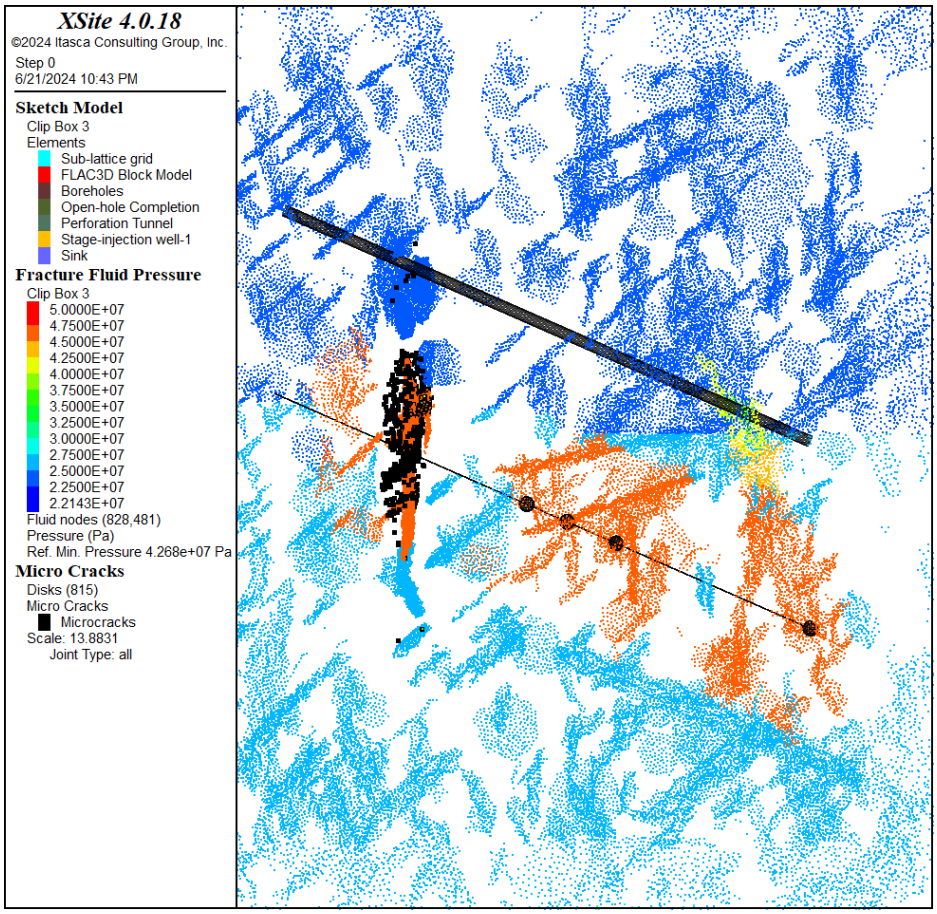

Figure 6 Fracture fluid pressure (Pa) contours and induced microcracks (black dots) after 4.7 hours of injection in a vertical section along the sub-horizontal section of well 16A(78)-32. The wells are shown as inclined line segments, and the injection points are spheres.

The downhole pressures obtained from the refined model compared with the pressures calculated using the recorded pressures (the downhole pressures calculated from the recorded surface pressures using the approach presented by Xing et al. 2023) are shown in Figure 7. This model matches the trends and magnitudes of the pressure history, indicating a reasonable approximation of the reservoir condition by the assumed permeability field (shown in Figure 5).

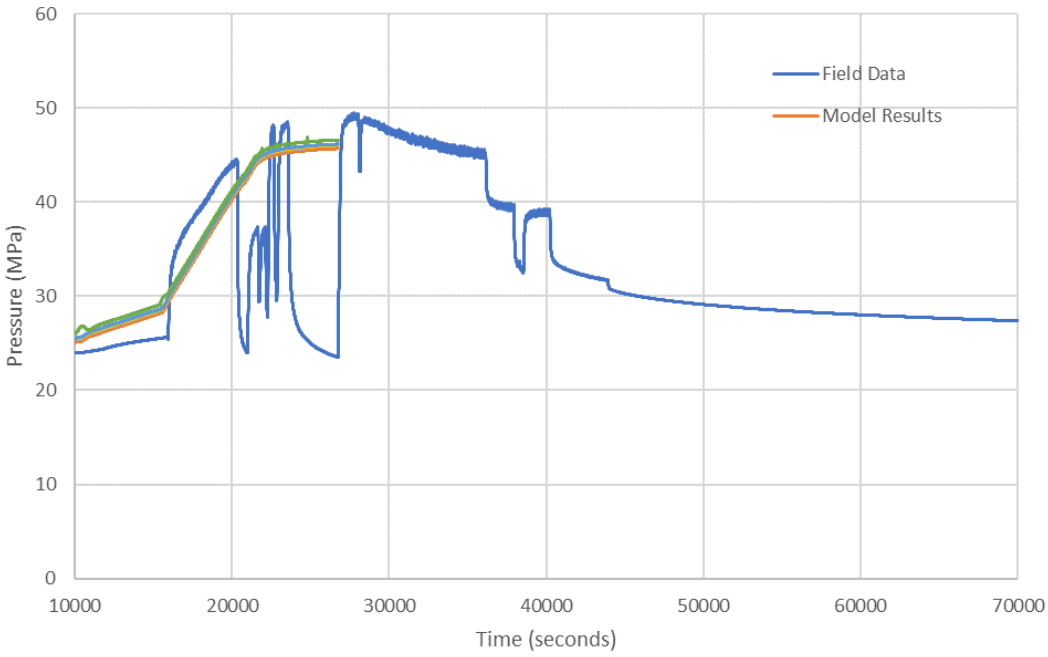

Figure 7 The downhole pressure histories as calculated from the field data and obtained from the calibrated model.

5.2 Long-Term Circulation

The fluid pressure contours after 80 days of fluid circulation by injection into three stages at the toe of well 116A(78)-32 are shown in Figure 8. The contours of fluid temperature after 80 days are shown in Figure 9. The history of produced water temperatures is shown in Figure 10. The entire injected water is recovered from the production well because a limited number of fractures completely disconnected from the rest of the DFN are included in the model. In that sense, this model is unconservative because it does not include any risk of losing some of the injected fluid. The temperature of the produced water is calculated by volume averaging temperatures of water produced from all fractures intersected by the production well. In 80 days, the temperature of the water produced drops 31°C (for a 100 m well spacing). The rock temperature contours, shown in the vertical cross-section along the wells in Figure 11, are consistent with the temperature histories of produced water. Only a “skin” of rock cools along the fracture length between wells 16A(78)-32 and 16B(78)-32. Skin cooling explains the relatively small effect of temperature changes on fracture apertures and injectivity observed in the model.

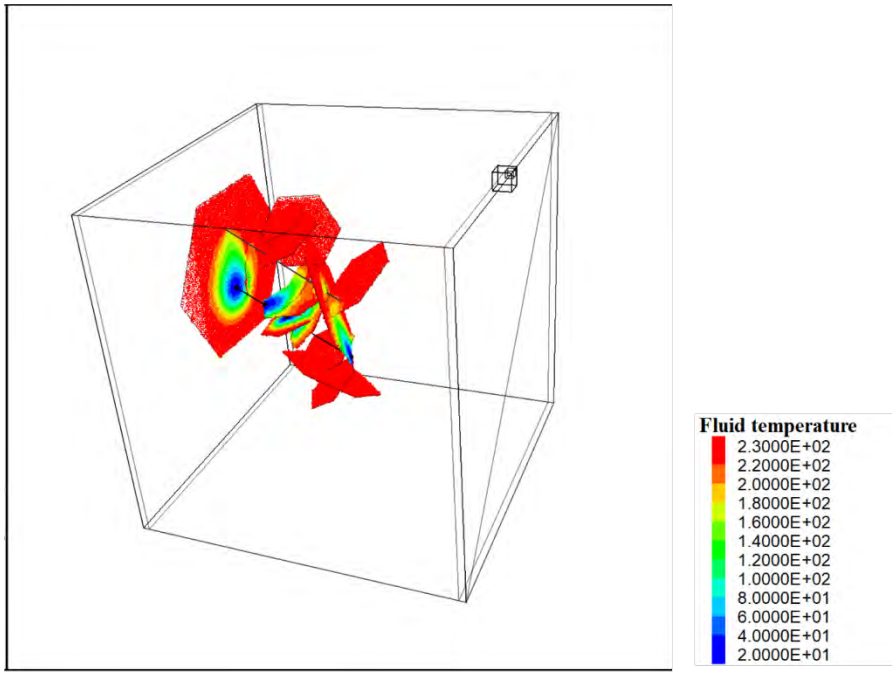

Figure 9 Fluid temperature (ºC) contours after 80 days of circulation.

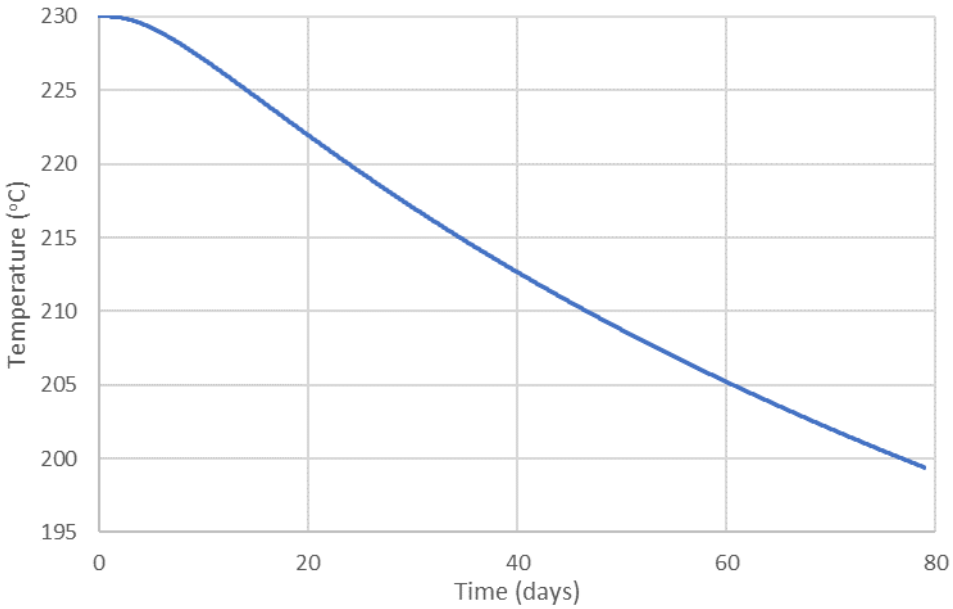

Figure 10 Temperature history of produced water.

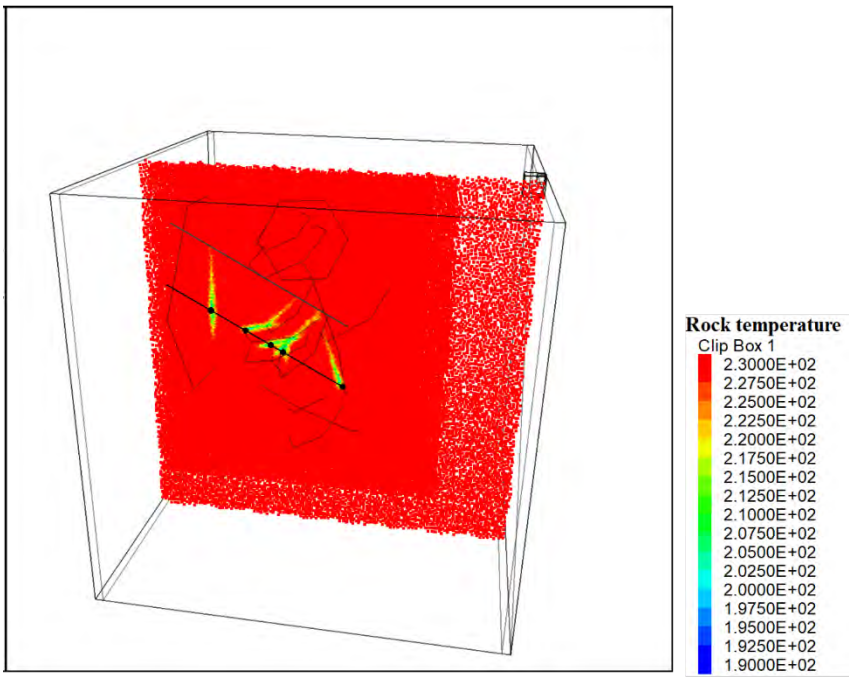

Figure 11 Rock temperature (°C) contours after 80 days of circulation.

6. Discussion

The injection pressure was recorded during Day 1 of Circulation Test 1. The results of the numerical model calibrated to those pressures indicate a stimulated volume around well 16A(78)-32 with some residual permeability for more than one year after stimulation. The extent of the domain with residual permeability is uncertain, but its radius around well 16A(78)-32 seems to be

tens of meters. The modeling results indicate that the stimulated reservoir volume (i.e., permeable and connected DFN) is smaller than the microseismic cloud.

During injection at 0.5 bpm, fluid percolates into the permeable and connected DFN without significant pressure and permeability increase. At rates of 2.5 bpm, the hydro-mechanical coupling becomes more dominant, causing hydraulic aperture changes greater than the initial apertures. Further increase of the rates to 5 bpm seems to result in fracture propagation.

A simulation of water percolation for 80 days at 5 bpm shows a relatively fast decrease in the temperature of the produced water. Thus, the flow rate through these three stages should be less than 5 bpm for long-term heat production.

7. Conclusion

A fully coupled hydro-mechanical model with explicit representation of the DFN and capability to simulate hydraulic fracturing was used to back-analyze Day 1 of Circulation Test 1 conducted at the FORGE project in July of 2023. The recorded injection pressure history was used to calibrate the numerical model. Day 1 of Circulation Test 1 was conducted from well 16A(78)-32 by fluid injection at relatively low rates, between 0.5 and 5 bpm, simultaneously in all three stages stimulated in April of 2022. The objective of the numerical modeling was to use a calibrated model to interpret better the effect of stimulation on reservoir (or DFN) permeability more than one year after the stimulation was conducted.

The modeling study results indicate a domain around well 16A(78)-32 with increased residual permeability more than one year after the stimulation. Such a domain is manifested by a relatively small pressure increase early and for a small injection rate (0.5 bpm). The stimulated domain with increased permeability seems smaller than the extent of the microseismic cloud. The model matched the pressure increase when the rate was increased to 2.5 bpm and hydraulic fracture propagation for the rate of 5 bpm if the DFN was assumed impermeable outside a cylinder with a 50-m radius around well 16A(78)-32.

A simulation of water percolation for 80 days indicates that the flow rate through these three stages should be less than 5 bpm for long-term heat production. Consequently, economical heat production would require a significantly larger number of stimulated stages.

ABSTRACT

The solidified and crystallized magma in the earth's crust forms igneous rocks such as quartzite and granite. Depending on the depth and geological age, the temperature of these formations is relatively high, and thus, they contain a considerable amount of thermal energy. These formations are not permeable nor contain pore fluid. However, they are brittle and can be stimulated by hydraulic fracturing to gain permeability. The stimulated igneous formations that contain a large amount of thermal energy are considered enhanced geothermal reservoirs. Extracting thermal energy from enhanced geothermal reservoirs requires the presence of a geothermal fluid. Water is the most common geothermal fluid with excellent specific heat capacity; however, the hydraulic properties of water can create undesirable fast paths through large fractures from an injection well to a production well. This phenomenon will reduce the enhanced geothermal reservoir's heat extraction efficiency and sustainability. A large-scale experimental setup of a high-temperature flow loop system was fabricated to simulate the geothermal fluid hydraulics in two different fracture apertures of granite rock slabs. The two fracture systems are equipped with heating jackets and insulated using high-temperature fiberglass insulation, and they can be controlled independently. The inlet and outlet pressures for the small fracture and the fluid temperature were monitored during the tests. Water as a geothermal fluid was tested to investigate the flow behavior in the small fracture. The initial results for water for single fracture tests flowing through the small fracture produced different pressure drop trends and heat transfer characteristics with varying flow rates. This paper presents the results for single fracture under varying temperatures. Preliminary results showed that heat absorption is a function of applied temperature, flow regime, and flow rate.

1. Introduction

Geothermal energy has been recognized as a valuable alternative to fossil fuels and nuclear power, as it is renewable and reliable. Deep geothermal energy, such as enhanced geothermal systems

(EGSs), has the potential to supply 60 gigawatts of electrical capacity (GeoVision, 2019). The process of geothermal heat extraction for EGS consists of deep injection and production wells drilled in a hot geothermal formation (Figure 1). The working fluid is circulated via the injector down into the hot formation, which flows through rock fractions and absorbs heat from the formation. The hot working fluid reaches the production wells and expands, generating electricity using turbines.

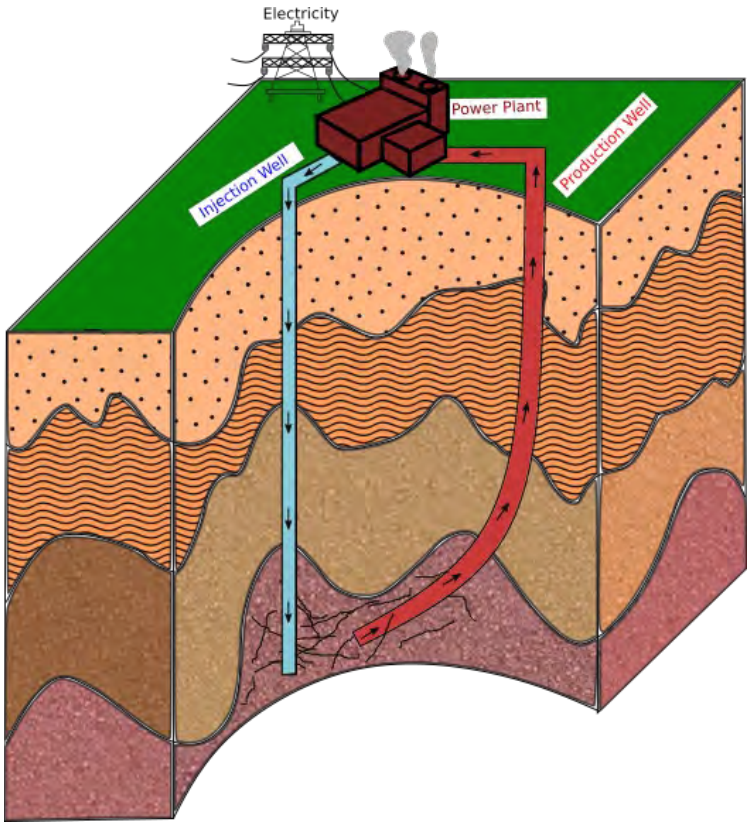

Figure 1: Enhanced geothermal system representation

Throughout the injection and production process, many factors can influence the heating potential of the working fluid. These factors include the working fluid, rock permeability, fracture size, and flow path. Working fluids play a crucial role in the operation of geothermal wells. They transfer heat from the hot rocks and fluids to the surface, which can be converted into electricity. Working fluids are selected based on their ability to transfer heat efficiently, compatibility with the geothermal reservoir, and environmental impact.

Water is commonly used as a working fluid; however, different fluids, such as supercritical CO_2 (Brown, 2000; Gao et al., 2023) and ionic liquids (Atashnezhad et al., 2023; Kazemi et al., 2020; Momoh et al., 2023) have been proposed as alternative fluids. Water as a geothermal working fluid is abundant and has excellent heat transfer properties, making it an efficient working fluid. It is also compatible with most equipment used in geothermal power plants. However, its usage may face constraints due to accessibility, quality, and ecological repercussions. The performance of geothermal systems is closely tied to the properties of the working fluid. Characteristics like heat capacity, thermal conductivity, viscosity, boiling point, corrosiveness, environmental impact, cost, and availability all play a role in determining the system's efficiency.

Some of the challenges EGS faces include the initial capital cost required for drilling and completing the wells. Geothermal reservoirs are characterized by low permeability, where reservoir stimulation is necessary. Another challenge with EGS is the rapid thermal decline of heat extraction, which is caused by fluid flowing through higher conductivity fractures, a phenomenon known as geothermal short-circuiting. The phenomenon of geothermal short-circuiting occurs when the injected fluid tends to flow through the path of higher conductivity, cooling the adjacent rock matrix and causing further fracture aperture increase and enhancing the flow concentration (Hu and Ghassemi, 2020). This phenomenon becomes an issue because the flow concentration only utilizes larger fractures, which decreases heat extraction efficiency as the smaller, hotter fractures are not utilized.

The effect of fracture aperture in a 1.5-inch granite core sample focused on chemical and mechanical attributes was investigated experimentally using a triaxial apparatus (Caulk et al., 2016). The experimental results indicated chemical dissolution was the primary mechanism for decreasing permeability over time. Similar triaxial apparatus experiments investigated heat transfer and fracture evolution (Huang et al., 2019; Zhang et al., 2022). The experimental investigation by Huang et al. (2019) indicated that fractures with large roughness decrease seepage, which is highly affected by confinement pressure. Zhang et al. (2022) experimental results showed that fracture apertures and permeability decreased using distilled water, while a decrease in aperture and permeability was noticed using simulated geothermal fluids. Using 3D printing technology, Xie et al. (2021) investigated the effect of fracture roughness in a 7.5-inch long cross-fracture flow, where it was found that a large rough fracture branch exhibits higher pressure drop loss, and with increasing injection pressure, the pressure drop loss tends to decrease. Hu and Ghassemi (2020) used a cubical 13-inch granite block consisting of an injector and several producers, where it was concluded that the effective fracture area controlling the heat extraction and the distance between the injection and production wells needed to be optimized.

Many experimental systems have been studied to investigate fluid flow and heat transfer characteristics in EGS. However, limited research has considered multi-fracture configurations. The multi-fracture EGS configurations still had limitations with varying fracture temperatures and singular inlet/outlet configurations (Cherubini et al., 2017; Hu and Ghassemi, 2020). Another limitation is the scalability of the proposed experiments, especially for heat extraction, as most of the performed experiments were on the core sample scale, i.e., less than 8 inches.

This work aims to design a large-scale dual fracture experimental flow loop to address fluid flow and heat transfer in EGS settings. The experimental design is a dual fracture system that can control each fracture temperature independently at constant and varying temperatures. This paper presents the experimental results for a single fracture with water as the working fluid.

2. Methodology

2.1 Experimental setup

The dual-channel experimental setup consists of granite rock slabs with specific dimensions to form the desired fracture anatomy for each channel. Each slab has a 10 ft long test section, as shown in the diagram of the experimental setup in Figure 2, and Figure 3 shows the setup configured in the laboratory.

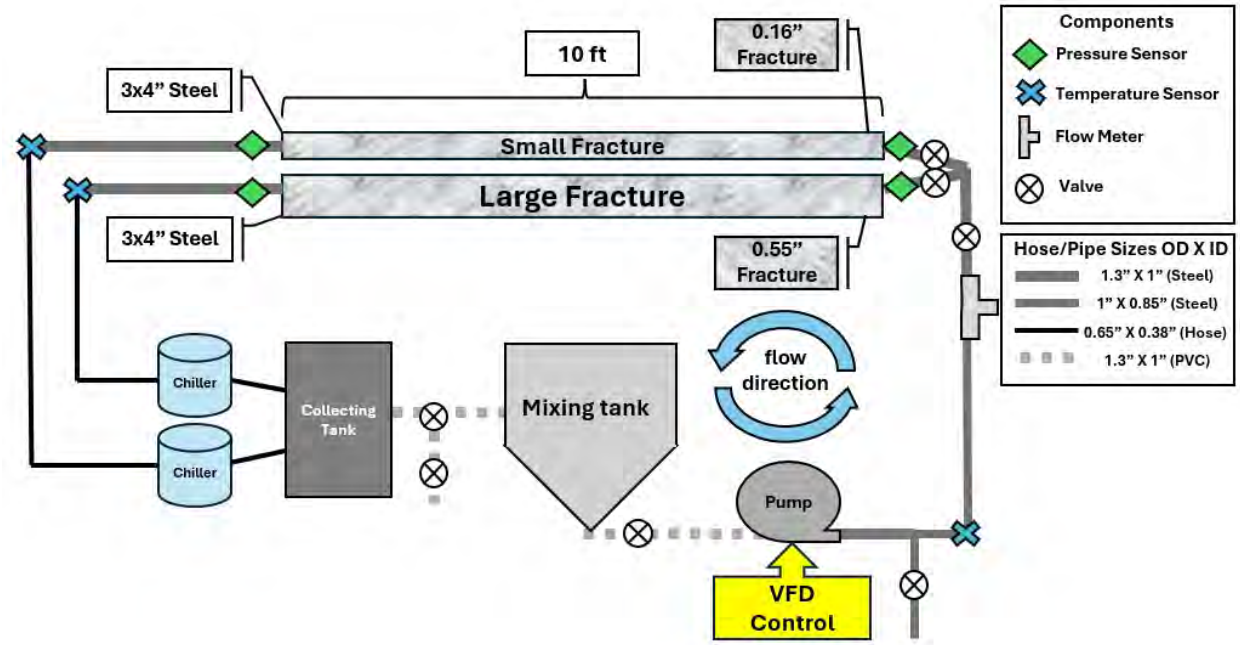

Figure 2: Experimental flow loop diagram

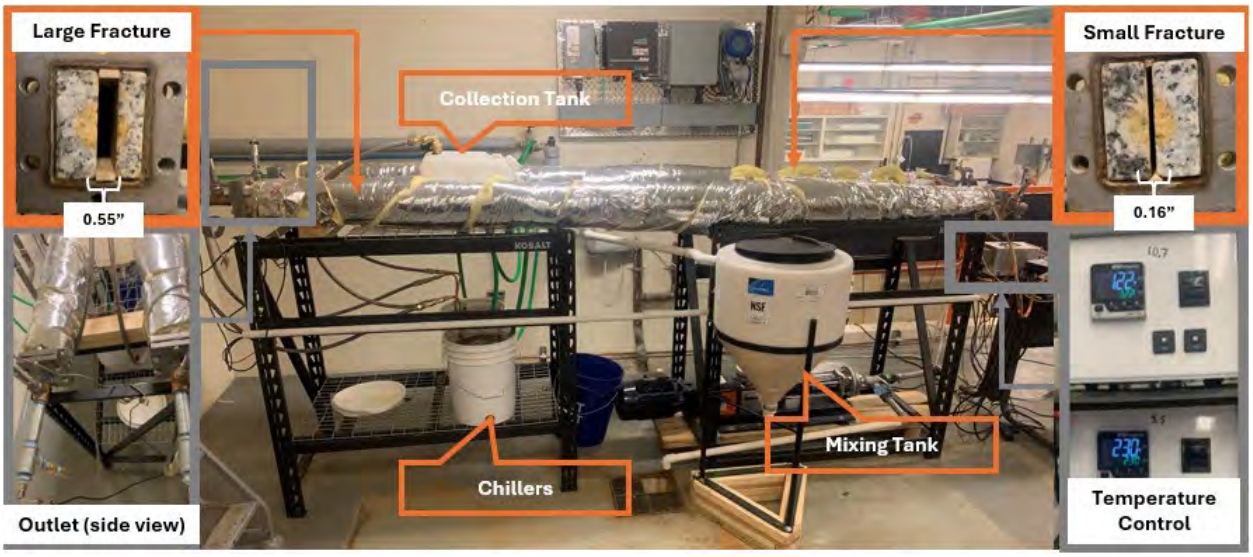

Figure 3: Geothermal flow loop design

A progressive cavity pump, controlled by a variable frequency device (VFD), injects the working fluid into a single pipe. Following the pump is a flow meter installed at the inlet, where the flow branches into the two fractures. Each branch consists of a valve at the inlet side, allowing the system to be used as a single fracture configuration and a dual fracture configuration. The 10 ft flow channels consist of a small fracture with an aperture of 0.16 in (4mm) and a large aperture fracture of 0.55 in (14 mm), as shown in Figure 3. Four pressure sensors are installed at the inlet and outlet of each fracture, and Resistance Temperature Detector (RTD) temperature sensors are installed at the inlet and outlet to collect the fracture's inlet and outlet temperatures. The small and

large fractures are heated and controlled independently with two heating cables on each fracture. Each flow channel is insulated with one high-temperature fiberglass layer and four aluminum-covered fiberglass layers. The data from the flow loop is collected from all the sensors using an analog data acquisition module. Once the working fluid has reached the end of each fracture, it flows into the chillers and is cooled by tap water. Following the chillers, the fluid is combined in the collecting tank, which then returns the fluid to the mixing tank, completing the flow loop and allowing for continuous circulation of the working fluid.

2.2 Testing procedure and data analysis

In this paper, the flow loop was configured to have the large fracture valve closed to analyze the behavior of the small fracture. Water was chosen as the working fluid for these experiments, and twenty different test scenarios were performed. The test scenarios consisted of five flow rates and four applied temperatures. The applied temperature was set for the small fracture by setting the thermostat for the temperature controller. The pump started with the VFD control using LabView, and pressure and temperature sensor data were collected for approximately 180 seconds, initiated by the user starting the data recording software.

The raw data was processed to generate pressure drop vs. flow rate analysis for each temperature to summarize the effect of each applied temperature scenario. The raw data was processed for the room temperature tests by removing the data during the start and end of the test and averaging the steady data to calculate the pressure drop across the fracture. For the tests where the temperature is applied, pressure drop behavior was analyzed at the maximum fluid outlet temperature period and 180 seconds from the start of the test to capture the fracture's heat loss behavior.

3. Results

The small fracture data was analyzed for twenty different data sets for each flow rate and applied fracture temperature. The raw datasets included inlet and outlet pressures, inlet and outlet temperature, and calculated pressure drop using the inlet and outlet pressures. The testing matrix consisted of four flow rates, including 1, 1.25, 1.5, 1.75, and 2 gallon/min (GPM), where the applied fracture temperature consisted of Room Temperature, 122 °F, 176 °F, and 230 °F.

The raw data for the room temperature tests for different flow rates is shown in Figure 4, where temperature indicates the measured outlet temperature of the fluid. The outlet temperature remained relatively constant at 75 °F for each room temperature test. The inlet and outlet pressures (P_i , P_o) and calculated pressure drop (ΔP) stay within the same 0.10-0.45 psi range. The system remains relatively constant over time, and the increase in flow rate causes an increase in pressure drop. Each test had a similar amount of fluctuation and no significant abnormalities.

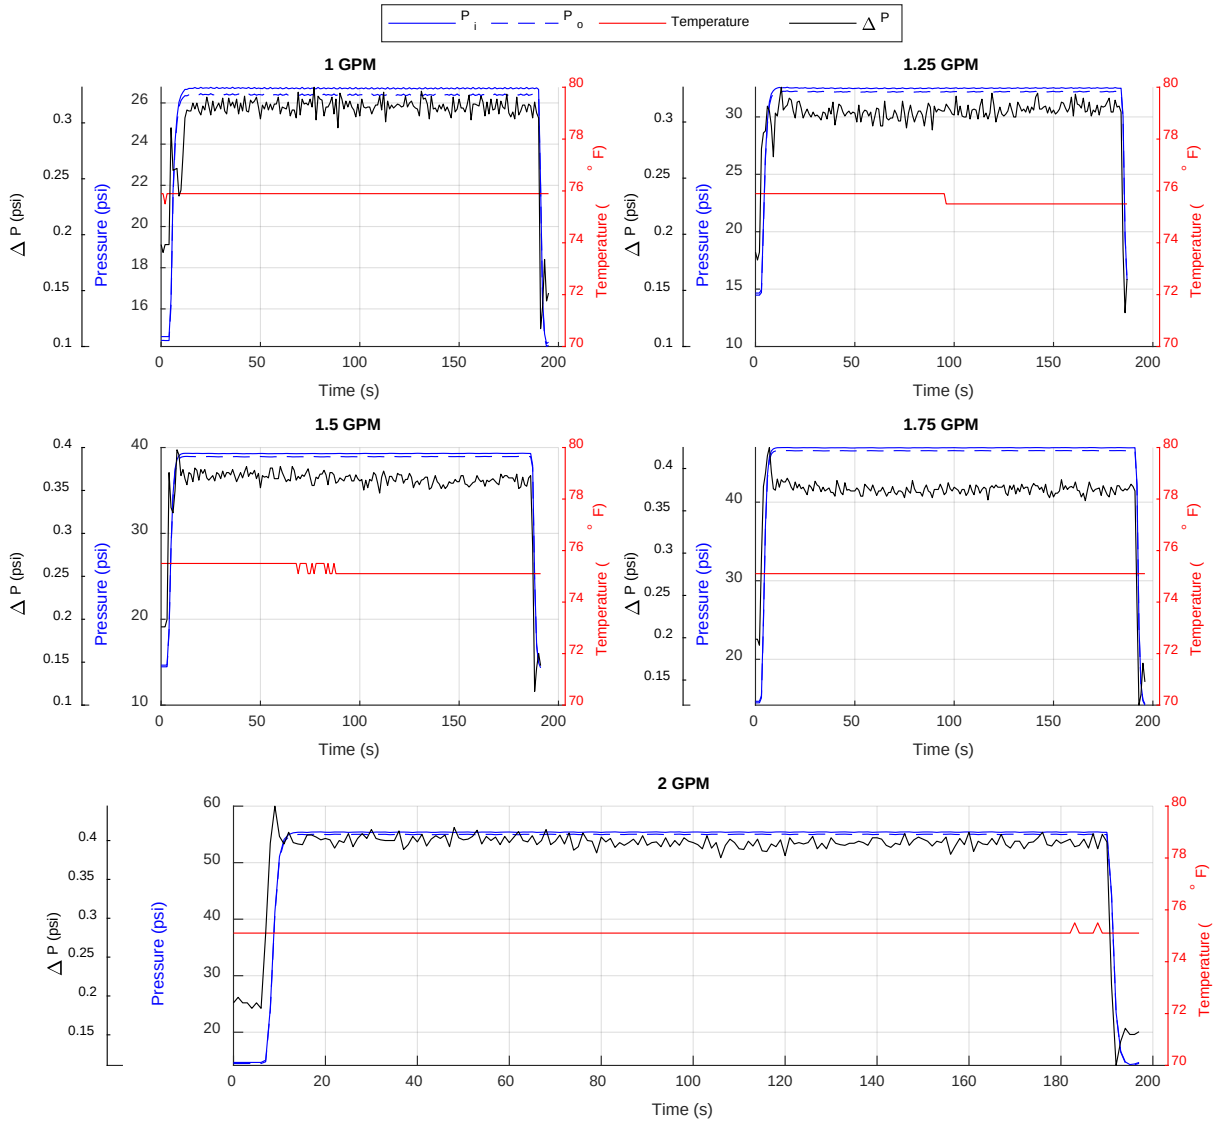

Figure 4: Experimental results showing the raw data for room temperature with different flow rates.

A single test was chosen to compare the raw data system behavior when the fracture is at a higher temperature and mid-range flow rate. Figure 5 shows the raw data for 1.25 GPM at an applied fracture temperature of 230 °F. The difference between the room temperature tests and the 230 °F applied temperature test is that the temperature readings for room temperature remain constant. In contrast, with the 230 °F applied fracture temperature readings, the outlet temperature decreases, and the inlet temperature increases with time. The pressure drop value exceeds the room temperature range at 0.1-0.6 psi. The pressure drop changes over time, increasing with increasing time. This behavior of increasing pressure drop with increasing temperature is due to increased water viscosity when the temperature decreases. As the granite begins to cool, the flow temperature decreases, which impacts the water's properties. Higher water viscosity creates higher resistance; therefore, more pressure drop is required to initiate flow movement. Overall, the raw data shows a difference between the system response when higher temperatures are applied.

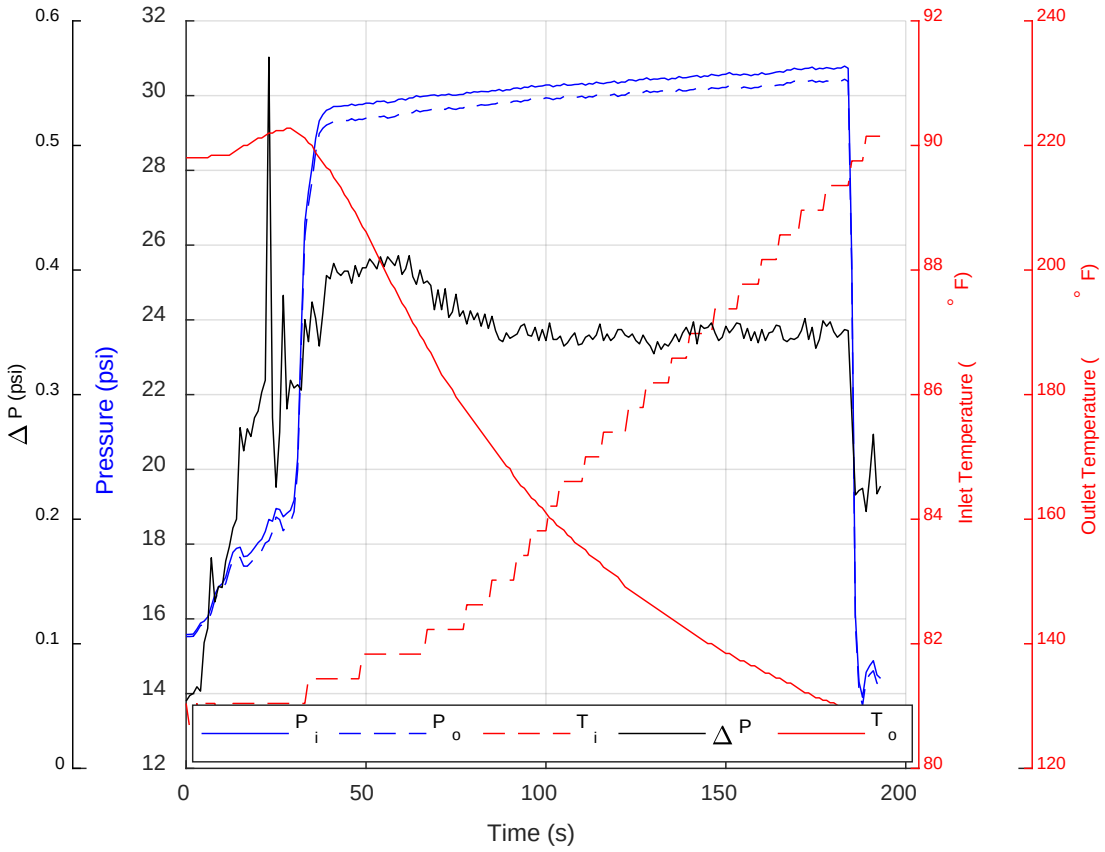

Figure 5: Raw flow loop data for 1.25 GPM at an applied temperature of 230 °F.

Figure 6 summarizes the effect of temperature on pressure drop when the maximum temperature is reached. Room temperature displayed an increasing pressure drop as the flow rate increased. For increasing temperature, the expected trend is to see a decrease in pressure drop compared to water due to a reduction in viscosity. However, not all the tests behaved consistently with increasing temperature. Tests at 122 °F and 176 °F primarily decreased in pressure drop with increased temperature compared to room temperature tests, but the 230 °F did not follow this trend. The 230 °F test followed this trend for only one flow rate at 1.75 GPM. The overall trend for comparing pressure drop versus flow rate is that pressure drop increases with increasing flow rate and decreases with increasing water temperature.

The pressure drop versus flow rate after 180 seconds of flow is shown in Figure 7. The pressure drop results after 180 seconds show a similar pattern for most applied temperatures compared to the pressure drop at the maximum temperature. The pressure drops tend to increase with increasing flow rate. When comparing room temperature to the other applied temperatures, there is a similar trend to the previous analysis, with 122 °F and 176 °F having decreasing pressure drops and 230 °F not following the same trend.

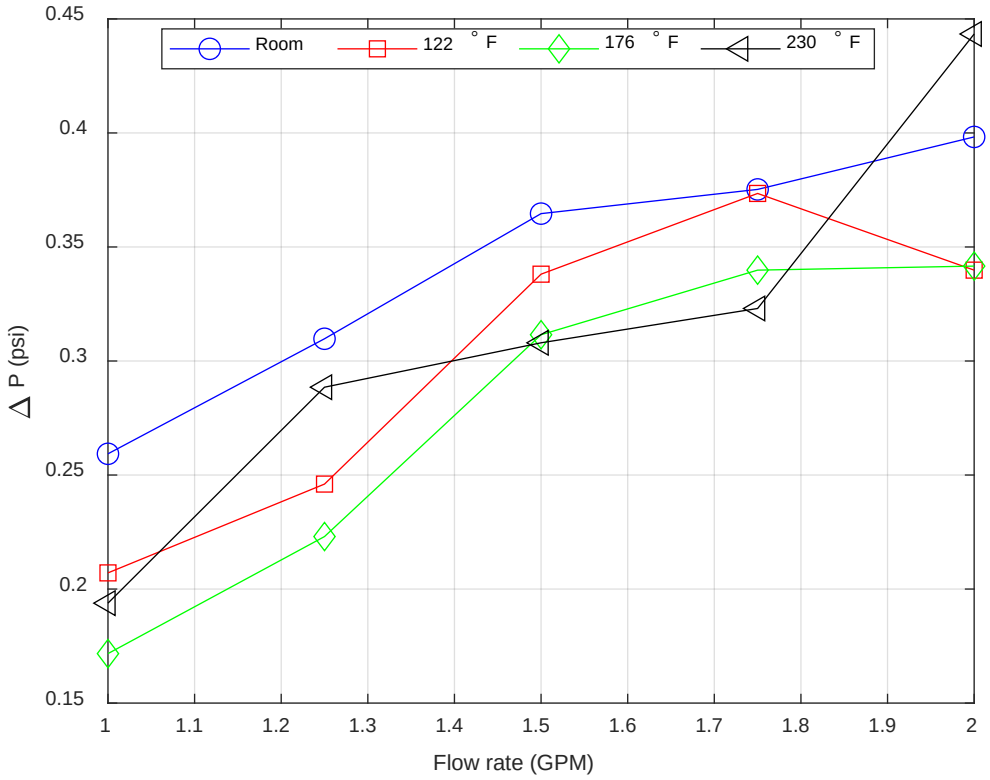

Figure 6: Pressure drops vs flow rate for varying temperatures at maximum fluid temperature.

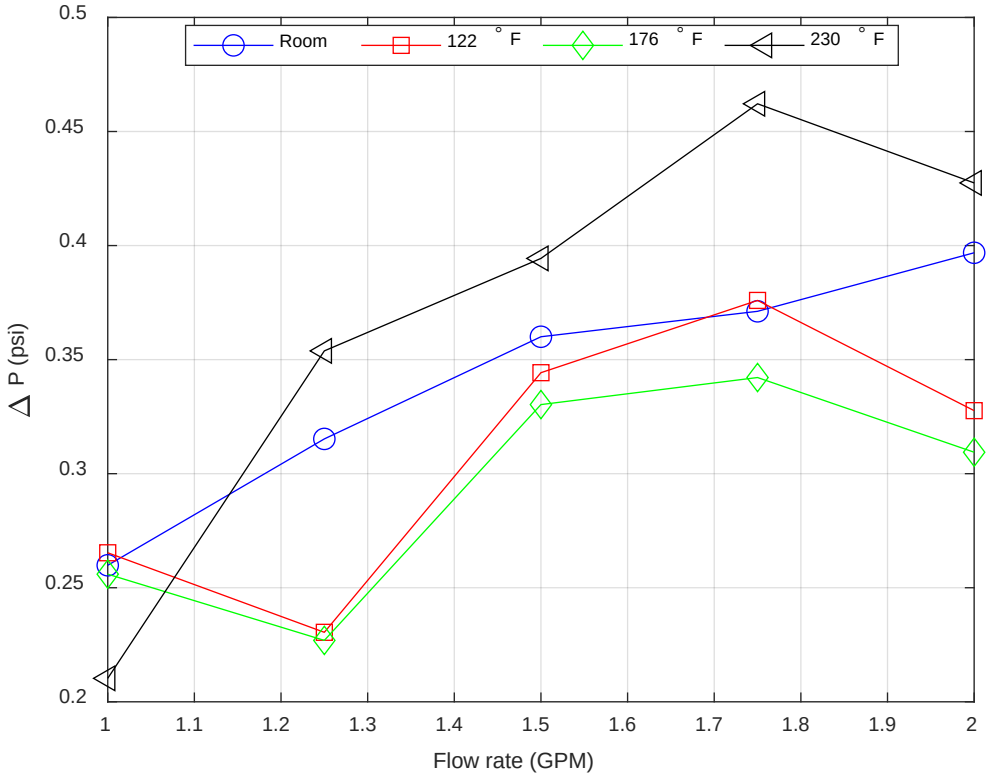

Figure 7: Pressure drops vs flow rate for varying temperatures after 180 seconds.

Overall, comparing the results at the maximum temperature and 180 seconds confirms the system's behavior is relatively consistent compared to room temperature tests, except for the 230 °F test. Due to 230 °F showing the most variation and inconsistency, additional analysis on flow regime behavior was performed to determine whether the temperature or flow regime is the more dominant factor in pressure drop analysis. Figure 8 shows the pressure drop vs Reynolds number for varying flow rates and applied fracture temperatures. This figure shows that most applied temperature tests have some turbulent behavior at differing flow rates. Room temperature remains primarily in the laminar and transitional flow regimes, while 230 °F is primarily in the turbulent flow regime region. This explains why the 230 °F tests did not follow a continuous pattern along with the other high temperature tests. This change in flow regime is also likely causing the 122 °F and 176 °F tests to vary after a specific flow rate is reached. Overall, this analysis with flow regime explains the variation in the pressure drop behavior and gives further insight into the behavior of the small fracture of the flow loop.

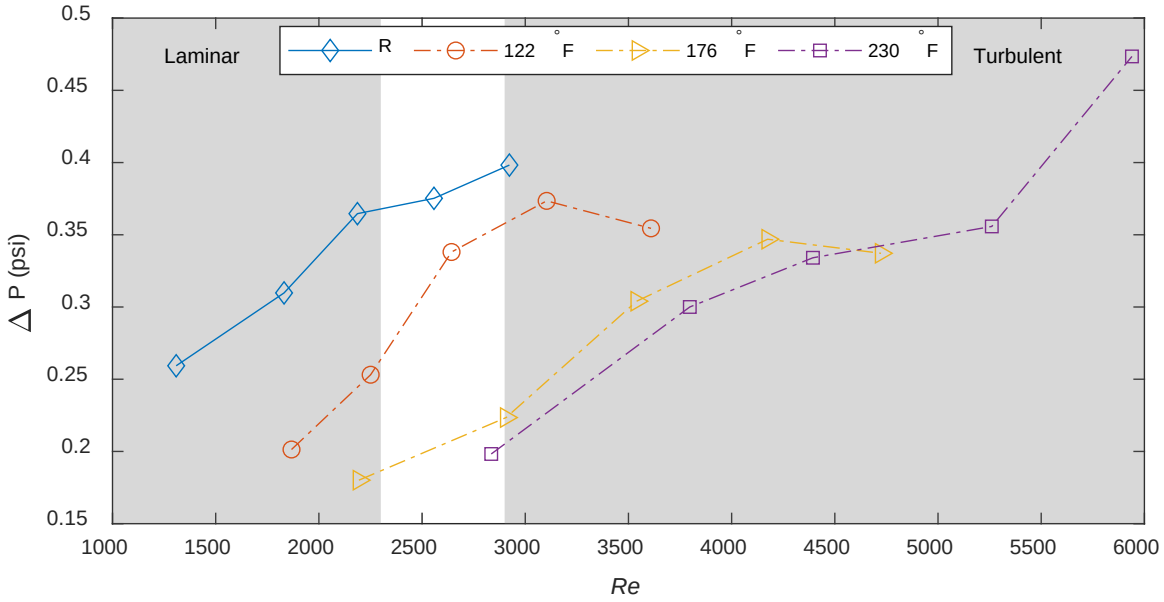

Figure 8: Pressure drop vs Reynolds number for varying flow rates and applied fracture temperatures

To analyze the decline in fluid temperature, i.e., heat extraction, the difference between the peak temperature and temperature at 180 seconds was calculated. This temperature difference was then divided by the time difference from peak temperature to the temperature at 180 seconds to obtain the rate of temperature change. This value was then plotted for each applied temperature as a function of flow rate, as shown in Figure 9, and the results are summarized in Table 1.

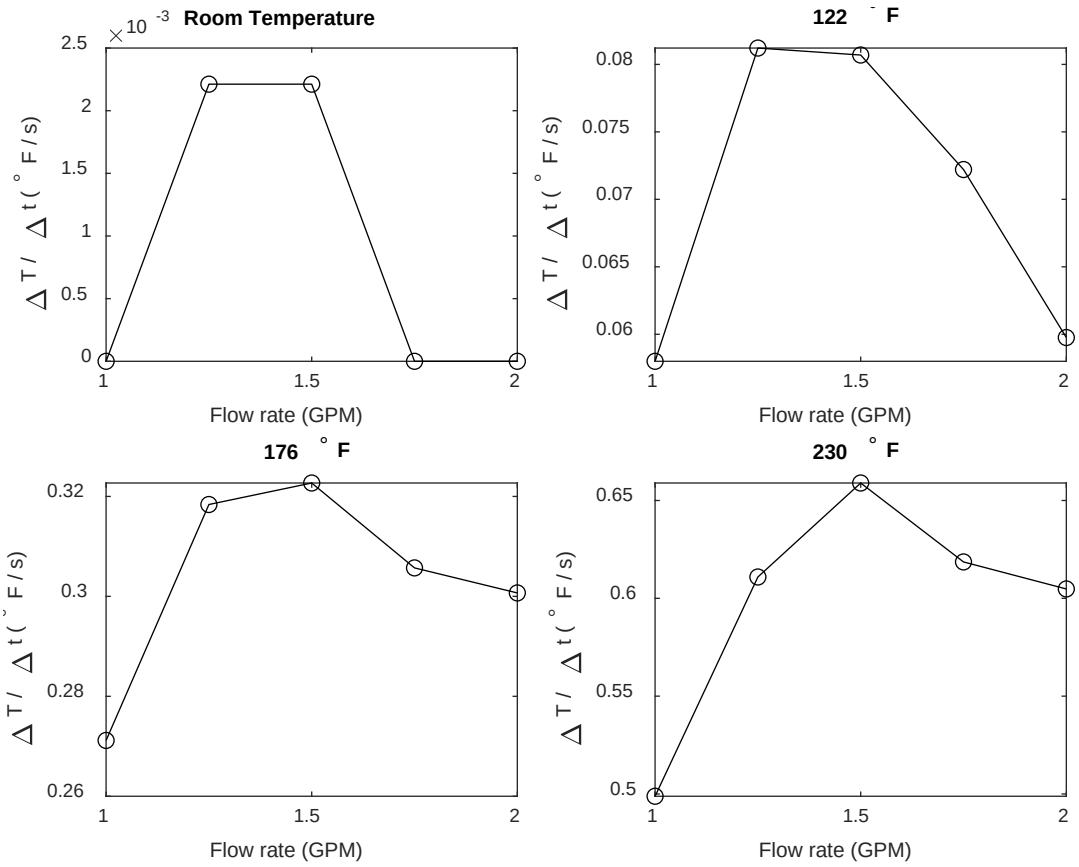

Figure 9: Rate of temperature change versus flow rate for varying applied temperatures.

Table 1: Summary of the rate of temperature change versus flow rate for varying temperatures.

Flowrate (GPM)	ΔT / Δt (°F / s)			
	Applied Temperature (° F)			
	Room	122	176	230
1	0.00	0.06	0.27	0.50
1.25	0.00	0.08	0.32	0.61
1.5	0.00	0.08	0.32	0.66
1.75	0.00	0.07	0.31	0.62
2	0.00	0.06	0.30	0.60

Figure 9 shows that the small fracture system reached a relatively consistent optimum heat extraction rate at a flow rate of 1.5 GPM. Additionally, Table 1 shows a consistent increase in temperature change over time as the applied temperature increased. Room temperature showed an expected result of little to no heat extraction, and 230 °F showed the highest heat rate at 0.66 °F/s. Overall, these results show a component of flow behavior that changes at 1.5 GPM, resulting in an optimal heat extraction rate.

4. Conclusion

The small fracture results for this project show relatively consistent behavior except for applied temperature tests at 230 °F. The tests were analyzed further with dimensionless number analysis to confirm that the flow regime affected the fracture's pressure drop, which caused some high temperature tests to have differing behavior. The results for the small fracture heat extraction rate over time for varying temperatures show promise for developing more efficient heat extraction strategies. These results show that the single fracture system reaches a consistent optimum value, creating the potential for further studies to investigate optimization techniques for enhancing geothermal heat extraction. Future work includes analysis of the large single fracture configuration data, dual constant temperature fracture analysis, varying large fracture temperature analysis, and running the same tests with different working fluids in the flow loop.

ABSTRACT

The study explores the value extraction through the fracture geometry calibration component of end-to-end lifecycle simulations for the 16A(78)-32 and 16B(78)-32 injector-producer pair at the Utah Frontier Observatory for Research in Geothermal Energy (FORGE). Forward modeling was conducted with rigorous geomechanical, fracture propagation models calibrated with micro earthquake (MEQ), production logging, and strain data during fracturing and circulation.

The 3D geomechanical model was built from the structural geologic features and the thermal and mechanical properties profiles. In the first step of calibration, elastic properties were calculated from openhole logs and empirical core test data. A high-fidelity discrete fracture network (DFN) was used as an input in the 3D geo-model. The DFN was built based on data sets collected from five wells, microseismic monitoring during a 2022 stimulation campaign to constrain fracture orientations and intensity, and fracture characterization in well 16B(78)-32. The simulations were conducted in a 3D nonhomogenous mode with stress shadowing and fracture interactions. Next calibration was conducted using the MEQ data acquired in the stage 3 stimulation of well 16A(78)-32 in April 2022. The stress model, leakoff, DFN, stress anisotropy, fracture toughness were calibrated. Forward modeling was then conducted for phase2 stimulation in April 2024 with the calibrated properties. Connection efficiency of the doublet was also inferred from the modeling results. All the modeling results including fracture hits and connection efficiency were validated with the newly acquired MEQ, strain evolution, thermal strain datasets.

1. Introduction

Optimizing fracture propagation and network generation is critical for enhanced geothermal systems (EGS) development. The induced hydraulic fractures provide conductive systems through proppant packs. These enhanced flow-paths allow fluid to circulate throughout the fractured hot rock system and transfer heat through conduction. This heat is transported back to surface. An alternate success strategy for EGS could rely on large preexisting fractures such as in the Soultz project. But this precursor often does not exist in EGS candidates, pushing us to ensure successful fracture optimization. All the necessary, relevant aspects such as fracture propagation, stress interference, slurry flow, interaction with natural fractures, and materials selection (fracturing

fluid, proppant, circulation fluid) need to be considered. Also, changes in the thermoelastic, geomechanical, and geochemical dynamics during the lifecycle of EGS become pivot points for decision-making.

Integrated subsurface modeling facilitates strategy optimization for 15-30-year lifecycle of the project. The modeling needs to account for aspects related to fracturing, circulation, heat transfer mechanisms, and fluid-rock interactions. Coupled thermo-hydro-chemical-mechanical processes and stochastic techniques are critical. Kresse et al. (2024) have detailed a review study identifying research gaps and technological challenges in these domains.

Utah Frontier Observatory for Research in Geothermal Energy (FORGE) is a dedicated underground geothermal field laboratory for developing, testing, and accelerating breakthroughs in EGS technologies to advance geothermal resource development. Eight wells have been drilled at the Utah FORGE site. Five (58-32, 56-32, 68-32, 78-32 and 78B-32) are primarily for in-wellbore testing and monitoring purposes. A water well was drilled late in 2023 to provide water for a fracture stimulation program performed in April 2024 and an upcoming circulation test in early August 2024. There highly deviated 16A(78)-32 and 16B(78)-32 wells serve as doublets to evaluate the EGS concept. **Fig. 1** shows the location is on the flank of the structure separated from the conventional hydrothermal reservoir in the East Blundell power plant by the Opal Mount fault. The doublet subhorizontal wells are landed around 200°C with the deviated section covering from 6,000-ft to 8,000-ft in vertical depth. The reservoir comprises of low permeability granitic basement rock.

In the part-I of this paper related to the lifecycle simulations for the FORGE project, we cover the fracture simulations, measurements, and calibration component. All the logging and measurements from multiple wells, microearthquakes (MEQs), and strain data from fiber optics (FO) were used for the fracture modeling and calibrations.

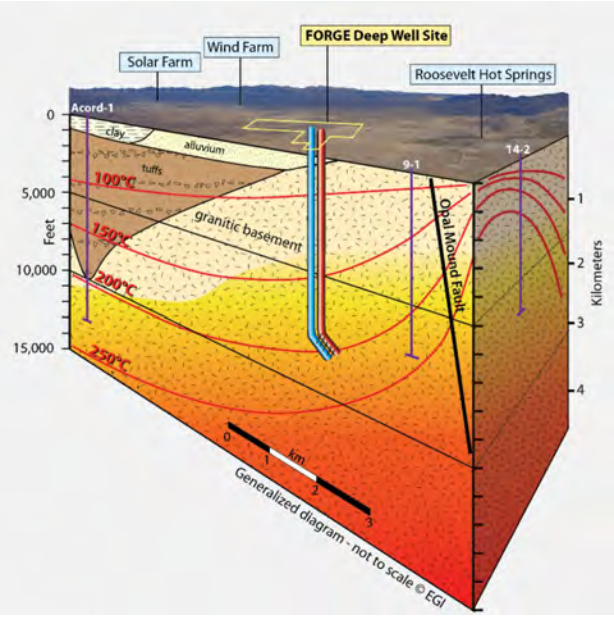

Figure 1: Cross section of the injector-producer doublet at the FORGE site with the subsurface isothermal contours (Moore et al. 2020).

2. Fracturing and Completion Summary at Utah FORGE

Injection well 16A(78)-32 was drilled and completed between October-2020 and January-2021. Following completion, injection tests were performed in the 200-ft openhole section below the 7” casing shoe to determine formation properties of the granite reservoir (Xing et al. 2021).

In April-2022, equipment was mobilized for fracturing treatments to determine fracture initiation and propagation behavior in the openhole section of the wellbore and through perforation intervals. Three fracturing stages were pumped (1 in openhole, 2 through perforations). The perforated stages were strategized to connect with the pre-existing fractures analyzed through image logs. Fracturing execution was conducted. The MEQ interpretation showed differences in fracture geometry and was used as the guide for drilling the production well to intersect the MEQ event clouds (McLennan et al. 2023).

In April-2023, the production well 16B(78)-32 was drilled with a 65° deviated section with the wellbore parallel, at the same azimuth, and 300 ft vertically directly above the 16A(78)-32 wellbore. A circulation test was performed by injecting water into 16A(78)-32 and monitoring the pressure and outflow from 16B(78)-32. Pressure increase was observed in 16B(78)-32 during two two-day injection periods, and outflow from 16B(78)-32 was still increasing during the second injection period when test was stopped. However, the outflow rate was very low compared to the injection rate into well 16A(78)-32. This was attributed to the recharge of the fracture network system between the two wells due to the large amount of fluid that flowed back from the fracturing treatments pumped in April 2022.

Three separate FO cable were run outside the 7” casing: two of the cables near the 7” casing shoe and one cable to a depth just after the end of the build section. The cable run to just below the end of the build section was for a pressure and temperature gauge that was ported into the 7” casing. After the special section of the wellhead was installed and the surface connections were completed and tested, the cementing treatment for the 7” casing was pumped and monitored by the fiber optic cables.

Following a wellbore cleanout run with the drillstring, a second circulation test was performed. The maximum injection rate was increase to 7.5-bpm from 5-bpm in the first circulation test. With the 7” casing cemented in place, the only place for the wells to communicate would be the 739-ft openhole section of 16B(78)-32. The second circulation test was also performed over a two-day period. On the first day, the injection rate into 16A(78)-32 was 5-bpm for most of the time and then increased to 7.5-bpm. Wellhead pressure and outflow rate were monitored on well 16B(78)-32, and results were similar. There was a very rapid pressure connection between the two wells, and the outflow rate was increasing throughout the injection; however, the outflow rate was still very low compared to the injection rate into 16A(78)-32. On the second day, a production logging tool (PLT) was run in 16A(78)-32 at rates of 2.5, 5.0 and 7.5-bpm to determine the distribution of fluid into the Stage 1 (openhole), Stage 2 (perforated) and Stage 3 (perforated) intervals. The results of both circulation tests are detailed by by Xing et al. (2024).

The second phase of multistage fracture stimulation at Utah FORGE was planned for commercial-scale treatment designs with a larger number of stages evaluating the effect of fluid viscosity, number of clusters per stage, cluster spacing, proppant type, etc. Since well 16B(78)-32 was equipped with FO, the design strategy was to pump all the stages in 16A(78)-32 and use the FO

strain data to fracture hit locations. In 16A(78)-32, the pump-down plug and guns multistage fracturing method was utilized. The 3-ft guns were loaded at 6 shots/ft with 60° phasing. The number of clusters varied from one to eight, and the cluster spacing ranged from 25 to 50 ft. The proppant pumped was 100-mesh and 40/70-mesh silica sand. In one of the stages, a 30/80-mesh ultralightweight proppant was added in addition to the silica sand proppant to evaluate the effect on proppant transport and post-closure placement within the proppant-pack. For well 16B(78)-32, the 4-ft perforation guns were loaded at 10/350° phasing and oriented to avoid perforating the FO cables. The perforation operations were performed via tubing-conveyed perforating (TCP). The proppant pumped in 16B(78)-32 was also 100-mesh and 40/70-mesh silica sand.

The first stage (3R) was a refrac of the three frac stages pumped in April 2022, with the addition of proppant. Stage 3R was pumped as designed with slickwater. Stage 4 was a single cluster pumped as designed with slickwater. Stage 5 was a single cluster pumped as designed with crosslinked CMHPG. Stage 6 was treated at high pressure, but the pump rate was not high enough to begin pumping proppant. The treatment was shut down and an additional perforation gun was run near the original perforation cluster. The stage schedule was restarted, but pressure was still at maximum allowable pumping pressure, with minimal improvement in injection rate. Stage 7 guns were pumped down and three clusters were perforated. Stage 7 behaved similarly to Stage 6 and no proppant was pumped. After shutdown, it was suspected that geological anomalies may have been the reason for the problems experienced in Stages 6 and 7. Stage 8 was perforated with eight clusters spaced 25-ft apart. The stage was pumped as designed with crosslinked CMHPG fluid and placed a total of 1,081,500 lb_m of proppant at a pump rate of 80-bpm. Stage 9 was also perforated with eight clusters and 25-ft spacing, and the fluid was slickwater. Treating pressure began to increase during the 40/70-mesh steps, and flush was started prematurely to avoid a screenout. A total of 730,000 lb_m of proppant was placed into the formation, which is 68% of the designed amount. Stage 10 was added to the schedule with the same design as Stage 6, which included the 30/80-mesh ultralightweight proppant added with the silica sand proppant. Stage 10 was pumped to completion as designed with slickwater.

After analysis of the FO data in well 16B(78)-32 during the 16A(78)-32 frac stages, it was determined to increase to five stages compared to the originally planned four stages, to accommodate the TCP gun string design conditions. The first four stages were all pumped to completion as designed. Unfortunately, Stage 5 was not able to be pumped because there were no frac plugs available to isolate Stage 4. Stage 5 was perforated and could be stimulated at a later time.

Fig. 2 below shows all the relevant steps to consider while modeling and calibrating fracture propagation and geometry. It illustrates Phase 1 and Phase 2 of fracturing and related activities, providing context to the steps taken in the modeling workflow.

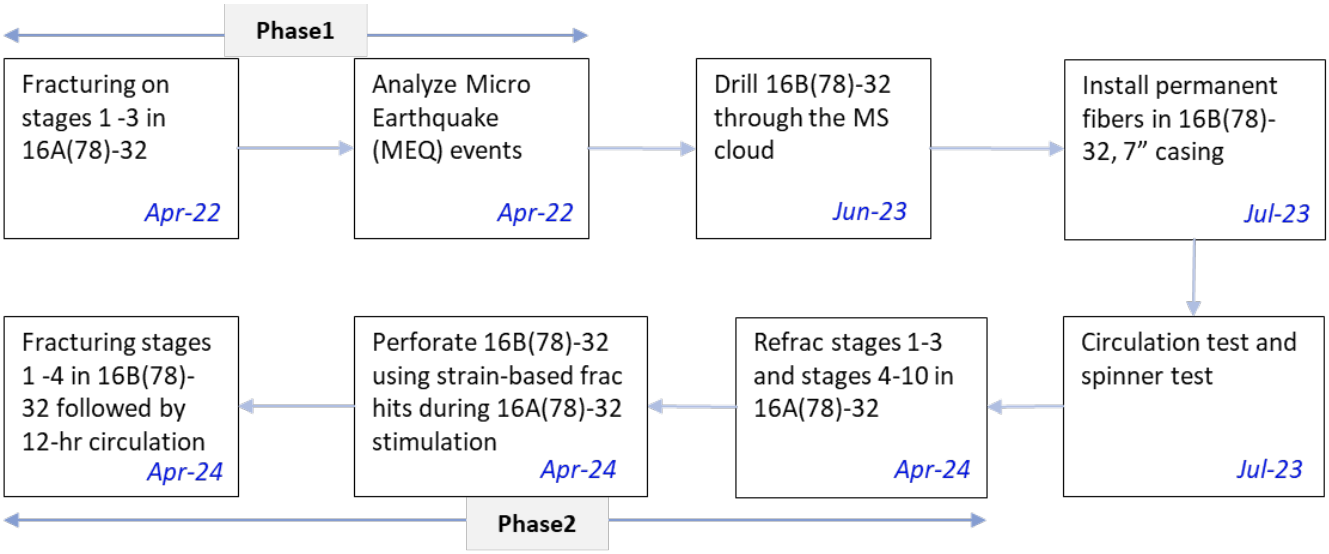

Figure 2: Event-wise workflow in phases 1 and 2 of fracturing at the FORGE site.

3. Geomodel Construction

The 3D model built for this study starts with the structural and geologic model based on faults and horizons. The model used here was built by Mulyani et al. (2024) and **Fig. 3** below shows the features and zonal 3D model based on the first steps in their work.

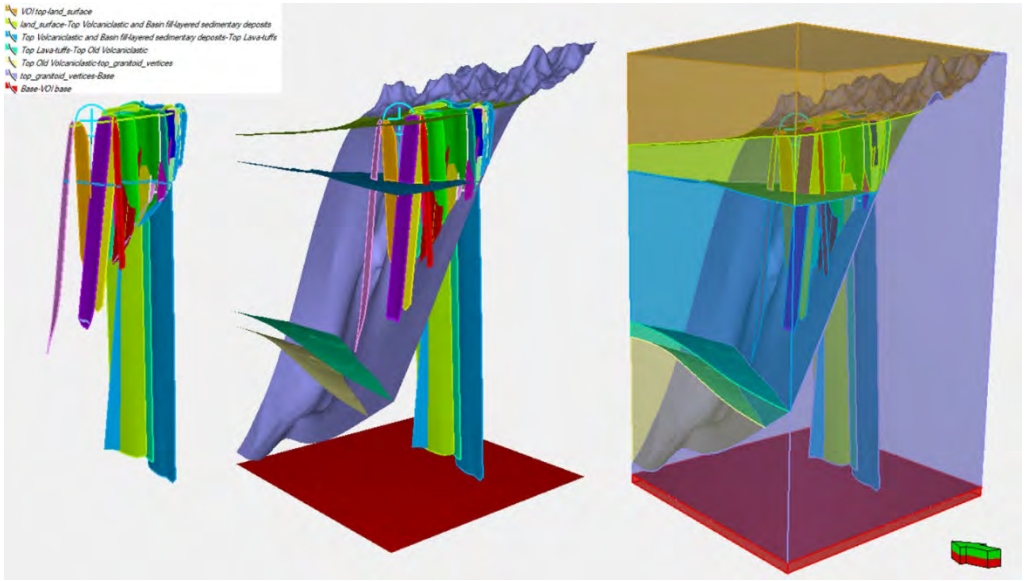

Figure 3: The geological structural model developed by Mulyani et al. (2024) showing (from L-R) faults, horizons, and zones constructed for 3D grid based on the horizon boundaries.

The structural tops (from top to bottom) used the volcaniclastic and basin fill layered sedimentary deposits, lava tuffs old volcaniclastic deposits, and granitoid vertices. The elastic properties model (in-situ stress, Young's Modulus, Poisson's ratio, etc.) demonstrated in **Fig. 4** was derived from

the continuous openhole logs measured in 16B(78)-32 across the lateral trajectory. The calculated elastic properties were propagated along the 3D structural model. Note that, compared with Figure 3 above, the 3D model is slightly truncated for fracture modeling. It captures the structural dip based on the isothermal contours, and the future parts will use the full structural model.

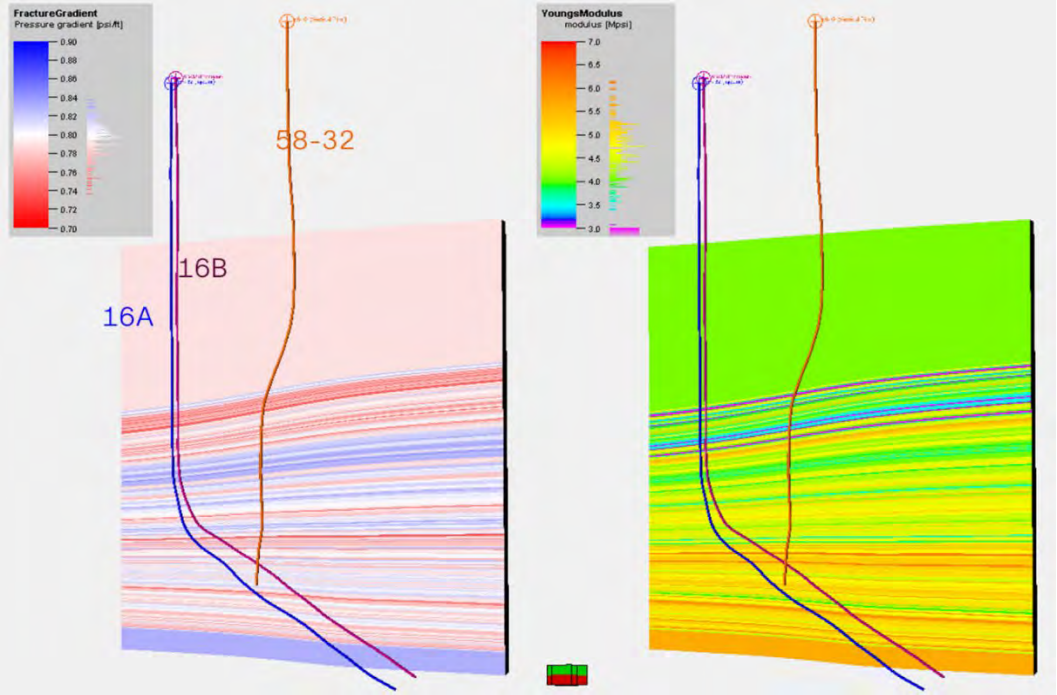

Figure 4: Elastic rock properties montage: (left) discretized fracture gradient and (right) Young's Modulus variation displayed in cross section across the vertical pilot well and the injector-producer doublet.

In addition to the layered zoneset, the properties used in the simulation model setup for the final calibrated model are detailed in **Table 1**. The tensile strength and fracture toughness inputs are from static triaxial testing conducted on the extracted cores (McLennan, 2018). The fracture azimuth (preferred fracture plane/S_{Hmax}) is taken from the 2000 fractures from FMI logs in well 58-32 (**Fig. 5**). The stresses in the base case model were slightly increased to match the MEQ data.

Table 1: Properties for the calibrated zone set model used for fracture simulations.

Fracture gradient	0.72 – 0.85	psi/ft
Young's Modulus	4 - 8	MMpsi
Poisson's Ratio	0.24 – 0.32	
Horizontal fracture toughness	1730	psi-in$^{1/2}$
Vertical fracture toughness	1520	psi-in$^{1/2}$
Tensile strength	1520	psi
Overburden gradient	1.13	psi/ft
S_{Hmax} gradient	0.79 – 0.92	psi/ft
Pore pressure gradient	0.46	psi/ft
S_{Hmax} azimuth	25	deg
Matrix permeability	0.00001	mD
Matrix porosity	0.2 - 2	%
Rock specific gravity	2.3	
Rock compressibility	1E-005	1/psi
Horizontal stress anisotropy	500 - 750	psi

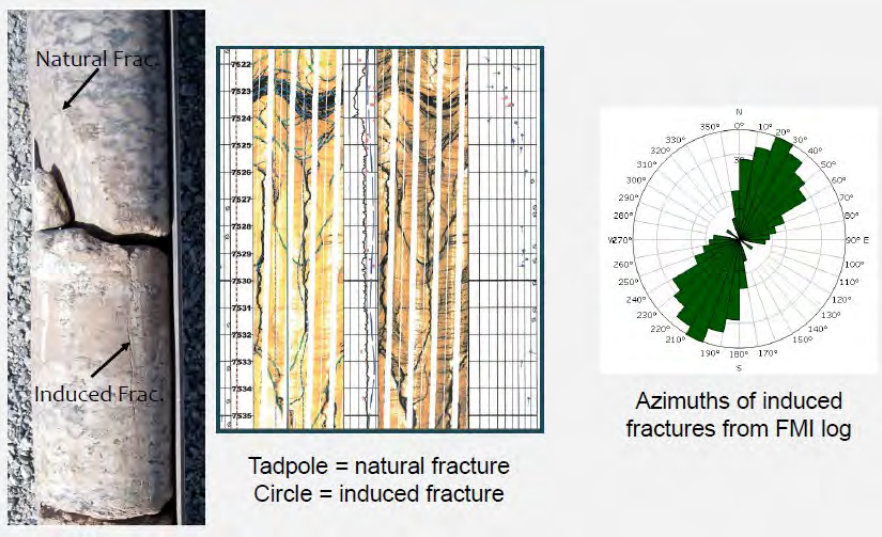

Figure 5: Core depiction, FMI log and rose diagram and poles predicted to upper hemisphere for induced fractures azimuth, in well 58-32. (Moore, 2019; McLennan et al. 2023)

The reference discrete fracture network (DFN) model for the FORGE, in this study is used to characterize both the natural fractures present in the reservoir and induced fractures created during hydraulic stimulation (Finnila and Jones, 2024). A deterministic set for fractures intersecting wells 58-32, 56-32, and 16A(78)-32 was included based on those features identified in the FMI log interpretation. It also includes fracture planes fitted to the seismic point cloud generated from the stimulation of well 16A(78)-32. In the most recent version, data from vertical well 78B-32 and deviated well 16B(78)-32 have been analyzed to refine fracture orientations and intensities.

Fracture sizes of this deterministic set were generated using the same truncated power-law distribution as the stochastic set, but only those larger than the minimum DFN size cutoff of 10-m radius were kept in the model. There are four fracture sets in total (refer to **Table 2** and **Fig. 6, left**). This 3D DFN was used to extract a total of 10,000 elements in a 2D DFN for fracture simulations (**Fig. 6, right**).

Table 2: Update fracture set parameterization (Finnila and Jones, 2024)

Set name	Description	Trend/Plunge [deg]	Strike/Dip [deg]	Fisher concentration	%
1	SSW-striking, vertical	114/2	204/88	22	30
2	South-striking, moderately dipping West	91/37	181/53	7	29
3	North-striking, moderately dipping East	230/52	320/38	4	21
4	East-striking, sub-vertical dipping South	354/16	84/74	9	20

Wells are colored by cluster label number using k=6 (Finnila and Jones, 2024); (right) Two-Dimensional DFN extracted from 3D DFN above for fracture simulations. Perspective looking north with the injector-producer doublet.

4. Fracture Model Exploration

The choice of an appropriate fracture model is crucial for obtaining comprehensive and reliable results on fracture shape. Historically, the development of hydraulic fracture models for oilfield applications started in the 1950s with simplified analytical and semi-analytical models. With the increase of the size of hydraulic fracturing treatments, the need for more advanced models applicable in layered reservoirs and needed for proper evaluation of the height of hydraulic fractures led to the development of Pseudo-3D (P3D) and eventually more complex planar 3D models. The review and description of these models could be found in Adachi et al, 2007.

While P3D models are CPU efficient, they are built on an assumption that reservoir elastic properties are homogeneous and averaged over all layers containing fracture height, which is applicable in many field cases. However, P3D models cannot handle complex reservoir stress profiles when the stresses vary non-monotonically as a function of depth or when unconfined height growth occurs. They cannot predict hourglass-shaped footprints when the middle layer in a multilayer system is stiffer than bordering layers. Planar 3D models were developed to handle these situations correctly while still considering the planar fracture geometry, predicting fracture growth in two-dimensional mesh, properly handling any stress profile for layered formations, and providing fully 3D width profile of the fracture (Adachi et al, 2007). Planar 3D models are successfully used in many field applications and considered as a “good enough” fracture propagation model for EGS applications. One of the disadvantages of these models is CPU performance, which has been considerably improved recently with the development of high-performance computing tools. However, planar 3D multi-cluster stimulations are still more expensive than P3D-based approaches and cannot handle interactions with pre-existing natural fractures. However, planar 3D multi-cluster stimulations are still more expensive than P3D-based approaches and cannot handle interactions with pre-existing natural fractures.

With the shale development, pressure analysis and matching, and by reviewing the MEQ events clouds in multiple wells and formations, it was concluded that fracture geometry is not always

planar, which could be attributed to interactions of hydraulic fractures with pre-existing discontinuities, stress shadow effect between closely located clusters, and to anisotropic 3D zone properties variation in some formations. These factors led to the development of complex fracture models (Kresse et al, 2012; Fu et al, 2012; McClure and Horne, 2013; Wu and Olson, 2015). The complex fracture models could be CPU intensive, so some simplifications are usually made to make them more CPU efficient while still capturing and properly handling the layer-related physics (Cohen et al, 2015). In many cases planar 3D models are used initially for fracture height evaluation, and then complex fracture models are applied with appropriate height restrictions.

When there is a need to pick the proper fracture model for EGS applications, several questions arise: What is the model expected to handle? What kind of formations, fluid Rheologies, proppant properties, and time scales are involved? Are there natural fractures or faults to be considered? The proper fracture model should be able to predict fracture propagation and height growth while accounting for the propagation regime and reservoir properties (impermeable, brittle, very hot rock), model fracture initiation, and model fluid and proppant transport while accounting for temperature and rheology changes. It should accommodate an advanced heat transfer model, including advection by fluids, heat transfer between the fracture and the rock, and heat conduction within the rock. It should also account for hydro-shearing and hydro-fracturing mechanisms in both stimulation and circulation phases, and account for thermoelastic and poroelastic stress changes and fracture reopening due to cooling during circulation.

We investigated both planar 3D and complex models (UFM) for EGS applications in this study to understand the implications of each and to determine the preferred one based on some observations.

5. Fracturing Simulations/Calibrations

This section will cover the calibration and forward modeling efforts with the available pumping data, acquired MEQ data, FO strain data, and PLT data (**Fig. 7** describes the workflow). The basecase was modeled to check the performance and compare with the MEQ point cloud, followed by the calibration workflow and forward modeling for all the stages on the lateral well 16A(78)-32. Note that in this part-I of the paper, the fluid flow modeling was not conducted.

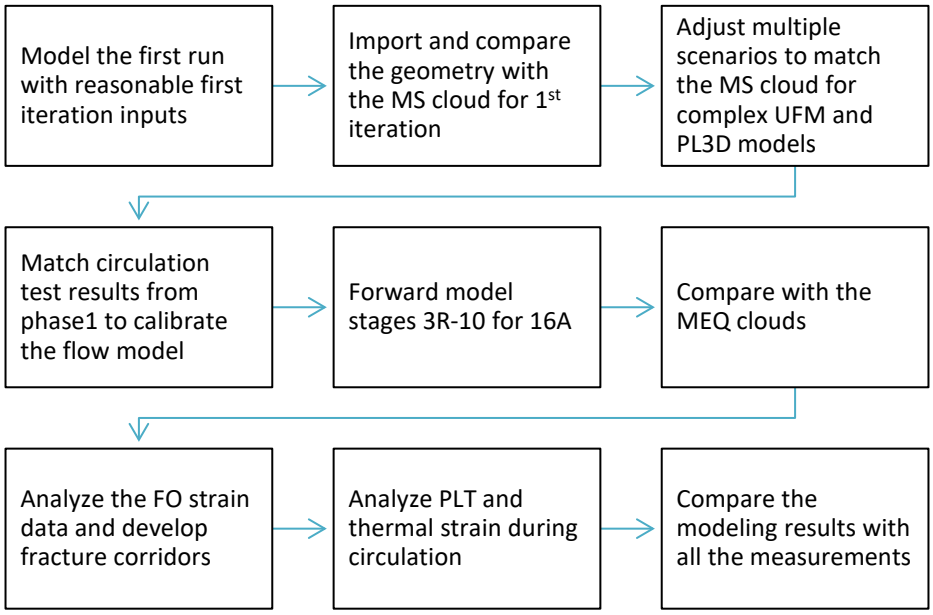

Figure 7: Modeling and calibration workflow using the MEQ, fiber and flow data.

5.1 Observations from the Microearthquake events

MEQ event cloud observations and interpretations and understanding are critical for calibration. **Fig. 8** shows the data from phase 1 of stimulation. Stage 1 showed the poorest event quantity (211 events) and quality (141-ft error) compared to Stage 2, which had 948 events and 41-ft error due to failure of some geophones. Stage 3 showed the best MEQ catalog with 1432 events with a mean error of 56-ft.

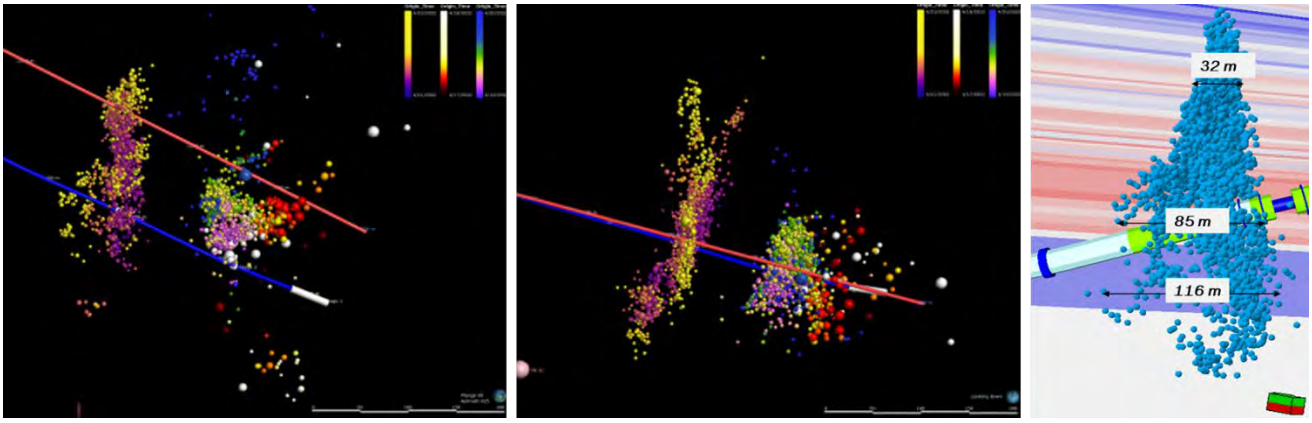

Figure 8: MEQ projection after 3-stage fracturing in phase 1. Perspectives looking north in vertical section (left) and plan view (middle). Events zoomed for stage 3 looking south showing the width of the network based on events up to 116-meters (right).

Finnila et al. (2023) provides some interesting observations in the process of extracting planes from the MEQ clouds. A total of 11 planes were fit to the full event cloud (4, 5, and 2 planes for Stages 1, 2, and 3, respectively), showing that Stages 1 and 2 grew in a relatively complex fashion

compared to stage 3. Even with Stage 3, there are two distinct planes, and focusing on the MEQ cloud, it also shows a width (S_{hmin} extent) of upto 116-meters, which indicates possible non-planarity. These two observations could be an impact of the DFN causing bending of the dominant fracture.

In phase 2, the event clouds show complex developments for the initial stages and stage 8 shows multiple networks. Stage 9 shows more planarity with some bending due to possible interaction. In the side view (**Fig. 9, middle; Fig. 9, right**), the complex event development is more evident. Moreover, the bottom barrier observed in phase 1 seems to be competent and most fracture height growth is observed towards the top which makes the producer lateral landing strategy viable (**Fig. 9, left**). The planarity of the fractures based on phase 2 data seems to be impacted by the treatment size and viscosity (crosslinked fluids).

MEQ events could either indicate the extending tensile fracture at the tip or a slip on a preexisting fault or plane of weakness. The latter would not contribute to fracture growth. Here, moment tensor inversion was conducted to impress the focal mechanism for tensional events. Additionally, a quality control exercise was performed to examine the magnitude and eliminate most of the shear slip events and noise.

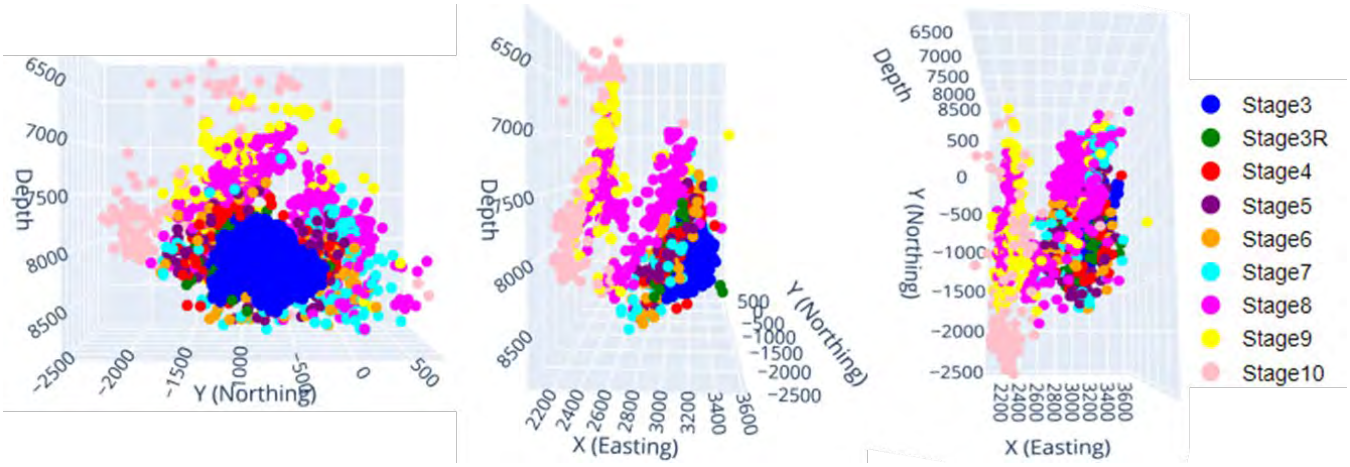

Figure 9: MEQ events projection during fracturing in phase 2. (left) gun-barrel view showing extension in the SHmax direction, i.e. fracture length; (middle) side view, network development in Shmin direction; (right) top view

5.2 Stimulation phase1 calibration workflow

Since Stage 3 gave the best MEQ event cloud with good accuracy, the chosen approach was to use Stage 3 to calibrate the basecase model. The modeling was conducted using complex UFM model as well as a planar 3D model. The leakoff model, stress model, and near-wellbore open perforations were changed for both models. Additionally, horizontal stress anisotropy and complexity index were calibrated for the UFM case. **Fig. 10** and **Table 3** show the comparison for both models. During the calibration exercise, it was observed that the length propagation was much higher for planar 3D model. We attempted to reduce the length propagation by increasing the total leakoff coefficient, but this significantly reduced the fracture height. It is important to note that if the

vertical (based on acoustic measurements) and lateral (structural consideration) variation in the 3D stress model is not considered, the upward height growth with the planar model can be misleadingly high. A constant stress gradient model across the vertical interval would lead to such modeling results. The UFM model matches the MEQ cloud better because of possible termination at a DFN element. Based on this observation and other compelling reasons provided by reservoir characterization through core testing, FMI logs, DFN modeling, etc. it was decided to utilize the UFM model for the forward modeling approach on the consequent stages.

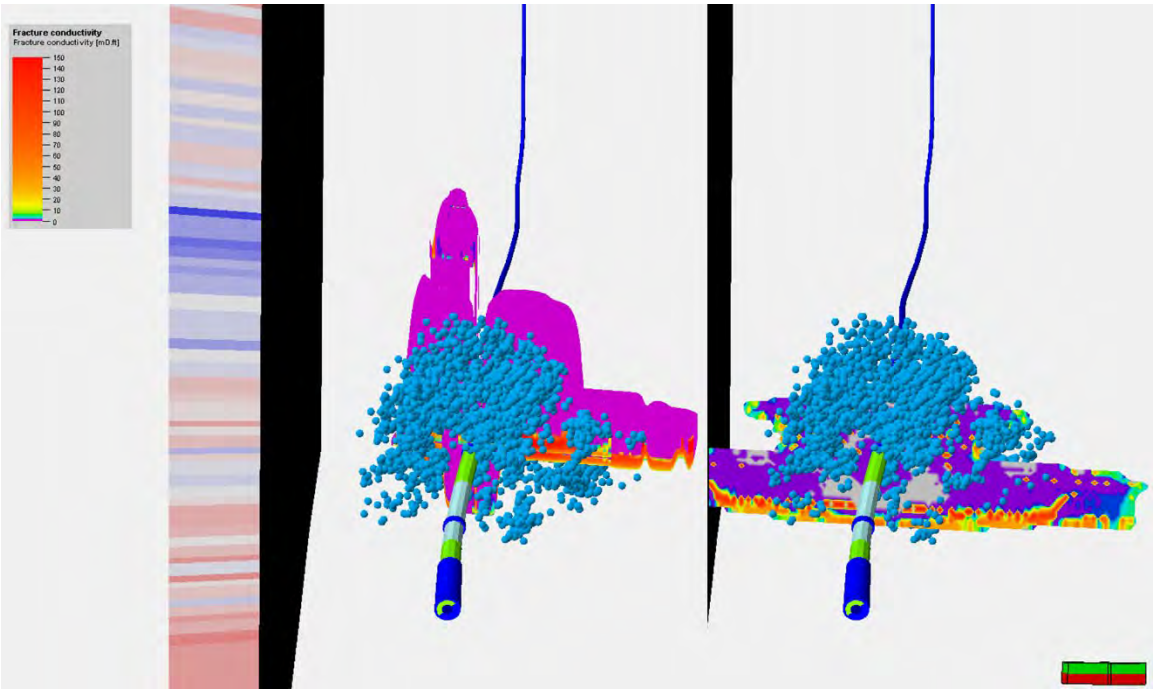

Figure 10: Fracture geometry after stress and leakoff model calibration with the complex UFM model (left) and the planar 3D model (right).

Table 3: Fracture geometry comparison for both propagation models.

	MEQ Point Cloud	UFM	Planar3d
Fracture half-length [ft]	522	596	1034
Max Fracture height [ft]	874	1159	519
Avg. Fracture conductivity [mD*ft]	NA	52.2	129.9

Another important aspect considered in this phase is to look at the expected downhole rheology of the fluid. The model uses rheology curves with exposure times at multiple temperature points. The viscosity is then interpolated by the solver as a function of temperature and exposure time at each grid block across the fracture. **Fig. 11** shows that most of the fracture geometry is exposed to a static rock temperature of 410°F, and the second largest fracture area is exposed to ~350°F. McLennan et al. (2023) presented a rheology curve for the CMHPG system, showing viscosity reduction below 40 cP and 10 cP after 2 and 3 hours of exposure, respectively. The same rheology profile was used in the model. Above 375°F, the viscosity input was 1 cP. It is noteworthy that the shear experienced by fluid is typically higher than tested in lab rheometers, so the expected fluid quality will be even lower. With these low viscosities, most of the proppant is expected to settle before fracture closure occurs. Hence, the conductivities in the upper part of the fractures could

cause multiple pinch points, affecting the connection efficiency between the doublets. This consideration was factored in phase 2 to account for accurate proppant transport, settling and also to conduct preliminary investigation on the impact of light weight proppant, pumped in Stage 10 of well 16A(78)-32.

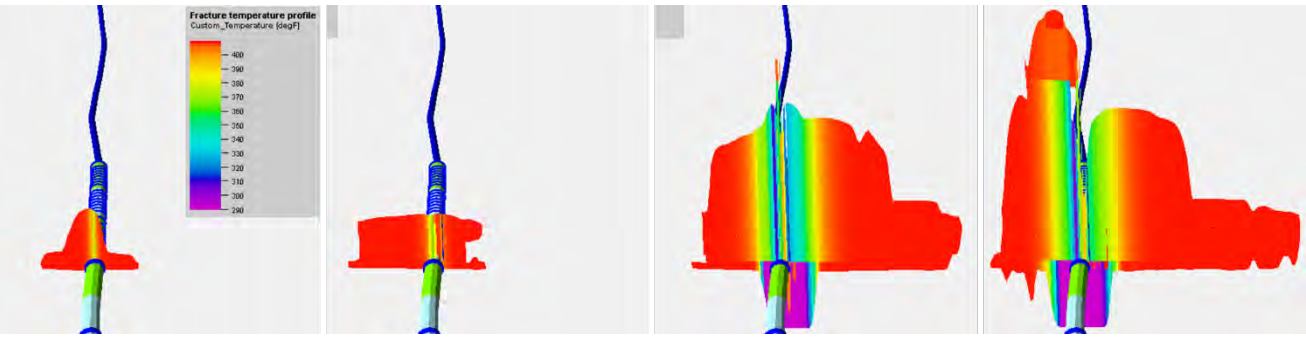

Figure 11: Temperature profile across fracture during pumping stage 3. Four snapshots at 1-hr intervals. The temperature scale here varies from 290°F to 410°F

5.3 Stimulation phase2 modeling

All the calibrated parameters from Phase 1 were used for the forward modeling presented in this section. Leakoff had to be reduced slightly for some of the stages to capture the larger fracture footprints. This could be due to the changes in system permeability as a consequence of DFN variations. Even though Stage 6 and Stage 7 were not successfully pumped, they were modeled because fluid was pumped in different attempts. **Fig. 12** shows a few perspectives of fracture network development. It is important to note that the middle and bottom figures have cutoffs implemented and do not represent the full hydraulic geometry. Stages 8, 9 and 10 show higher fracture conductivity development. The fracture propagation shows a limited impact of DFN in terms of complexity generation in the toe-side stages compared to heel-side. This is because the orientation of the fracture traces evolves from wellbore perpendicular to wellbore parallel as we move to the heel stage. The termination of a fracture when interacted with a DFN element depends on multiple criteria relevant to the fracture elements such as the approach angle, length, density, cohesive strength, etc. Hence, using the complex geomechanical propagation model is optimal whenever DFN is present in the formation. **Table 4** shows the comparison of the MEQ data with the modeling results. The relative results show a good agreement (also see figure 9), but the absolute results of the model are smaller. This is expected because the extent shown for MEQ is the furthest events captured and might just be due to critically stresses fracture slips or reactivation. The table also shows the Sh_{min} extent which is indicative of the fracture complexity versus planarity.

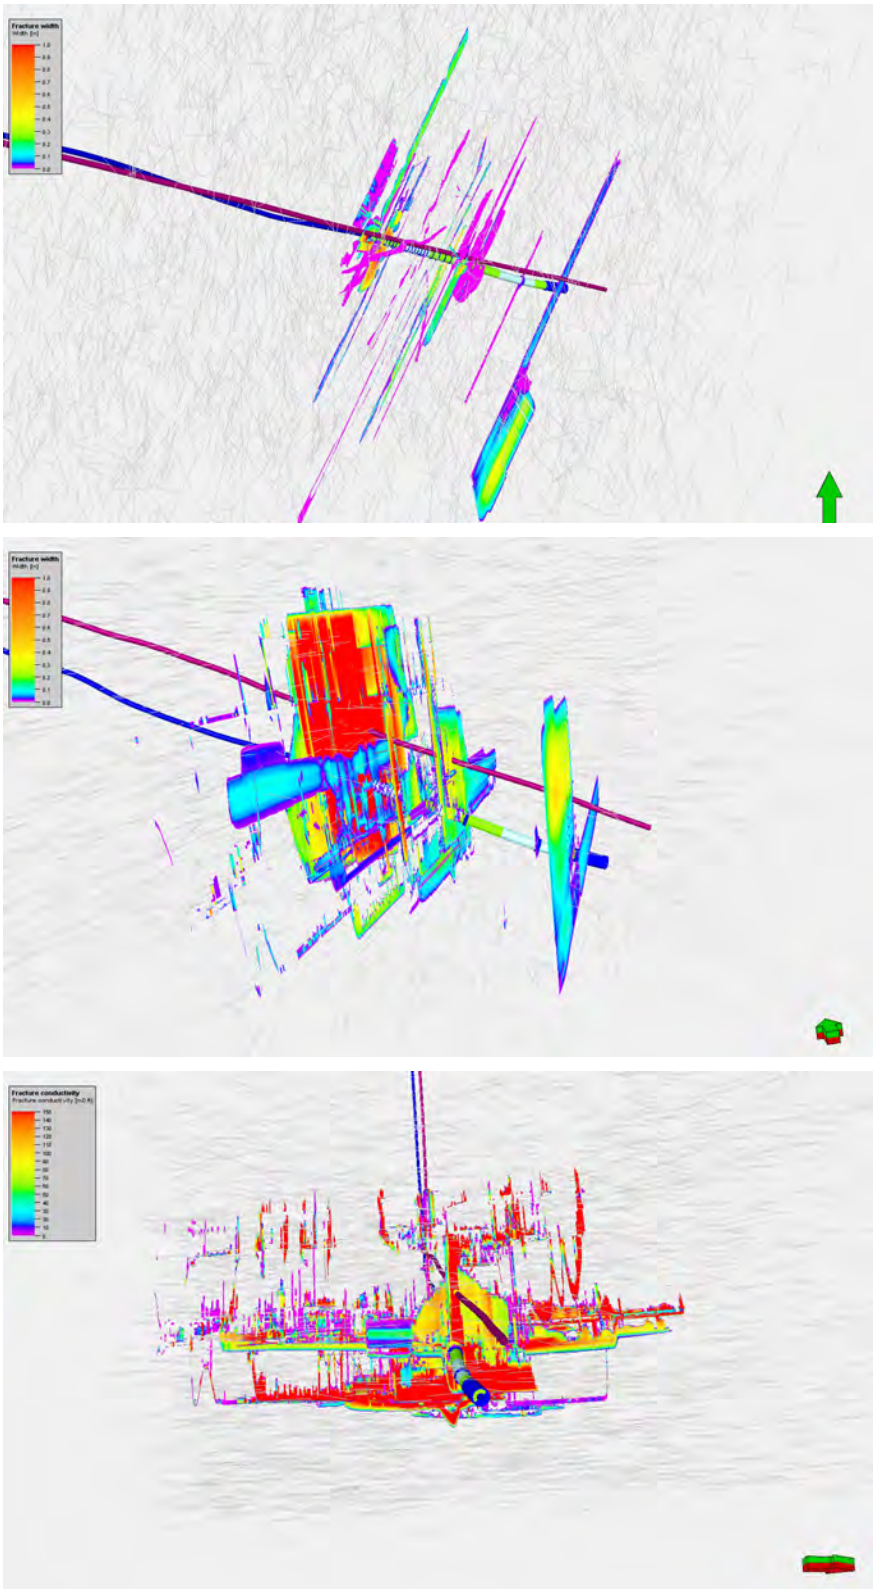

Figure 12: Fracture footprint for stages 1 – 10 with the DFN elements in grey. (top) fracture width profile in plan view; (middle) looking north with a fracture width cutoff of 0.1-in; (bottom) looking west, gun barrel, with conductivity cutoff of 1md.ft.

Table 4: Fracture geometry comparison (in principal stress directions) MEQ versus fracture modeling for phase2.

	MEQ		Fracture Model - UFM		MEQ
	S_{Hmax} Extent	Vertical Extent	S_{Hmax} Extent	Vertical Extent	S_{hmin} Extent
Stage 3R	1350	870	1193	1259	640
Stage 4	1500	1110	1561	984	680
Stage 5	1640	1280	1165	1347	670
Stage 6	1970	1360	1938	1266	650
Stage 7	2220	1650	2220	1084	910
Stage 8	2270	1900	1935	1441	1110
Stage 9	2230	2000	2493	1057	1430
Stage 10	3120	2530	1293	1680	1330

5.4 Production Logging Results Utilization

PLT results were insightful in modeling and understanding the large fracture geometries for stages 8 and 9. The fluid intensity was designed for 8 clusters but the cluster efficiency in these stages might have been ~50% with more fluid for the dominant clusters. The initial runs with the UFM model showed slightly higher cluster efficiency of 60-70% and the flux distribution data in **Fig. 13** helped calibrating that. The logging tool had limited access below stage 6. Low contribution from stage 7 stresses the importance of proppant. Stage 8 could not be decomposed to cluster level due to operational issues. Stage 9 highlights the heterogeneity and cluster non-uniformity considerations in EGS development.

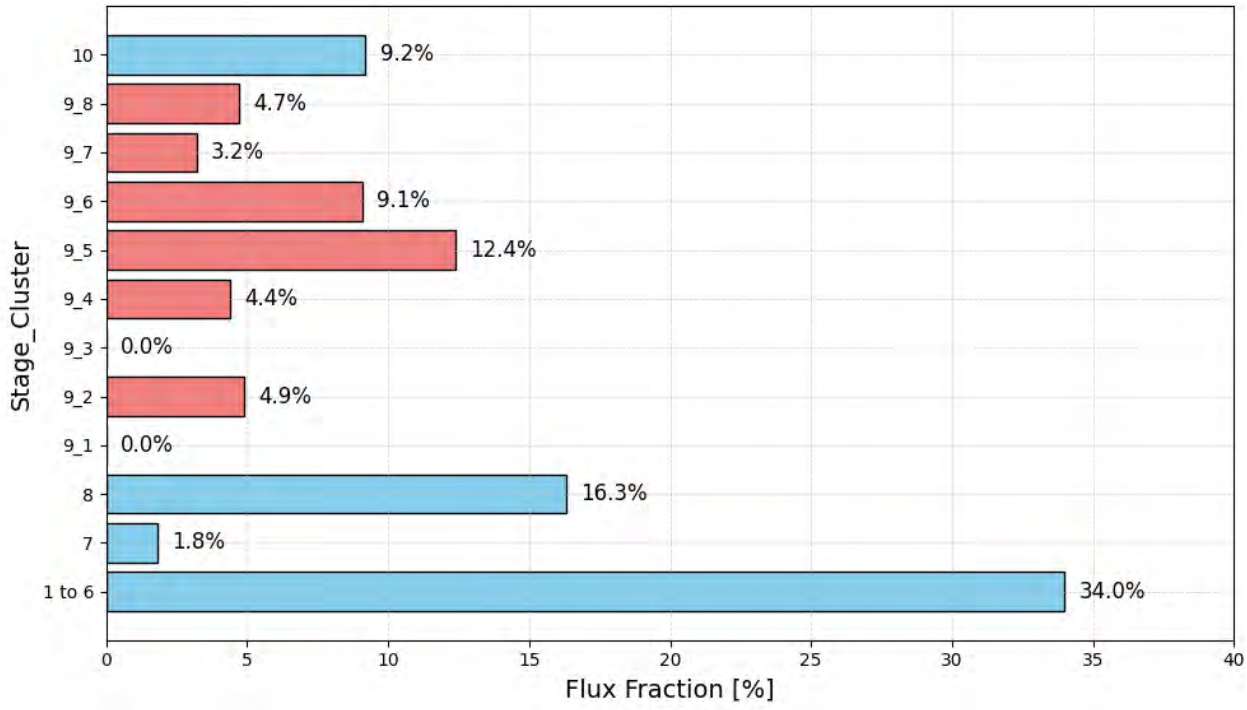

Figure 13: Production logging results after the 12-hr circulation test.

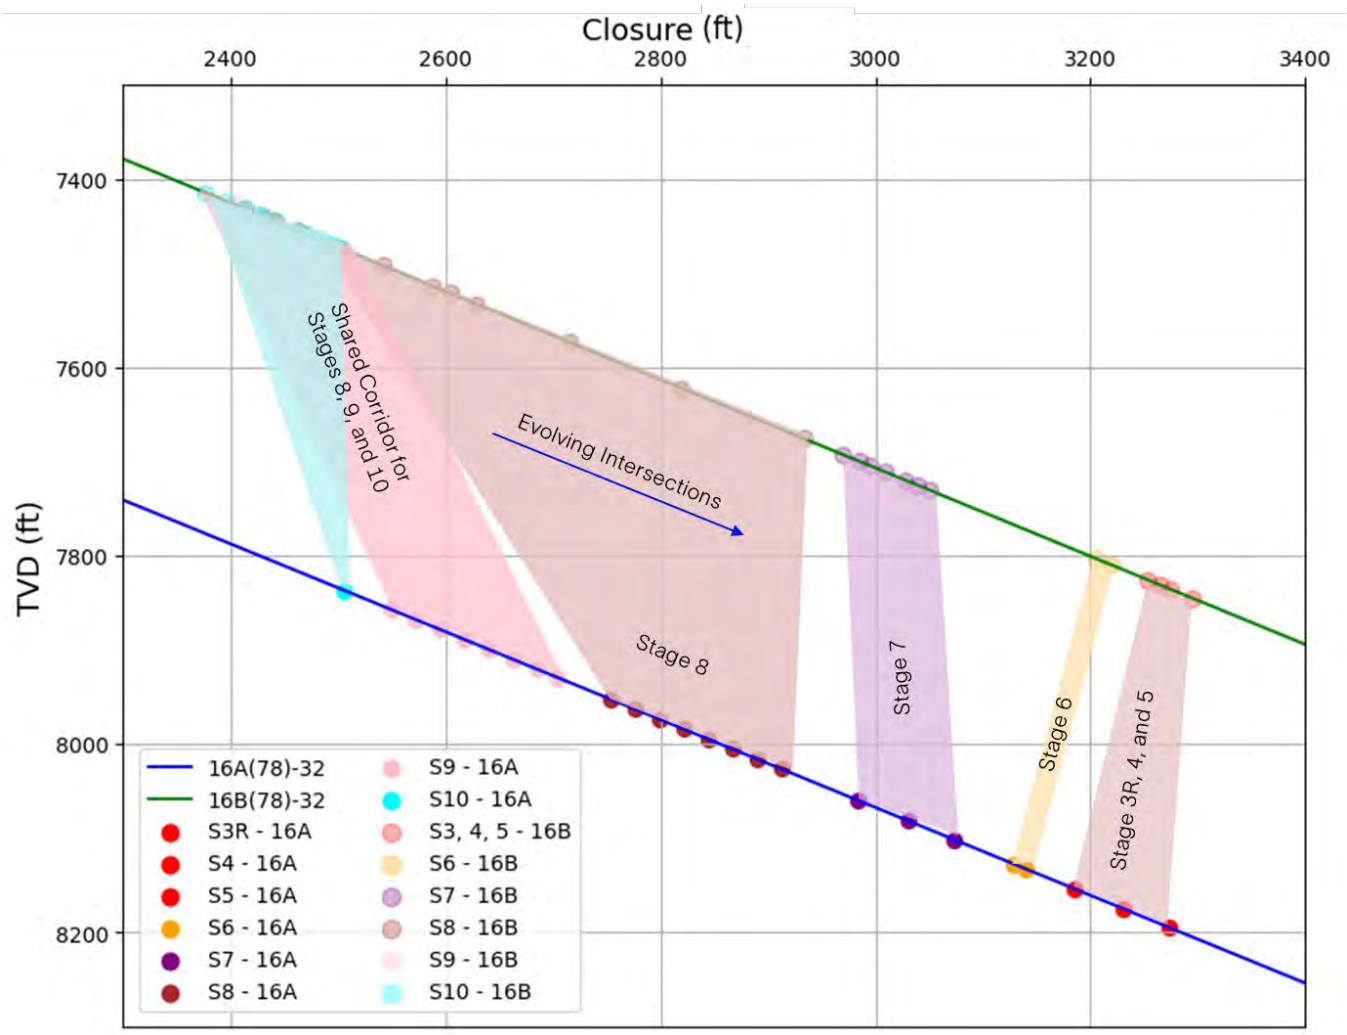
5.5 Fracture hits summary

The strain data was acquired during the 16B(78)-32 fracturing from the permanent FO installation in 16B(78)-32. A total of 49 hits were analyzed and fracture corridors were developed based on those (**Fig. 14, top**). Stages 8, 9 and 10 showed a lot of interaction with intersecting corridors. Analyzing the stage10 MEQ and strain data, it is evident that stage10 merged into a lot of existing fracture networks from previous stages. The large fracture geometry and multiple hits with much smaller fluid intensity can be explained through these interaction mechanisms. Also, stage 8 MEQ and strain data show a large network development. **Fig. 14, bottom** also shows a similar view from fracture modeling results. The corridors are very similar with obvious variations in stage 10 which are hard to predict.



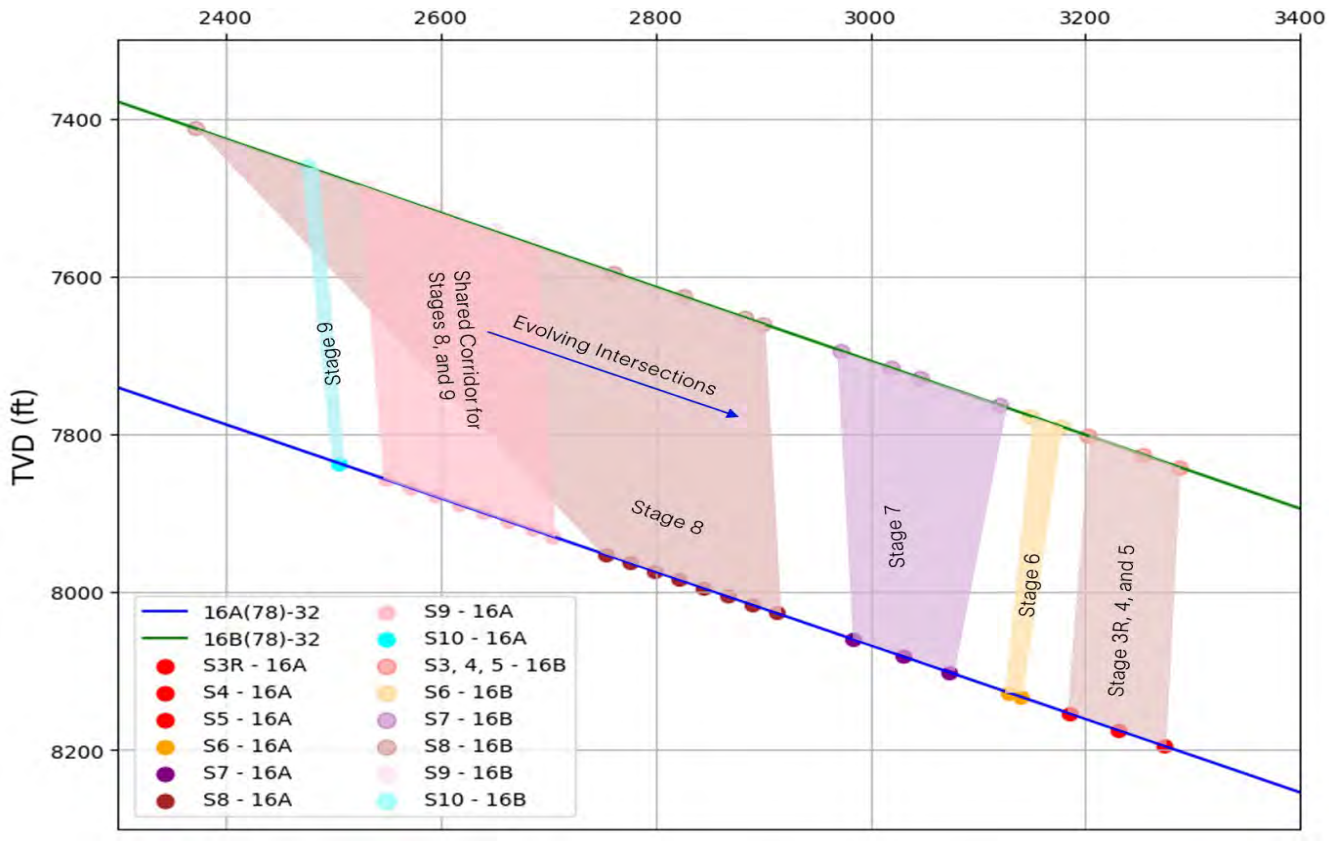


Figure 14: Fracture corridors constructed from 16A(78)-32 to 16B(78)-32 based on (top) fracture hits from Low Frequency DAS data; (bottom) fracture hits from the UFM complex fracture model.

Detailed analysis of fracture hits in the model revealed that most of the fracture hits show hydraulic width development but a 'near 0' end-of-treatment conductivity due to proppant settling and closure mechanics which could impact the connection efficiency. Hence the thermal strain analysis during the circulation test yields valuable insights into the interaction between injected cold fluid and hot fractured rock system, as well as the effectiveness of the fractures in facilitating fluid movement from the injector to the producer. Note that 4 fracturing stages were pumped with proppant in the 16B(78)-32 before the circulation. **Fig. 15** shows the thermal strain development in time. As the cold fluid enters the fractures, rapid temperature drop leads to rock contraction around the fracture, resulting in compressional strain. Hence, blue regions indicate the rock contraction and show that stages 9 and 10 were the first to receive and circulate the fluid. At the same time stages 7 and 8 show extensional behavior which could be a dynamic effect of the rock contraction in the nearby rock. For stages 9 and 10, as time progresses, the extensional (red) regions become more prominent, possibly due to the ongoing circulation of the cold fluid and the equilibration of thermal effects within the rock matrix. This transition might indicate areas where the fluid has moved further into the fracture network, causing redistribution of stress and inducing extensional strain. At this time stages 7 and 8 show compressional strains indicative of cold fluid arrivals here. Finally, cold fluid arrivals signals can also be seen in stages 3 through 6. This is intuitive based on the modeling and fracture corridors developed because even stage 8 shows strong interaction with the overlapping networks around stages 9 and 10. Moreover, the arrivals are faster and more conductive fractures are observed in areas where fracturing and proppant placement was done from injector and producer to overcome the 'near 0' conductivity at producer

purely from the injector stages. Also, the fracture driven strain curve peaks aligned with the waterfall show around 20 effective fractures which agrees with the fracture modeling results.

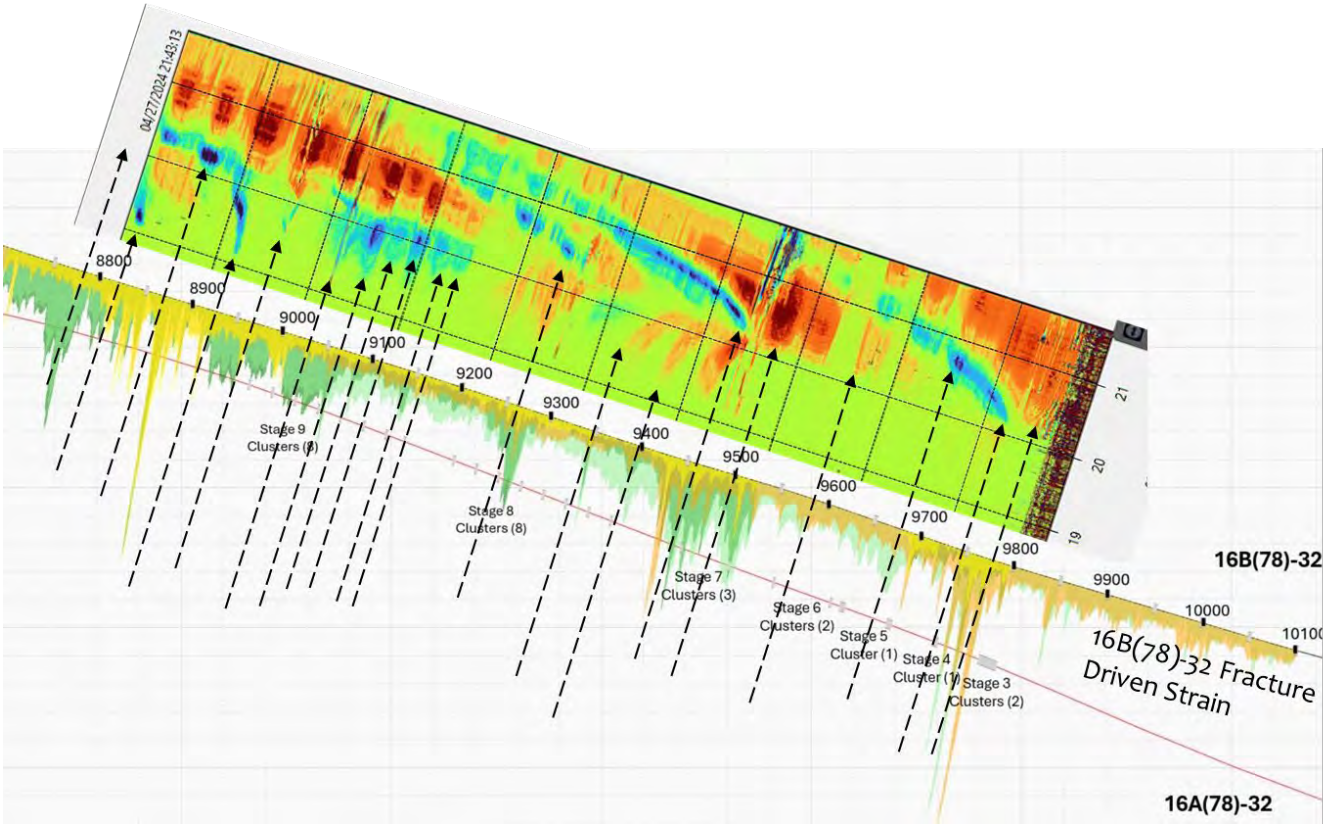

Figure 15: Thermal strain evolution (waterfall plot) during 12-hr circulation test (3 hour time scale shown on Y-axis) along with the fracture driven strain (continuous curve) along 16B(78)-32 (Courtesy Neubrex Energy Services).

Table 5 details the macro stagewise summary of the fracture hits achieved with well 16B(78)-32. The connection efficiency (>100%) observed from the strain-based frac hits dictates fracture network development more than planarity. The total effective fracture connection efficiency from the fracture driven strain during circulation agrees with the model, even though stage-wise distribution varies. Appendix-A provides details on the frac hit locations.

Table 5: Stagewise summary of frac hits from 16A(78)-32 to 16B(78)-32.

Stage#	Total Clusters	Cluster Spacing [ft]	Total frac hits			Connection Efficiency		
			DAS	Model	Circulation	DAS	Model	Circulation
3R	1	-	4	1	1	133.3%	100.0%	100.0%
4	1	-		1	1		100.0%	100.0%
5	1	-		1	1		100.0%	100.0%
6A, 6B	2	12.5	2	2	1	100.0%	100.0%	50.0%
7	4	50	7	4	2	175.0%	100.0%	50.0%
8	8	25	12	5	3	150.0%	62.5%	37.5%

Total	26		49	20	20	188.5%	76.9%	76.9%

6. Discussion, Summary, and Way Forward

As much of the industry is beginning its journey of understanding how to put EGS concepts into practice, this paper presents a similar attempt. Using existing oil and gas simulators to try and plan and predict EGS work, up through future circulation events, brings various learning opportunities. As the authors discovered, these learned opportunities are larger than a single paper can encompass.

Part-I, encompasses the calibration of fracture systems and reservoir mechanical properties. Part-II will investigate strategies such as simultaneous injection to improve circulation efficiency and optimize the doublet connection efficiency. The optimization will also investigate DFN utilization to increase the circulating fluid's residency time, thereby increasing heat transfer. Hence, the 16B(78)-32 stimulation will be critical for part-II. Part-III will explore the end-to-end workflow investigating the circulation effect on the thermoelastic stress alterations of the rock and shear fractures generation. Part of this exploration will evaluate how the DFN properties manifest themselves and alter flow during long-term circulation.

Within this paper, much attention has been given to the model calibration, including the DFN. A lot of work has been dedicated to building the DFN using image logs and other tools to evaluate size, distribution, and orientation (Finnila and Jones, 2024). Even though some of the MEQ point clouds suggest planarity, a certain degree of complexity is possible based on the interpretations provided in this paper. While there may be an open debate about how to correctly predict fracture dimensions, what should be evident is that taking the DFN into account is critical in the long run for EGS. Even if the pumping schedule choice leads to less complexity, i.e., using crosslinked fluids, the DFN may still have an effect in reducing fracture growth in the preferred direction (as observed from phase 2 results). This effect will largely depend on the magnitude of stress anisotropy and principal stress reorientation during the EGS lifecycle in the circulation phase.

If we look at analogous shale plays such as Eagle Ford, which shows more planar features, or the Barnett, which shows complex MEQ cloud development, it becomes clear that a generic inference cannot be drawn. These observational findings can be extrapolated for EGS to infer that complex models will be more relevant than planar models for future EGS development. Moreover, if the system model neglects the DFN, then premature thermal breakthrough prediction with forward models could be missed, reducing the economic efficiency of the EGS installation.

Thermoelastic stress induction has not been considered in the fracture modeling here because, once the temperature transient equilibrates with the cooldown temperature, the thermal stress alterations would be minimal. However, in circulation phase, it is imperative to model this mechanism. McClure et al. (2024) have provided a robust forward modeling study using the thermoelastic effect during circulation and demonstrated stress changes upto 1,000s of psi, resulting in significant fracture apertures upto 1.5-in. Their results stress the importance to consider the systemic compliance changes (based on tensile strain) when DFN is also considered as a system

component. The next steps will be to calibrate the flow model from longer (30-day) circulation tests data and conduct forward modeling for 15-year and 30-year circulation tests results. As part of the ongoing study, propositions for the optimum fracturing strategy for EGS will also be made.

An important learning from the Phase 2 stimulation was the problems related to rock breakdown, injectivity, and proppant placement issues associated with Stages 6 and 7. This behavior is typical in high tectonic influence heterogenous clastic formations (Asif et al. 2024). This experience pronounces the importance of considering the vertical and lateral heterogeneity in the formation for EGS lifecycle modeling. Almutary et al. (2024) provide a data based approach to enhance placement quality. We will be investigating this using discrete indices calculated from the continuous logs and 3D geomodel, such as reservoir quality, completion quality, placement quality and geologic quality.

7. Conclusions

The paper provides a comprehensive workflow for calibrating and forward modeling for the FORGE EGS project. The subsurface structural and geologic model is used to build a 3D model along with a comprehensive DFN inclusion. The basecase inputs use the reservoir and rock characterization data conducted with triaxial core testing, openhole logs, and MEM calculation. Calibration utilizes the pumping pressures, MEQ event clouds, fiber optic, and PLT data. The modeling provides a comparison of complex and planar fracturing models and provides recommendation to use models that can incorporate DFNs, as their effect and potential impact can be critical for EGS lifecycle simulations. Significant proppant settling is observed due to the low viscosity, even with crosslinked fluids, as a temperature effect degrades the polymer. Fracture hit analysis and fracture corridor development from 16A(78)-32 to 16B(78)-32 was also presented, resulting in a 188%, 77% and 77% connection efficiency based on strain measurements during fracturing, modeling, and strain measurements during circulation, respectively. The fracture corridor development showed a marked similarly between the measured strain data and the model. These results can be explained by the hydraulic width development at the producer during fracturing but ‘near 0’ conductivity by the end of treatment leading to less effective connection quality.

Enhanced geothermal systems, life cycle modeling

ABSTRACT

Enhanced geothermal systems (EGS) represent a promising avenue for sustainable energy production. However, the extreme temperatures pose an implementation and optimization challenge for EGS projects. Success depends on fracture propagation, proppant placement, and establishing circulation at sufficient rates to generate energy economically and efficiently. In this paper we review different aspects across different stages of the EGS life cycle and make some recommendations for data collection, rock characterization, and laboratory testing to understand material behavior, numerical modeling, etc.

1. Introduction

Naturally occurring geothermal systems require three elements for economic viability: heat, fluid, and permeability. In the absence of natural permeability, an EGS creates a man-made geothermal reservoir.

In EGS, hydraulic fractures open new or naturally-fractured pathways—creating permeability. Injected fluid circulates throughout the hot, fractured rock, absorbing the Earth's heat. Operators pump heated water to surface powerplants where it generates electricity.

Degradation of an EGS can occur when preferential flow channels open, short-circuiting the system. Long-term success depends on controlling flow distribution to achieve uniform heat sweeping.

The largest EGS projects within recent history are the Utah FORGE, Fervo's Projects Red and Cape. Smaller attempts such as the Newberry site, Ormat's wells in Desert Peak, Nevada, and Calpine's facility at The Geysers in California tried using "shear-fracturing" to connect nonproductive hydrothermal wells.

2. Prefracturing Phase

Forecasting the dynamic behavior of an EGS requires a thorough understanding of the initial states of (t)hermal, (h)ydraulic, (m)echanical, and (c)hemical (geochemistry) attributes (THMC). All the dynamic phenomena are governed by intrinsic properties of the host rocks and surroundings which must be modeled accurately and consistently. This process, known as "static modeling," is distinct from the numerical modeling of the system's behavior (section 3).

Characterizing and modeling such properties is challenging because of geological, structural, and mechanical complexity associated with EGS sites. The acquisition, interpretation and modeling techniques derived from other energy industries (oil and gas) may not be suitable for non-sedimentary rocks.

Different host-rock and natural-fracture properties will influence behavior during stimulation treatments or circulation regimes. These properties are often correlated, so it is crucial to adopt an integrated, multidisciplinary approach to characterize them—while preserving consistency across modeling stages.

2.1 Rock and Fracture Characterization

Understanding geothermal system geometry is the first step to build an integrated model. Suitable techniques to describe the system depends on geothermal type (IGA). Existing geological interpretation available from regional studies and public research institutions can be combined with surface sampling to infer flow paths from fluid, gas, and soil geochemistry, while accurate structural imaging is achieved through geophysical surveys (Wright et al., 1985).

Seismic surveying yields accurate results in sedimentary geothermal reservoirs, but gravity, magnetics, or magnetotellurics methods are better in volcanic contexts. Wellbore markers and borehole images enable refining the understanding of structure and stratigraphy. Integrated interpretation of these data enables building qualitative conceptual and structural models (Mulyani and Sarmiento, 2019), forming the basis of the site's static model.

Geophysical methods, surface sampling, and regional geological information can provide properties of different rock layers. Wellbore logs complement the information by providing insight on mineralogy. A combination of conceptual facies models and lithology logs are used to build 3D-lithofacies models (Mulyani and Sarmiento, 2019) to which numerical property models can be constrained.

While sedimentary reservoir modeling typically focuses on the rock matrix's hydraulic properties, e.g., porosity and permeability, EGS reservoirs contain negligible permeability, so the existence of natural-fracture networks, or the ability to create hydraulic fractures, becomes crucial for success.

The most accurate source of information to build realistic fracture models come from well logging and coring. Wellbore image logs are used to derive fracture geometry (density, inclination, and azimuth) and to infer some properties (mineralization and "openness") (Das et al., 2023). Resistivity images can be complemented with other logs, such as acoustic, flowmeter ("spinner logs"), temperature log anomalies, and observed drilling mud losses.

Rock thermal behavior is defined by its thermal conductivity and heat capacity. The thermal-response test (TRT) is commonly used for very low-temperature resources but, paradoxically, thermal properties can vary as a function of temperature.

Two groups of properties are required to model a rock's mechanical behavior: elastic moduli and rock strength properties. The thermoelasticity; i.e., additional stress and strain due to thermal energy, is defined by the thermal expansion coefficient.

2.2 Lab Experimentation

2.2.1 Fracturing Fluid, Proppant Testing

API_RP_39 (1998), *API_RP_19C* (2018), and *API_RP_19D* (2021) provide guidelines for fracturing fluid rheology, proppant specifications, and long-term conductivity, respectively. API procedures need enhancement for EGS:

1. Conditions: current temperatures up to 150°C, while EGS require up to 250°C.
2. Hysteresis: Temperature cycling during circulation requires fluid to go through heating-cooling cycles. A temperature ramp simulating these and comparing the upsweep/downsweep gives indications of thermal lag as a fluid quality indicator.
3. Chemical interactions: Due to the length of contact, material interactions (fluids, proppants, formation, etc.) should be characterized. Moreover, EGS fluid's properties (salinity, pH, TDS, etc.) may differ from oil and gas.
4. Proppant conductivity: Current tests measure 50-hour exposures for each stress point, and do not capture the proppant alterations on conductivity evolution.
5. Proppant dissolution: Temperature and geochemical alterations on proppant degradation is critical.
6. Corrosion and scaling: High temperatures require specialized chemistry, additives, and procedures.
7. Thermal breakthrough: Impact of thermal breakthrough on proppant channels and conductivity need study.

2.2.2 Triaxial Testing

Triaxial testing is crucial for understanding rock behavior and properties. Some laboratory experiments (Zhang et al., 2022) provide insight into fracturing mechanisms and processes but do not address issues with upscaling to extract critical parameters for field exploration. The influence of temperatures on fracture dynamics, as detailed by Hu et al. (2016), demonstrates generation of multiple fracture traces in the near-wellbore region, impacting fracturing pressure and flow resistance. Salazar et al. (2022) demonstrated equipment and testing with the integration of fiber optic sensors in triaxial testing devices. Below are some actionable areas:

1. True triaxial testing: Use apparatus capable of conducting testing with three independently controlled principal stresses and high temperatures (Frash and Gutierrez, 2012).
2. Testing conditions: Testing should achieve 250°C and 150 MPa.
3. Sample size and condition: Small sample sizes with smooth, enlarged, and lubricated end-platens to avoid high shear resistances (Liu et al., 2022).
4. Loading speed: Rapid loading and dynamic conditions are critical.

5. Other considerations: Due to complex interfacial properties, assuming a perfect bond between sample/loading platens might be invalid. Areas of focus are anisotropy, upscaling effects, data interpretation, and understanding fracture propagation and network development.

2.3 Fracturing Materials

2.3.1 Fracturing Fluid

Fracturing-fluid system requirements are typically: (a) sufficient viscosity to create fractures and suspend/transport the proppant; (b) be nondamaging to the proppant pack; (c) be nondamaging to the reservoir, i.e., limit plugging or precipitation within the rock matrix; (d) cost efficient; (e) low environmental impact. EGS needs are similar, but the host conditions (temperature, rock minerology) and requirements for circulation, e.g., thermal shocks through cooldown-warmback and continuous injection of nonnative fluid, bring further challenges.

Required viscosity is typically achieved by crosslinking high-molecular-weight polymers. At EGS temperatures, thermal degradation of polymers will be rapid - challenging for most fluid systems. Polymer residues on the fracture face that decrease circulation rates or heat transfer rate are further challenges.

A critical question in EGS applications is if the status quo of using water fracs (Project Red by Fervo—Norbeck et al., 2023) or existing crosslinked systems, i.e., FORGE, is appropriate. The authors' opinion is there should be continuous effort to keep looking for alternative systems.

Almulhim et al. (2020) and Almutary et al. (2021) successfully used CO_2-laden diutan-gum systems in Middle Eastern tight clastic and carbonate fields, respectively. Similar directions were explored at the laboratory scale comparing four systems: (a) water, (b) CO_2, (c) CO_2 with water, and (d) CO_2 with 1% polyallylamine (PAA) polymer, whose tests were conducted up to 200°C. The research found that CO_2 in hot dry rock (HDR) environment attains the highest conductivity during injection, followed by the CO_2 + 1% PAA system (Fig. 1, Jian et al., 2020).

Pumping water into HDR can cause supersaturated silica to precipitate and heal the fracture during cooldown or in the absence of flow. Therefore, the conductivity is less than 1 μm^3, for water, while CO_2-based systems are generally higher across various conditions.

To create complex networks in EGS, cryogenic options (liquid N_2) have been investigated. Due to thermal-stress effects, up to a 52% reduction in breakdown pressure (Yang et al., 2021) was achieved. Fracture patterns were characterized by cryogenic scanning electron microscopy and coiled tubing scanning.

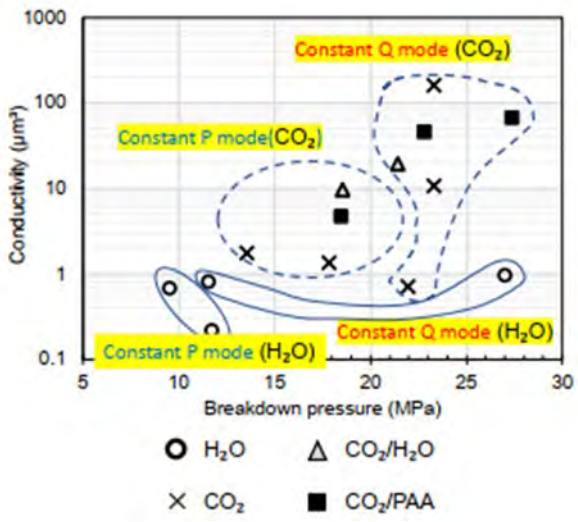

Figure 1: Conductivity at varying pressures for fluid systems at different injection modes (Jian et al., 2020).

EGS' needs invite multiple research areas for fracturing and circulation fluid chemistry. CO_2 and N_2, in energized and foamed conditions, should be investigated (Khan et al., 2023a). The introduction of free-polymer chains to nanoparticle superlattices can enhance thermal stability without disrupting internal organization, allowing for better control over particle interactions and the creation of ordered arrays in nanocomposites (Wang et al., 2021). Ruela et al. (2011) demonstrated an approach using a mixture of cationic or anionic polymers with specific zeta potential ranges, which exhibit salt tolerance and increased viscosity at temperatures above 150°C. Almubarak et al. (2018) developed a hybrid, dual-polymer hydraulic-fracturing fluid with enhanced thermal stability, stable to 205°C, by adjusting polymer loadings, using metallic crosslinkers, and incorporating buffers and oxygen scavengers.

2.3.2 Injection/Circulation Fluid

A good EGS circulation fluid should elevate heat transfer, reduce geochemical interactions, and be cost efficient. Fluids such as water, brine, and CO_2 all interact differently with rock. For example, groundwater injection leads to changes in mineralogy, impacting the reservoir's physical properties and circulation dynamics. To overcome this, pumping reactive fluids (weak acids) could enable continuous dissolution, thereby enhancing permeability and mass flow rates. Reactive transport modeling simulates fluid-rock interactions and predicts evolution of EGS projects by considering chemical reactions within the system (Adams et al., 2005).

As another example, supercritical CO_2 as the circulation fluid has potential because of its lower viscosity and density, leading to enhanced circulation efficiency and higher flow rates (Zhou et al., 2022). Toth and Bobok (2013) also investigated CO_2 as a circulation fluid in EGS. They found that heat transfer, for constant thermal mass, is lower for CO_2 than water (smaller thermal diffusion), but transport through fractured systems, because of lower pressure losses, and its ability for continuous carbonate dissolution, make it a viable option. Hence, comprehensive techno-economic analysis is critical during strategy planning to ensure a balance between energy output, cost effectiveness, and environmental considerations.

2.3.3 Proppant

The main function of proppant is to keep the tensile fracture open when pressure inside the fracture equalizes with reservoir pressure; thus older projects, such as the Newberry Volcano, which used hydroshearing as the main fracturing mechanism, did not use proppant. Norbeck et al. (2018) studied the Fenton Hill Field observations numerically, which indicated mixed-mode fracturing where generated tensile fractures closed shortly after treatment ended. This might explain its flow rate performance: Fenton Hill managed flow rates of ~7 L/s compared to ~64 L/s in Fervo's Project Red (~11% in comparison). Similar experience was seen at FORGE; this evolution shows promise in creating propped mixed-mode fractures to support conductivity of tensile fracture systems.

2.4 Proppant for EGS

At high temperatures proppant can become chemically unstable (dissolution and re-precipitation) depending on fracturing or circulation static and dynamic conditions. Understanding their long-term performance is important. In EGS context, a proppant should demonstrate higher chemical and thermal stability, mechanical strength, and acid resistance. Proppant solubility depends on the silica content of contacting fluids (reservoir or circulating). Waters with lower silica content demonstrate higher dissolution.

Brinton et al. (2011) studied bauxite, quartz, and their mixtures with granite at 200 to 230°C for up to 11 weeks in water, water-spiked silica, and the Raft River geothermal water (RRGW). Post-aging analysis showed higher dissolution of bauxite than quartz. This could be because RRGW is undersaturated in silica. Stoddard et al. (2010) found that conductivity is reduced by 48% at 90°C and 61% at 200°C.

Mattson et al. (2016) conducted a 2-month proppant strength study with a mixture of RRGW, granite, and bauxite/ceramic proppant, at unreacted and reacted conditions. The results confirm the significant crush-strength alteration over time (Fig. 2). However, Kryptosphere illustrated a higher degree of influence with proppant crushing ~9X higher post-chemical interactions at 13,000 psi.

Ko et al. (2023) investigated proppant pack performance for multiple proppants in the presence of water for 14 days up to 320°C. Noncoated proppant generated 3 to 4% additional fines at heated conditions. The rate of fines generation decreased with time, indicating proppant strength stabilization at a critical temperature where thermal damage plateaus.

Resin- and hydrophobic polymer-coated proppants showed 8 to 15% additional fines with removal of coating, cracks, and scale growth, leading to more crushing and lack of pack integrity (Fig. 3).

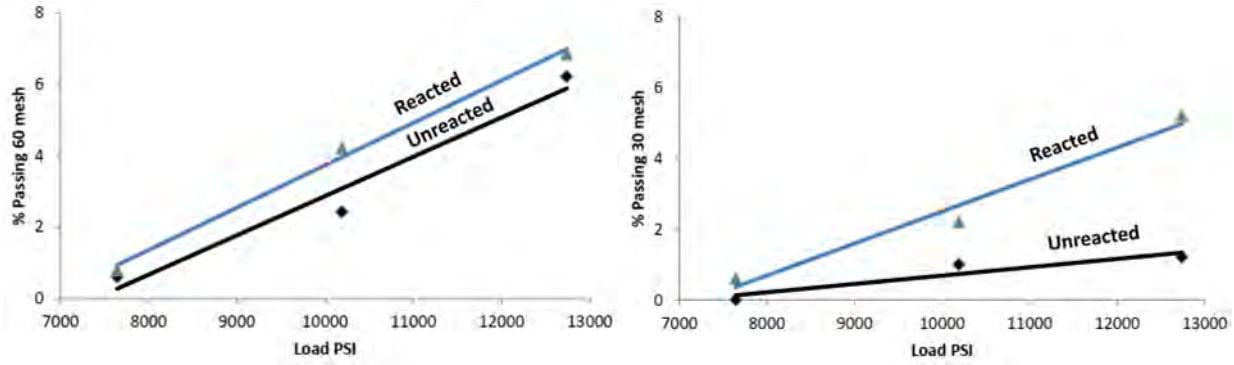

Figure 2: Crush-testing results for reacted and unreacted proppants at 250°C. (left) bauxite. (right) ceramic proppant (Mattson et al., 2016).

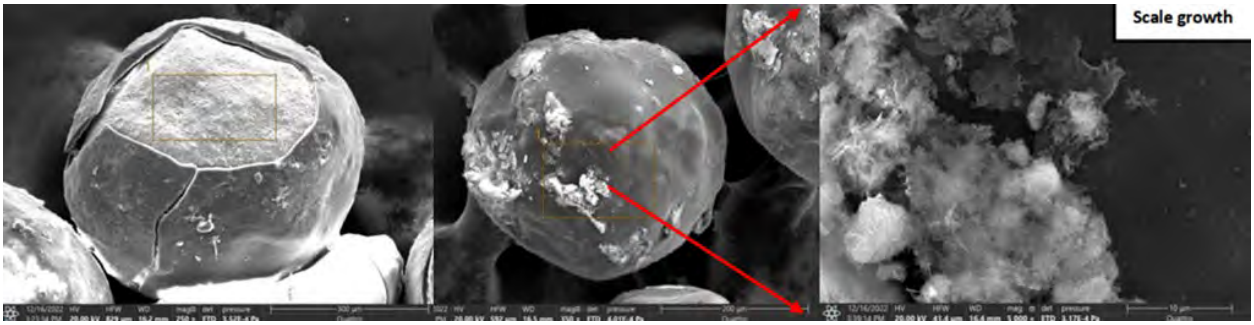

Figure 3: SEM scans of resin-coated proppant after 14 days at 320°C showing cracks and scale growth (Ko et al., 2023).

Lisabeth and Norbeck (2020) examined the impact of hydrothermal alteration on proppant brittleness and found that despite some surface changes, proppants retained mechanical integrity. Different proppant materials were reacted with brine and reservoir minerals (phyllite and diorite) up to 63 days at 250°C (Fig. 4). Results showed that quartz was most affected, resin-coated (RC) proppants are nonreactive, and high-feldspar proppants lead to dissolution and precipitation of clays but did not impact overall brittleness.

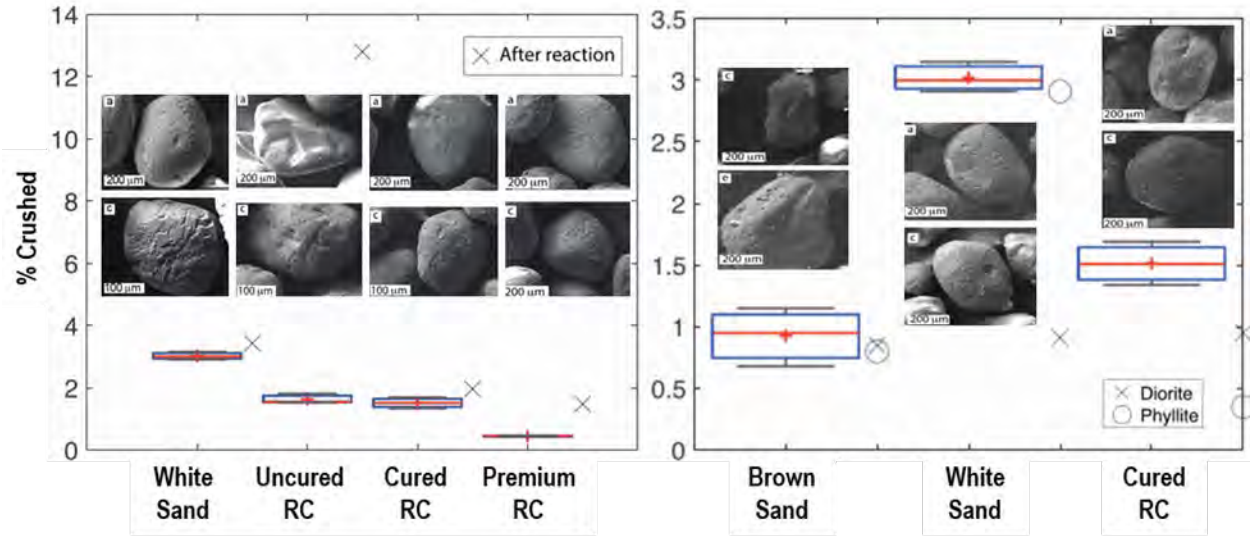

Figure 4: Summary of proppant testing showing % crush at 27.6 MPa and the inset images showing SEM scans (left) reaction for 7 days at 250ºC and 15.9 MPa. SEM scans show before (top) and after (bottom) reaction; (right) reaction for 63 days at 200ºC and 13.8 -Pa SEM scans show reaction with phyllite (top) and diorite (bottom (Lisabeth and Norbeck, 2020).

2.5 Innovative Materials, Techniques, and Avenues

Knox and Weaver (1989) evaluated multiple quartz proppants and quartz strengthened with alumina and zirconia. These showed better stability but still some dissolution. Nickel-plated sand showed good performance but was costly. Steam-resistant gravel (SRG) is highly resistant to dissolution and fines generation at 550°F.

Al Balushi et al. (2023) detailed proppants with negative thermal expansion coefficients, which demonstrate varying conductivity as a function of temperature, enabling uniform flow across fractures. This work posits that over 50 years, an additional 31.4% heat can be extracted. By optimizing flux through different parts of the network, this can effectively delay thermal breakthrough. This research presents a comprehensive workflow for proppant development (Fig. 5).

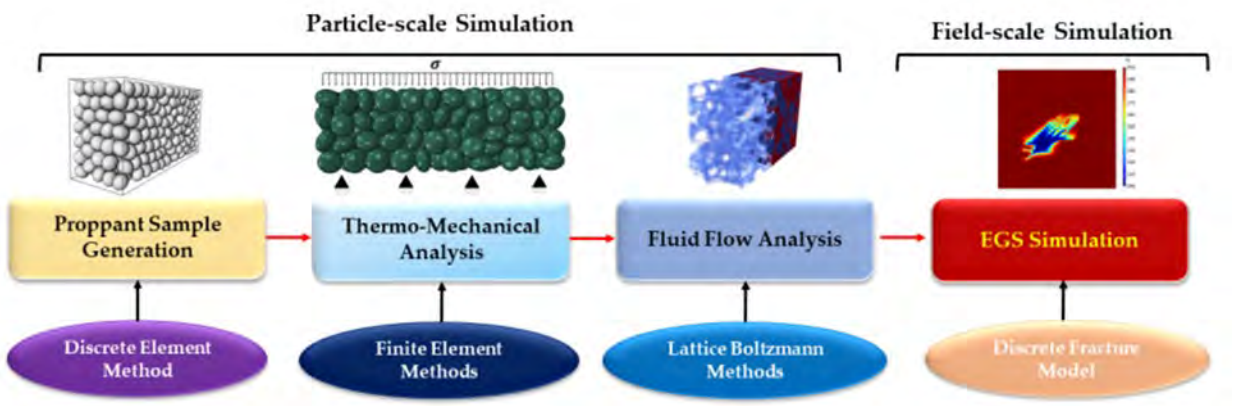

Figure 5: Comprehensive workflow combining interparticle modeling and field-scale analysis to study the novel proppant with negative thermal expansion (Al Balushi et al., 2023).

Kumar et al. (2019) have shown, numerically, that microproppants (~200 mesh) have potential in early EGS development to ensure uniform proppant placement in large networks.

Proppant flowback and redistribution is a major concern under various drawdown conditions. Similar damage is detrimental to EGS systems. High-aspect-ratio proppants, fibers, and 4D modeling can be effective (Khan et al., 2023c).

3. Numerical Modeling

To model and optimize EGS, one must consider various physical processes simultaneously, including fluid flow, heat transfer, geomechanics and geochemistry (Blöcher et al., 2010), necessitating multiple simulators. The key physical phenomena considered in multiphysics reservoir simulation are:

(1) Fluid dynamics: Fluid flow within porous media (Darcy's law, continuity equations), which consider hydrodynamical properties, pressure conditions, fluid properties, and heat transfer. Neglecting thermal effects could lead to inaccurate predictions, e.g., water-steam phase change, changes in hydrodynamical properties, cooling-induced fault reactivation, subsidence, etc. (Sullivan et al., 2001).

(2) Heat transfer within porous media: Temperature differences between injected and reservoir fluids, reservoir fluids and rock, and heat-source proximity. Three types of heat transfer mechanisms may occur: conduction, convection, and radiation (Zhao et al., 2015). However, radiation is often neglected because its contribution is insignificant in comparison.

(3) Geomechanics: Deformation of porous media caused by changes in pressure, temperature, and stress. Geomechanical deformation leads to changes in hydrodynamical properties of the rock and fractures (effective porosity and permeability), induced seismicity, and well stability (Li et al., 2020a).

(4) Geochemistry: Intense fluid-rock interaction can arise by injection of considerable volumes of working fluids (water, CO_2) during heat extraction (Gao et al., 2024). Fluid-rock interaction can lead to complex geochemical reactions (dissolution/precipitation of minerals, changes in rock

properties) and impact permeability and mechanical properties of the system as well as efficiency of heat extraction. Finally, corrosion risk on completion materials contacting fluid should also be addressed.

The main goal for fracturing in EGS is to permanently enhance permeability, thereby facilitating high fluid flow rates to produce economically.

Selecting a simulator that can model the creation of a hydraulic fracture network and is capable of evaluating fluid and heat transport between injector and production via the fracture network during the circulation phase is a challenge. Khan et al. (2024) presents an approach to life cycle modeling of EGS with complex fracture modeling.

3.1 During Fracturing

Hydraulic fracturing (HF) is the main part of EGS treatments and should be modeled simultaneously with wellbore and reservoir simulators.

Modeling of EGS HF simulation is intended to evaluate in-situ conditions and optimize EGS design to achieve sustainable heat production. Factors affecting EGS project success include creating a fracture surface area large enough to allow enough heat exchange to produce electrical energy at a commercial level and the ability to control the flow rate through fractures, lengthening thermal longevity and avoiding premature thermal breakdown (LBNL, 2021).

In oil and gas reservoirs, the target formation is stimulated to solely enhance the permeability of the formation. However, in EGS, the aim is to enhance the permeability and increase the contact area between hot rock and the circulating fluid. Having multiple fractures with smaller apertures is more advantageous than having a single fracture with larger aperture, as the fracture network provides larger contact areas for heat exchange.

Because heat extraction would decrease the temperature of the formation along the fracture, adjusting fracture conductivity to control flow rates would lead to more uniform heat extraction from the formation and therefore delay thermal breakthroughs. Thermal breakthroughs occur when preferential paths exist where the working fluid finds “shortcut” paths to quickly travel between the injector and producer wells. The fluid flow in EGS is dominated by flow in fractures rather than in rock matrix. For unpropped fractures, fracture conductivity is proportional to the cube of the fracture width, and wider fractures may provide higher conductivity (preferential flow path) to attract most of the circulating fluid, leaving massive amounts of untapped heat behind, and not allowing enough residence time for the passing fluid to heat up. This could shorten the lifetime of EGS. Controlling the flow rate through fractures to avoid premature thermal breakdown is crucial (LBNL, 2021).

More challenges for hydrofracturing for EGS include accounting for rock plasticity at high temperatures, creating large, simulated volumes with low water methods, and achieving minimum residency time for the circulating fluid to be heated. On the wellbore side it is necessary to ensure even governed flow distribution between the fractures (Kresse et al., 2023) and ensure high injection rates during an extended period.

Another uncertainty is the unpropped fracture conductivity at EGS conditions. High rates, limited-entry techniques, stress shadow effect, fracture complexity, and interaction with natural fractures contribute to larger offset/mismatch between fracture walls in field conditions than predicted by laboratory experiments.

HF simulators for EGS should include geomechanical components (stress orientation, rock strength), fracture mechanics (initiation and stimulation through hydrofracturing and hydroshearing, interaction with natural fractures, stress shadow effect), and fluid mechanics (fluid and proppant transport within the fractures, leakoff to reservoir rock) (Kresse and Weng, 2018; Kresse et al., 2024). Many oilfield-related simulators have been extended for EGS applications (Riahi et al., 2014; McClure and Kang, 2017; Kumar and Ghassemi, 2018; LBNL, 2021; Zheng et al., 2021; McClure et al., 2022; Kumar et al., 2023;). Among other studies we should mention Li and Lior (2015), Fu et al. (2016), Nadimi et al. (2018) and Cheng et al. (2019).

Proper HF models for EGS should include: fracture initiation criteria in impermeable, hard, brittle, very hot rock; fracture propagation during fluid circulation; stress changes caused by fracture opening due to temperature changes in the matrix; thermoelastic and poroelastic stress changes for fracture reopening during circulation; temperature-related material properties; multiphase flow; leakoff during heat extraction; 3D heterogeneous permeability; shear failure of rock matrix; permeable natural fractures; induced seismicity, etc.

HF models must involve advanced modeling of thermal effects in fractures accounting for temperature changes within the reservoir, including advection by fluid, heat transfer at the interface between fracture and rock, and heat conduction within the rock (Gringarten et al., 1975; Riahi et al., 2014; Fu et al., 2016; Hwang et al., 2022).

Two fracture simulation mechanisms may occur during hydraulic fracture treatment: hydrofracturing (creation of fractures in tension), and hydroshearing when overpressure induces slip along preexisting fractures, leading to irreversible permeability caused by rearrangement of asperities during shear dilation.

While permeability enhancement through shear slip has been considered by many as a standard for EGS, especially during circulation, HF can be used to achieve more conductive fractures at lower injected volume compared to hydroshearing. The review of historic EGS projects confirmed that both hydroshearing and hydrofracturing mechanisms occur and must be considered while modeling EGS.

3.2 Post-Fracturing Circulation Phase

Fractured systems in EGS could last up to 15+ years. This phase of long-term injection is less well-known and requires careful evaluation with proper predictions and analysis of multiple scenarios.

The main challenge for modeling circulation is to find the optimum conditions for sustainable heat production (LBNL, 2021; McClure et al., 2022; Kumar et al., 2023) considering that system properties could change during long-term cyclic heating and cooling or plastic creep.

3.2.1 Reservoir Simulation

Modeling EGS systems accurately while capturing the influence of each component; e.g., T, H, M, and C, and maintaining computational efficiency remains a challenge.

Fractured reservoirs can be modeled using equivalent continuum models (implicit approach), discrete fracture networks (DFNs) (explicit approach), or hybrid techniques (combination of explicit and implicit approaches) (Fig. 6).

The main limitations for the single-porosity model (a common equivalent continuum model) are that the rock and fractures are a volume-based average—an assumed single-permeability system. These simplifications cannot capture effects of THM coupling; e.g., heat transfer between rock and matrix or deformation of either.

The limitations of a dual-porosity model (two overlapping continua; Fig. 6c), (Barenblatt et al., 1960) are the idealized fracture network characteristics and simple fracture morphology.

Explicit representation of DFNs (Dershowitz et al., 2000) (Fig. 6d) are currently used in EGS simulations (Qarinurab et al., 2019). DFN models are more statistically data-demanding and computationally intensive than continuum models.

A hybrid model (Fig. 6e) combines the benefits of the continuum and discrete models (Cacas et al., 1990) but is still limited. Modern hybrid techniques; e.g., embedded discrete fracture model (EDFM), efficiently model matrix-fracture flow by embedding the DFN model into the 2D- and 3D-equivalent porous medium (Hajibeygi et al., 2011). EDFM, a generalized dual continuum (dual-permeability, dual-porosity), contains three connections (fracture-fracture, fracture-matrix, and matrix-matrix), to describe the fluid-heat exchange between fractures and matrix (Li et al., 2020a).

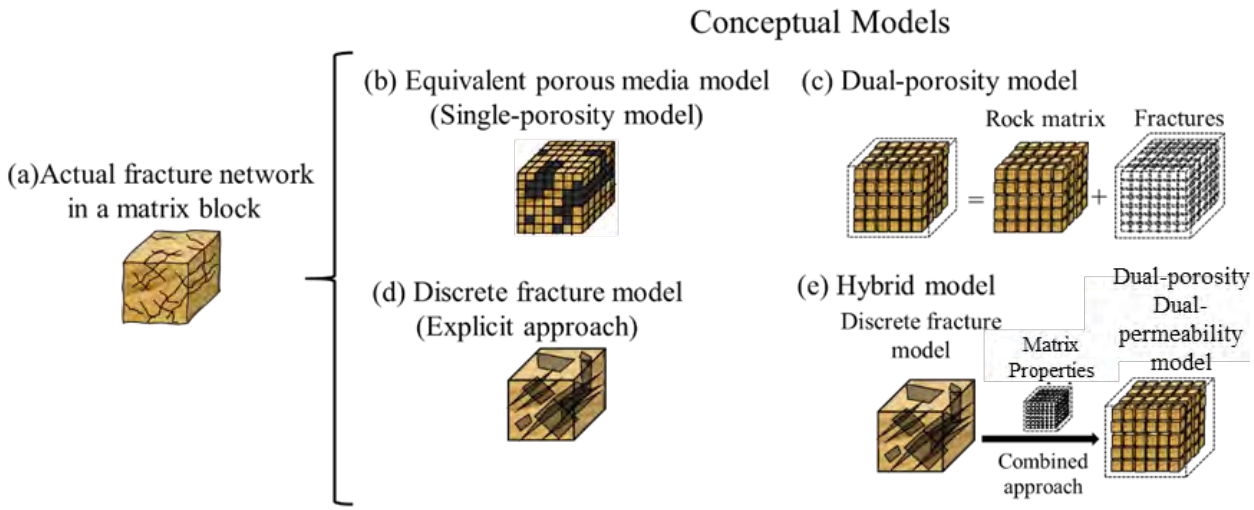

Figure 6: Model conceptualizations for fractured rock (a), equivalent porous medium (b), dual-porosity model (c), DFN model (d), and hybrid model (e).

The minimum modeling requirement for EGS can be achieved via thermohydrodynamically (TH) coupled models, which intend to represent the effects of the temperature gradients on hydraulic processes through changes in fluid density and viscosity with energy and mass conservation.

In Fig. 7, the coupling between the THM fields in a dual continuum (rock matrix and fracture) model is depicted as follows: items 3, 4, 5 and 19 illustrate stress and flow coupling; items 6, 7, 11 and 12 stress and temperature coupling; items 14, 18 and 19 for temperature and flow coupling. The most relevant coupling effects needed for EGS optimization are: (a) changes in stress due to temperature or pore pressure changes (items 11 and 19), (b) fracture aperture/permeability changes due to stress disturbance (items 3 and 4), (c) matrix porosity and permeability changes due to strain variations (item 5), (d) convective heat transfer in fractures (item 6), and (e) the heat conduction and convection modes of heat transfer (items 8, 9 and 18).

Geothermal numerical tools have been around for several decades, e.g., TETRAD and TOUGH2 (Pruess, 1990; Vinsome and Shook, 1991). Testing the accuracy and proficiency of geothermal simulators against historical data is still quite limited because of scarce or insufficient information. Furthermore, interpretating and processing data requires the human factor, which can invite biases.

The Geothermal Technologies Office (GTO) under the US Department of Energy (DOE) conducted a code comparison study program (White and Phillips, 2015). The program focused on examining existing codes, identifying dissimilarities, and modeling capabilities of several numerical simulators across six benchmark problems. This was redone in 2016 under the Code Comparison Study (GTO-CCS) to identify the capabilities and development areas of numerical simulation tools for EGS (U.S. Department of Energy, 2016), using seven benchmarks. In both analyses none of the simulators had all the necessary features to solve all problems (Ghassemi et al., 2015; U.S. Department of Energy, 2016).

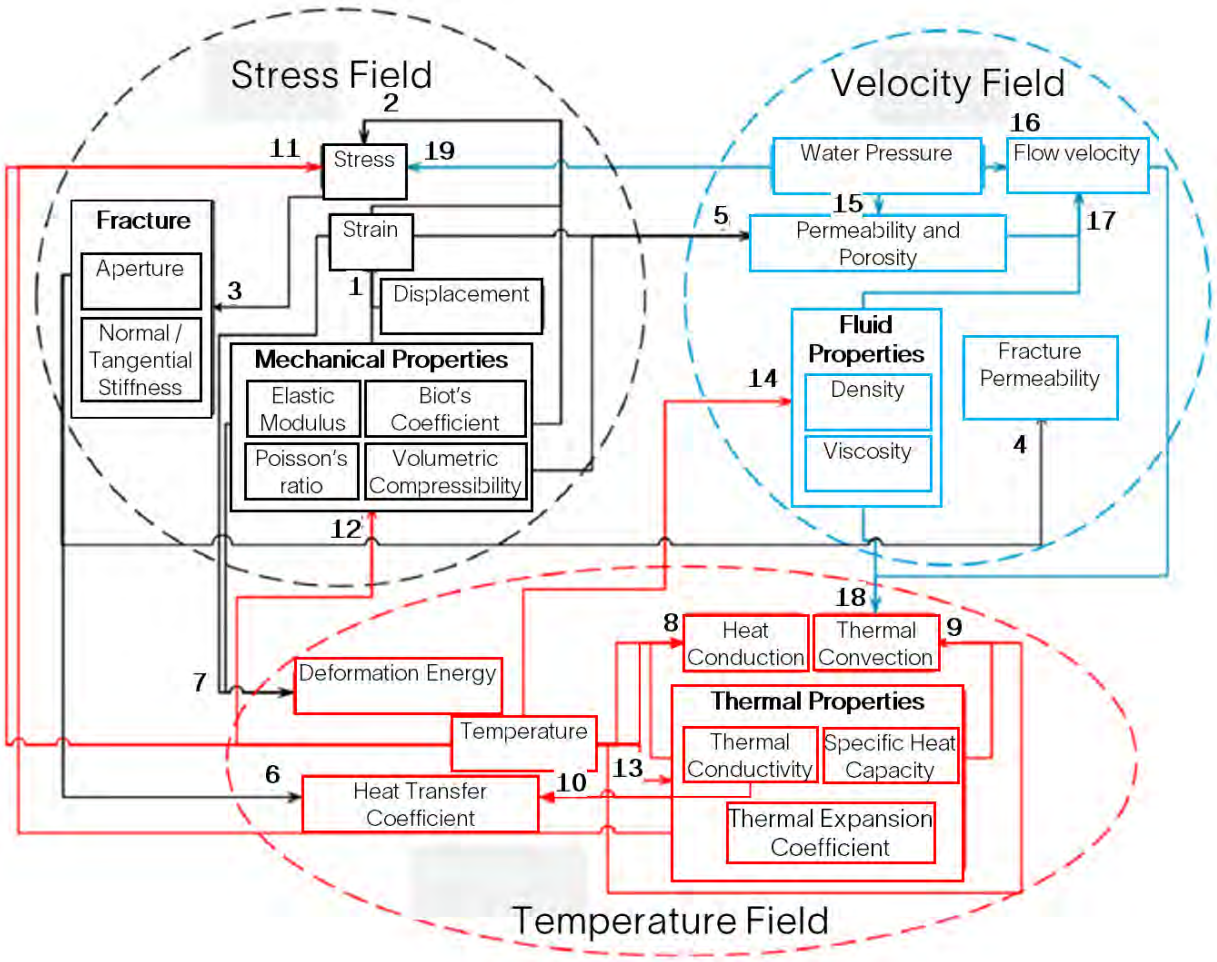

Figure 7: A scheme of a fully coupled THM model of a dual-continuum representation. Modified after Zhou et al. (2022).

In recent years, the HEATSTORE consortium (HEATSTORE, 2019) studied a variety of simulators to model operations at different sites, including high-temperature aquifer thermal energy storage (HT-ATES) sites. Among those numerical simulators were many respected software packages. The simulators comprise multiple numerical schemes. Mindel et al., (2021) concluded that although the simulators in the study were suitable to solve HT-ATES subsurface simulation problems some crucial discrepancies were discovered within the equations-of-state for thermal and enthalpy-injection modeling.

Another source of simulators comes from the oil and gas industry. (CMG Ltd., 2024; SLB, 2024a; SLB, 2024b; RFD, 2024) being the recognised simulators for thermal modeling.

Numerical simulations of multiphysics processes in EGS remain a valuable tool, enabling us to identify and evaluate risks to support management decisions. Furthermore, understanding underlying assumptions and model limitations can ensure better decisions.

3.2.2 Chemical Processes in Reservoir and Fractures

Chemical processes inside the reservoir and fractures include scale deposition, rock and proppant dissolution, change of fluid properties because of bulk or surface reactions, etc. Chemical compositions of circulating fluid can drastically change over short periods of time because of interactions with host rocks (<34 hours, Jones et al., 2023). These interactions can reduce porosity and permeability, leading to reduced injectivity and transmissivity. A reactive transport model that numerically simulates these processes is needed to predict chemical and physical evolution of the circulating fluids and associated reservoir damage, thereby mitigating scaling and corrosion.

Modeling of chemical processes is well established in geochemistry (e.g., Reed, 1982; Bethke, 2008; Bozau et al., 2015; Leal et al., 2017). However, with rapidly evolving fluid compositions, fluid-mineral equilibrium is unlikely during the life cycle of an EGS, and geochemical reactions should not be expected to be exclusively thermodynamically controlled. This also has implications for the use of aqueous geothermometers (Pang and Reed, 1998). Thermodynamic databases used in geochemical modeling are compiled from experimental and calculated data (Oelkers et al., 2009). Expanding and validating these databases over the pressure- temperature range and chemical (pH, salinity, and redox) conditions in geothermal systems are essential to enable accurate predictions of geochemical processes (Zhang et al., 2020).

Modeling chemical processes includes transport of components to and from the reaction site and the reaction itself. As shown in Fig. 8, the chemical process model needs fluid velocities to be used in the components transport model. As a result of the reactions, fluid properties may change, which should be accounted for in the fluid flow solution. Fracture geometry calculated in the geomechanics model defines boundary conditions for components transport and reaction models. At the same time, because of chemical processes, rock or proppant can be dissolved or their volume can be increased due to scale deposition; mechanical properties (Young's modulus) of the rock and proppant pack can also change and should be accounted for in the geomechanical solution. Temperature is an important input for chemical processes that comes from the heat transfer model. During the reaction, some heat may be released or absorbed, which should come back to the heat transfer model.

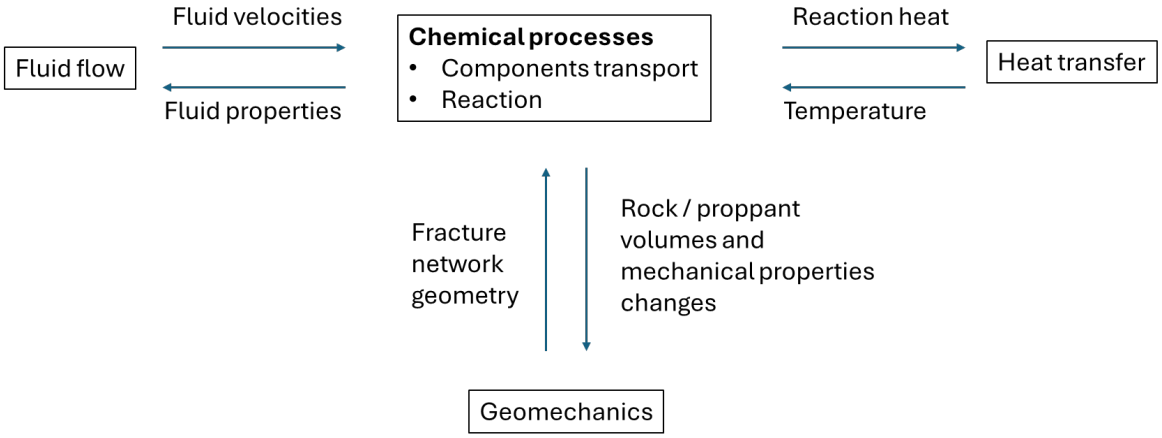

Figure 8: Chemical processes coupling.

Chemical processes coupled with fluid flow and heat transfer are part of the commercially available reservoir simulators or geochemical and reactive transport simulators.

Geomechanical coupling may be important when the rock and/or proppant volume decrease due to dissolution, which leads to reduction of in-situ stresses and subsequent opening or propagation of pressure-induced fractures. Such coupling is used in some acid fracturing models (Li et al., 2020b).

5. Conclusions

EGS projects resemble most shale installations from the past 15 years. Many components are similar; e.g., long-horizontal, multicluster wells using massive fracturing treatments. The US DOE (Smith, 2024) put it this way, “EGS technologies build on developments from the oil and gas industries—including directional drilling and fracking (or stimulation) technologies… Now, researchers supported by DOE and industry are working to adapt those technologies to geothermal conditions and applications.”

However, EGS’ needs in the modeling realm are different. For instance, EGS fractures will see continuous circulation throughout their life, requiring geomechanical modeling during the long-term circulation phase. Moreover, igneous and metamorphic rocks can behave radically different from shale and other sedimentary rocks.

Also, no longer can any of the models or decisions be siloed. EGS demands leveraging full THMC modeling to ensure a project can be delivered economically and efficiently.

In this paper we suggest key areas for EGS evaluation and differences from a conventional perspective. Currently, no single model or software considers all aspects, leaving room for improvement with each project.

ABSTRACT

Estimating in-situ stress in Enhanced Geothermal Systems (EGS) faces many complexities due to the limitations of simplified models used for traditional reservoir analysis and data interpretation. Due to the inherent high-temperature characteristics of EGS reservoirs, wellbore cooldown caused by injection and circulation can induce changes in the thermal stress field and create more complex fracture patterns. These conditions can also significantly influence the borehole pressure history recorded during fracturing tests, which will also cause problems for interpretation of hydraulic fracturing in-situ stress estimation methods. By implementing laboratory-scale block fracturing experiments under Utah FORGE conditions and analyzing post-peak wellbore pressure data, this study focuses on examining the validity of the classical interpretation methods, which are based on an assumption of simple planar fracture geometry. Incorporating the shut-in, reopen, and step-rate phases into the post-peak stage allows access to the closure pressure inferred by the laboratory G-function plot and reopening pressure by the reopen and step-rate tests. Our results indicate that the classical horizontal maximum stress estimation method does not provide stress estimates consistent with the actual applied stresses, particularly in cases with complicated fracture patterns that are likely caused by the substantial cooling of the wellbore prior to fracturing. Consequently, our work motivates future endeavors to develop a more robust approach for stress estimation in EGS reservoirs, accounting for near-wellbore fracture complexity caused by thermal stress induced by wellbore cooling.

1. Introduction

Accurately estimating in-situ stresses, especially minimum horizontal and maximum stresses, plays an important role in many engineering applications such as optimizing hydraulic fracturing designs, stabilizing the wellbore, and assessing fault reactivation (Bao & Burghardt, 2022; Kim et al., 2016; Xing et al., 2020). Classical theories and methods for estimating in-situ stresses mostly rely on two basic assumptions: the simplicity of fracture geometry and the simultaneous closing of the entire fracture surface (Cornet, 1981; Haimson & Cornet, 2003; Haimson & Fairhurst, 1967; Ito et al., 1999). However, these assumptions are based on ideal situations and may not reflect all cases encountered in practice. Following these basic assumptions, the estimation of in-situ stress can be determined by three components that can be captured or inferred from the hydraulic stimulation process: the breakdown stress (p_b), the fracture closure pressure (p_c), and the reopening pressure (p_r). The details of these definitions and their differences are well-explained by Guglielmi et al., 2023. However, more recent research (Guglielmi et al., 2023; Lu et al., 2024) has demonstrated that during the development of Enhanced Geothermal Systems (EGS), wellbore cooldown through injection and circulation can significantly alter the thermal stress field. Such changes are likely to generate more intricate and complex fracture patterns compared to those occurring in traditional reservoirs with low temperature. At the same time, this alteration substantially impacts the recorded borehole pressure history during fracturing tests, thereby rendering the interpretations of wellbore pressure less clear and perpetuating ongoing debates, particularly concerning the estimation of the maximum horizontal stress (σ_H). The original in-situ stress estimation equations were developed by Hubbert and Willis (1957). They initially proposed the expression for maximum horizontal stress (σ_H) as follows:

$$p_b = 3\sigma_h - \sigma_H + \sigma_t, \tag{1}$$

where the p_b is the breakdown pressure, σ_h is the minimum horizontal stress and σ_t is the tensile strength of the material. Subsequently, Haimson and Fairhurst (1967), Haimson et al. (2003), and Ito et al. (1999) introduced additional expressions for estimating the maximum horizontal stress, incorporating poroelastic effects and reopening pressures, respectively. Moreover, some researchers (Bredehoeft et al., 1976; Cornet, 1981; Gronseth & Kry, 1981) have pointed out that under certain circumstances, e.g., when fractures exhibit greater complexity than the sample geometry and when fractures do not completely close after each pressure cycle, the aforementioned theories and expressions for estimating the maximum horizontal stress may not be valid.

Considering these research gaps and challenges, we have undertaken a laboratory study and implemented analysis of post-peak pressure records from the triaxial loading hydraulic fracturing tests on 6-inch cubic granite blocks. Experiments were conducted under FORGE-relevant conditions. Laboratory-derived G-function, step-rate, and fracture reopening measurements can significantly enhance the identification of key components constituting the in-situ stresses. Additionally, this study provides an excellent opportunity to conduct numerous experiments, allowing us to quantitatively validate and examine the quality of current in-situ stress estimation methods under complex fracture pattern conditions. This approach not only augments our capacity to analyze and deduce in-situ stress in environments with complex fracture geometries, but also stimulates further research aimed at developing an accurate and more physically informed methodology for stress evaluation in Enhanced Geothermal Systems (EGS) reservoirs.

2. Experimental Setup and Methodology

The experimental setup involves testing 6-inch cubic granite blocks under two scenarios—room temperature and 200 degrees Celsius—using a hydraulic piston-actuated loading cell under true triaxial loading conditions with various combinations of in-situ stress. The St. Cloud Gray granodiorite is used here as the FORGE-analogue granite for laboratory testing purposes. This selection is primarily founded on acoustic anisotropy properties, assessed and calculated using the acoustic transmission system. This system can measure both S and P waves as they traverse the test sample. The velocity of these waves can serve as an indicator of the granite's anisotropy. To promote an even distribution of stress on the testing sample, aluminum loading plates with a minimum thickness of 3 inches are inserted between each side of the sample and the tilt saddle on the actuator. To further mitigate friction and prevent shear boundary conditions, Teflon sheets are placed between each face of the sample and the aluminum loading plate. For the second testing case, where the host block is heated to 200 degrees Celsius, thermal stress can be induced within the sample near the borehole by circulating room-temperature water through the borehole. As shown in Figure 1, this process results in a temperature drop of up to 140-150 degrees Celsius at the borehole wall when the circulation starts. The circulation time lasts around 15 minutes. During this time, a total of 2-4 liters of water is circulated through the borehole, and the borehole temperature continues to decrease, albeit at a slower rate, by approximately another 10 to 20°C. When the circulation is stopped, it waits for a period of time for the borehole temperature to recover to a relatively stable value. Then, the system's outlet is closed to initiate the hydraulic fracturing process. In the scenario without thermal stress, the hydraulic fracturing starts immediately after bleeding the air out of the system.

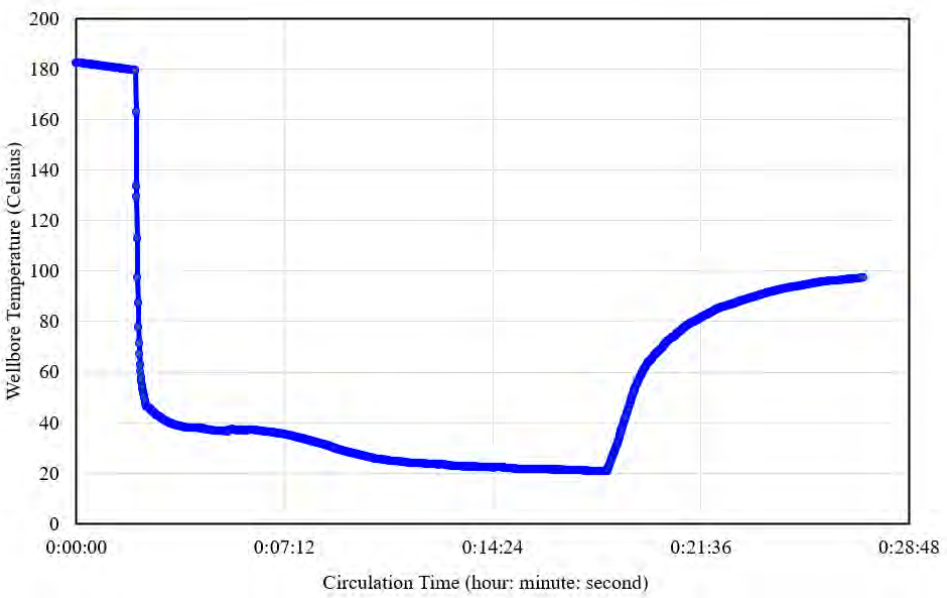

Figure 1: Wellbore temperature recording during water circulation.

During the hydraulic fracturing phase, the fluid is injected into the wellbore at a constant flow rate of 3 ml/min until the breakdown pressure is reached. After that, the injection is stopped and the wellbore pressure is monitored to observe post-peak pressure decline behaviors, which are referred to as the shut-in phase. The shut-in phase commences when the borehole pressure stabilizes at a constant value. After the shut-in phase, a reopening test is performed by injecting

the same fluid at the same flow rate into the borehole to observe pressure responses. Similarly, when the pressure reaches the peak in the reopening test, another shut-in phase is implemented. The procedure then moves to the step-rate pressure test, during which the borehole pressure increases in increments of 0.68 MPa (100 psi). Each subsequent step commences only after the current pressure level has stabilized at a constant flow rate. At each stage, the pressure level and corresponding flow rate are recorded and plotted for future analysis. Following the step-rate phase, another shut-in period occurs, after which the wellbore pressure decreases to ambient levels. With these steps completed, the entire test procedure is considered finished. These three phases constitute the whole process of the post-peak wellbore pressure analysis, as shown in Figure 2, and have provided the opportunity to infer the reopening pressure and minimum horizontal stress at different angles.

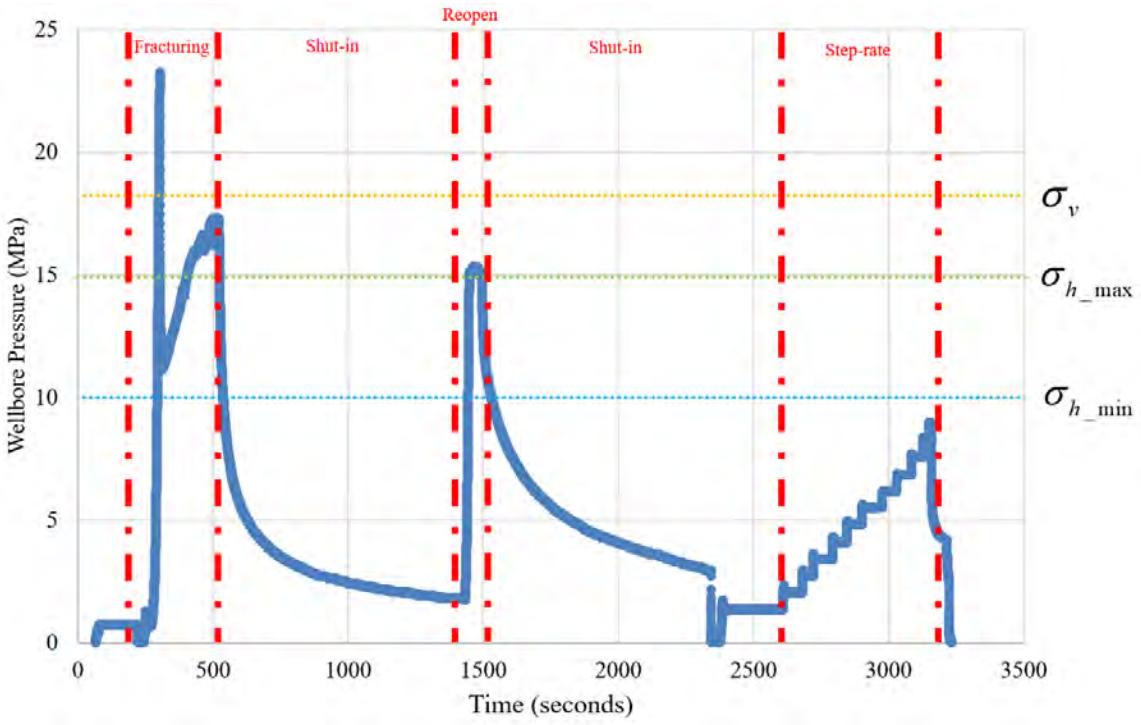

Figure 2: An example of full wellbore pressure record to show the lifecycle from fracturing to step rate testing.

3. Results

The testing scenarios covered in this section include three cases. In all these tests, the vertical and maximum horizontal stress are maintained at 17.5 MPa and 15 MPa, respectively. The borehole is parallel to the minimum horizontal stress direction. The magnitude of the minimum horizontal stress and the testing temperature are varied between tests. These tests are summarized below:

1) Horizontal well – Room temperature – Non-Thermal Stress with minimum horizontal stress values at 3 MPa (HR-NTS-3MPa)
2) Horizontal well – High temperature – Induced Thermal Stress with minimum horizontal stress values at 7 MPa (HH-ITS-7MPa)

3) Horizontal well – Room temperature – Non-Thermal Stress with minimum horizontal stress values at 7 MPa (HR-NTS-7MPa).

Figure 3 shows the results from testing case HR-NTS-3MPa, in which the hydraulic fracturing is carried out at room temperature without inducing any thermal stress. Figure 3 (a) shows the full pressure record during the four phases of the stimulation, i.e., hydraulic fracturing, shut-in, reopening, and the step rate. The breakdown pressure in this case is 42.5 MPa. By using the fracture compliance method (McClure et al., 2016), the G-function plot (Figure 3 b) from the first shut-in period indicates that the closure pressure is around 9 MPa, whereas the closure pressures picked up from the reopening tests (Figure 3 c) and the step rate (Figure 3 d) are around 14 MPa and 13 MPa, respectively. The fracture pattern observed within this testing is comprised of multiple-45-degree incline fractures, as shown in Figure 4.

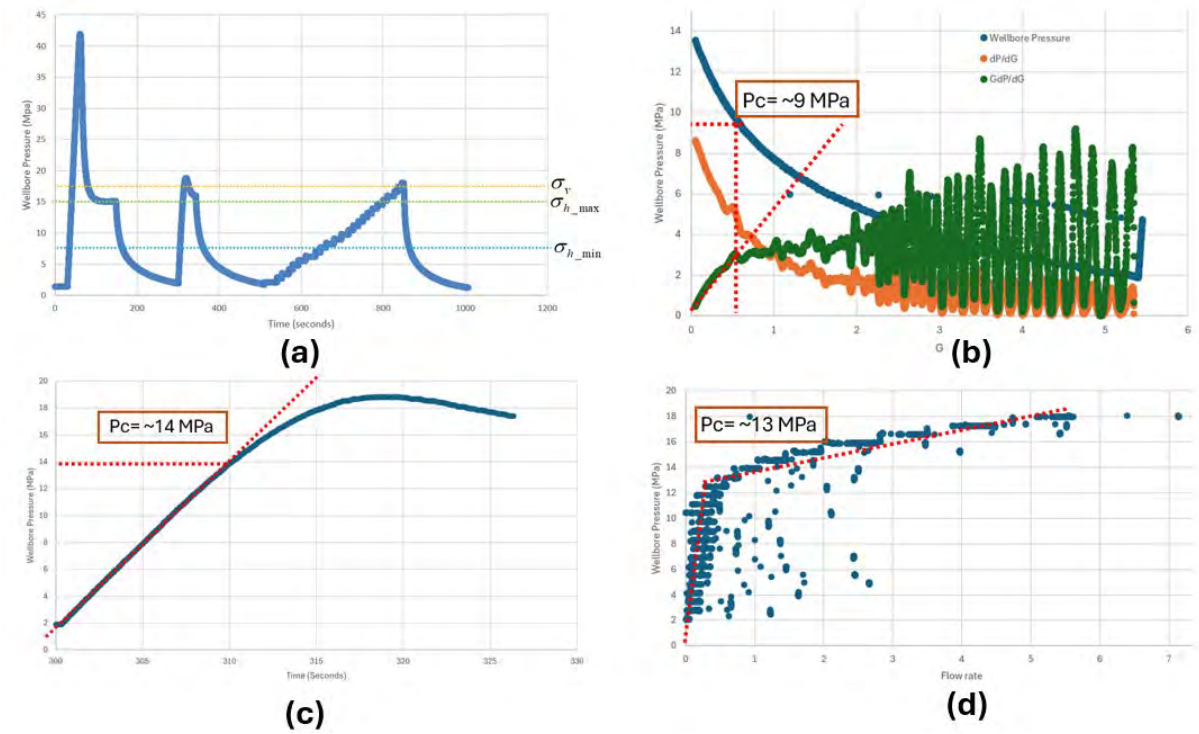

Figure 3: HR-NTS-3MPa test case: (a) Full wellbore pressure record; (b) G-function plot; (c) Reopening test pressure record; (d) Step rate plot.

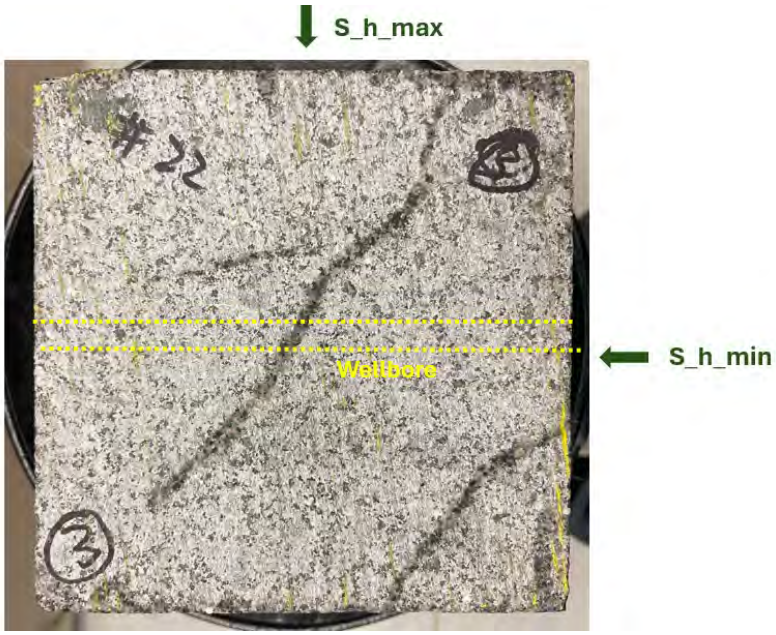

Figure 4: Fracture patterns observations from HR-NTS-3MPa.

In contrast to the non-thermal base case, the HH-ITS-7MPa testing case induces thermal stress by circulating cold tap water through the borehole in the center of the hot granite block (initially at 200 degrees Celsius) for 15 minutes before hydraulic fracturing starts. With the same applied stress combinations, the breakdown pressure shown in the Figure 5 is 15 MPa. Again, by the fracture compliance method (McClure et al. 2016), the fracture closure pressure picked from the G-function plot is 8 MPa, which almost aligns with the minimum stress applied in the experiment. In contrast, the closure pressures picked from the reopening and step rate tests are both 9 MPa, which is slightly above the applied minimum horizontal stress (7 MPa). The fracture patterns observed within this specimen consist of transversely oriented cracks, as shown in Figure 6.

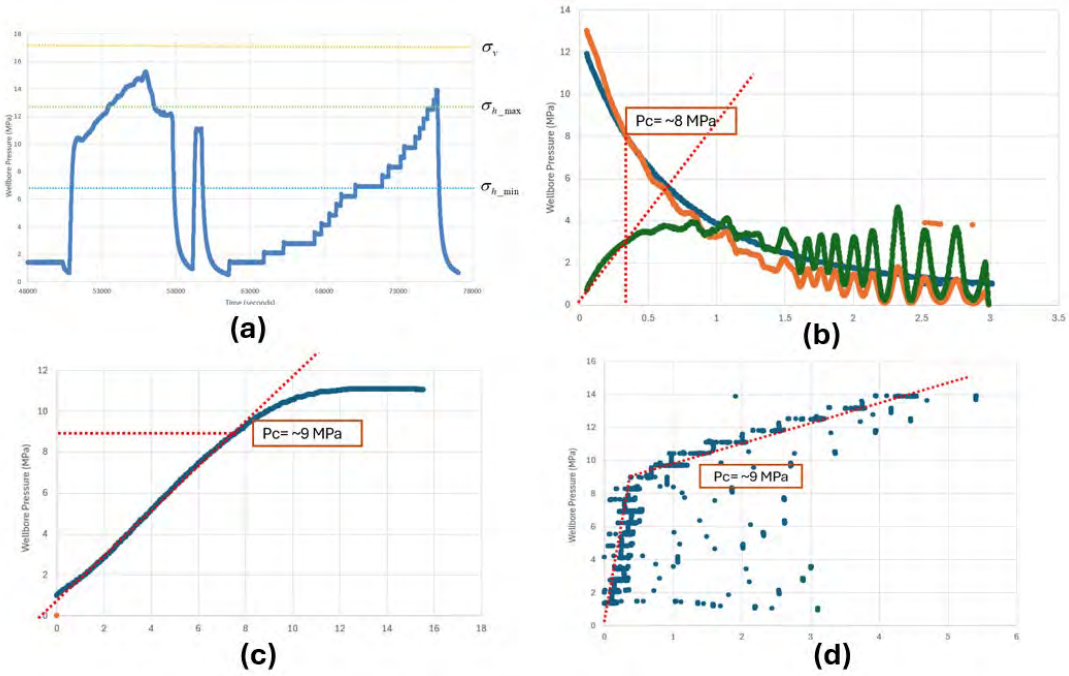

Figure 5: HH-ITS-7MPa test case: (a) Full wellbore pressure record; (b) G-function plot; (c) Reopening test pressure record; (d) Step rate plot.

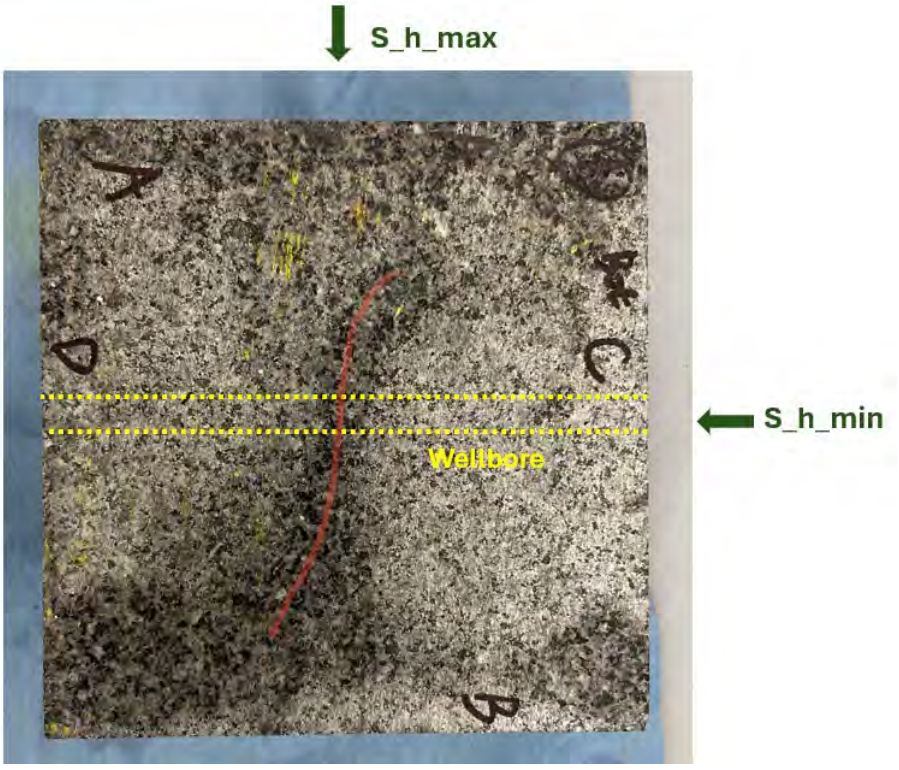

Figure 6: Fracture patterns observations from HH-ITS-7MPa (fracture location is indicated by red color).

The HR-NTS-7MPa testing case is different from the previous testing cases as no thermal stress is induced. As shown in Figure 7, the breakdown pressure is 21 MPa. The fracture closure pressures

derived from the G-function, reopening, and step rate tests are all around 6, 7 and 7 MPa. The fracture pattern observed, shown in Figure 8, consists of both longitudinal and transverse fractures.

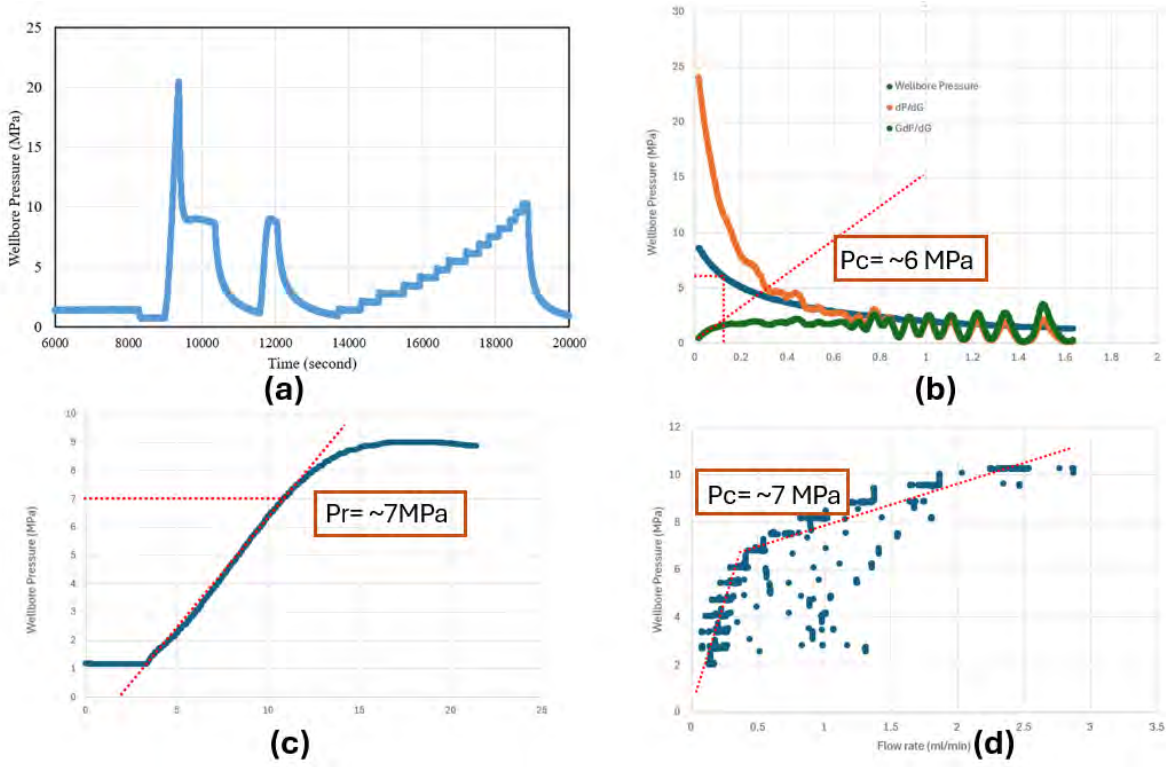

Figure 7: HR-NTS-7MPa test case: (a) Full wellbore pressure record; (b) G-function plot; (c) Reopening test pressure record; (d) Step rate plot.

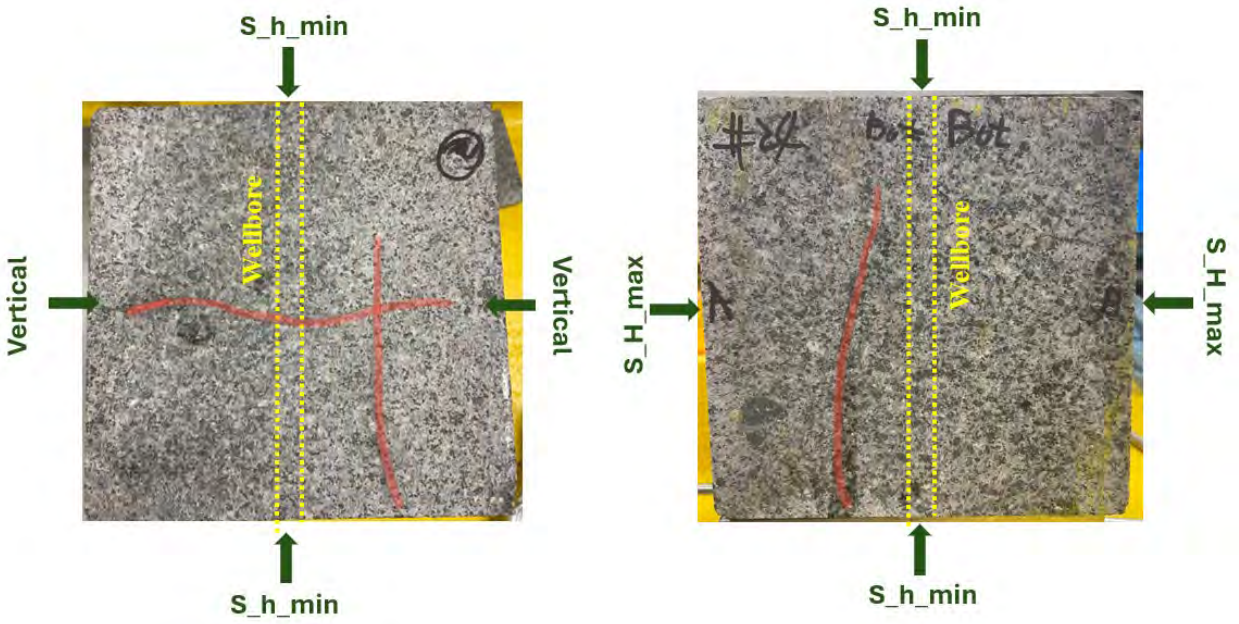

Figure 8: Fracture patterns observations from HR-NTS-7MPa.

4. Discussion

The results of the three testing cases covered in this paper are summarized in Table 1. First, by comparing the breakdown pressure between HR-NTS-7MPa and HH-ITS-7MPa, it is evident that the thermally induced stress from circulating room-temperature water into the hot testing sample can significantly lower the breakdown pressure. Secondly, by using Eq. (1) for each test, we determine the horizontal maximum stress by the actual applied minimum horizontal stress (σ_h) and p_b that is recorded from the experiment. These derived results are summarized in Table 1.

Examining these results, if the minimum horizontal stress is estimated by the closure pressure the G-function plot, and then reformulating Eq. (1), one obtains

$$\sigma_H = 3\sigma_h - p_b + \sigma_t. \quad \text{Eq. (2)}$$

Following the definition and explanations that Guglielmi et al., 2023 have provided about the relationships between the three terms, we can use the reopening pressure (p_r) to replace both the breakdown pressure (p_b) and tensile strength (σ_t), which leads to

$$\sigma_H = 3\sigma_h - p_r. \quad \text{Eq. (3)}$$

Table 1: Summary of the three testing case results

Testing Case	Closure Pressure G – function (MPa)	Reopen Pressure (MPa)	Step-rate Reopen Pressure (MPa)	Breakdown Pressure (MPa)	Actual Applied minimum horizontal Stress (MPa)	Actual Applied Horizontal Maximum Stress (MPa)	Calculated Horizontal Maximum Stress (MPa)
HR-NTS-3MPa	9	14	13	42.5	3	15	7.5
HH-ITS-7MPa	8	9	9	15	7	15	12
HR-NTS-7MPa	6	7	7	21	7	15	11

By using Eq. (3), we can estimate the maximum horizontal stress by using the closure pressure obtained from the G-function as an estimate of σ_h, and using the average value of the reopening pressure and step-rate reopening pressure as p_r. The calculated estimated maximum horizontal stress value is recorded in the last column of Table 1. For each case, the estimated horizontal maximum value deviates from the actual value by 20% to 50%. One possible reason for this difference is that the current maximum horizontal stress estimation model is built for an ideal fracture geometry. Let us consider the HH-ITS-7MPa case as an example where the generated fracture is almost ideally perpendicular to the direction of the minimum horizontal stress. The reopening pressure is around 9 MPa which is slightly above the minimum horizontal stress, and the estimated maximum horizontal stress would be approximately 12 MPa, slightly below the actual value. However, in the case of the HR-NTS-3MPa, because the generated fracture has a 45-degree inclination relative to the wellbore drilling direction —making it more complex than the ideal situation— using the reopening pressure under the 45-degree inclined fracture scenarios

could cause some deviation from the real value when using Eq. (3) to estimate the maximum horizontal stress. If one takes a step further, which could easily calculate the normal stress for this 45-degree incline fracture with the help of the well-known 2D stress transformation equation (Timoshenko & Gere, 2012), one could obtain the reopening pressure for this case as 11 MPa, which is not far from what has been recorded in the experimental measurements.

With this being said, the current theory underlying maximum horizontal stress estimation may not be suitable for application in complex EGS reservoir conditions, particularly when thermal stress is induced during the stimulation process. This thermal stress alters the original stress field, potentially generating a complex fracture pattern. This can be seen most clearly by comparing the testing cases of HR-NTS-7MPa and HH-ITS-7MPa, where the only difference is the latter case has introduced thermal stress. Due to the change in thermal conditions, the generated fracture geometry has altered from having both longitudinal and transverse fractures to having only transverse fractures. This example shows the potential for thermal stress to substantially impact fracture geometry. Furthermore, different combinations of in-situ stress could also generate very different fracture patterns under the EGS conditions. For example, when comparing the testing cases between HR-NTS-7MPa and HR-NTS-3MPa, where both cases are not induced with thermal stress and the only difference is the magnitude of the minimum horizontal stress, we can see that the fracture geometry is very different: the HR-NTS-7MPa has both longitudinal and transverse fractures, whereas the HR-NTS-3MPa has multiple-45-degree incline fractures.

5. Conclusions

Block tests have been performed on granite cubes subjected to true-triaxial confinement in which hydraulic fractures are created, allowed to close under shut-in conditions, and then reopened both rapidly and under step-rate conditions. This loading sequence enables analysis using classical in-situ stress estimation techniques. The testing cases are designed to examine the potential role of cooling of the wellbore prior to hydraulic fracturing along with evaluation of the impact of non-ideal fracture geometry on the fidelity of the stress estimations. By obtaining the relevant stress estimated the lab-scale G-function analysis, reopening pressure, and step-rate tests, we obtained estimated minimum horizontal stress and maximum stress. The results show that reopening occurs at a similar stress level for rapid repressurization and step-rate tests, and if evaluated in the classical way to obtain an estimate of the maximum horizontal stress, gives values that are around 20% - 50% above or below the actual applied values. Through a thorough analysis, we confirmed that the current maximum horizontal stress estimation method is valid when its assumptions are largely met, that is, the generated fractures are in a simple planar shape and in the desired direction. However, when the fractures become more complex, such as reoriented and multi-fractures crossed or even having longitudinal and transverse fractures simultaneously, the current horizontal maximum stress estimation method becomes less accurate. It must be realized that these complex fracture patterns are more prone to occurring under EGS conditions where thermal stress is induced from cooling via circulation. Overall, these findings have inspired us to conduct additional experiments under various EGS-related testing scenarios and to seek more accurate and physically interpretable expressions for estimating horizontal maximum stress under complex fracture patterns.

Keywords

EGS, multistage stimulation, seismic risk mitigation

ABSTRACT

The experiences with the seismic risk in the EGS Basel project in 2006 were sobering and delayed the development of deep geothermal energy in Switzerland for almost 20 years. Since these dramatic experiences, there has been an increase in scientific progress as well as new setbacks, such as in the Pohang project. This failure has in turn provided many insights into mitigating seismic risks. Some of these lessons learned led to further developments that are now being tested, verified, and qualified in underground rock laboratories such as Bedretto (Switzerland) and in large-scale R&D field tests such at the Utah FORGE project (USA). These progresses include the field testing of multi-stage EGS stimulations, methodologies for risk studies, Advanced Traffic Light Systems, development of monitoring tools for high temperatures and their field verification and qualification. We will present an overview of the recent works and their implementation plans for the new EGS Haute-Sorne project in Switzerland.

1. Introduction

The lessons learnt from the Basel 2006 EGS project with a massive injection of 12’000 m^3 of water showed that control of seismic risk can be achieved by limiting the radius of each of the stimulated fracture surfaces to a few hundred meters (Meier et al., 2015). The fundamental consideration leading to this approach is based on observed data from many projects all over the world showing a clear correlation between the stimulated fracture plane areas and the seismic magnitudes. This correlation was also confirmed by detailed numerical modeling studies done for the risk study for the Haute-Sorne project.

A schematic representation of the massive hydraulic stimulation approach used in Basel compared to the planned multistage stimulation system in Haute-Sorne (Canton of Jura, Switzerland) is shown in Figure 1.

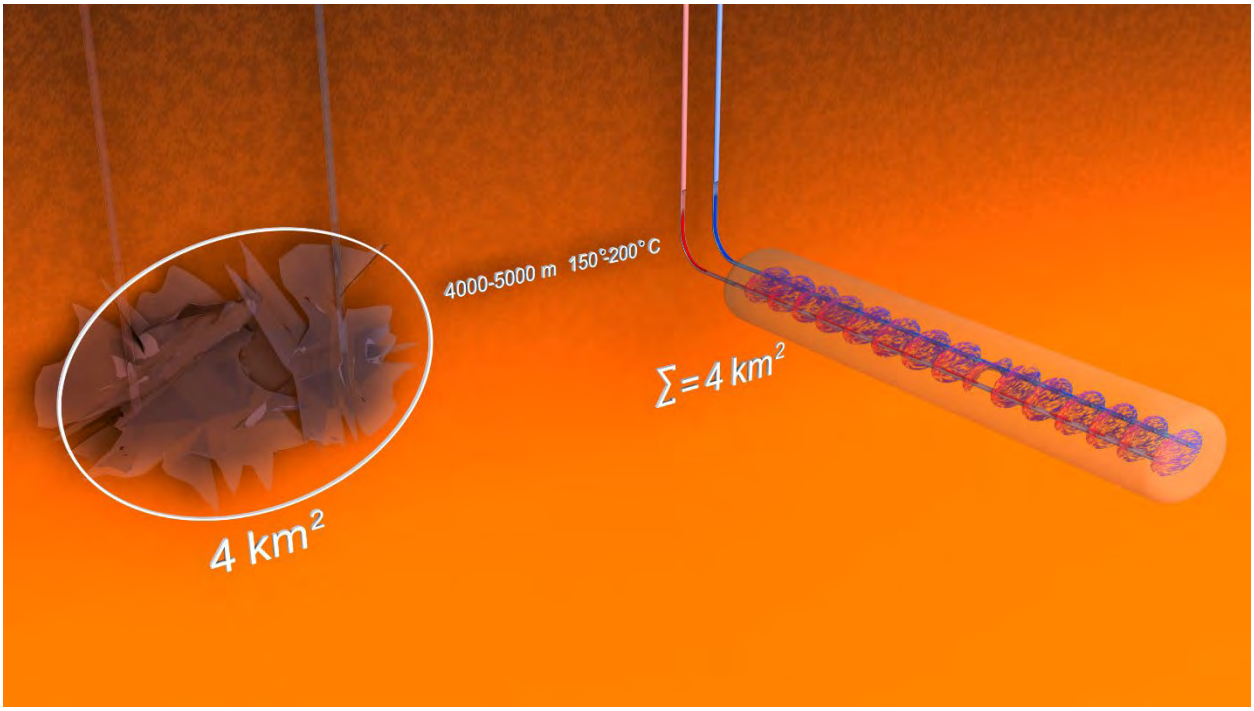

Figure 1: Schematic representation of the massive hydraulic stimulation concept like in Basel (left) in comparison to the multistage stimulation concept planned for future EGS projects in Switzerland (right).

2. Conclusions from the Pohang project

For nearly a year, several specialists from Geo-Energie Suisse analyzed and interpreted the data from the geothermal project and the earthquake of November 2017 in Pohang. These studies, requested by the permitting authorities of the Canton Jura shortly after the Geo-Energie Suisse had informed them, established that the very high-pressure water injections made in the vertical borehole probably played a decisive role in triggering the earthquake within a nearby fault.

The first vertical borehole did cross a major fault zone but not the second, which led to this fault being sandwiched between the two boreholes (this situation is represented schematically in Figure 2). For nearly two years, numerous water injections (stimulations) were carried out to try to circulate water between the two boreholes and thus produce energy on the surface. To achieve this, very high pressures, up to 900 bar at the surface, were applied in the vertical well. Such a pressure is more than 3 times the maximum injection pressure used in Basel.

The repeated injections at very high pressures into the vertical well led to an accumulation of pressure on a fault that was probably already in a naturally unstable state. Indeed, the study of the stress field and the numerical models carried out by Geo-Energie Suisse show that the local orientation of the natural tectonic stresses may have favored the activation of this fault (Meier et al. 2021; Bethmann et al., 2021; Alcolea et al. 2024).

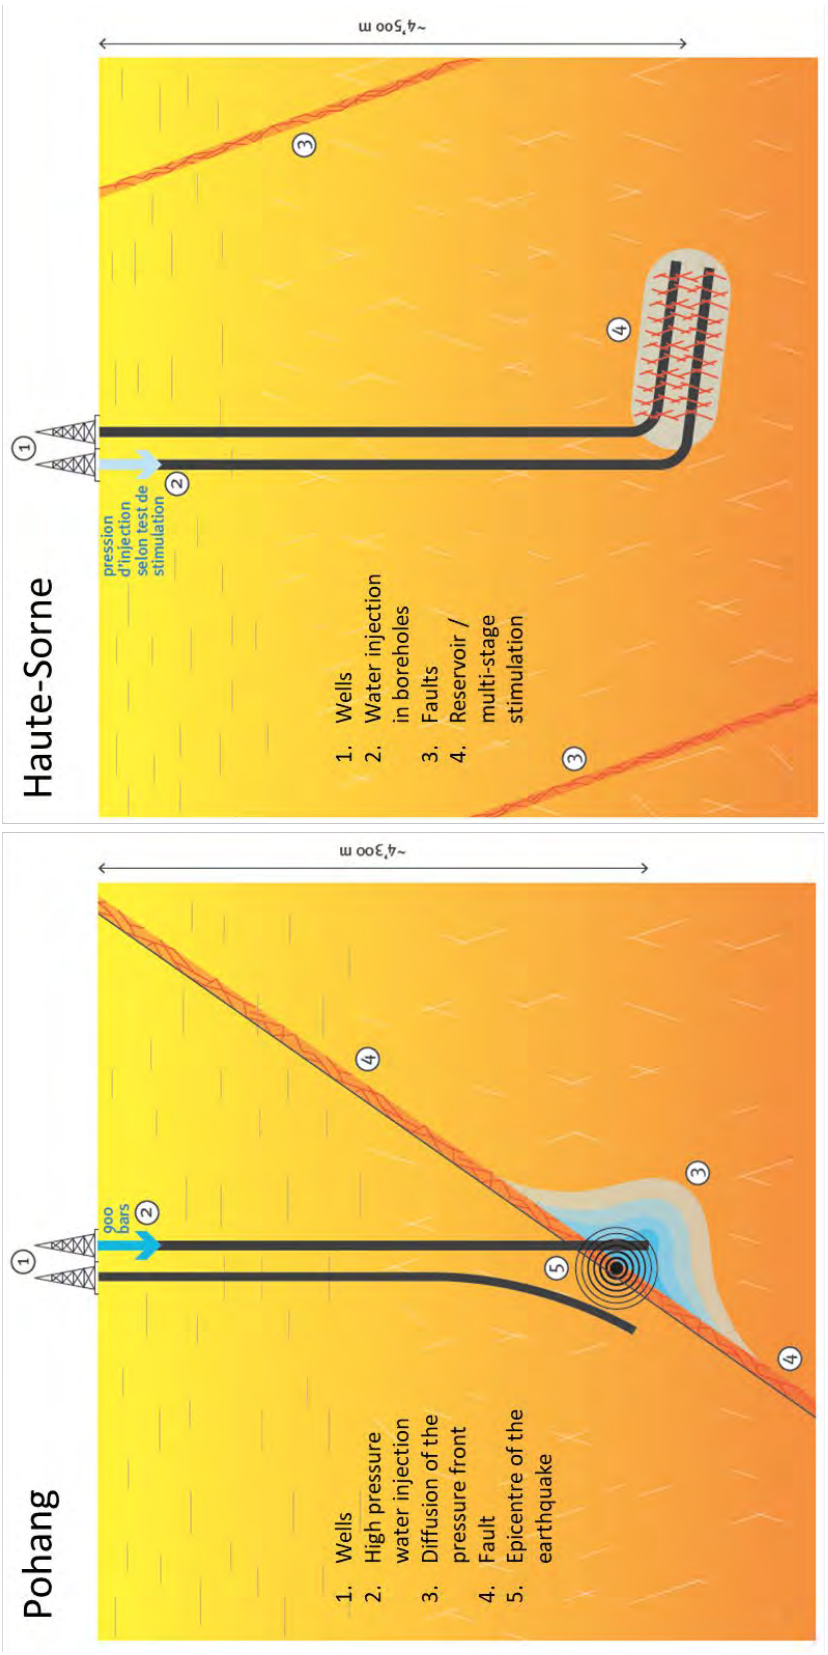

Figure 2: Comparison of the concepts of the Pohang and Haute-Sorne projects.

Timely parallel to the GES work but independently from each other the South Korean government had created official investigation commissions (ORAC/KERT) of the Pohang earthquake which published their report on March 20, 2019 (Geological Society of Korea (2019)). It is important to note that the main conclusions of both reports on the understanding of the trigger mechanisms of the Pohang earthquake are in very good agreement.

The realization of the Haute-Sorne project is subject to 136 conditions by the cantonal authorities. Of these, 21 address induced seismicity. The results of our investigations carried out on the Pohang project allow us to demonstrate that the application of authorization conditions similar to those of Haute-Sorne would have made it possible to stop and then abandon the Pohang project, as early as the first stimulation phase in January 2016 (Zingg and Meier, 2019).

Within the framework of the new Swiss energy law, which came into force on 1 January 2018, and in order to maximize the chances of success and further reduce the risks, Geo-Energie Suisse has reviewed its operational approach and decided to carry out its project in two phases (Figure 3). The first phase will be dedicated to exploration. The first well will be drilled to the depth of the reservoir. All measurements to characterize the deep crystalline rock mass such as fracturing state, permeability and stress field orientation will be carefully performed. Only a stimulation test carried out according to a predefined protocol in a particularly careful and monitored manner, with small injection volumes and low pressures, will be carried out.

Finally, the risk study will be updated on the basis of the parameters actually measured in the Haute-Sorne borehole and the lessons learned from the projects in the Bedretto underground rock laboratory and most importantly at the Utah FORGE site (Moore et al. 2023). Only then will it be possible to move on to the second phase, namely the drilling of the second well and stimulation of the reservoir.

3. Results from the R&D work in the Bedretto rock laboratory

The multi-stage hydraulic stimulation concept proposed by Geo-Energie Suisse, based on lessons learned from the Basel EGS project, was successfully demonstrated in 2020 and 2021 at the Bedretto underground rock laboratory in the granite of the Swiss Alps at a depth of 1100 m (Meier et. al. 2023). The three main success criteria were met: first, a significant increase in flow rates and thus an increase in the energy output of an EGS project; second, detailed monitoring and mitigation of induced seismicity; and third, validation and qualification of advanced multi-stage stimulation devices from the oil and gas industry for geothermal applications.

The increase in flow rates predicted in 2016 (Meier and Ollinger, 2016), using numerical modeling by factors between 3 and 6 for the multi-stage stimulation concept compared to single-stage stimulation was demonstrated in Bedretto in-situ at a reservoir scale of 1:3. Scaling the results from the field work to a deep EGS project such as Haute-Sorne in the Swiss canton of Jura yields a range of flow rates from 78 to 160 l/s. This value significantly exceeds the success criteria set at 65 l/s for the Haute-Sorne project. This is also a positive result given the inherent uncertainties. Applied to practice, this means that the electrical power of an EGS project can be increased from about 1.5 MW - if a single stimulation stage is carried out over the entire borehole reservoir section - to about 4.5 to 6 MW if a multi-stage stimulation approach is used.

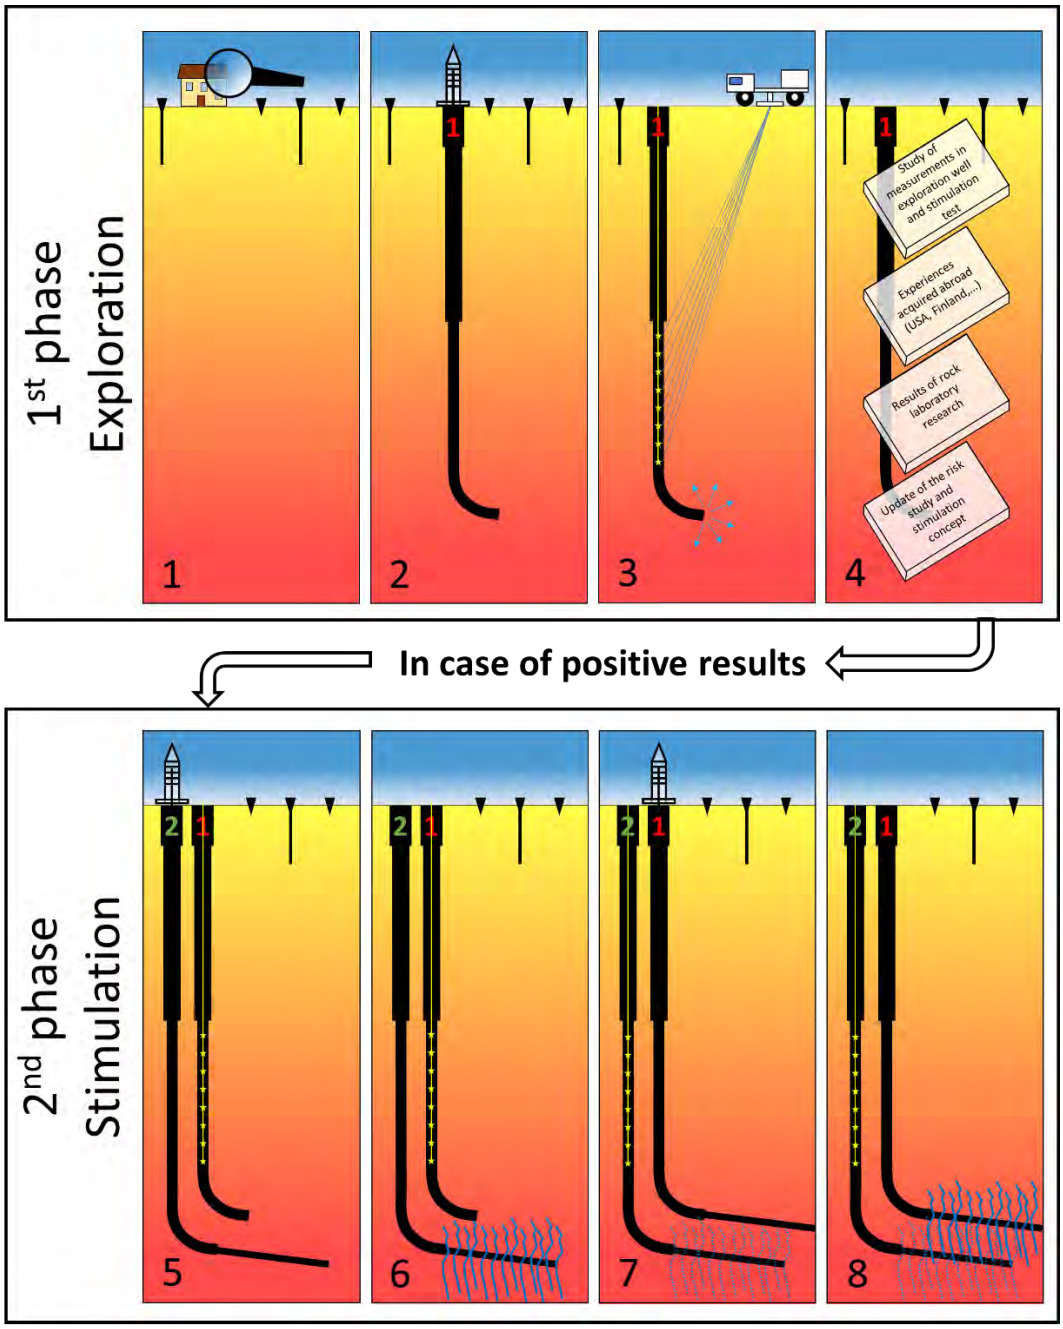

Figure 3: Steps for the implementation of the Haute-Sorne pilot project. Exploration phase: 1) Preservation of evidence and deployment of the seismic monitoring network (surface stations and boreholes) 2) Drilling of the first exploration borehole 3) Measurements in the reservoir and stimulation test with low pressures and small volumes 4) Study of the results of the measurements and stimulation test, integration of experience gained abroad and underground rock laboratory research, update of the risk study and the stimulation concept. Depending on the current state of planning, this is done in the absence of the drilling rig, but technical or logistical considerations may also decide otherwise. In case of positive results, transition to the Stimulation Phase: 5) Completion of the 2nd borehole; the first is equipped with a seismometer string to complete the seismic monitoring network 6) Stimulation of the reservoir under control of the seismic monitoring system 7) Completion of the 1st borehole, the second is equipped with the seismometer string and 8) if necessary, additional stimulation of the 1st borehole under control of the seismic monitoring system.

Real-time monitoring and mitigation of induced seismicity and associated risks - the second main criterion for proving success - was also successfully demonstrated. The maximum moment magnitude of -1.6 within the stimulated rock volume was lower than naturally occurring seismicity (up to a magnitude of 0.0) at greater distances of about 1000 m from the stimulated reservoir.

For years, there has been an intense debate among experts as to whether open-hole multi-packer systems or the classic cemented and perforated casing approach offer better hydraulic conditions for stimulation in fractured rocks. We have now been able to demonstrate, within the usual uncertainties of subsurface work, that in principle both methods are good for multi-zonal stimulation (Meier et al. 2022). This is good news for the geothermal industry. In planning borehole completions, drilling engineers can now focus on more reservoir-independent issues when deciding on one concept or the other, such as site-specific borehole conditions, borehole breakouts, borehole stability, temperature, equipment reliability, deployment risks, equipment availability and costs.

4. Results from seismic monitoring tools and advanced traffic light testing at the Utah FORGE site

Geo-Energie Suisse joined Utah FORGE (Moore et al., 2023) to provide high quality micro seismic locations and to qualify and verify high temperature down-hole monitoring tools, that can be utilized for longer term monitoring at the Haute-Sorne project. An important objective for monitoring the micro seismicity at Utah FORGE is to resolve the zonal isolation or overlap between the stimulation stages.

A special emphasis is put on the 3-component hodogram analysis from two- or multi-level three-component (3C) receiver strings, since in Haute-Sorne the stimulations in one of the two boreholes are planned to be monitored from the other deep well at a depth of more than 3500 m and temperatures in the range of 150 to 190 °C.

Geo-Energie Suisse also could improve the in-house seismic data processing and interpretation software by adding the capability to include seismic data from DAS (distributed acoustic sensing) cables that were installed behind casing or lowered inside of cased boreholes. In addition, Geo-Energie Suisse tested a prototype of fully fibre optic 3C receivers, that can support temperatures above 200 °C.

A plot with the preliminary evaluation of the micro seismicity during the main stimulation campaign in April 2024 is shown in Figure 4.

With respect to the performance of the monitoring system and individual tools the following general conclusions are:

- The high-temperature, digital, eight-level, three-component (3C) receiver strings worked up to about 3 weeks of continuous high temperature operation with satisfactory precision of the hodograms.
- The single or two-level retrievable, high-temperature 3C analog receivers worked for more than two months, after deployment related issues could be solved. The analysis of their hodogram precision is still on-going. If the hodogram precision is found to be acceptable, the analog receivers may be better suited for long term monitoring at Haute-Sorne than the digital tools.

- A combination of data from the DAS cable installed behind the casing with one or more 3C receiver strings has turned out to be very satisfactory.
- The first trials with a prototype of fully fibre optic 3C receivers are promising and considered to open new perspectives for long term seismic monitoring at high temperatures.

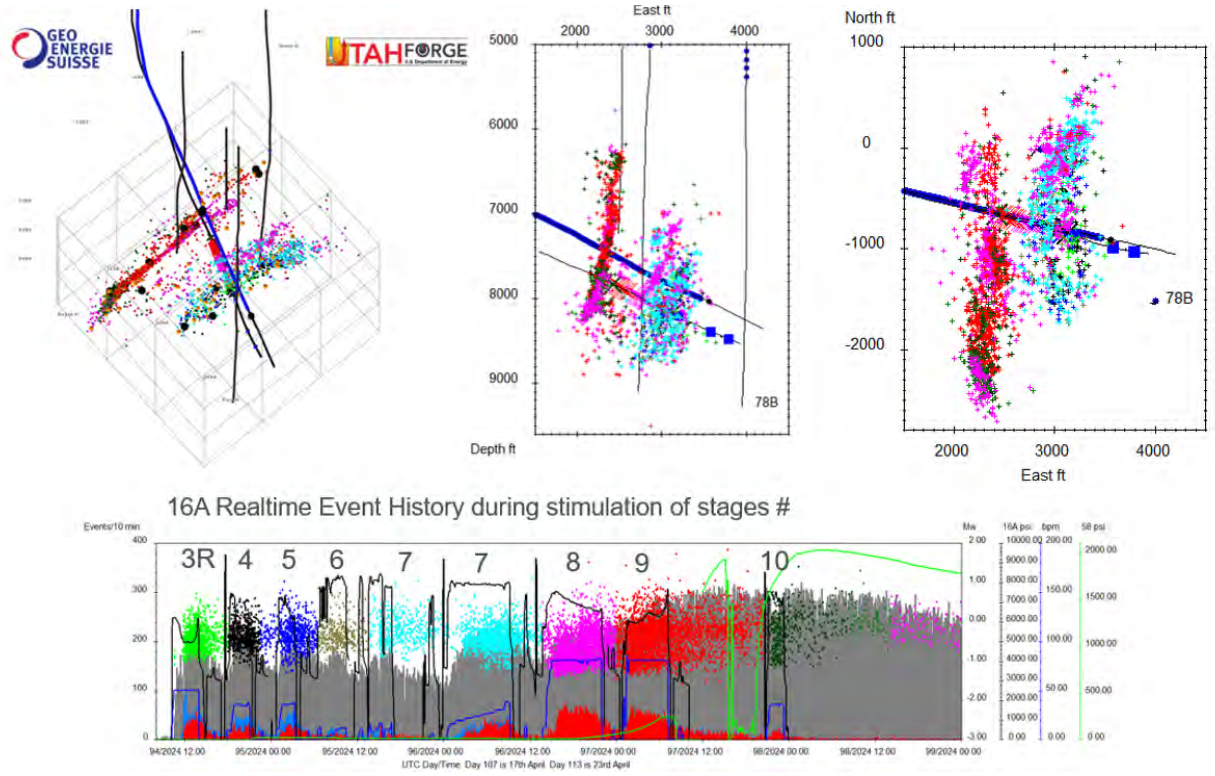

Figure 4: Distribution of micro seismicity during the stimulation of stages 3 to 10 in the deeper borehole 16A at Utah FORGE. Upper figures: 3D view (left), vertical view (middle), top view (right). Lower figure: Seismicity rate (grey: triggers, red: located events), injection rates (blue line) and injection pressure at 16A (black line) and pressure at observation well 58 (green line) during the main stimulation.

In addition to verifying and qualifying down-hole tools the abundant high quality data from several multi-stage stimulations provided a unique opportunity to test out the real time seismic risk forecasting procedure called Advanced Traffic Light System (ATLS). The ATLS provides a quasi-real time forecast of the probability that certain prefixed magnitude thresholds may be exceeded. As an example, the prediction for stimulation stage 3 is shown in Figure 5.

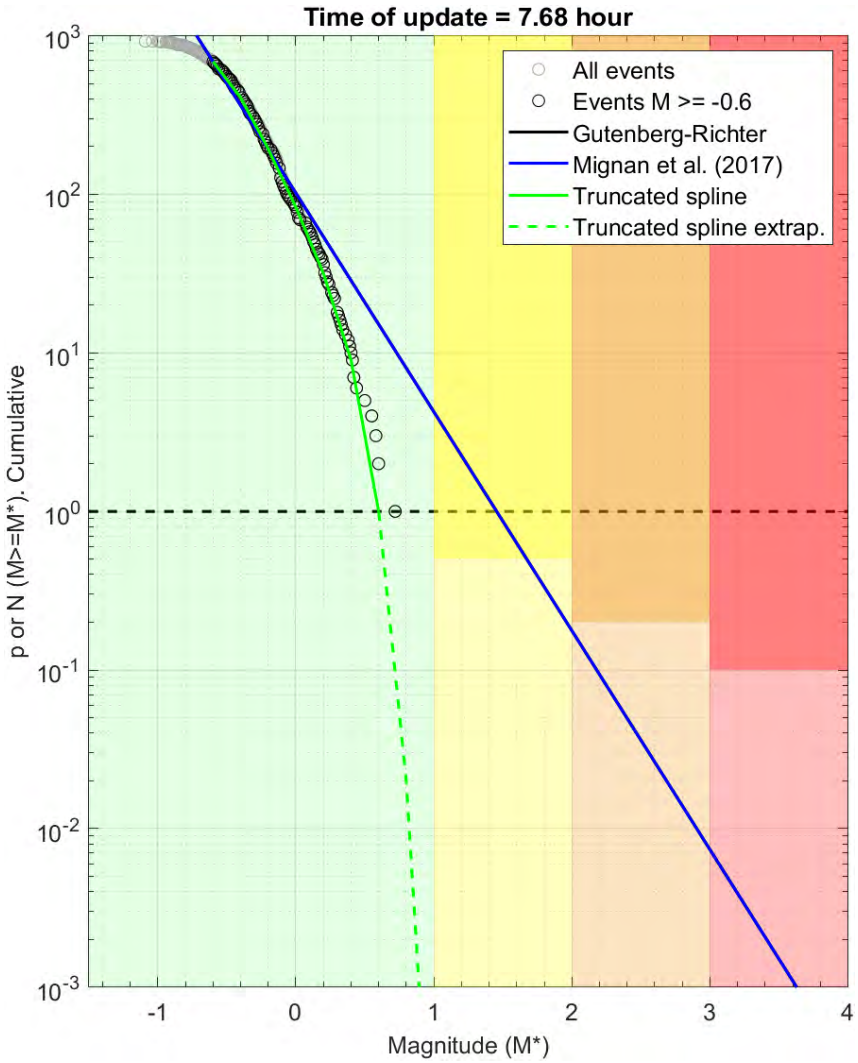

Figure 5: Advanced traffic light prediction at the end of the shut-in phase for stage 3. The predictions with the commonly utilized Gutenberg-Richter as well as the formulation after Mignan et al. (2017) overestimate the actual observed magnitudes. This behavior has been observed for most of the stimulated stages.

5. Transfer to the Haute-Sorne multi-stage stimulation project: stimulation test

Drilling of the first well has been started on May 21, 2024. The crystalline basement has been prognosed at depths between 1500 and 2500 m. After about one month of drilling through the typical sedimentary sequence of north-western Switzerland the crystalline basement has been reached at a depth of 1783 m. At the moment of writing no information is available on the rock mechanical properties of the targeted crystalline section.

The 13-3/8” casing covering the sedimentary formations will be set at a depth of 1820 m. The borehole information and the planned depth for the stimulation test are shown in Figure 6. At 4000 m depth the borehole with a diameter of 12-1/4” will be cased.

After a detailed analysis of the logging and cuttings data the most adequate depth for the test stimulation in the first quarter of 2025 will be determined. At that depth the casing will be

perforated such that several seismic monitoring 3C receivers of a digital tool string or the two-level analog 3C receivers evaluated at the Utah FORGE site can be placed with a cable that includes fiber optic lines for DAS below the perforations in order to avoid flow noise during injection.

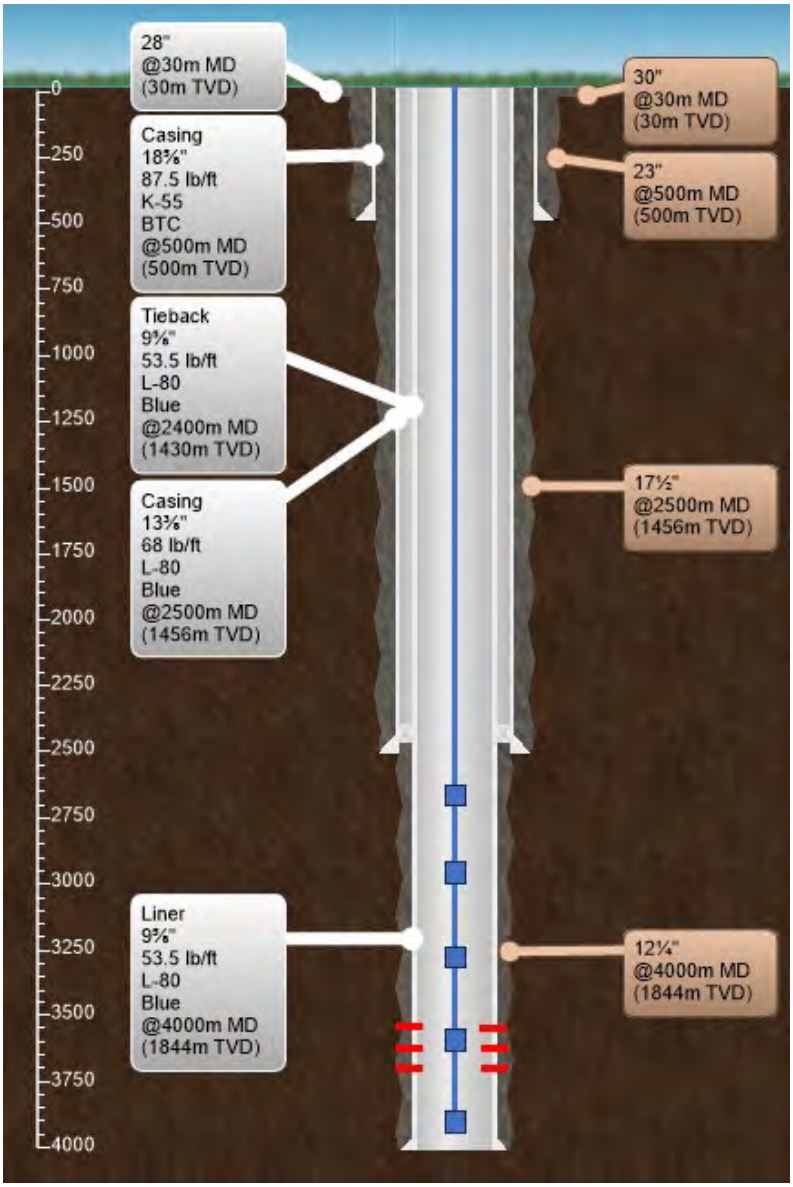

Figure 6: Borehole information with schematic drawing of the perforations and the seismic receiver string.

The stimulation test design will be based on data from Basel, Bedretto and Utah FORGE (Figure 7). The injected volume will be in the order of 500 m^3. We expect the moment magnitudes to attain values between the Basel and the Utah FORGE 2022 stimulations of stages 1 to 3 and the stimulated areas reaching an equivalent radius between 60 and 100 m.

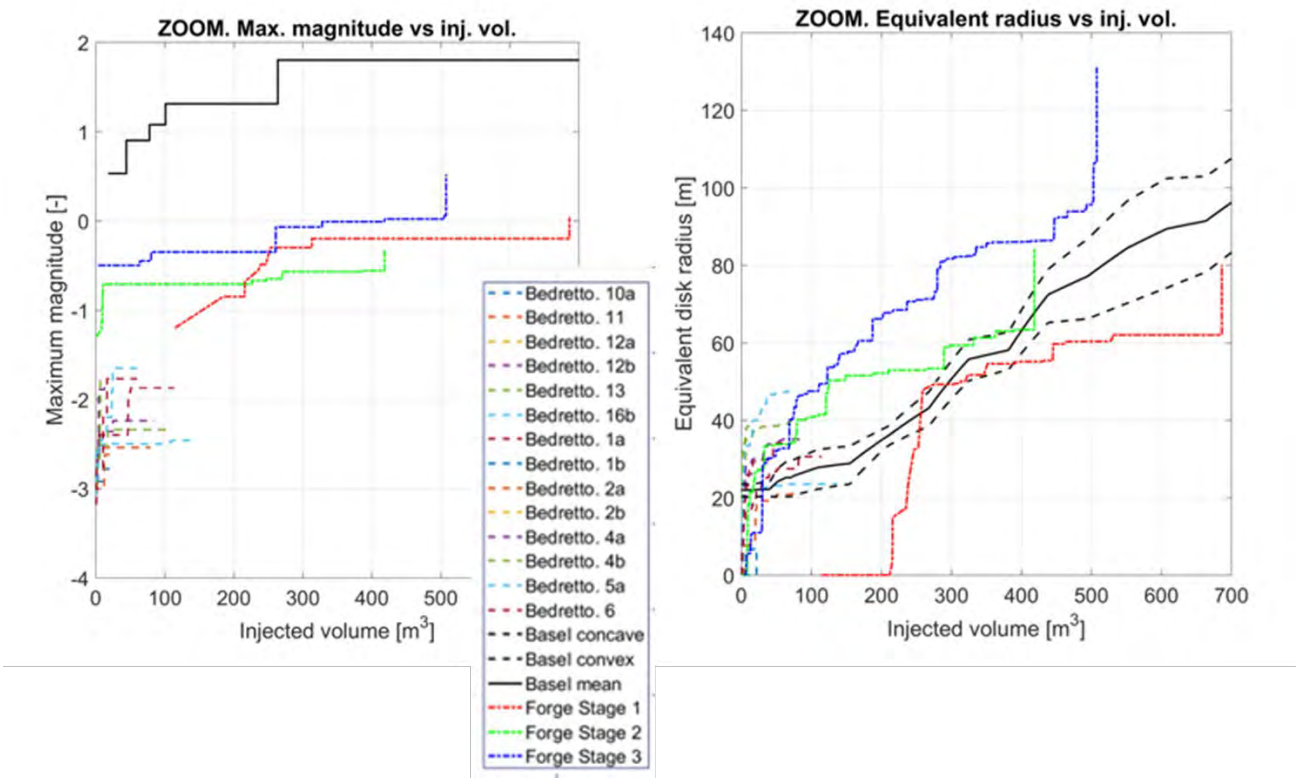

Figure 7: Design criteria for Haute-Sorne test stimulation: Maximum magnitudes (left) and radius of stimulated areas (right) as a function of injection volume at the Basel, Bedretto and Utah FORGE 2022 stimulations.

The current state of planning is summarized in the following sequential main steps:

1) Pressure static recovery (PSR): After installation of the geophone chain the well is shut-in at surface and pressures are monitored.

2) Constant head injection test including recovery for evaluating transmissivity before the test stimulation.

3) First test stimulation cycle:

a. Step-wise increase of injection rates with 10, 20, 45, 60 l/min. The duration of the first three steps is two hours each. The forth step is continued until the b-values can be estimated reliably from micro-seismicity. Adjust flow rate in function of the tolerable noise on the geophones.

b. Observation of pressures to identify processes of shearing, jacking or fracturing.

c. Stop injection if pressures at the wellhead are close to the equipment pressure limit of 50 MPa.

d. Stop injection if magnitudes Mw > 1.0.

e. Stop injection at an injected volume of 500 m3.

f. Prepare for backflow according to instructions of traffic light system (TLS).

g. Prepare for shut-in and/or backflow according to instructions of the advanced traffic light system (ATLS).

4) Shut-in: Pressure static recovery after shut-in at the wellhead for at least 24 hours or until a quasi-stable pressure trend will be attained for conducting a subsequent hydraulic test.

5) Constant head injection head test including recovery for evaluating transmissivity after the test stimulation.

6) After analyzing the data, a decision will be taken, if a second test stimulation cycle shall be performed.

6. Conclusions

The learning curve since the Basel 2006 EGS project has been long in time but important in know-how gain. The newest available technologies have been evaluated and thoroughly tested in field situations to mitigate seismic risks and maximize chances of success of a new EGS project in Switzerland. If the expected success can be realized, Switzerland will get its first power producing geothermal plant by 2029 in Haute-Sorne, Canton Jura. This example shows also the important role of R&D collaboration at experimental field sites between international partners for the development and realization of new technologies.

Geopressured Geothermal Systems, backpressure, pressure-propped fractures, injection pump parasitic losses, system impedance, no proppant, modeling pressurized systems

ABSTRACT

Conventional geothermal systems rely on production from naturally occurring subsurface hot aquifers, while Hot Dry Rock (HDR) geothermal technology is a method of extracting geothermal energy from deep underground formations where there is hot but dry rock. A downhole heat exchanger is created by water being injected into the rock through one or several wells at high pressure, causing the rock to fracture and creating a network of permeable pathways. Water is then circulated through these artificial or natural fractures, absorbing heat from the hot rock and bringing this heat to the surface.

High impedance in the fracture network and near the wellbore area is a main contributor to high parasitic energy losses in HDR systems and makes commercial-scale implementation very difficult. The Fenton Hill Hot Dry Rock (HDR) tests, from the 1980s and early 1990s, showed that an increased backpressure can reduce markedly the impedance in the system. In so-called doublet (or two-well) Enhanced Geothermal Systems (EGS), horizontal sections of two wells are connected with fractures filled with proppant to prevent these fractures from closing and creating very high resistance to water circulation. This paper provides an alternative solution to the traditional EGS approach and discusses a recently introduced Geopressured Geothermal System (GGS) that keeps the surface and subsurface systems constantly pressurized above fracture opening pressure or, in other words, relying on pressure-propped fractures to keep impedance low.

Focusing on the hydro-mechanical (HM) performance of GGS, and reserving the full thermal-hydro-mechanical (THM) analysis for a later publication, the results show that the single-well pair GGS is superior to other systems in terms of HM performance. The methodology of this single-well pair GGS builds on that of mechanical storage in deep hydraulic fractures as field tested in South Texas in early 2023.

Numerical simulations were performed to demonstrate how properly engineered GGS resolves crucial surface challenges not previously addressed in heat extraction systems and how these geothermal systems experience a lower system impedance while maintaining commercial flow rates. Comparisons are made between GGS with the base case of a doublet EGS whose fractures are proppant-propped. The mathematical modeling of GGS is a natural extension of the recent modeling for mechanical storage that was additionally validated and calibrated against real-time field data.

1. Introduction

Extraction of heat from fractured hot dry rock (HDR) was first proposed in the Los Alamos National Laboratory in New Mexico in the early 1970s (Brown et al. 2012). An early theoretical approach to the heat extraction system studied there comprised two parallel vertical wells drilled to depths reaching dry hot rock with the second well intersecting the vertically oriented fracture produced by hydraulic fracturing the first well (Robinson et al., 1971). However, a more complex HDR system was created from the many years of field development and testing that ensued at Fenton Hill, New Mexico (physical site chosen by Los Alamos; see photo in Figure 1) and which continued until the mid-1990s. A great deal of valuable information was obtained from this pioneering HDR program.

Among the many lessons learned, the Fenton Hill field tests demonstrated that *impedance*, a measure of the resistance to circulation of a fluid through a subsurface system, is greatly reduced by holding an elevated backpressure on the production wellhead which assists in pressure propping the fracture(s) (DuTeau and Brown 1993; see Figure 1 for a recorded table). The potential for electric load-following methods was also verified, but the findings revealed that these backpressure operations: (1) demand a higher injection pumping capacity to maintain a pressurized subsurface system; and (2) expose the surface equipment to higher pressures (Brown and DuTeau 1995).

Geopressured Geothermal Systems (GGS), that pressurize the surface and subsurface systems as described in Section 2, are an alternative to previously proposed heat extraction systems as GGS address by design the challenges mentioned above. First, the use of a GGS surface injection kit

connected to a high-pressure binary plant allows the use of pressure energy usually wasted at surface to dramatically decrease power lost to the injection pump overcoming impedance; traditional systems simply vent pressures at surface from the production well. Next, fractures are *pressure propped*, defined here as fractures being inflated with fluid pressures above the minimum in-situ stress; the phrase 'fractures are *operated open'* is also often used. Pressure propped fractures: (a) considerably reduce system impedance, hence reduce friction losses; (b) allow larger lateral well spacing that enable larger fracture areas that are conducive for heat extraction (as opposed to having extensive fractures but short well-to-well distances in each fracture); and (c) enable a single-well pair solution for heat extraction when "huff-n-puff" (cyclical injection-production) operations are implemented instead. Lastly, GGS do not rely on proppants, which induce high friction losses and cannot be uniformly distributed, and thus the associated costs and time of proppant treatments are eliminated.

Because both temperatures and stresses generally increase with depth, a subsurface system reaching practical commercial geothermal temperatures will lead to higher surface pressures if fractures are pressure propped. Hence, the need for a GGS design that can operate with higher pressures both at surface and subsurface. It is noted that operating fracture fluid pressures above the minimum in-situ stress does pose risk to fractures growing. This may lead to fluid being lost as it can be trapped by the fracture at further distances away from the well. More importantly, if fracture growth is uncontrolled, fluid pressurization may trigger seismic activity, particularly if a fault is nearby. Therefore, fluid pressures in opened fractures are further restricted to be below fracture propagation pressures.

Mathematical models have been developed using coupled hydro-mechanical (HM) processes to compare Geopressured Geothermal Systems against a two-well EGS with fractures filled with proppant. A future work will compare the complete thermal-hydro-mechanical (THM) processes of GGS versus EGS. In particular, a future publication will show that the thermal drawdown behavior of a GGS is comparable or better than that of a proppant-laden EGS.

The framework of the engineered systems analyzed in this paper is introduced in Section 2, while Section 3 describes pumping power consumption and system impedance for traditional EGS versus GGS. Completed models are presented in Section 4 and include the deformation and multi-scale nature of fracture propagation; wellbore, perforation, and fracture frictional losses; pressure response due to fluid circulation that includes injection pumping and production; power lost to the injection pump; and system impedance. This section also presents the simulations for all systems and comparisons are made. The final section concludes that the single-well pair GGS, based on cyclic (or huff-n-puff) operations, outperforms any other system.

2. A Proppant-Laden EGS and Three Geopressured Geothermal Systems

The following systems are ordered according to the natural progression from a traditional two-well EGS to the single-well pair GGS design:

I. Two-well system with proppant-laden fractures and continuous circulation of fluid.
II. Two-well system with pressure-propped fractures and continuous circulation of fluid.
III. Three-well system with pressure-propped fractures and continuous circulation of fluid.
IV. Single-well pair system with pressure-propped fractures and huff-n-puff operations.

2.1 Traditional Two-well EGS versus a Two-well GGS.

A two-well Geopressured Geothermal System (GGS) is shown on the right of Figure 2, and this is compared directly with a traditional EGS shown on the left. Both systems have a subsurface design that includes an injection well whose lateral is hydraulically fractured, possibly by employing zonal isolation methods and limited entry completions, and a production well drilled to intersect the multiple fractures created. A first distinct characteristic of the two systems is that the traditional EGS has fractures filled with proppant whereas the GGS does not. In both systems, fluid is circulated down the injector well, through the fracture system and up the producer well.

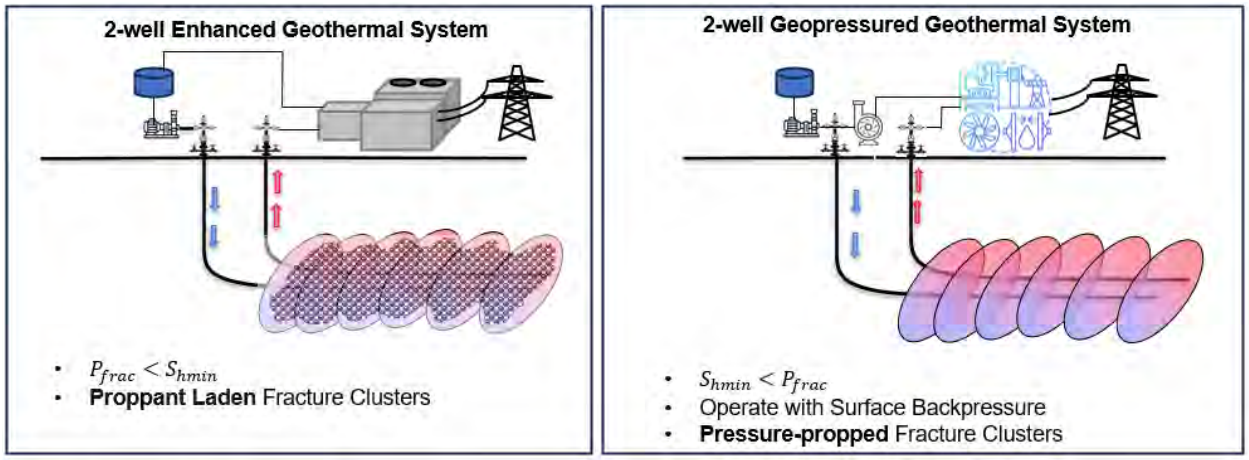

Figure 2: Comparison of a two-well EGS with a two-well GGS.

A second distinction is that the GGS is operated with an elevated backpressure maintained by a controllable choke that connects to the production wellhead. This backpressure is always maintained above fracture opening pressure and thus above the minimum in-situ stress allowing fluid to circulate with minimal impedance.

Although an elevated backpressure reduces the fracture impedance, the injection pump parasitic load increases and this leads to differences in surface design. In a GGS, a high-pressure binary plant (high pressure heat exchanger) maintains the high pressure from the production wellhead side to markedly reduce the pumping power needed by the GGS surface injection side. In this approach, the surface system utilizes pressure energy that is otherwise wasted (vented at surface) in traditional EGS, and allows the subsurface system to be maintained pressurized. A process flow diagram of the surface configuration of the two-well GGS is shown in Figure 3.

This coupling of surface and subsurface leads to a pressurized circulation loop that requires only make-up water to account for losses from evaporation and leak-off to the rock matrix. It should be noted that it is possible for a fracture wing not intersecting a producer well to potentially grow uncontrollably due to the high pressures; this situation is considered in Section 4.

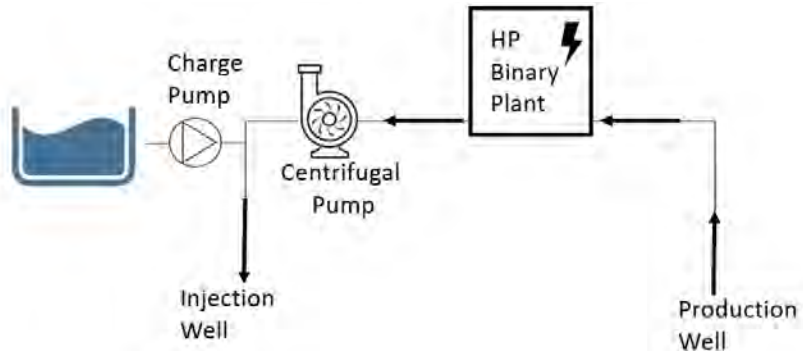

Figure 3: Process Flow Diagram for a two-well GGS; wells are connected at surface by a high-pressure binary plant and a GGS injection surface kit to pressurize the surface system.

2.2 A Pressure-propped Three-well System.

Drilling a second producer well to intersect the fractures of the previous two-well GGS, so that the lateral of the injector well is between both producer laterals, leads to the three-well GGS displayed in Figure 4 (Gedzius et al. 2011). The second producer intersecting the wings previously not containing a producer well reduces the risk of fractures growing out of control.

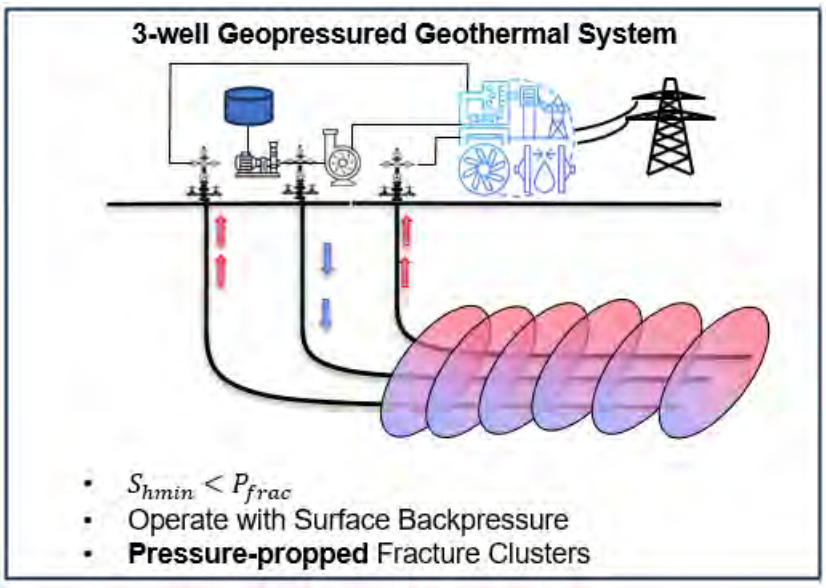

Figure 4: A three-well GGS as an extension of a two-well GGS.

In this design, fluid is circulated down the injector (middle) well, through the fracture cluster, and up through both producer wells. Fractures are opened by the elevated backpressure maintained by controllable chokes at the surface, one on each producer, with fracture fluid pressures maintained above the minimum in-situ stress. The high-pressure heat exchanger in the binary plant uses the high pressures flow from both production wells to significantly reduce the power required by the surface booster injection pump. As in the two-well GGS, this design does not require any proppants to be placed in the fractures.

2.3 A Single-well Pair Geopressured Geothermal System.

A single-well pair GGS operating at two different times is shown in Figure 5 as a 'huff-n-puff' system. In this design wells A and B are not connected in the subsurface and each well has its own set of fractures. This eliminates altogether the expensive task of connecting two or more horizontal wellbores with a fracture system created to establish subsurface circulation. The well stimulation operations are much simpler because each leg can be fracked individually and no intersections are required. The surface system is exactly the same as in other GGS where wells are connected at the surface by a high-pressure binary plant.

The system is initiated by injecting a pre-designed fluid volume and pressurizing fractures in both wells with fluid pressures above the minimum in-situ stress. Fractures in one well are given more fluid than fractures in the other well, and that extra percentage (around 20-30%) of the full fracture fluid volume will be the only volume that is moved back and forth between wells during the cyclic operations. The system is shut-in when the desired pressures and volumes (as calculated to meet power objectives) are reached. The system is now primed and cyclic operations may commence as described next.

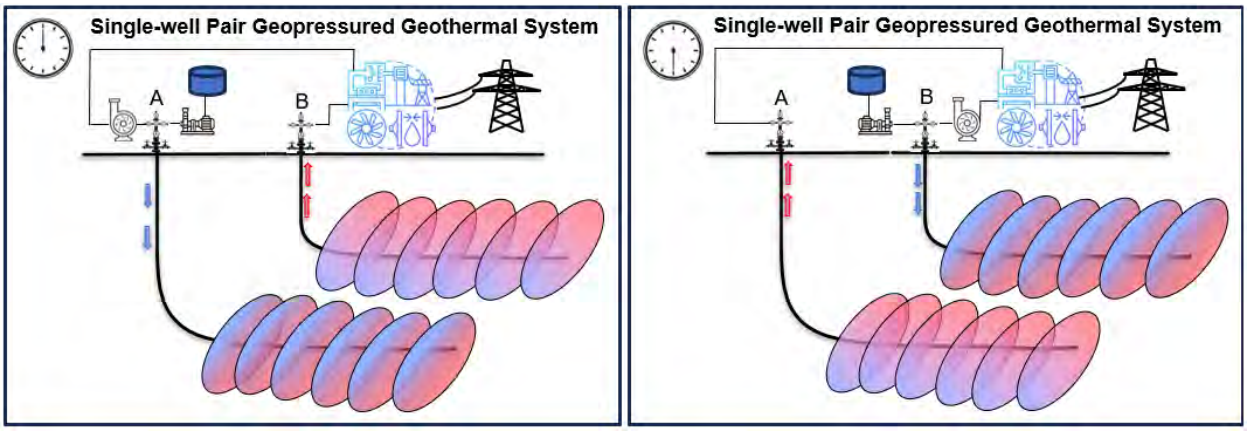

Figure 5: Framework of a single-well pair GGS. Wells are disconnected in the subsurface. Left shows producing from well B and injecting into well A, whereas the right shows producing from A and injecting into B. Surface equipment is not duplicated as flow paths at surface are simply redirected.

Using Figure 5 for illustration, a *cycle* starts at 12 o'clock when well B is opened and the produced fluid is produced to the high-pressure heat exchanger of the binary plant. Then the cooler fluid coming out of this heat exchanger is injected into well A while maintaining high pressure. As mentioned above, only a percentage of the total fluid volume is moved from well B fractures to well A fractures. The extra percentage of (cooler) fluid injected into well A fractures mixes with the volume of fluid injected during the initiation phase that is by now additionally heated. This percentage is calculated so that the system, in the example of Figure 5, runs until 6 o'clock, at which time well A fractures have the bigger fracture fluid volume. Now the wells are shut-in and then flow is reversed to begin the second half of the cycle, as in the right side of Figure 5. It is also possible to have a shut-in period before reversing the flow but this depends on power objectives. In this second half of the cycle, well A produces hot (due to mixing) pressurized fluid into the high-pressure binary plant and the same surface injection kit now injects the cooler fluid into well B. This A-to-B flow runs until 12 o'clock, the time when a full cycle is complete and well B fractures again have a larger volume than well A fractures. The wells are shut-in at 12

o'clock to then reverse the flow and start the second cycle. Running consecutive cycles creates the cyclic (or huff-n-puff) operations of this single-well pair GGS.

3. Minimizing the Power Lost to the Injection Pump and Impedance

The pressurized surface system in a general GGS arises from the need to decrease pump power consumption for the overall system to be practical. Since the power consumed by a pump is given by

$$Power_{pump} = \frac{(P_{pump} - P_{suction})\dot{m}_{inj}}{\rho_{inj}\eta_{pump}}, \quad (1)$$

where $(P_{pump} - P_{suction})$ is the pressure differential across the pump, $\dot{m}_{inj}$ is the mass flowrate at the injector well, ρ_{inj} the density of the fluid and η_{pump} is the efficiency of the injection pump, power is minimized by minimizing the pressure differential across the pump. An innovative solution to reduce the power consumed by the pump is to maintain the backpressure through the whole surface system. This leads to two types of surface systems where one operates with a low suction pressure (LSP) pump and the other with a high suction pressure (HSP) pump. In the simulations presented here, the efficiencies for the pumps are assumed to be 0.7 and 0.85, respectively, for the HSP and LSP pumps.

Figure 6 shows hydraulic schematics for two surface/subsurface systems where the subsurface system is either connected by fractures (left) or disconnected (right). The pump in either schematic may be LSP or HSP.

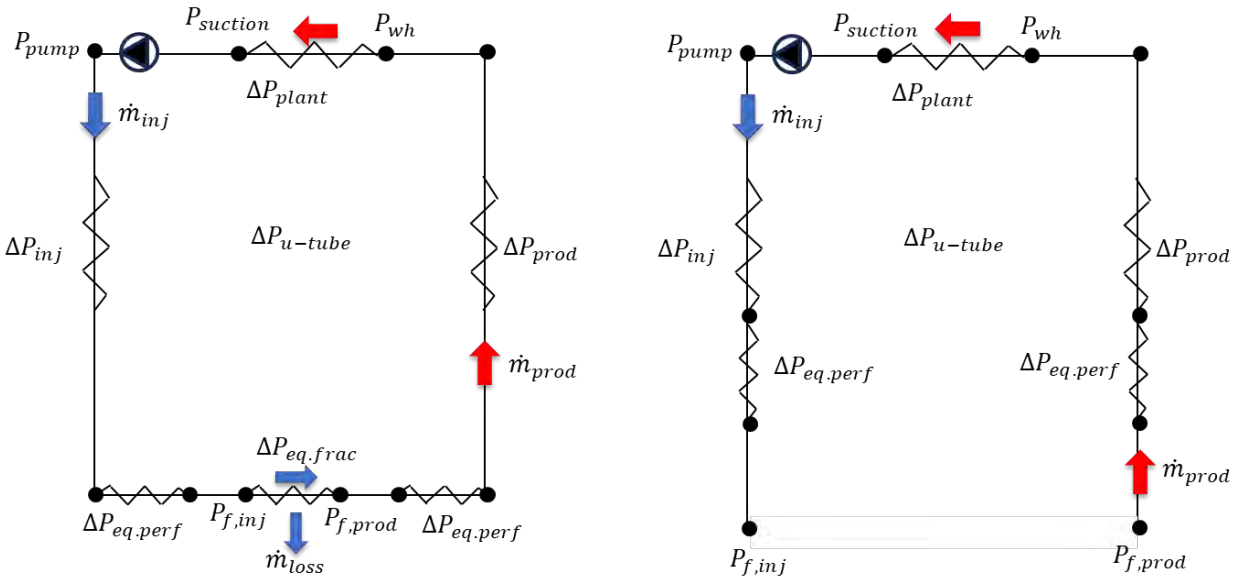

Figure 6: Hydraulic schematics of the surface/subsurface system comprising two vertical wells connected by fractures (left) and disconnected in the subsurface (right).

Using the hydraulic schematic on the left in Figure 6, the pressure balance for a system that circulates fluid is given by

$$P_{pump} - P_{suction} = \Delta P_{plant} + \Delta P_{wells} + \Delta P_{eq.perfs} + \Delta P_{eq.frac} + \Delta P_{u-tube} \quad (2)$$

where $P_{suction}$ is the suction pressure, ΔP_{wells} combines the injection and production well pressure losses denoted by ΔP_{inj} and ΔP_{prod}, respectively, $\Delta P_{eq.perfs}$ is pressure loss due to perforations, $\Delta P_{eq.frac}$ is fracture pressure loss, and ΔP_{u-tube} is the hydrostatic differential pressure between wells. The *system impedance* that the pump needs to overcome is

$$\text{Impedance} = \left(P_{pump} - P_{suction} - \Delta P_{u-tube}\right)/Q_{prod} \quad (3)$$

where Q_{prod} is the volumetric flowrate at the production side.

When wells are disconnected at subsurface (right side of Figure 6), both formulas are the same except that the fracture pressure difference $\Delta P_{eq.frac}$, between $P_{f,inj}$ and $P_{f,prod}$, refers to fracture fluid pressures in the same fracture (when circulating fluid between wells in the subsurface) or pressures in disconnected fractures (when cycling fluid between wellbores to surface, without subsurface connection). When more than one fracture or producer well is involved, then the schematics of Figure 6 extend, and so do the formulas, in a similar fashion as in parallel circuit analysis.

4. Modeling and Results for Pump Power Consumption and Impedance

Simulations for the GGS designs while in operation were made here with a hydro-mechanical (HM) solver. Fractures are assumed to be height constrained and below an effective stress and pressure sealing formation to prevent upward growth. The deformation and near-tip behavior of propagating fractures governed by competing processes is captured by the solver by modeling fractures as one-dimensional objects embedded in a two-dimensional reservoir. Fluid balances, leak-off, and fracture contact are also handled. The simulator includes wellbores connected to fractures with perforations and simulates the pressure response due to either circulating fluid through the entire subsurface system or cycling fluid between two disconnected well/fracs system. For the surface system, the simulator also calculates power lost to the injection pump and system impedance.

The wells for each of the modeled cases reach a true vertical depth of 7500 ft (2286 m), and laterals 3281 ft (1000 m) long connect with 100 fractures for all cases except the single-well pair GGS that only has 8 fractures on each of its 262 ft (80 m) long laterals; 7” casing for the entire lengths of the wells is assumed for each well; when wells are connected by fractures the spacing between laterals is set to be 656 ft (200 m). Pore pressure is taken to be hydrostatic and a gradient of 0.7 psi/ft is assumed for the minimum horizontal stress, with a normal fault regime. The reservoir rock at the given depth is assumed to have a permeability of 0.1 mD, a Young’s modulus of 20 GPa, and a Poisson’s ratio of 0.25.

The fluid in each of the systems is assumed to be water, and though temperature is not explicitly modeled, it is prescribed at 40 °C for injection wells and 150 °C for the reservoir/fractures and production wells. As fluid properties depend on pressure and temperature, thermophysical properties of the fluid are obtained by the equation of state using REFPROP (Lemmon et al. 2018).

All of the above also holds for the traditional two-well EGS, except that fractures are modeled differently. They are treated to be in the ideal case where each fracture is filled with uniformly distributed proppant so that a 0.5 porosity, a fracture conductivity of 25 md-ft, and a 1.5 mm aperture is assumed for each fracture.

4.1 Impedance and Pump Power Consumption in a Traditional Two-well EGS

A traditional two-well EGS, as in the left of Figure 2 but with 100 fractures, is modeled here under the assumptions given above. In the following, the simulator has filled the fracture/well system to initiate modeling of the system in full operation.

Figure 7 shows the simulated behavior of this two-well EGS operating for two days. A constant 50 l/s (793 gpm) injection flowrate is specified for the entire modeled time, while the backpressure is controlled to stepwise increase from a constant 100 psi (0.69 MPa) on the first day to a constant 200 psi (1.38 MPa) on the second day.

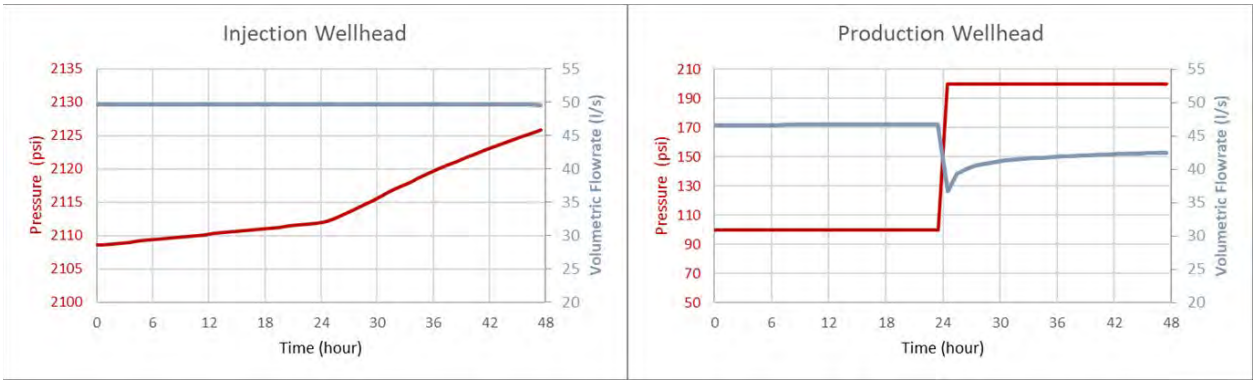

Figure 7: Simulated behavior of a traditional two-well EGS with 100 proppant-laden fractures operated with constant backpressures on each of the two days.

The simulation shows that on both days the production flowrate remains near constant, with approximately 47 l/s (745 gpm) on the first day and then drops and rebounds to the lower value of about 42 l/s (666 gpm) on the second day when the production backpressure is stepwise increased. The injection wellhead pressure builds up approximately linearly on both days, but at a much faster rate on the second day in response to the increased backpressure.

Figure 8 provides the friction pressure losses experienced during these two days of operation that circulates fluid down the injector well, through the 100 proppant-laden fractures and up the producer well; the part that makes up the U-tube effect is shown in the secondary vertical axis.

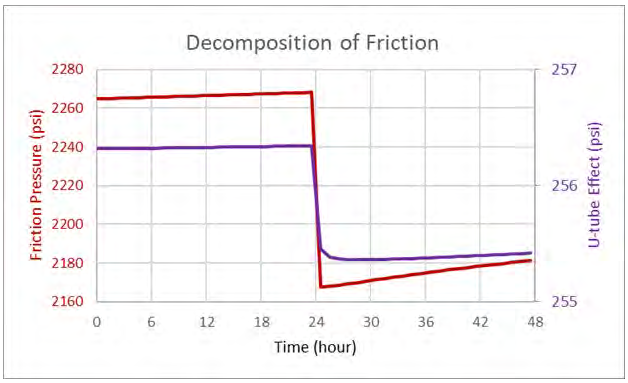

Figure 8: Friction pressure and U-tube effect of the two-well EGS with 100 proppant-laden fractures.

During the first day, the friction pressure remains around 2265 psi (15.62 MPa), and drops to 2167 psi (14.94 MPa) on the second day after the backpressure stepwise increases. This friction pressure

increases just slightly on the first day and moderately on the second day. It is observed that the U-tube effect follows a similar trend, but with magnitudes equal to 256 psi (1.77 MPa), on average, throughout the two-day operation.

Now the system impedance and pump consumption of power, are displayed in Figure 9. When the surface system is pressurized and an HSP pump used, then the system impedance on the first day is observed to be 0.35 MPa/(l/s) and increases and rebounds to 0.37 MPa/(l/s) on the second day as a consequence of the added resistance when the production backpressure is increased. When the surface system is not connected and an LSP pump is used, the impedance is 0.36 MPa/(l/s) on the first day and 0.40 MPa/(l/s) on the second day. This gives only a 3-8% drop in impedance when pressurizing the surface system.

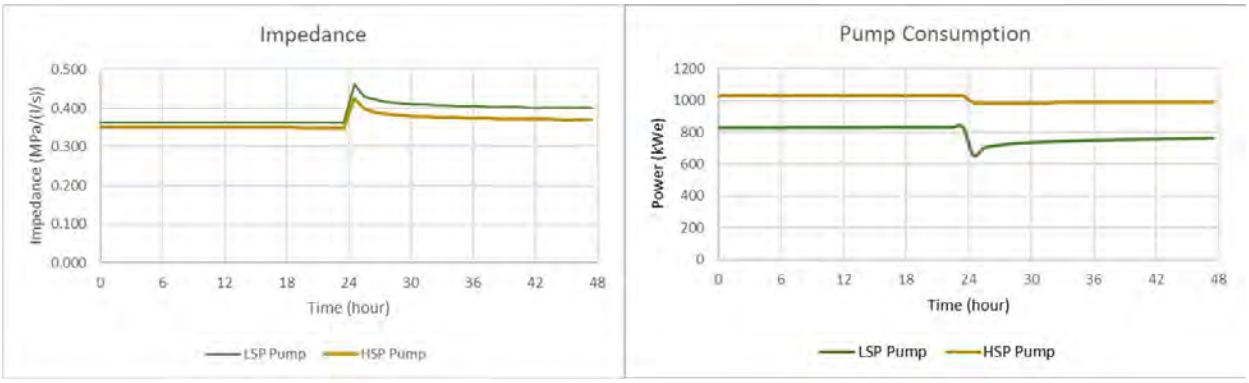

Figure 9: System impedance and pump power consumption for a traditional two-well EGS with 100 proppant-laden fractures.

When the EGS is operated with an LSP pump, the power consumed by the pump is 830 kWe, on average, during the first day of operation, and this drops but gradually increases to 762 kWe during the next 24 hours to overcome the stepwise increased backpressure. If, however, this two-well system is pressurized at surface and an HSP pump is used, then the pump consumption is about 1031 kWe during the first day and drops to 983 kWe and gradually increases to 990 kWe during the second day.

Modeling thus shows that maintaining the surface pressurized in a system where fractures are proppant propped leads to higher impedance and a power consumption increase of about 201 kWe during the first 24 hours and about 228 kWe during the next 24 hours. This translates to an energy increase of 4,824 kWh on the first day and 5,472 kWh on the second. Therefore, pressurizing the surface system when propping the fracture system with proppant is undesirable.

4.2 Reducing Impedance and Pump Power Consumption in a Two-well GGS

This subsection shows that hastily pressure propping fractures and pressurizing the surface system of a doublet system may be unwise and that careful attention is needed for a properly engineered GGS. Here, a two-well system is considered, as in the right of Figure 2 but with 100 fractures that are pressure-propped as opposed to proppant-propped. Since the fractures are operated open, i.e. with fluid pressures above the minimum in-situ stress, the deformation part of the simulator is enabled. In the following, the simulator has filled and pressurized the fracture/well system to initiate modeling of the system in full operation. Fractures fluid pressures are above the minimum in-situ stress but below the pressure that would lead to fracture propagation.

Figure 10 shows the simulated behavior of this two-well GGS operating for two days. A constant 50 l/s (793 gpm) injection flowrate is specified while maintaining a constant backpressure of 2132 psi (14.7 MPa) for the entire simulation.

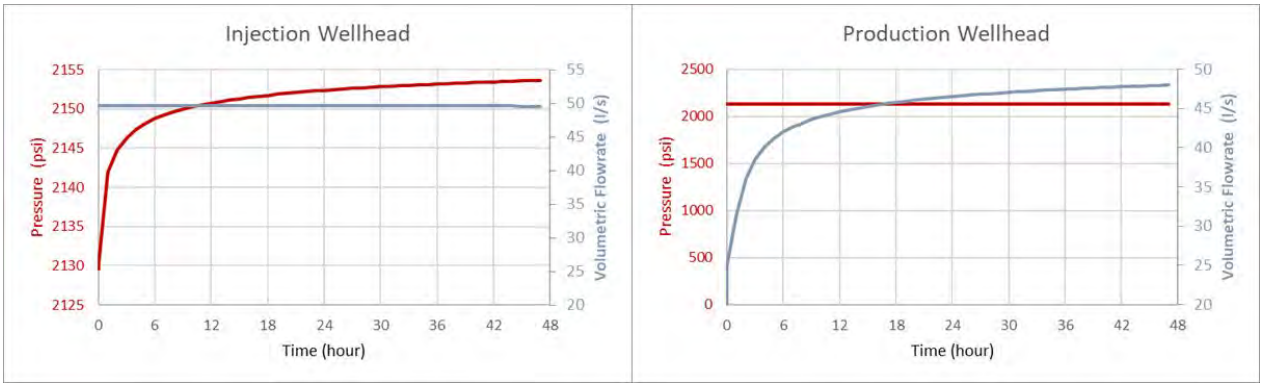

Figure 10: Simulated behavior of a two-well GGS with 100 fractures operated with a constant backpressure during the entirety of two days.

The simulation shows that the production flowrate increases from 25 l/s (396 gpm) to reach 48 l/s (761 gpm) at the 48th hour of operation as the increasing rate slows down. It is seen that the injection wellhead pressure builds up sharply during the initial 4 hours and continues to increase afterwards but at a much slower rate.

The friction pressure losses experienced by this pressurized system during these two days of operation is shown in Figure 11; the part that makes up the U-tube effect is again separated into the secondary vertical axis. The friction pressure is about 254 psi (1.75 MPa) for the 23 hours after having sharply increased in the first hour from the initial 156 psi (1.08 MPa). This friction pressure increases very slowly in the last 23 hours of operation. The U-tube effect is close to 233 psi (1.61 MPa) during the modeled time.

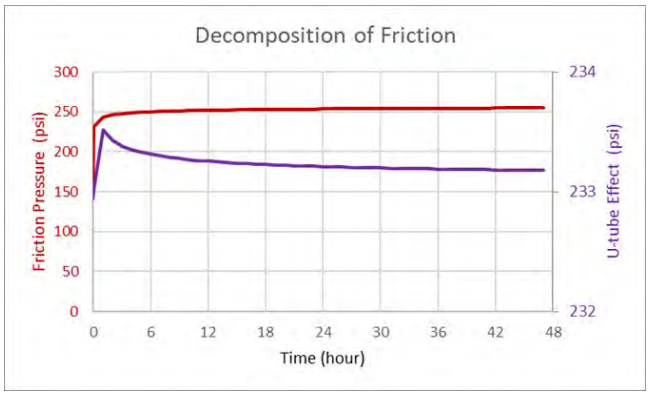

Figure 11: Friction pressure and U-tube effect of the two-well GGS with 100 fractures.

Figure 12 displays the system impedance and pump consumption of power. If the surface system is pressurized and uses an HSP pump, the system impedance is around 0.053 MPa/(l/s) for the majority of the two days, though it is gradually decreasing. If the surface is not pressurized and is equipped with an LSP pump, then the impedance is about 0.36 MPa/(l/s) throughout the modeled time. The impedance of the fully pressurized system is about an order of magnitude less than when the surface is not pressurized; this is also true when comparing with the proppant-laden EGS case.

Moreover, the maximum fracture aperture observed was 0.8 mm when fractures are pressured propped, almost half the aperture size of the proppant propped factures.

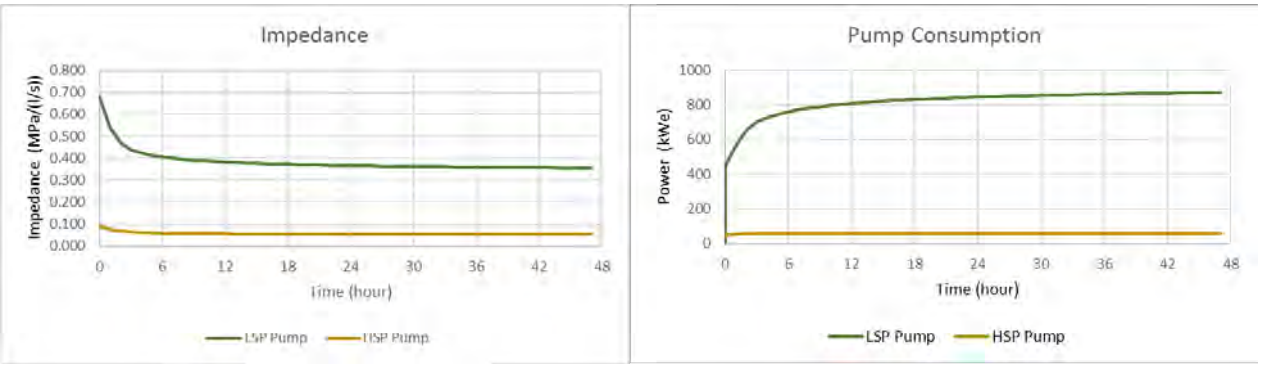

Figure 12: System impedance and pump power consumption for the two-well GGS.

Consider now the pump consumption behavior for this two-well system. Suppose first that this system is operated with an LSP pump. Figure 12 shows that the power consumed by the pump is 798 kWe, on average, during the two days of running the system. If, however, the surface system is pressurized and equipped with an HSP pump, then the pump consumption drops to 58 kWe during the modeled time. Thus, maintaining the surface system pressurized drastically reduced the power consumption of the pump. In fact, the drop in power consumed by the pumps implies an energy drop of 35,520 kWh during these two days.

The reduced impedance, the energy difference and the favorable system performance observed seems to undoubtedly warrant the use of a GGS surface injection kit for a two-well system. However, the simulations reveal a serious issue. Figure 13 shows a plan view of reservoir pressure focusing on one fracture in the system, and where the injector/producer well pair (two points) roughly are, respectively, at the centers of the red/blue region in the first frame, with this well distance fixed in all four frames. The simulation shows that the fracture keeps growing to the right, whereas the producer well serves as a pressure barrier and obstructs fracture growth to the left. Continued fracture growth is unwanted when continuously operating any heat extraction system as fluid is lost in the 'opposite direction'. More importantly, in scenarios of low fracture toughness, as in the simulation, the risk of uncontrolled fracture propagation is possible and may lead to seismic activity. As this may not always happen, operating a two-well system with fractures pressure propped and with a pressurized surface should be done with great caution if not avoided.

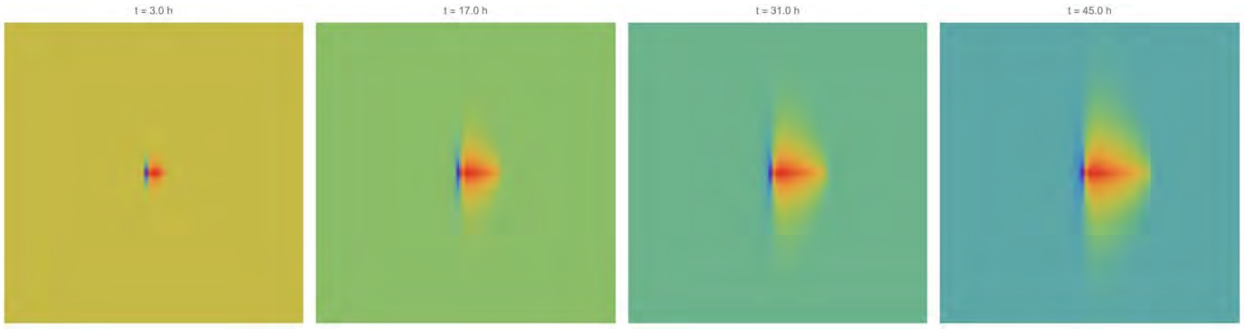

Figure 13: Plan view of reservoir pressure at hour 3, 17, 31 and 45 of the simulation displaying one fracture continuously growing to the right.

These modeled results align with the observations at Fenton Hill where the field tests of the (much more complex) subsurface system subjected to high injection and production pressures showed micro-seismic activity that implied further reservoir growth (Brown 1994). The recommendation from the Los Alamos National Laboratory to include a secondary production well, opposite the first relative to the injector well, is simulated next.

4.3 Reducing Impedance and Pump Power Consumption in a Three-well GGS

This subsection models operating a three-well GGS as in Figure 4 but with 100 fractures. As in the two-well GGS, fracture deformation is fully accounted for by the simulator. To initiate modeling of the system in full operation, the simulator fills the subsurface system and pressurizes the fractures with fluid pressures above the minimum in-situ stress but below the threshold that would lead to fracture propagation.

Figure 14 shows the simulated behavior of this three-well GGS operating for 48 hours. A constant injection flowrate of 50 l/s (793 gpm) is again specified for the entire modeled time, but the backpressure is controlled, in this case, to decrease stepwise from a constant 2132 psi (14.7 MPa) on the first day to a constant 2103 psi (14.5 MPa) on the second day.

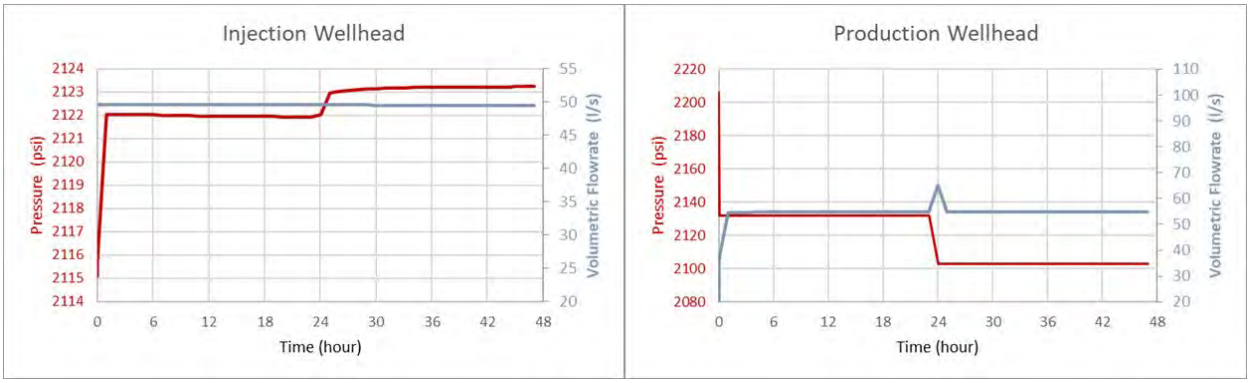

Figure 14: Simulated behavior of a three-well GGS with 100 fractures with fluid pressures above the minimum in-situ stress but below fracture propagation.

On both days the production flowrate remains a near constant of 55 l/s (872 gpm), with a small spike around the 24th hour when the backpressure is stepwise reduced. The injection pressure (approximately) stepwise increases from 2122 psi (14.63 MPa) on day one and to 2123 (14.64 MPa) on day two in response to the decreased backpressure in this system where fractures are operated open.

Figure 15 displays the friction pressure losses experienced during these two simulated days of injection and production; the part that makes up the U-tube effect is again on the secondary vertical axis. Compared with results for the EGS recorded in Figure 11, the friction pressure in this three-well GGS is lower by one order of magnitude. While operating this three-well system, the friction pressure loss is 223 psi (1.54 MPa) on the first day, and increases to 254 psi (1.75 MPa) on the second day after the backpressure stepwise decreases. The U-tube effect follows a similar stepwise increasing behavior, but is on average about 233.5 psi (1.61 MPa). Note that this U-tube effect, and that of the two-well GGS case, are close to the 256-psi average U-tube effect for the proppant-laden two-well EGS.

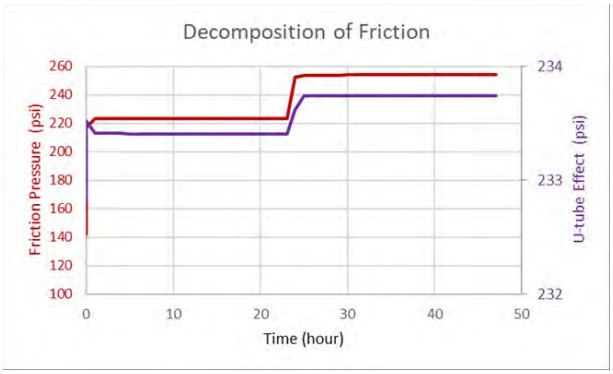

Figure 15: Friction pressure and U-tube effect of the three-well GGS with 100 fractures.

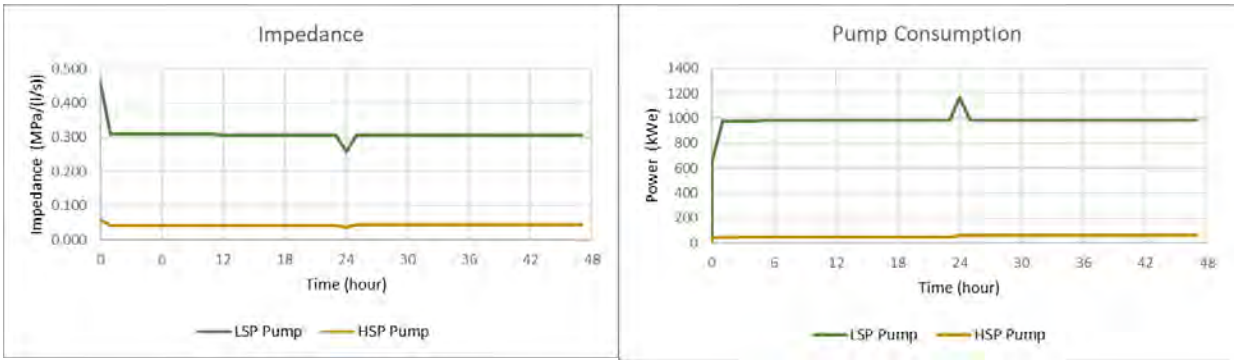

Figure 16: System Impedance and Pump Power Consumption for a three-well GGS with 100 fractures.

When the surface is pressurized and an HSP pump is used, Figure 16 shows that the system impedance is 0.041 MPa/(l/s) on the first day and increases to 0.044 MPa/(l/s) on the second day when the backpressure is stepwise decreased. When the surface is not connected and an LSP pump is used, the system impedance is 0.307 for the majority of the simulated time. As with friction pressure, the impedance of this pressurized system is an order of magnitude less than the unpressurized surface case; this observation is also true when comparing with the proppant-laden EGS case. The maximum fracture aperture observed when fractures were pressure propped was 0.95 mm, 37% less than the fracture aperture in the EGS case.

If the three-well subsurface system is operated with an LSP pump, the power consumed by the pump is 958 kWe during the two days simulated operation. However, if the surface system is pressurized and an HSP pump used, then the pump consumption stepwise increases from 43 to 58 kWe from day one to day two. This (small) jump results since the production backpressure is lower on the second day.

The simulations thus show that pressurizing the surface system leads to a power consumption drop of 907 kWe, on average, during the two-day operation. This translates to an energy drop of 43,536 kWh during this two-day simulation.

4.4 Reducing Impedance and Pump Power Consumption in a Single-well Pair GGS

This last design, the single-well pair GGS as in Figure 5 but with 8 fractures, is operated with cyclic, or huff-n-puff, operations, so the modeling results are displayed in a slightly different manner. As in the previous GGS designs modeled, fracture deformation is fully accounted for by the simulator as fractures are pressure-propped. To initiate modeling of the system in full operation, the simulator fills and pressurizes the fractures on both wells with fluid pressures above the minimum in-situ stress but below the pressure that would yield fracture propagation.

Figure 17 shows the simulated behavior of this single-well pair GGS operating for 52 hours. Consider first the flowrate profile of well A (in black). For the first 5.5 hours, fluid is being produced by well A at a rate of 50 l/s (793 gpm) and injected into well B; this is indicated in the plot by the negative volumetric flowrate value for well A. This production phase is followed by a one-hour shut-in phase of well A, and subsequently a 5.5-hour phase of injecting fluid (from well B) into well A at a rate of 50 l/s (a positive value in the plot). Another shut-in phase for one hour of well A follows, and then this production-injection process is repeated for well A. This creates the cyclic operation of well A, and well B is operated similarly but with the flow opposite that of well A. The accompanying plot shows that wellhead A pressure, for example, decreases when well A is producing, rebounds when shut-in, and increases when injecting into well A. Well B follows the same wellhead pressure behavior.

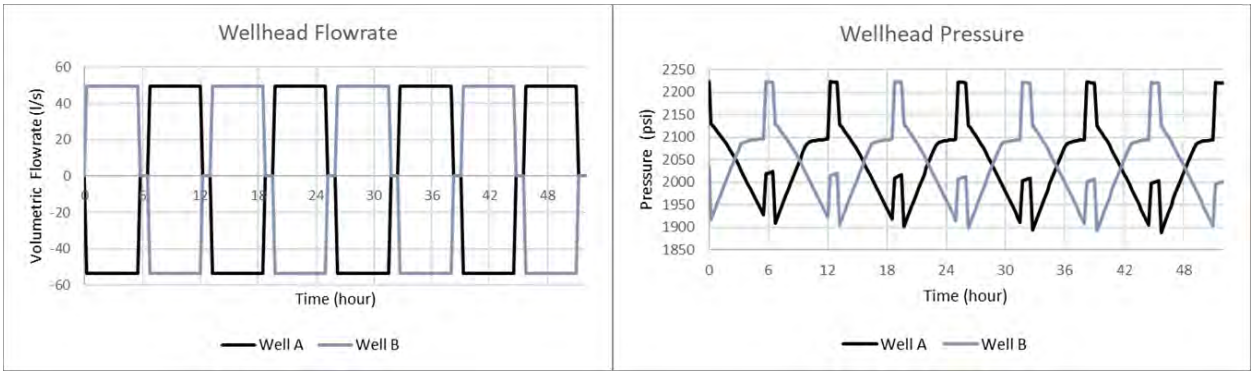

Figure 17: Simulated behavior of a single-well pair GGS with 8 fractures per well and huff-n-puff operations.

Figure 18 displays the friction pressure losses experienced during these 52 hours of huff-n-puff operations; the part that makes up the U-tube effect is shown in purple.

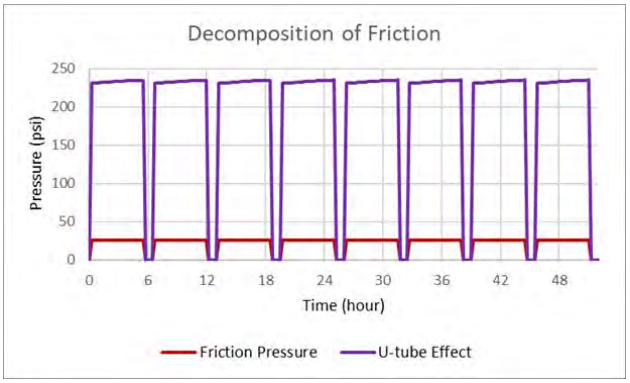

Figure 18: Friction pressure and U-tube effect of the single-well pair GGS with 8 fractures per well.

Unlike the other GGS designs, the friction pressure losses for the single-well pair GGS are one orders of magnitude lower than that experienced in the EGS with proppant-laden fractures; this single-well pair GGS has a friction pressure loss of 26 psi (0.18 MPa). The U-tube effect for the single-well pair GGS is 233 psi (1.61 MPa) when flowing, similar to the previous two GGS designs.

From Figure 19, the system impedance for the single-well pair design with the surface system pressurized (and thus with an HSP pump) has a value of 0.16 MPa/(l/s) when flowing. If the wells are not connected at surface and an LSP pump is used, then the system impedance is 1.16 MPa/(l/s), which is almost an order of magnitude higher than with the HSP pump. The maximum aperture observed for this case was 0.7 mm, which is less than half the aperture size in the EGS case.

If this two-well system is operated with an LSP pump, then the power consumed by the pump is 856 kWe, on average, during the simulated transfer of fluid. However, if the surface system is pressurized and an HSP pump is used, then the pump consumption is 80 kWe, on average, when flowing.

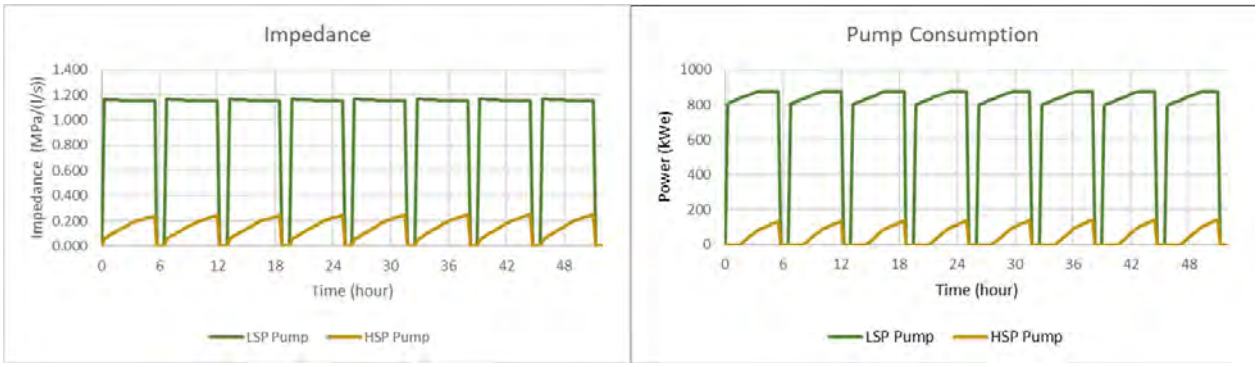

Figure 19: System Impedance and Pump Power Consumption for a single-well pair GGS.

Results from the simulation thus shows that maintaining the surface system pressurized leads to a power consumption drop of about 776 kWe during the 5.5 hours of flow. This translates to an energy drop of 4,265 kWh (on average) for each of these 5.5 hours of fluid transfer, or 34,144 kWh in the time when flowing.

5. Summary and Conclusion

These simulation results show that subsurface systems with pressure propped fractures have an impedance about one order of magnitude lower when the surface system is pressurized and when using a High Suction Pressure (HSP) pump versus not pressurizing the surface and only using a Low Suction Pressure (LSP) pump. This holds regardless if fluid is circulated through a connected subsurface or if huff-n-puff operations are used between two wells disconnected at the subsurface. The two-well and three-well designs where the surface and subsurface systems are pressurized have an impedance one order of magnitude lower than in the traditional two-well EGS with proppant propped fractures and an LSP pump. The pressurized single-well pair design with wells disconnected at the subsurface, but connected and pressurized at the surface, has half the impedance experienced in the EGS case.

If the surface system is pressurized and an HSP pump used when operating fractures open, then the power consumed by the injection pump is only 6-9% of the power consumed if an LSP pump is utilized (and if the surface system is not pressurized). In other words, maintaining the whole system pressurized, instead of wasting pressure on the production side, allows to drastically cut injection pump parasitic costs.

However, care should be taken when pressurizing the entire system. When applying this methodology to a two-well, multi-fracture system, the simulations show that continuous operation of the system (with practical performance at surface) leads to continued fracture growth, hence major fluid losses. Therefore, a GGS design should be operated with fracture fluid pressures above the minimum horizontal stress and below that which would induce fracture propagation. Both the three-well and single-well pressurized systems successfully use this pressure window. Longer lateral spacing is also demonstrated by the three-well design. The pressurized single-well pair design based on huff-n-puff operations is seen to be superior to the other systems in terms of the hydro-mechanical performance and it simplifies the stimulation operations and reduces the number of fractures by an order of magnitude.

Complementing the presented analysis of the GGS approach, a next publication will treat the full thermo-hydro-mechanical performance of GGS design.

Thermal short-circuiting, preferential flow, fracture permeability, fracture modification , nano-modified polymers, microcapsule transport

ABSTRACT

We are developing polymer-based materials that can be selectively injected into fractures to modify their permeability and consequently control the resulting flowrate through the fracture and the heat exchange with the formation. These polymer injectates offer an engineering solution for problems associated with preferential flow that can lead to thermal short-circuiting; namely, thermal breakthrough, decreasing energy extraction efficiency, and reduced service life. A nano-modified polymer has been developed and characterized that meets the target service requirements for geothermal applications; notably, they possess desirable properties (e.g., viscosity, bond strength) and do not degrade in temperatures up to 275 °C. Microcapsules are being developed to deliver the polymer catalyst and serve to control locations where the polymer will be deployed. We have fabricated monodisperse capsules with diameters ranging from 100 to 500 um and shell thickness ranging from a few hundred nanometers to many microns in radial thickness. We created microcapsules with two distinct monomeric blocks and demonstrated that capsules fabricated from these blocks have unique thermal degradation behavior at temperatures from ~ 250 °C to above 300 °C at ambient pressure. We are also investigating the movement of the microcapsules through rough fractures, with an emphasis on understanding the controls on microcapsule exclusion from small fractures that do not require permeability modification and microcapsule entry into larger fractures that are targeted for modification.

1. Introduction

Preferential flow can lead to thermal short-circuiting in enhanced geothermal systems (EGS), which is one of the most important challenges that must be overcome in order for EGS to be economically successful (Lowry et al., 2017). Thermal short-circuiting leads to thermal breakthrough, decreasing energy extraction efficiency, and reduced service life. We are developing polymer-based materials that can be injected into fractures at targeted locations away from the wellbore to modify their permeability and consequently control the resulting flowrate through the

fracture and the heat exchange with the formation. These polymer-based injectates offer an engineering solution for problems associated with preferential flow and thermal short-circuiting. The injectate could be used during initial stimulation and development of the EGS fracture network to tune the fracture network and optimize thermal productivity. Moreover, the injectate could be applied if there is an indication of thermal short-circuiting developing because of the thermal feedback loop. The injectate is designed to displace water from the fracture and harden to form a porous material which bonds to the rock surface (Stormont et al 2020). The injectate is designed to be durable at EGS temperature and pressure conditions. The degree of permeability modification will be adjustable so that the resulting permeability can be tailored for the specific needs of an EGS fracture network.

A schematic of the deployment of the polymer-based injectate is shown in Figure 1. The injectate is introduced into the fracture that is to be modified. The injectate is a mixture of four principal components: a polymer resin, a catalyst (i.e., hardener) to initiate polymerization, a pore-former (polyethylene glycol) and a high-temperature solvent that together will render the polymer porous. The catalyst, the pore former and the solvent can be delivered in microcapsules that incorporate a clocking mechanism based on temperature so they are released at a target location away from the wellbore. The porous nature of the material will allow control on the resulting permeability of the fracture, and prevents the treatment from completely sealing of the fracture. Microcapsules are sized to prevent entry into smaller fractures. Microcapsule rupture initiates as their temperature increases as the moving fluid is heated by the formation. Porous polymer begins to form and bond to the rock due to interaction of polymer resin, catalyst, and solvent. The permeability decrease can be progressively controlled by multiple applications of the injectate. Alternatively, the effect of the intervention can be reversed by adding select acids that will break the bond of the polymer to the rock, and thereby permitting the polymer to be displaced.

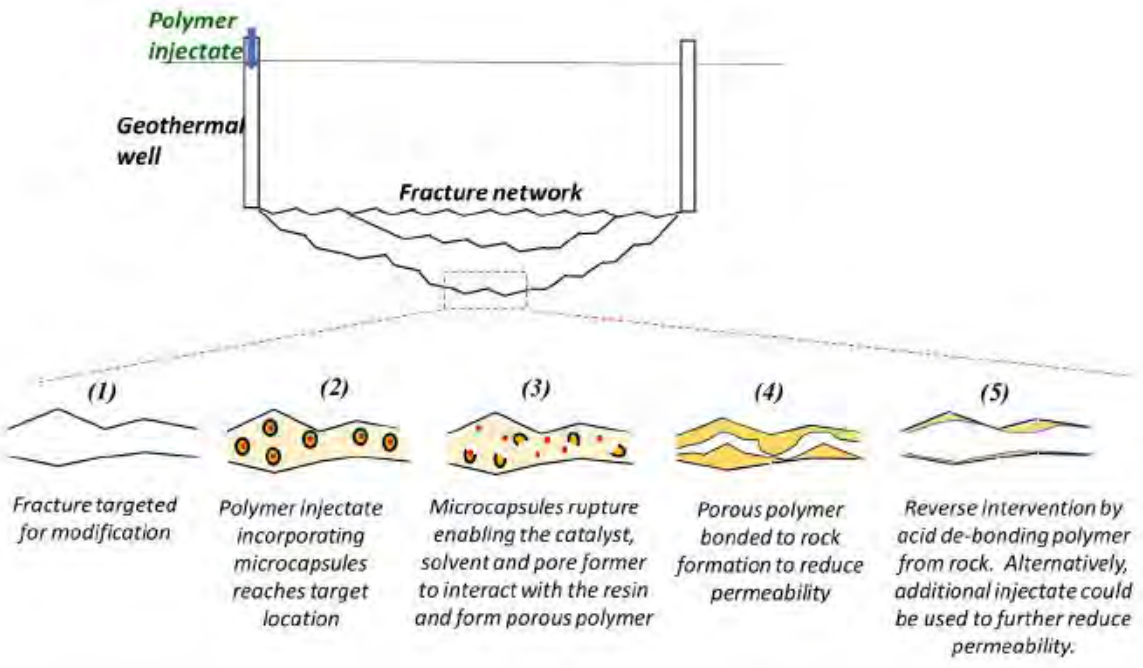

Figure 1: Deployment sequence of a porous polymer to modify fracture permeability.

In this paper, we summarize work directed at advancing this technology toward deployment. The project work is described in terms of polymer development, microcapsule fabrication, and microcapsule transport in rough fractures.

2. Polymer Development and Properties

A new nano-modified Resole-Phenol co-polymer resin was developed. The nanoparticles used were COOH-functionalized multi-walled carbon nanotubes (MWCNTs) or graphene nanoparticles (GNPs). The functionalization of the nanoparticles with the COOH carboxylic groups has been proven to improve the dispersion efficiency (Douba et al., 2017; Soliman et al., 2012). Five formulations of the nano-modified Resole-Phenol co-polymer resins were developed and characterized. The Resole resin was first deactivated using a Phenol deactivation agent then the Resole-Phenol co-polymer resin was reactivated using a curing agent. The degree of crosslinking was measured using differential scanning calorimetry (DSC) to quantify the degree of the Resole resin deactivation as shown in Figure 2. Formulation 5 of the Resole-Phenol co-polymer resin incorporating MWCNTs/Graphene nanoparticles showed the least degree of crosslinking of 15% and therefore was used in the subsequent step.

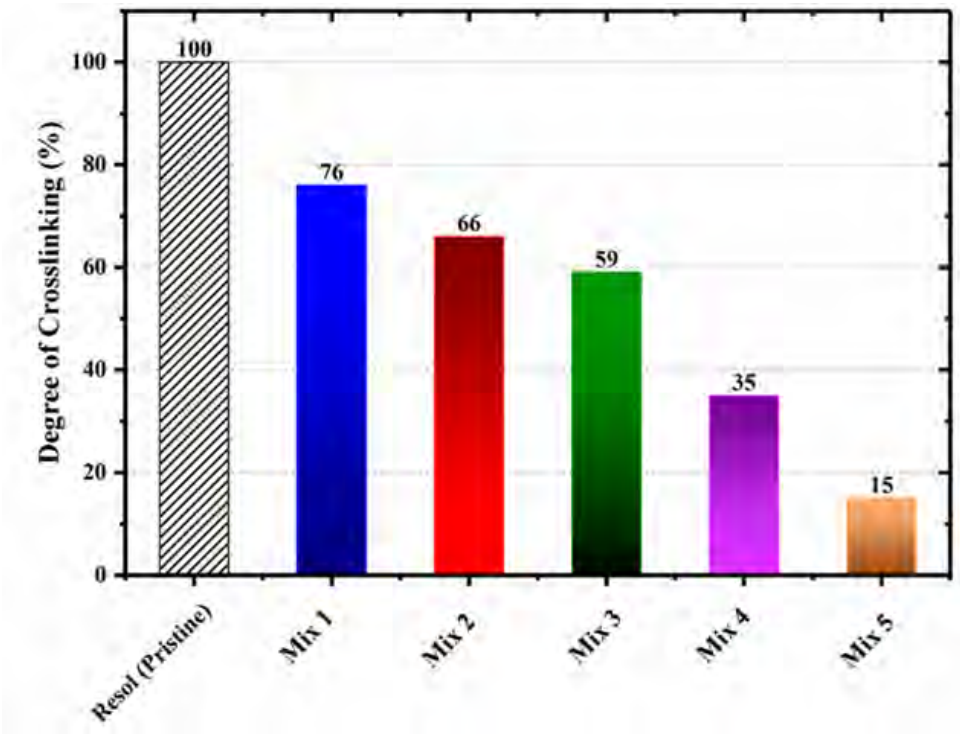

Figure 2: Degree of crosslinking of Pristine Resole resin and five Resole-Phenol formulations. The degree of cross-linking is used to describe the level of the new resin deactivation.

Rheological measurements using a high-temperature rheometer were performed for formulation 5 of the deactivated nano-modified Resole-Phenol co-polymer resin. High-temperature viscosity measurement was performed at 125℃ corresponding to the maximum weight loss observed from the thermal gravimetric analysis (TGA) of the deactivated resin. The new nano-modified Resole-

Phenol co-polymer resin showed a viscosity below 190 cP for 45 minutes which is a relatively low viscosity, very suitable for flow in wellbores and to penetrate microcracks.

Formulation 5 of the deactivated Resole-phenol resin was reactivated using a curing agent. Figure 3 shows the degree of cross-linking of 7 reactivated Resole-Phenol polymers using different curing agents and several mixing ratios. Experimental validation using DSC confirmed the chemical deactivation/reactivation processes, optimizing performance under varying conditions. Two formulations denoted Mix 5_3 and Mix 5_6 was shown to achieve the required level of deactivation necessary to be used as a polymer injectate.

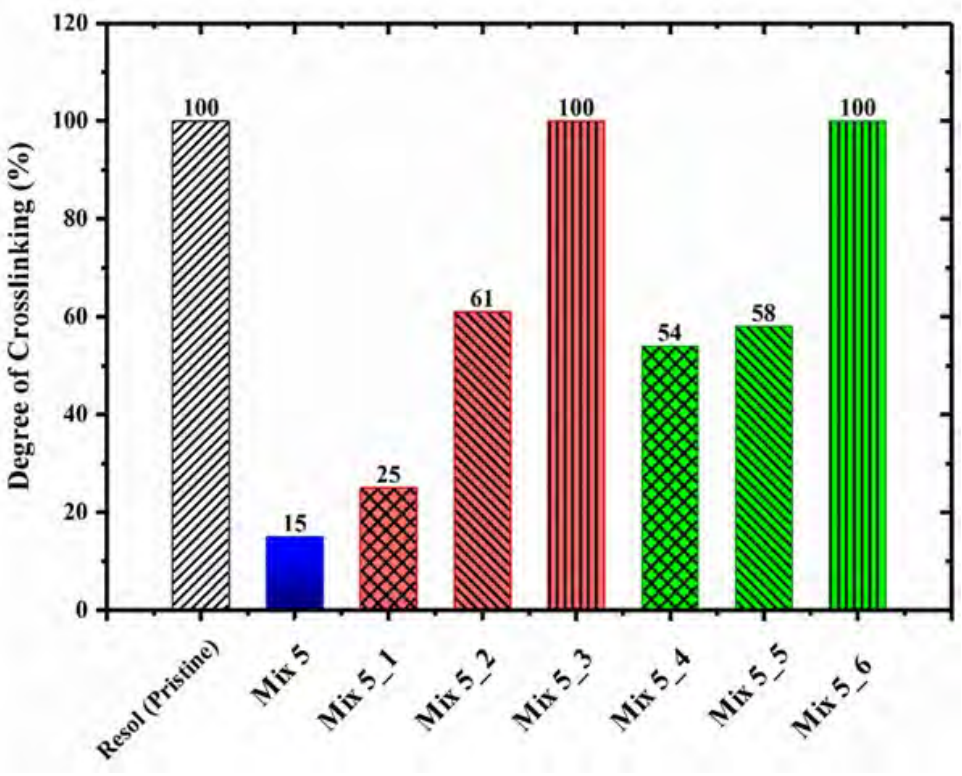

Figure 3: Reactivation of Formulation 5 using different curing agents and mixing ratios

TGA was used to characterize the thermal stability of the activated nano-modified Resole-Phenol co-polymer injectate. The new polymer injectate showed excellent post-curing thermal stability up to 475°C. Based on the analysis from Figure 4, Curing Agent 1 was chosen for further analysis since the activation temperature for Curing Agent 2 is very high. Moreover, using Curing Agent 2 results in the evaporation of the injectate at a temperature below 200°C before activation of the curing agent. Mix 5_6 was selected for further analysis based on the results above-mentioned. The DSC results showed no post-cured crosslinking, crystallization, or melting peaks for the nano-modified Resole-Phenol polymer injectate. The DSC results also showed an increased degree of crosslinking due to the incorporation of COOH-functionalized nanomaterials.

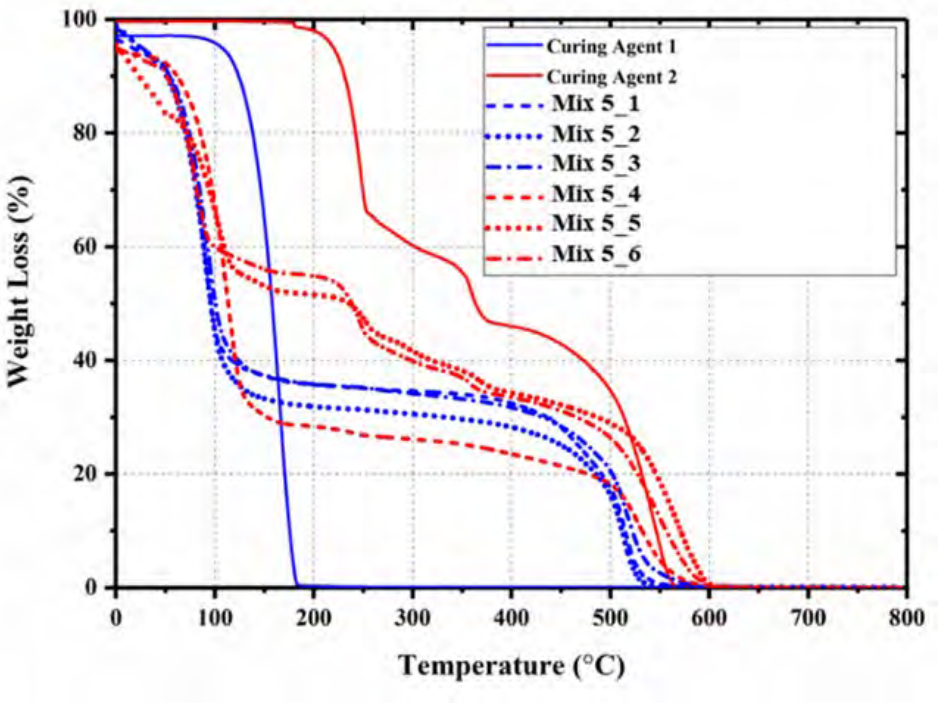

Figure 4: TGA analysis of the nano-modified Resole-Phenol polymer injectate

Characterization of the new nano-modified Resole-Phenol co-polymer injectate included identifying the gelation and setting times and comparing it with the pristine Resole. The new nano-modified polymer injectate showed a gelation time of about 30 minutes and a set time of about 45 minutes compared with 12 minutes of gelation time and 30 setting time for the pristine Resole. The 30-45 minutes of gelation and setting shall be sufficient to apply and use the new polymer injectate in the process to control the permeability of the geothermal wells. Furthermore, the radial and longitudinal shrinkage of the nano-modified Resole-Phenol co-polymer injectate was tested and showed no radial shrinkage and exhibited signs of longitudinal expansion, which could significantly enhance its sealing capabilities. We also performed some wettability measurements of the nano-modified Resole-Phenol co-polymer injectate and found its contact angle to range from 10-25^{o} in ambient temperature and to increase above 40^{o} at high temperatures. The above work showed the feasible development and use of nano-modified Resole-Phenol co-polymer injectate for geothermal wells.

3. Microcapsule fabrication

Thermally stable polymeric shell microcapsules (MCs) containing aqueous or organic cargo were fabricated using double emulsion templates. Droplet microfluidic devices as described previously (Arriaga et al., 2015; Nabavi et al., 2015) were used to fabricate double emulsion templates with liquid monomeric shell material (Figure 5) for chemically diverse acrylic microcapsules with well-defined and monodisperse diameters ranging from 100-500 microns and tunable shell thickness ranging from hundreds of nanometers to microns (see Figure 6), excellent thermal stability and tunable shell thermal decomposition temperatures and kinetics. Acrylic microcapsules are those formed by UV induced radical polymerization of acrylate-based monomers to produce thermosetting polymer shells. This strategy allows for the selection of diverse shell material

monomers to tune capsule (i) thermal stability at temperatures up to 250 °C and (ii) associated thermal decomposition induced release profiles.

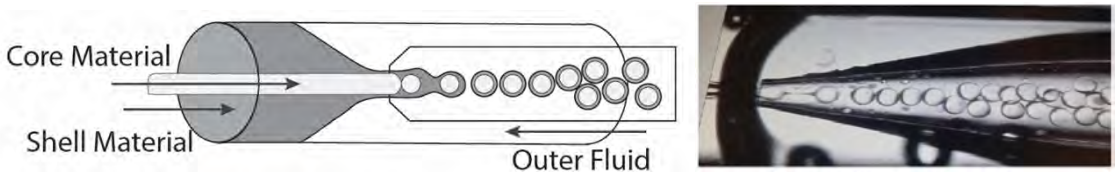

Figure 5: Schematic illustration (left) and microscopy image (right) of capillary microfluidic device used to fabricate double emulsion microcapsule templates.

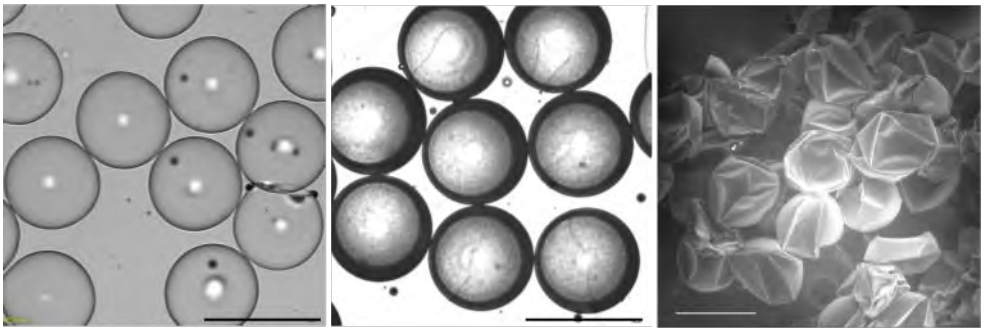

Figure 6: Optical (left, middle) and SEM (right) acrylic microcapsule images. Shell thicknesses can range from hundreds of nanometers (left, right) to microns (middle). Scale bars = 500 microns.

This tunable thermal decomposition behavior is highlighted in Figure 7 where TGA analysis of microcapsules with two different acrylic shells fabricated from acrylate or dimethacrylate monomer composites, respectively, shows resulting distinct thermal decomposition for the two monomers, ranging from around 250 to > 300 °C.

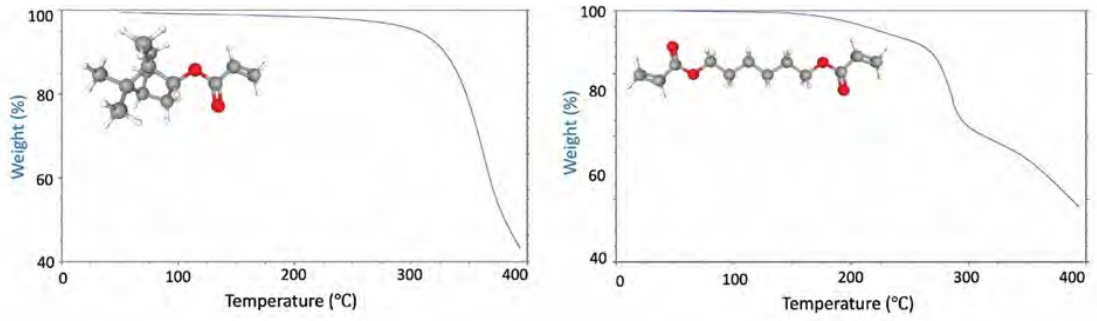

Figure 7: TGA signature curves for acrylate (left) and dimethacrylate (right) derived composite microcapsules.

With respect to thermally stable microcapsules that rupture at design time, we have demonstrated that dimethacrylate derived composite microcapsules rupture after 15 minutes at 320 °C under atmospheric pressure. The time path of rupturing for acrylic microcapsules was assessed by microscopy through imaging of capsules with an air core collected from a 320 °C heated sample (high temperature silicone oil as carrier fluid) at 5, 10, and 15 minutes. We replaced the aqueous core with air by evaporation because the capsules would undergo ‘steam explosions’ when exposed

to temperatures above 100 °C at atmospheric pressure. Results are shown in Figure 8 and reveal that thermal decomposition of the capsule shells results in the rupture of > 80% of the capsules at the 15-minute time mark.

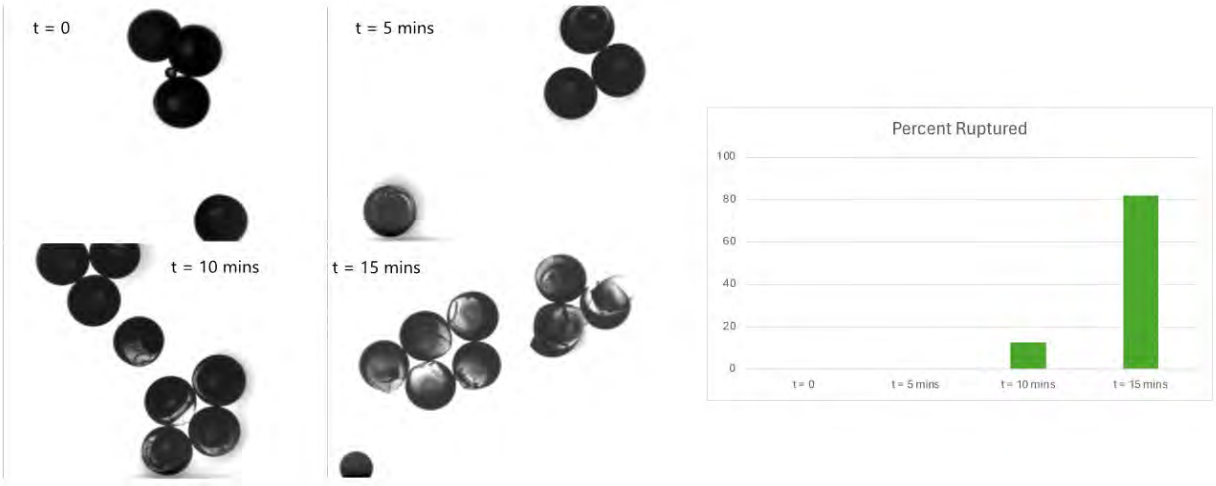

Figure 8: Time series microscopy images of acrylic microcapsules in silicone oil carrier fluid incubated at 320 °C indicate rupturing of >80% of the capsules at the 15-minute time mark.

4. Transport of microcapsules in rough fractures

An understanding of microcapsule movement into and through rough fractures is critical to the technology deployment: microcapsules should be excluded (blocked) from smaller fractures that are not meant to be modified with the polymer.

A flow visualization system has been developed to visualize microcapsule movement in rough fractures. This system has been used to measure microcapsule entry, transport and blocking within fractures to provide data to develop blocking functions for sheared and dilated fractures. The flow visualization system involves establishing steady flow through a transparent fracture replica, microcapsule introduction into the flow stream, video recording of the microcapsule movement, and application of particle tracking software.

Transparent fracture replicas were created from fractured granite specimens. Fracture topography data was obtained from profiling the fracture surface. The fracture replicas were integrated into a flow cell which allowed the fractures to be sheared and dilated to create a fracture network. Fluorescent 1 mm diameter microcapsules were passed through the fractures. By filming the experiments, we could determine the location and amount of blockage (retention) of the microcapsules in the fractures at different amounts of shear and dilation. In addition, a direct method to measure the aperture field of the fracture network was developed using a light transmission technique in which the light intensity through the fracture replica was measured with water and with a dye in order to interpret the fracture aperture field via the Beer Lambert Law. These results reveal that shear displacement creates complicated fracture networks that vary significantly with the amount of shear, consistent with the findings of others.

Particle trajectories within a fracture during flow are shown in Figure 9 for two conditions for the same fracture: normal displacement and shear displacement. When the fracture is normally

displaced, once the displacement allows microcapsules to enter, the flow of microcapsules is relatively uniform in the direction of the hydraulic gradient. In contrast, when this fracture is sheared, the flow of microcapsules is concentrated into channels and moves around locations of small aperture or where microcapsules become blocked.

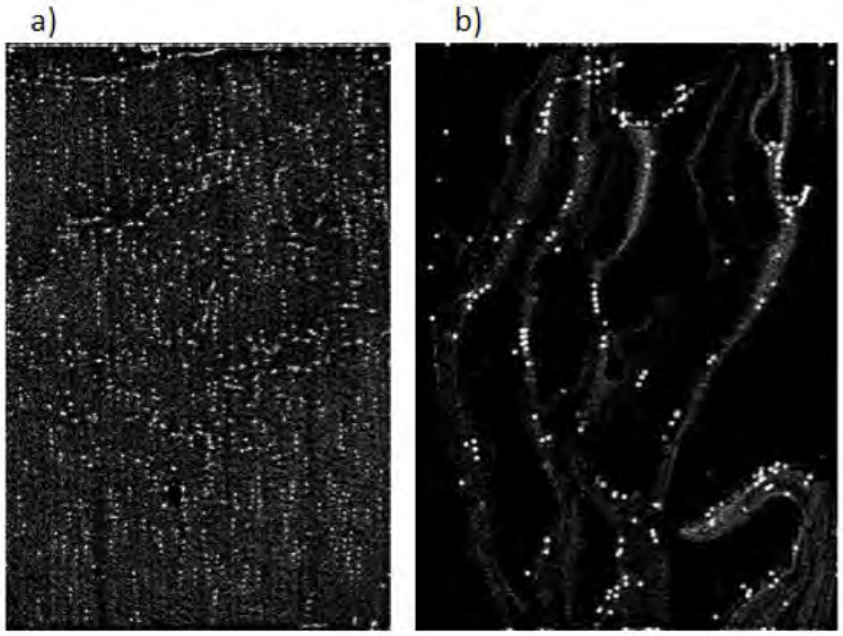

Figure 9: (a) Particle trajectories for normally displaced fracture revealing parallel flow paths over the entire fracture surface. (b) Particle trajectories for sheared fracture displaying tortuous flow concentrated in channels and excluded from large portions of the fracture. Flow direction is bottom to top of figure. White dots are microcapsules moving in well-connected flow paths.

We conducted tests on three different fractures with varying degrees of roughness: fracture C being the smoothest, fracture A of intermediate roughness, and fracture D being the roughest. We relate the blocking results to the hydraulic aperture of the fracture. The hydraulic aperture is the aperture of a smooth-walled parallel fracture that produces the same amount of flow as the rough-walled fracture, and can be related directly to the fracture permeability.

The ratio of hydraulic aperture to microcapsule diameter for complete blockage and no blockage is given in Figure 10. No blockage is the desired condition for fractures that we wish to modify: we can pass microcapsules into this region, and then they thermally degrade and the porous polymer will polymerize. Complete blockage including exclusion of microcapsules from the fracture is suitable for fractures we do not wish to modify, i.e., they are not preferential flow paths that lead to thermal short-circuiting. The results shown in the figure reveal that the hydraulic aperture for no blockage and complete blockage are different for different fractures. The rougher the fracture, the greater the hydraulic apertures are for these conditions. This suggests the blocking criterion may be a function of a roughness measure (such as the joint roughness coefficient or JRC) in addition to the hydraulic aperture.

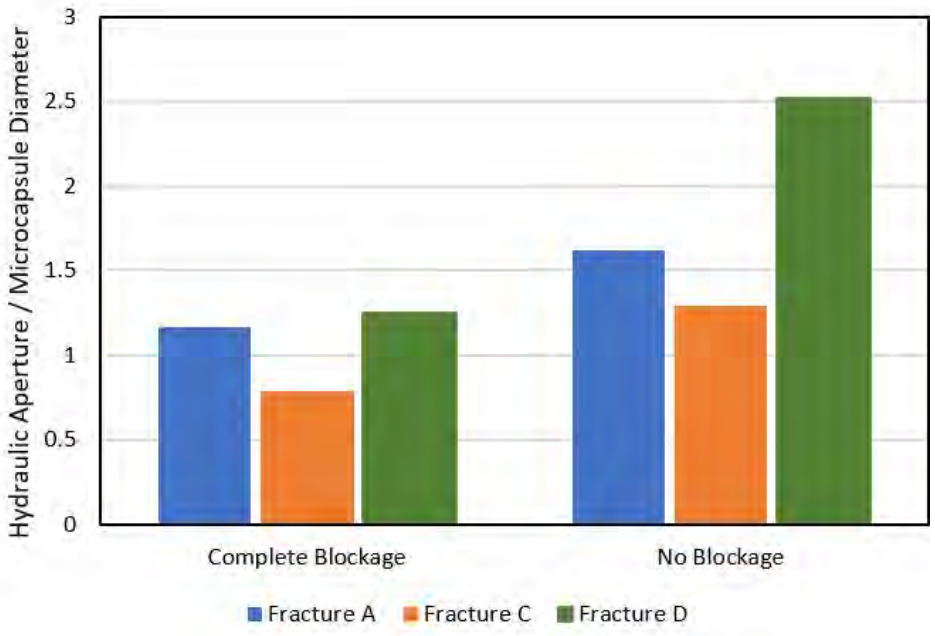

Figure 10: Hydraulic aperture to microcapsule diameter for complete and no blockage for three fractures of different roughness. Fracture C is the smoothest, followed by fracture A, and fracture D is the roughest.

5. Conclusions

Work to date has supported the concept of using a polymer injectate delivered by thermally degradable microcapsules to modify fracture permeability in geothermal wells. We have developed and tested a nano-modified Resole-Phenol co-polymer material, and have shown its properties are favorable for its use as an injectate in geothermal conditions. We have fabricated dimethacrylate derived composite microcapsules that rupture after 15 minutes at 320 °C, demonstrating cargo release as a function of time at geothermal-relevant temperatures. We have increased our understanding of microcapsule transport in rough fractures, demonstrating that the microcapsule to hydraulic aperture ratio for both complete exclusion from a fracture and free flow through a fracture with no blockage increases with the roughness of the fracture. Ongoing efforts are directed at verifying the permeability modification using the polymer in rough fractures, microcapsule survivability during injection, and tuning microcapsule release times for different temperatures.

Influence of Hydraulic Fracturing on Induced Seismicity Based on a Combined Flow and Geomechanical Model

Yuan Tian, Roland Horne

Dept. of Energy Science and Engineering, Stanford University

Keywords

Induced seismicity, hydraulic fracturing, fracture mechanics, fracture flow, EGS

ABSTRACT

This study used a combined flow and geomechanical model to investigate the important role that hydrological and mechanical properties of the stimulated hydraulic fracture played in the observed seismic sequences at the Pohang geothermal site, South Korea. According to the model, the elastic tensile stress transfer from opening of the hydraulic fracture contributed to the Mw 1.7 event that occurred around shut in. The model attributed the subsequent seismically dormant period to deactivation of the tensile stress caused by fracture closure, together with a delayed fluid pressure front. The Mw 5.5 event was explained in the model by a rapid increase in fluid pressure after arrival of the steep pressure front, which was influenced by pressure-dependent permeability in the hydraulic fracture.

1. Introduction

Induced seismicity during hydraulic stimulation in Enhanced Geothermal System (EGS) has been documented in several projects (Lee 2019, Deichmann 2009, Ellsworth 2019). The Mw 5.5 event in Pohang, Korea is the largest in EGS history resulting in huge economical loss and complete shutdown of the project. The Mw 5.5 earthquake occurred unexpectedly at the end of a seismic sequence in the final stimulation, which began with a relatively small seismic event (Mw 1.7) around shut in, which was followed by a seismically dormant period until the big Mw 5.5 event happened (Ellsworth 2019, Kim 2022). The failure of empirical relationships to constrain the maximum earthquake magnitude and the absence of small precursory seismic events to activate the mitigation strategy (the so-called traffic light system) indicates a gap in understanding of the underlying mechanisms. Therefore, there is a clear need to better understand the causal mechanisms to improve prediction and mitigation of induced seismicity.

Several mechanisms have been proposed for the observed seismic events at Pohang. A common effect shared by all the proposed mechanisms is fluid pressure (Ellsworth 2019) which suggests there was a connected hydraulic pathway between the injection well and the fault. The type of

hydraulic pathway influences the accompanying mechanisms in addition to the fluid pressure. One possibility is that the fault zone serves as the hydraulic pathway represented as a permeable porous medium for fluid to flow through. Ellsworth et al. (2019) proposed that pressure diffusion from the injection well to the fault was a key factor for the two largest seismic events in the two stimulations. Yeo et al. (2020) proposed that the combination of static shear transfer from seismic events in the previous stimulation, together with the fluid pressure, contributed to the Mw5.5 event. Chang et al. (2020) proposed that continuous poroelastic stressing accompanied with flow in the damaged zone, together with pressure diffusion, contributed to the Mw 5.5 event. For flow in permeable porous media, it is notable that both the pressure diffusion and the accompanying poroelastic stressing show a diffusive gradual evolution which could explain the occurrence of Mw 5.5 event but may not fully explain the seismically dormant period before it.

Another possibility is that the stimulated fracture served as the hydraulic pathway proposed by Kim et al. (2022). Mechanisms related to the hydraulic and mechanical properties of the stimulated fracture can provide alternative explanations for seismic events. Park et al. (2020) observed reversible and pressure-dependent permeability in the stimulated hydraulic fracture in PX-2, which contrasts to the less pressure-sensitive permeability in porous media. This pressure-dependent permeability results in a steeper pressure front compared to the smoother and more diffusive pattern in media with pressure-insensitive permeability such as a porous medium, which was analyzed in Hummel et al. (2009). The steep pressure front can result in a drastic increase in pressure after the arrival at the fault, which may shorten the time for fault slip to evolve into a large earthquake. Besides, the induced stress field associated with the deformation of the stimulated fracture can also perturb the in-situ stress of the fault and influence the pattern of seismic events. Kim et al. (2022) proposed that shear stress transfer from the hydroshearing fracture in PX-1 well could have contributed to the seismically silent period during PX-1 stimulation. It is possible that the tensile stress associated with the opening of the hydraulic fracture could also influence the induced seismicity in EGS although this has not yet been fully investigated for the case of Pohang. Evidence of the influence of tensile opening on perturbation of in-situ stress includes seismic anisotropy (Igonin et al., 2022) and the spatial-temporal distribution of seismic events (Kettlety et al., 2019). Therefore, further study is needed to better understand the role of tensile stress from fracture opening on seismic events in EGS.

We investigated the role that hydrological and mechanical properties of the stimulated hydraulic fracture may have played in the seismic sequences during the third stimulation in PX-2. The modelling results indicate that tensile stress transfer from the opening of the hydraulic fracture could have contributed to the relatively small seismic event (Mw 1.7) around the time of shut-in. The subsequent seismically dormant period can be explained by the deactivation of tensile stress because of fracture closure and the delayed arrival of the pressure front. The final large earthquake (Mw 5.5) could be attributed to a rapid increase in pressure once the pressure front arrived at the fault.

2. Problem formulation

This work investigated the influence of the hydraulic fracture in PX-2 well on the seismic sequence during the third stimulation where the large Mw 5.5 earthquake occurred with a two-month delay after the shut in. PX-2 is characterized as a hydraulic-jacking dominated well (Min et al. 2023) with the maximum wellhead pressure up to 90MPa, exceeding the minimal principal stress of

64MPa shown in Figure 1 (left). The third stimulation in PX-2 began in September 2017 with 2335 m^3 water injected. Figure 1 (right) shows the history of injection-volume and observed seismic events. An initial Mw 1.7 event happened around shut in, followed by a seismically dormant period with no detected seismic events. The Mw 5.5 earthquake then happened suddenly without observable increase in smaller precursory seismic events.

The conceptual figure of the model used to investigate the influence of hydraulic fracturing on induced seismicity is shown in Figure 2, which is based on the configuration of PX-2 injection well and the Mw 5.5 fault at Pohang. The stimulated fracture plane represents the hydraulic jacking dominated fracture in PX-2 which can intersect with a fault nearby. The blue point represents the injection well in PX-2 and the red point represents the fault which is 153m from the injection point. During the injection period, fluid pressure propagates towards the fault. The region around the injection point is under higher pressure and can induce opening when the fluid pressure exceeds the minimum principal stress. The induced tensile stress field associated with the opening can influence the stress field and perturb the in-situ stress of a fault nearby. Two contributions to the perturbation of the in-situ stress on fault are considered. One is fluid pressure which is active after the pressure front arrives. The other is tensile elastic stress transfer due to fracture opening as a long-range effect.

Figure 3 shows a flow chart of the modelling procedure. Based on the input injection strategy and hydrological parameters of the stimulated fracture, transient fluid pressure can be computed in the two-dimensional flow model. The pressure result is treated as an input into the fracture mechanics model to compute the tensile stress field away from the open hydraulic fracture. The total decrease of normal stress on fault is the sum of the tensile stress and the fluid pressure. The decrease is treated as input into the seismicity model, where slip evolution is computed as an indicator for seismic sequences.

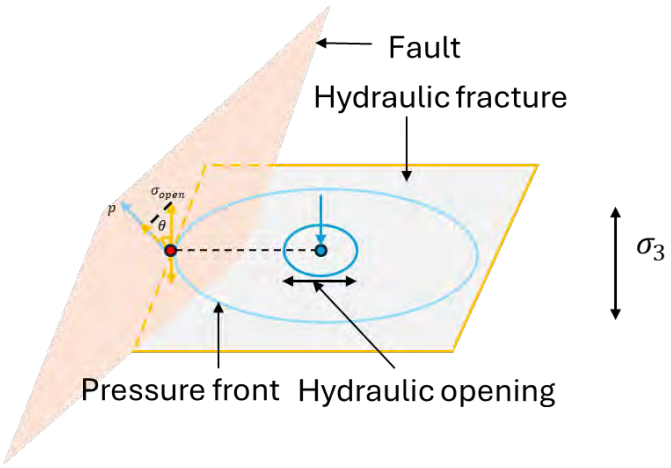

Figure 2: Induced seismicity on fault caused by the stimulated hydraulic fracture

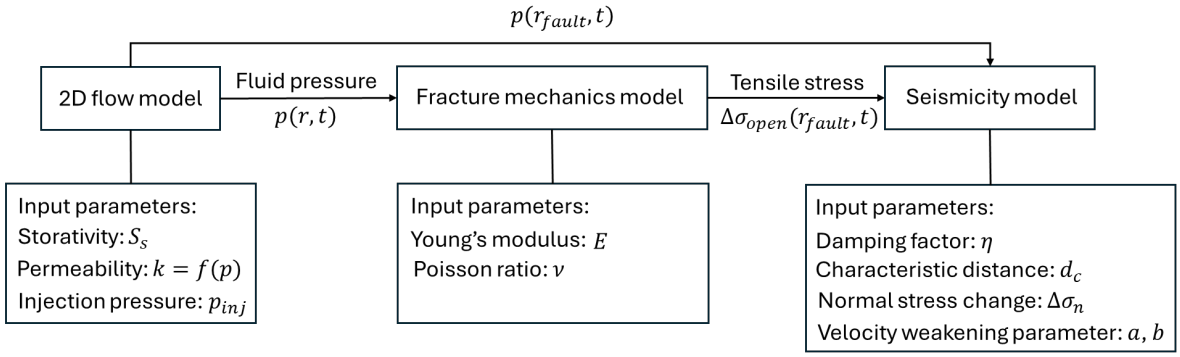

Figure 3: Flow chart of the modelling procedure: combine a flow model and a geomechanical model

2.1 Fluid flow: pressure diffusion in fracture

In Enhanced Geothermal Systems, fractures generally have larger permeability than the basement rock and are expected to become the dominant flow pathways. The permeability of fractures is dependent on the fracture aperture as described by the so-called cubic law in Witherspoon et al. (1980), which is influenced by effective stress on the fracture plane. This results in pressure-dependent permeability in fractures. Park et al. (2020) observed that the permeability of the stimulated fracture in PX-2 well showed nonlinear and reversible changes with wellhead pressure as shown in Figure 3 (left). When the wellhead pressure exceeds the minimal principal stress (around 60MPa), the aperture increases more rapidly. Hummel et al. (2009) analyzed the difference in pressure distribution under pressure-dependent permeability and constant permeability, showing that the pressure-dependent aperture combined with the cubic law results in a steeper pressure front compared to the smoother and more diffusive pressure distribution in the case of constant permeability. Therefore, it is necessary to account for the pressure-dependent permeability in fracture flow to obtain a more accurate pressure distribution. In this work, pressure-dependent permeability was considered based on the observed relationship between permeability and wellhead pressure in well PX-2.

2.1.1 Governing equations

The pressure diffusion equation is:

$$\rho S \frac{\partial p}{\partial t} = \nabla \left(\frac{\rho k}{\mu} \nabla p \right) + q_m \tag{1}$$

where $\rho(kgm^{-3})$ is fluid density, $S(Pa^{-1})$ is the specific storage coefficient, $k(m^2)$ is permeability, $\mu(Pa \cdot s)$ is fluid viscosity and $q_m(kgm^{-3}s^{-1})$ is a mass source. The permeability and the aperture-pressure relationship is expressed as:

$$k = \frac{b^2}{12} \tag{2}$$

$$b = b_0 e^{d_0 p} \tag{3}$$

$$k = f(p) = \frac{{b_0}^2 e^{2d_0 p}}{12} \tag{4}$$

2.1.2 Model settings

Figure 4 shows the geometry of the flow model used to simulate the two-dimensional radial flow on the stimulated fracture plane. The model geometry is a square in Figure 1(left) with fluid injected into the element in the center. Only the overpressure caused by injection is modelled and formation pressure is ignored. Initial pressure is 0MPa. It should be noted that the boundary condition at the injection point represents the wellbore. The wellbore condition used in the work is a simplification of the actual injection history. In the model, constant pressure control was used, and the injection pressure was fixed at 90MPa during injection, which was the maximum wellhead pressure during stimulation in PX-2. In future modeling, the real injection history will be implemented and a detailed calibration on the flow model parameters will be done by matching the wellhead pressure history given the injection rate history.

The aperture-pressure relationship can be matched with the observation data in Park et al. (2020) shown in Figure 3 (left) by an exponential function described in Rutqvist et al. (2003) shown in Figure 3 (right). The pressure-dependent permeability relationship is used in the flow model. Figure 3 (right) shows that permeability of the PX-2 fracture varies over three orders of magnitude from 10^{-12} to 10^{-8} m^2 from 0 to 90 MPa.

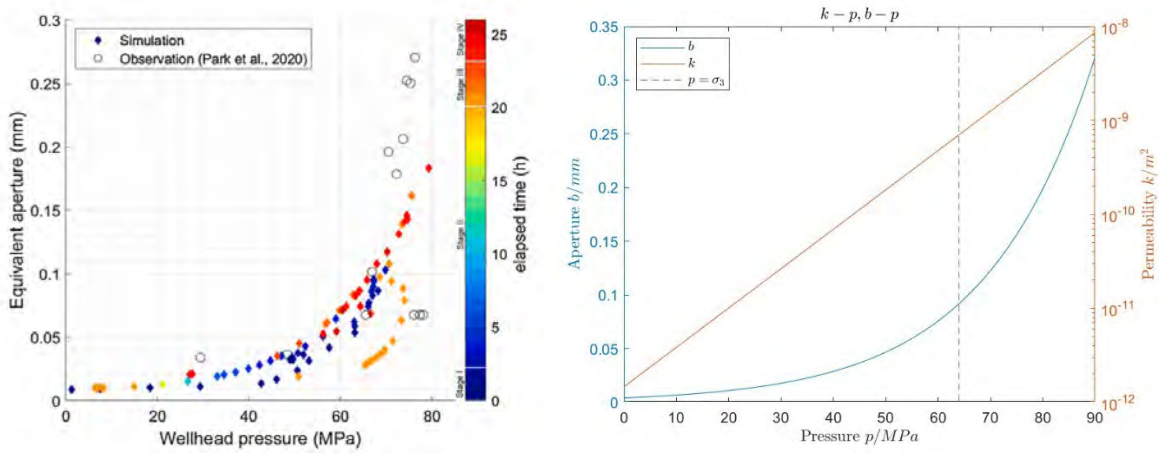

Fig 3: Observation on aperture-wellhead pressure relationship in PX-2 well (left) in Park et al. 2020, permeability-pressure and aperture-pressure relationship used in the simulation (right)

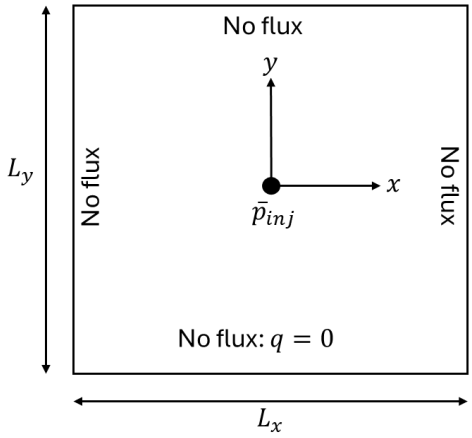

Fig 4: Flow model: geometry and boundary condition

Table 1: Parameter settings in the fluid flow model

Parameter	Value
Storage coefficient S	0.1
Initial aperture b	0.0042 mm
Curvature of aperture- pressure relationship d_0	0.0482 MPa^{-1}
Fluid viscosity	0.001 $Pa \cdot s$
Fracture length L_x, L_y	720 m
Injection pressure $\bar{p}_{inj}$	90 MPa
Duration of injection time t_{inj}	31200 s
Total time t_{end}	62400 s

2.1.3 Model limitations and future work

A key limitation of the current work is how well the spatial-temporal fluid pressure distribution produced by the fluid flow model represents the actual conditions at Pohang. As the first step in the modelling procedure shown in Figure 2, the accuracy of the fluid pressure results directly influences two factors contributing to the seismicity on fault: fluid pressure and tensile stress. Fluid pressure is influenced by hydrological properties (storativity coefficient, permeability), fracture length (model size) and injection strategy (boundary condition on the injection point). In this study, a simplified input injection strategy with an injection period and a subsequent shut in period was used. In comparison, the real scenarios at Pohang involved multiple cycles of injection and shut-in known as the cyclic injection, evidenced by the periods of stable injection volume shown in the injection volume-time data in Kim et al. (2022). Besides, model parameters including the hydrological properties and the fracture length need to be constrained by the output pressure at the injection point to match the wellhead pressure history observed in Pohang.

2.2 Fracture mechanics: Tensile stress caused by fracture opening

Based on the fluid pressure, the region where pressure is larger than the minimal principal stress σ_3 is identified as hydraulic opening segments The fracture opening, denoted as $[u]_n$, is assumed to develop under net pressure as p_{net} which is the difference between the fluid pressure and the minimal principal stress. The elastic opening is associated with a tensile stress field extending beyond the opening segments, which perturbs the stress field in the surrounding rock and influences the in-situ stress on a fault nearby.

2.2.1 Governing equations

Within the open hydraulic fracture $r < R_{open}(t)$ where r denotes the distance away from the injection point, the fracture opening can be related to the net pressure acting as the normal traction by the force equilibrium of rock with embedded displacing fractures. Because shear stress is assumed to be zero in the open fracture, the force equilibrium in three directions can be simplified to only in the normal direction shown in Eq. (5). The interaction coefficient matrix **C** relates the normal discontinuity (opening) and the normal traction on the fractures. The matrix is influenced by the fracture geometry and the mechanical properties of the rock as Young's modulus and Poisson's ratio. In this work, **C** was computed using the open-source Displacement Discontinuity Method code (DDFS) developed by Wong et al. (2021).

$$\boldsymbol{C}[\boldsymbol{u}]_n = \boldsymbol{p}_{net} \tag{5}$$

$$\boldsymbol{p}_{net}(t) = \boldsymbol{p} - \sigma_3 \tag{6}$$

For the region beyond the open hydraulic fracture $r > R_{open}(t)$, the stress field is influenced by the elastic tensile stress associated with the hydraulic opening fracture.

$$\sigma_{open}(r,t) = -\frac{E}{(1-\nu^2)4\pi}\int_0^{R_{open}(t)} \frac{\partial [u]_n(s,t)}{\partial s}\frac{sds}{r-s} \tag{7}$$

Based on the radius of the hydraulic fracture R_{open} and the net pressure inside $p_{net}(r)$ in the two-dimensional radial flow model, the tensile stress caused by the hydraulic opening beyond the hydraulic fracture $\Delta\sigma_{open}(r,t)$ can be obtained from the fracture mechanics model. The tensile stress $\Delta\sigma_{open}$ is perpendicular to the stimulated fracture and parallel to the minimal principal stress σ_3. r refers to the distance from the injection point.

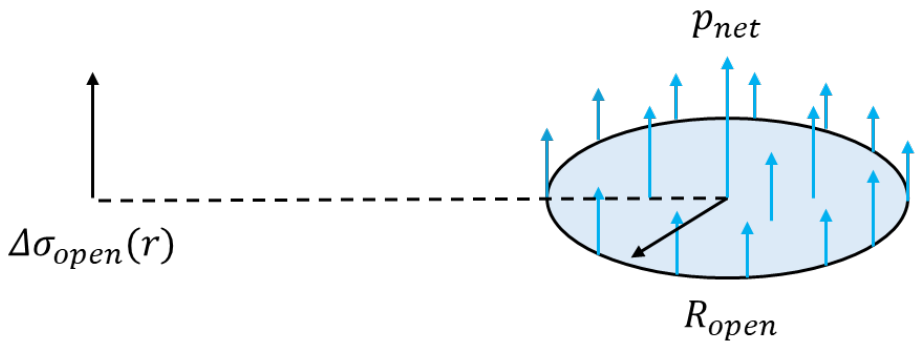

Fig 5: Tensile stress on associated with the opening of the hydraulic fracture

2.2.2 Model settings

A two-dimensional fracture plane embedded in the infinite elastic rock is modelled to simulate the opening in the open segments and the tensile stress beyond the opening fracture. Inside the radius of the open hydraulic fracture, the fracture opens up in the normal direction of the plane under the net pressure distribution. Tensile stress associated with the opening is computed based on the distance from the injection point.

Table 2: Parameter settings in the fracture mechanics model

Parameter	Value
Fracture radius R_{open}	Based on p
Net pressure distribution p_{net}	Based on p
Young's modulus	0.0482 MPa^{-1}
Poisson ratio	0.001 $Pa \cdot s$

2.3 Induced seismicity

From observations, induced seismicity often occurs as a series of seismic sequences. When in-situ stress of a fault is perturbed, the slip velocity and shear stress on the fault evolve in stages including nucleation, rupture propagation, rupture arrest and fault restrengthening. The rate-and-state friction model (Dieterich et al., 1992) is one of the commonly used constitutive models for friction coefficient, which can effectively capture the fault frictional behavior in induced seismicity (McClure et al., 2011).

2.3.1 Governing equations

$$\tau - \eta v = f(v,\theta)\sigma_n \tag{8}$$

$$\sigma_n = \sigma_n^0 - \Delta\sigma_n = \sigma_n^0 - \sigma_{open} - p \tag{9}$$

$$f(v,\theta) = f_0 + alog\frac{v}{v_0} + blog\frac{\theta}{\theta_0} \tag{10}$$

$$\frac{d\theta}{dt} = 1 - \frac{\theta v}{d_c} \tag{11}$$

The evolution of shear stress (τ) and slip velocity (v) in a seismic cycle under quasi-dynamic equilibrium can be described by Eq. (8). η is the damping factor accounting for the energy dissipation in slip. $f(v,\theta)\sigma_n$ is the shear resistance based on the normal stress σ_n. In the rate-and-state friction model, the friction coefficient depends on the slip velocity v and state variable θ described in Eq. (10). The state variable considers the influence of slip history described in Eq. (11). In this work, induced seismicity was assumed to be driven by a decrease of normal stress ($\Delta\sigma_n$) which includes contribution from the tensile stress from opening (σ_{open}) and fluid pressure (p).

2.3.2 Model settings

In this work, the fault was simplified to a single point at the intersection with the stimulated fracture, shown as a single red point in Figure 2. The evolution of slip velocity at the point driven by perturbation on normal stress of fault $\Delta\sigma_n$ was modelled to indicate the observable seismic magnitude. Eq. (8) to -Eq. (11) are solved using a third-order Runge-Kutta method (McClure 2011, Noda 2009, Ozawa 2023).

Table 3: Parameter settings in the seismicity model

Parameter	Value
Reference friction coefficient f_0	0.6
Reference slip velocity v_0	$10^{-6}\,m/s$
Direct effect parameter a	0.01
State evolution parameter b	0.013
State evolution distance d_c	$0.0015m$
Radiation damping coefficient η	50MPa·s/m
Stiffness	2.5MPa/m
Initial shear stress τ_0	60MPa
Initial normal stress σ_{n0}	99.5MPa
Initial state variable θ_0	0.6

3. Results and discussion

3.1 Transient pressure with pressure-dependent permeability

Figure 6 shows the pressure distribution in one dimension with the pressure-dependent permeability at the time of shut in and at the end of the simulated time. Figure 8 and Figure 9 show

the pressure and permeability distribution in two dimensions. A steep pressure front is observed in Figure 6 where the pressure changes rapidly within a small distance. Inside the pressure front, pressure is relatively high and close to the injection pressure. However, pressure drops to almost zero beyond the front. For comparison, the pressure distribution under constant permeability is shown in Figure 7 with high and low permeability levels. In the constant permeability case, pressure shows a smoother diffusive pattern. In addition, the pressure decrease around the injection point is more distinct compared to the pressure-dependent permeability case.

Based on the pressure distribution in the pressure-dependent permeability case, the length of the opening fracture which initiates around the injection point grows during injection. However, the length of the opening hydraulic fracture is smaller and almost zero under both constant high and low permeability cases shown in Figure 7 because of the large pressure drop around the injection point. After shut in, the pressure front under pressure-dependent permeability keeps going forward which is still steeper than constant permeability but smoother than during injection. For places far away from the injection point, it is possible that the fluid pressure front arrives after shut in and causes a large pressure increase.

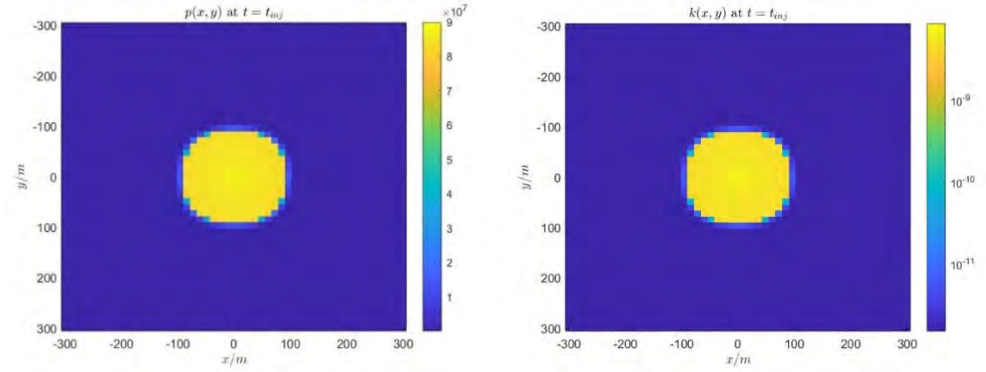

Figure 8: Fluid pressure and permeability on the fracture plane at $t = t_{inj}$: pressure dependent permeability

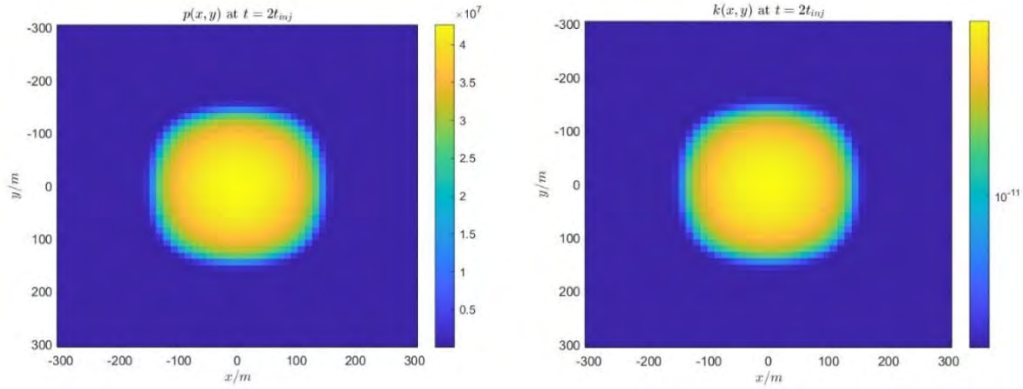

Figure 9: Fluid pressure and permeability on the fracture plane at $t_{end} = 2t_{inj}$: pressure dependent permeability

3.2 Tensile stress accompanied with opening in hydraulic fracture

Figure 10 shows the net pressure distribution within the open hydraulic fracture and the tensile stress beyond the fracture associated with the fracture opening. The tensile stress decreases with

distance away from the injection point in 1/r order. It has been noted that earthquake events can be triggered on critically stressed faults when the perturbation in normal stress on the fault reaches 0.01MPa (Ellsworth et al., 2019). In Pohang, the net pressure at the wellhead can reach up to 20 MPa. Based on the injection strategy used in this work, Figure 10 (right) shows that σ_{open} can exceed 0.01MPa when $r/R_{open} < 2$. This suggests that tensile stress can contribute significantly to the total change in normal stress change if the fault is located inside a region with a specific distance from the injection point. The distance from the PX-2 well and the activated Mw5.5 fault ranges around 200m. The fault was represented as a single point located at $r = 153m$ in the work.

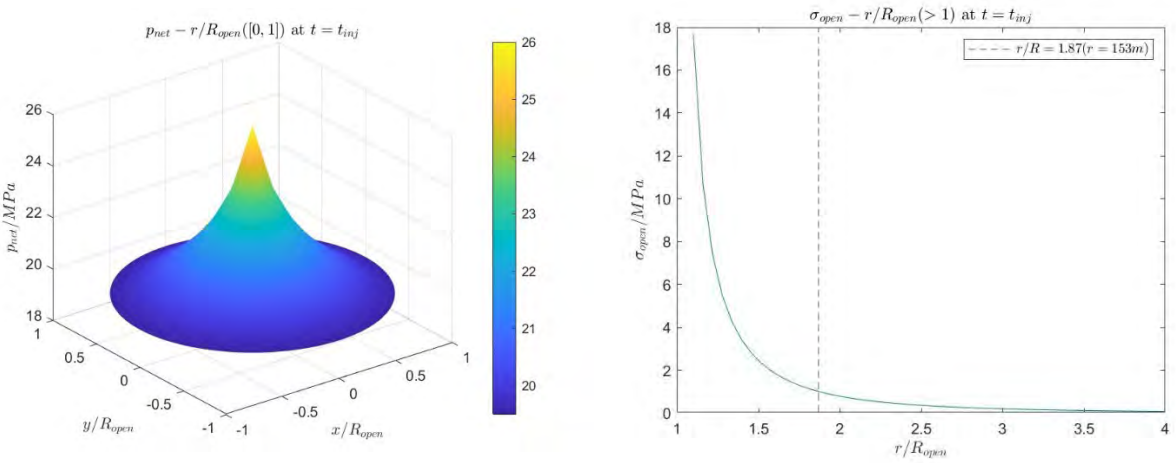

Figure 10: Tensile stress σ_{open} with distance away from the injection point r (left), net pressure p_{net} inside the hydraulic open fracture (right)

Figure 11 shows the evolution of the tensile stress and fluid pressure at the fault where $r = 153m$. Two key contributions to the total normal stress change on a fault include the tensile stress σ_{open} and the fluid pressure p. The simulated period can be divided into four stages based on the activation of the two sources.

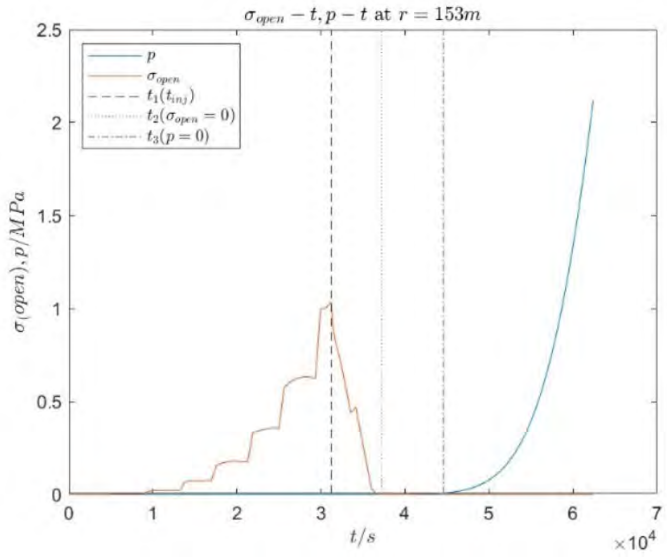

Figure 11: Tensile stress σ_{open} and fluid pressure p with time on the fault ($r = 153m$)

During the first stage from $t = 0 \sim t = t_1(t_{inj})$, only the tensile stress σ_{open} is prominent. The magnitude of σ_{open} increases with time because of the lengthening of opening fracture and reaches a peak around 1MPa at t_1 before injection stops at shut-in. Fluid pressure has not reached to the fault and the contribution from p is inactive. The second stage occurs from $t_1(t_{inj})$ to $t_2(\sigma_{open} = 0)$ during which σ_{open} decreases to zero in a short time after shut-in. After shut-in, the pressure around the injection point drops significantly and falls below σ_3. This pressure drop leads to the closure of the open hydraulic fracture and leads to inactivation of the tensile stress. The third stage ranges from $t_2\big(\sigma_{open} = 0\big)$ to $t_3(p = 0)$ during which both σ_{open} and p are inactive. The fourth stage occurs from $t_3(p = 0)$ to t_{end}. During that stage, the pressure front reaches the fault, causing a rapid rise in fluid pressure p over a short period. The maximum p is 2MPa reached by the end of the simulated time.

Based on the injection strategy, geological parameters in hydrology and mechanics, and fault location assumed in this work, the contributions of fluid pressure p and tensile stress σ_{open} on fault were active at different times throughout the stimulation. The tensile stress σ_{open} becomes active sooner than pressure p because of the long-range character of elastic stress transfer which outpaces the transport of the pressure front.

At the start, only tensile stress σ_{open} is active until around the time of shut-in, reaching its maximum value at the shut-in. Shortly after the shut-in, σ_{open} decreases to zero as the hydraulic opening closes. There is an interval between $t_2\big(\sigma_{open} = 0\big)$ and $t_3(p = 0)$ where both σ_{open} and p are inactive. Eventually, the pressure front arrives after some delay after shut-in causing a rapid increase in p. The maximum pressure is reached at the end of simulated time with a magnitude twice that of the maximum tensile stress.

3.3 Evolution of slip velocity on the fault

The tensile stress accompanying the hydraulic opening σ_{open} , together with the fluid pressure p contributes to the total decrease of normal stress on fault $\Delta\sigma_n$ as shown in Figure 12. Considering that the $M_w 5.5$ fault of Pohang seems to have been in a critical state (Ellsworth et al., 2019), the in-situ stress at the point representing the fault in this work was also assumed to be in a critical state. At this point, the initial shear stress τ_0 is balanced with the product of the static friction coefficient f_0 and the initial normal stress as σ_{n0}. When the normal stress decreases, it triggers the onset of a seismic cycle, with the evolution of slip velocity shown in Figure 13.

In Figure 13, slip velocity starts to increase as the injection starts, driven by the rising $\Delta\sigma_n$ contributed by the tensile stress from opening σ_{open}. A local peak in slip velocity is reached at the time of shut-in, coinciding with the maximum $\Delta\sigma_n$, which may indicate the occurrence of a small seismic event. Although the increase in slip velocity happens after the pressure surge upon arrival of the pressure front, the slip velocity spikes with four orders of magnitude increase from 10^{-6} m/s to 10^{-2} m/s over a short time, which could suggest the occurrence of a large earthquake at the end of the simulated time, considerably later than the shut-in.

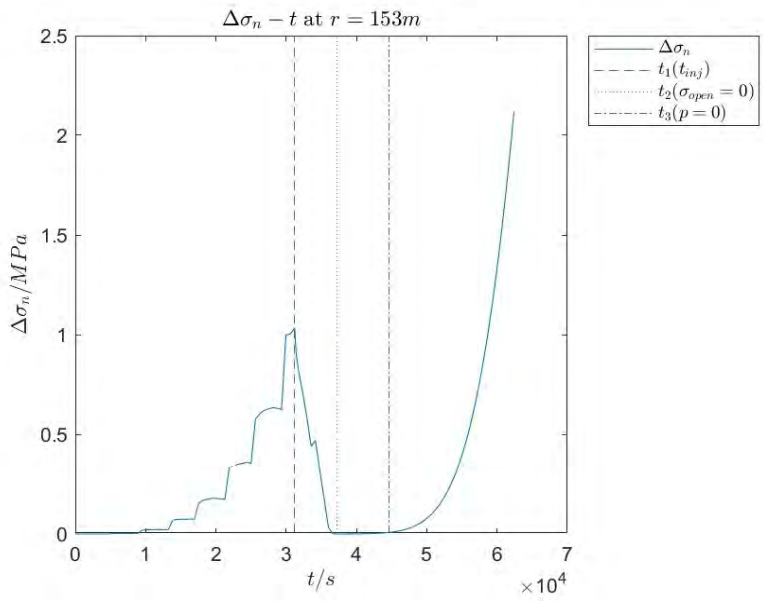

Figure 12: Total decrease in normal stress with time on $r = 153m$

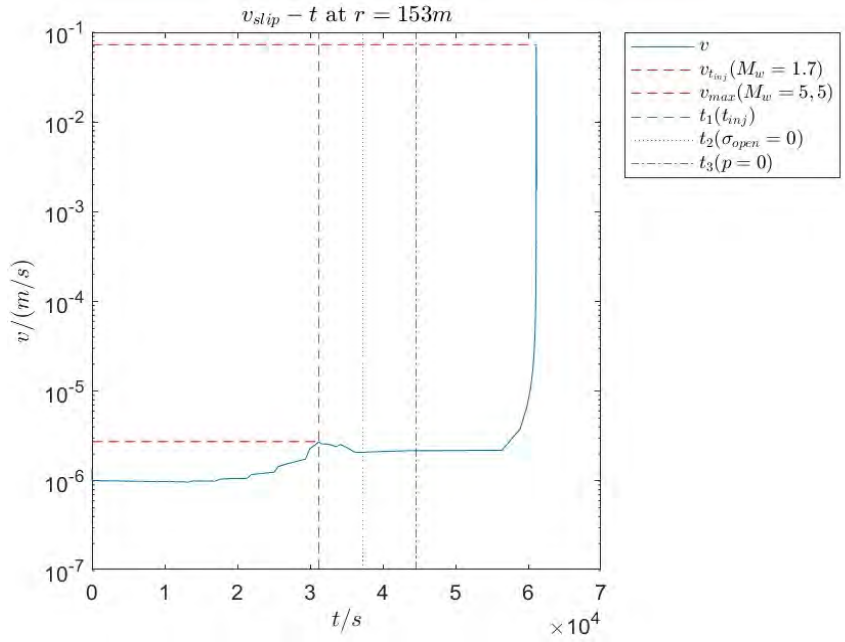

Figure 13: Slip velocity with time under the total decrease in normal stress on $r = 153m$

3.4 Discussion on the proposed alternative mechanism for seismic events in Pohang compared with the existing mechanisms

This work investigated the influence of stimulated hydraulic fractures in well PX-2 on the seismic events observed in the third stimulation of well PX-2. During the stimulation, a small seismic event Mw 1.7 was observed around the shut-in time, followed by a seismically dormant period before a large seismic event Mw 5.5 that occurred two months after the shut-in.

The combined effects of the mechanical and flow properties of the hydraulic fracture could be an alternative mechanism explaining the observed seismic events. Tensile stress transfer from the opening of the hydraulic fracture initiates the slip contributing to the Mw 1.7 event around shut-in, which is shown as a local velocity peak in Figure 13. Tensile stress becomes inactive shortly after shut in due to the fracture closure resulting from the pressure drop. The fluid pressure pattern, which is influenced by the pressure-dependent permeability of the stimulated hydraulic fracture, accounts for both the seismically dormant period and the occurrence of the Mw 5.5 earthquake later. The spatial distribution of pressure shows a steep pressure front under the pressure-dependent permeability condition compared with the smoother, more diffusive pressure pattern under the constant permeability condition. Before the pressure front arrives, the fluid pressure remains inactive which contributes to the seismically dormant period shown as relatively low slip velocity. The rapid increase in fluid pressure after the arrival of the front contributes to the delayed large Mw5.5 earthquake shown as a spike in slip velocity.

Several mechanisms have been proposed to account for the observed seismic events in Pohang during alternative stimulation between the two wells and cyclic stimulation in a single well. The proposed alternative mechanism shares some similarities with these existing mechanisms but also differs in both the mechanism and the specific time range of the seismic events it focuses on. A common mechanism shared by all the mechanisms is the fluid pressure, which assumes a connected hydraulic pathway between the injection point and the fault. Different types of the assumed hydraulic pathway result in different accompanying mechanisms besides fluid pressure.

On one hand, the hydraulic pathway can be provided by the fault zone, with fluid flowing from the injection point to fault through a permeable porous medium with either homogeneous or heterogeneous permeability. Studies by Yeo et al. (2020) and Ellsworth et al. (2019) considered a fault zone with heterogeneous permeability, characterized by a high-permeability damaged zone around the injection point and a low-permeability fault core. The damaged zone facilitates pressure propagation from the injection point, while the fault core slows down the diffusion around the fault. Ellsworth et al. (2019) shows that fluid pressure on the fault which is hundreds of meters away from the injection point can reach the level capable of triggering the earthquakes and the pressure can persist months after the injection period. This pressure behavior contributed to the Mw 3.4 event and the delayed Mw 5.5 event later associated with the PX-2 well. Yeo et al. (2020) proposed that static shear transfer from the Mw 3.4 event in the previous stimulation, combined with fluid pressure, contributed to the delayed Mw 5.5 event. Chang et al. (2020) assumed a constant permeability fault zone and proposed that the continuous poroelastic stressing under alternate stimulation between two wells, together with pressure diffusion along the fault, contributed to the Mw 5.5 event.

Another possibility is that the stimulated fracture serves as the hydraulic pathway connecting the injection point and the fault (Min et al., 2022). Mechanisms related to the hydraulic and mechanical properties of the stimulated fracture can provide alternative explanations for seismic events. A decrease in permeability after shut in as a result of the pressure-dependent permeability could slow down pressure diffusion and contribute to the delayed Mw 5.5 event after shut-in of PX-2. Additionally, shear stress transfer caused by hydroshearing fractures in well PX-1 decreases shear stress on part of the fault contributing to the seismic dormancy during PX-1 injection.

This work assumed that the stimulated hydraulic fracture in PX-2 connects the injection point and the fault. Based on this assumption, the results suggest that the tensile stress transfer from the

hydraulic opening and the fluid pressure under the pressure-dependent permeability could serve as an alternative mechanism accounting for the seismicity sequences observed during the third stimulation of PX-2.

4. Conclusions

This study proposes an alternative mechanism explaining the observed seismic sequences during the third stimulation of well PX-2 at Pohang, focusing on the role of stimulated hydraulic fracture. Distinct observations of seismicity include a relatively small seismic event (Mw 1.7) around shut-in, followed by a seismically dormant period until the larger seismic event (Mw 5.5) happened long after shut-in. In the model, the Mw 1.7 event was attributed to the tensile stress transfer from the opening in hydraulic fracture before injection stops. The subsequent seismically dormant period was explained by deactivation of the tensile stress due to fracture closure after shut-in, together with the delayed arrival of fluid pressure front. The Mw 5.5 event is explained by a rapid increase in pressure after the arrival of the steep pressure front caused by the pressure-dependent permeability in the stimulated fracture.

ABSTRACT

In April 2022 and July 2023, a series of hydraulic stimulation and fluid circulation experiments were executed at the Utah FORGE injection well 16A(78)-32, accompanied by high-resolution seismic monitoring. These experiments have shown a consistent pattern of upward migration in seismic cloud development, indicating the ascendant propagation of both hydraulic fractures (HF) and natural fractures (NF) upon fluid injection. Building on our prior numerical simulations, the results have demonstrated that the upward growth of hydraulic fractures may interact with natural fractures leading to a more complex stimulated reservoir volume (SRV) consisting of a HF/NF network (Kumar, Liu, & Ghassemi, 2023). In this study, we performed a theoretical analysis to further analyze fracture propagation behavior in response to fluid injection in Utah FORGE. Leveraging rock properties derived from FORGE core samples, in-situ stress assessments from borehole image logs (Ye et al., 2022; Ye & Ghassemi, 2024), and stochastic fracture set orientations within the Utah FORGE context (Finnila & Jones, 2024), our investigation aimed to analytically evaluate the growth of the SRV and fracture evolution. Our findings indicate that fracture set 2 (South-striking, moderately dipping West) and fracture set 4 (East-striking, sub-vertical dipping South) are likely to be among the first to slip and propagate during fluid injection. Additionally, our analysis reinforces the dominance of upward fracture migration as the primary propagation mechanism within the FORGE stimulations. We also discuss the results with reference to the hydroshearing conceptual model and its implications for SRV size and geometry.

1. Introduction

Enhanced geothermal systems (EGS) are proposed as a solution to unlock the vast potential of geothermal energy from hot-dry rocks at depth, which are typically deficient in water and permeability. Despite nearly a dozen EGS field demonstrations conducted worldwide since the 1970s, fundamental technical barriers persist, limiting the large-scale commercial production of

geothermal energy. The Utah FORGE project, sponsored by the U.S. Department of Energy (DOE), aims to develop and test new technologies for characterizing, creating, and sustaining continuous fluid flow and energy transfer within an EGS reservoir (Moore et al., 2020). At Utah FORGE, a pair of highly deviated wells were drilled for injection (well 16A(78)-32) and production (well 16B(78)-32). Hydraulic stimulations were conducted, and may continue to be conducted, to create an EGS system in granitoid rocks with bottom-hole temperatures near 230 °C.

The EGS reservoir rocks at Utah FORGE are characterized by an abundance of natural fractures of varying scales and sizes, identified as four major sets through borehole image logs and core samples (Finnila & Jones, 2024). During pressurized fluid injection for stimulation, these natural fractures play a critical role in influencing reservoir permeability and induced seismicity. In April 2022 and 2024, a series of hydraulic stimulation experiments were conducted at the injection well 16A(78)-32, accompanied by high-resolution seismic monitoring. These experiments consistently demonstrated an upward migration pattern in seismic cloud development, indicating the ascendant propagation of both hydraulic and natural fractures upon fluid injection. Moreover, the complex geometry of the seismic clouds further suggests a stimulated reservoir volume likely involving interactions between hydraulic and natural fractures. Building on our prior numerical simulations, the results indicate that the upward growth of hydraulic fractures may interact with natural fractures, leading to a more complex SRV comprising a hydraulic fracture/natural fracture (HF/NF) network (Kumar, Liu, & Ghassemi, 2023).

The shear stimulation or hydroshearing approach is a conceptual model considered in the FORGE project. A critical research objective in FORGE stimulation is to investigate the role of natural fractures in EGS stimulation and the associated seismicity activities. Therefore, analyzing the shearing behaviors of natural fractures at the FORGE stimulation site is of significant interest. Following our previous modeling studies (Kumar, Liu, & Ghassemi, 2023; Lee & Ghassemi, 2023), we conducted a theoretical analysis to further understand fracture propagation and seismicity migration in response to fluid injection at Utah FORGE, aiming to provide insights into the operation and characterization of hydraulic stimulation at this site. Initially, we performed laboratory experiments to characterize the relevant geomechanical properties of granitoid rocks from the Utah FORGE reservoirs. The experimental results, along with in-situ stress data and fracture characteristics (e.g., orientation) identified from borehole image logs, were then used to conduct a theoretical analysis of the response of FORGE natural fracture sets to fluid injection. The analysis employed the approach proposed by Pine & Batchelor (1984), which was modified by Nygren & Ghassemi (2005). Using static analysis, the spatial migration of the stimulated volume was assessed by comparing the gradients of the driving shear forces and the resisting shear strength. This analysis also demonstrated the criticality of different fracture sets at the toe of the FORGE injection well as a function of their properties.

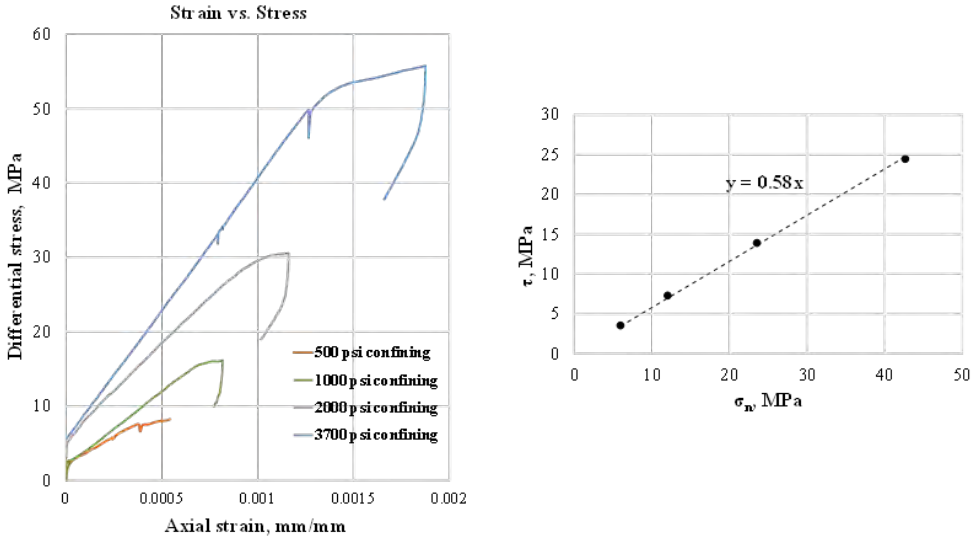
2. Experimental Characterization of FORGE Reservoir Rocks

To determine the related mechanical properties for the theoretical analysis of fracture shearing migration, a series of laboratory experiments were conducted on the granite samples from the FORGE reservoir. The Young's modulus and Poisson' ratio determined from a triaxial compressive test are 62 GPa (9.0×10^6 psi) and 0.27, respectively. The uniaxial compressive strength (UCS) is 121 MPa (1.7×10^5 psi).

In addition, multistage triaxial shear tests were conducted on a saw-cut smooth fracture (Figure 1(a)) and a tensile-induced rough fracture (Figure 1(b)) to estimate the friction properties of FORGE natural fractures. During a triaxial shear test, a given confining pressure, σ_3, is first applied, and then differential stress (σ_1- σ_3) is raised until the fracture slips. However, results under different confining pressures are required to construct the shear strength envelope. Thus, a multistage test strategy was applied: progressively, for each consecutive stage, a different confining pressure was applied, and the axial load was increased via strain control until fracture slip occurred. Then, the axial load was lowered to the applied confining pressure level and a new stage was started at a higher confining pressure.

(a) (b)

Figure 1: (a) Saw-cut fracture created on a FORGE granite sample at ~2074 m (6802.92 ft.); (b) Rough fracture created on a FORGE granite sample at ~2073 m (6802.73 ft.). The procedure regarding creating saw-cut or rough fracture on cylindrical granite samples can be referred from Ye & Ghassemi (2018).



(a) (b)

Figure 2: (a) Saw-cut fracture created on a FORGE granite sample at ~2074 m (6802.92 ft.); (b) Rough fracture created on a FORGE granite sample at ~2073 m (6802.73 ft.). The procedure regarding creating saw-cut or rough fracture on cylindrical granite samples can be referred from Ye & Ghassemi (2018).

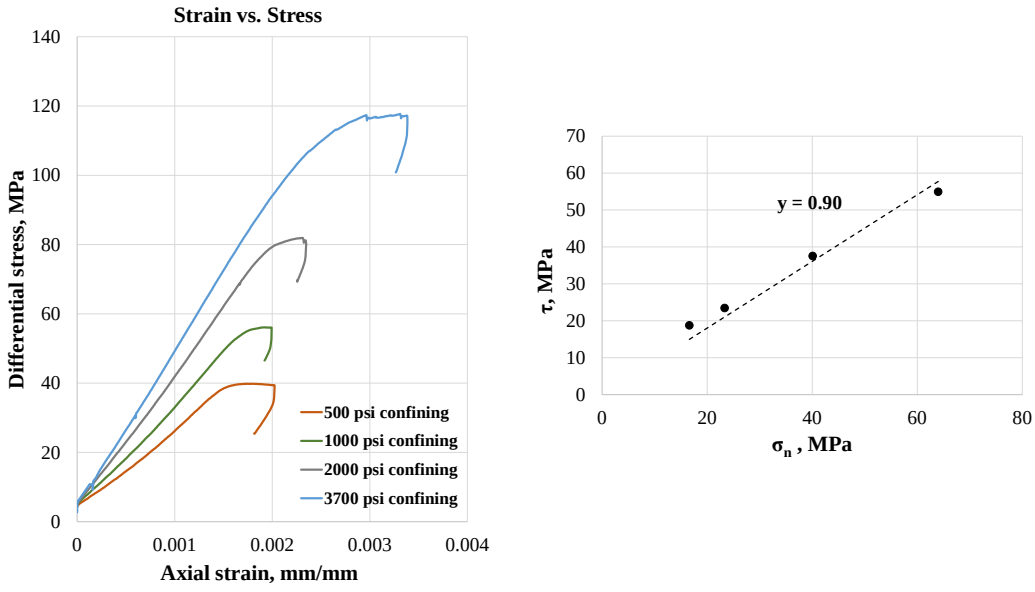


Figure 3: (a) stress-strain curve of triaxial shear test on FORGE granite sample at ~2073 m (6802.73 ft.) with a tensile-induced fracture; (b) shear strength envelope of the tensile-induced fracture test with a friction angle of 42º.

According to the results from several stages with different confining pressures, the shear strength envelope and frictional properties can be determined based on the tests conducted on a single rock fracture (Ye & Ghassemi, 2016). The results of multistage shear tests for the two fractures (one saw-cut smooth fracture and one rough fracture) are shown in Figure 2 and Figure 3, respectively. As expected, the tensile-induced fracture with rough fracture surfaces has a larger shear strength and friction coefficient than that of the saw-cut fracture. The friction angle of the tensile-induced fracture is ~42°, while the saw-cut fracture has a friction angle of ~30°. Considering natural fractures are generally with various surface topography/roughness, a reasonable range of the friction angles of FORGE natural fractures can be estimated as from 30º-50º.

3. Theoretical Analysis of Fracture Shearing in FORGE Stimulation

3.1 Natural Fractures and In-situ Stresses at FORGE

Four major sets of natural fractures have been identified from the data of borehole image logs and core samples in FORGE stimulation site (Finnila & Jones, 2024). The intensity and orientations of the natural fracture sets are listed in Table 1.

Table 1: General intensity and orientation of the natural fractures in the FORGE stimulation zone

		F1: SSW-striking, vertical	F2: South-striking moderately dipping West	F3: North-striking, moderately dipping East	F4: East-striking, sub-vertical dipping South
	[%]	30	29	21	20
Mean Set Orientation	Strike [deg]	204	181	320	84
	Dip [deg]	88	53	38	74
	Fisher Concentration	22	7	4	9

The in-situ stresses at the FORGE reservoir are detailed in Table 2. The vertical stress (σ_v) determined from the density logs is 25.56 MPa/km (1.13 psi/ft, Moore et al., 2020), and the pore pressure (P_p) is considered as 9.79 MPa/km (0.433 psi/ft, hydrostatic pressure gradient). The minimum principal stress (σ_h) is estimated to be an average value of 16.85 MPa/km (0.75 psi/ft) by reexamining the injection tests carried out in the stimulation well 16A(78)-32 in January 2021. The maximum principal stress (σ_H) is constrained to an average value of 21.15 MPa/km (0.94 psi/ft) based on drilling-induced fractures and breakouts observed from the borehole image logs (Ye et al., 2022; Ye & Ghassemi, 2024). The in-situ values of the friction angle (ϕ')) for the fracture sets are not known. Therefore, laboratory test results conducted on FORGE reservoir rocks (including both smooth and rough fractures), described in Sec. 2, will be used as a proxy, suggesting that the friction angle (ϕ')) ranges from 30° to 50°. Other relevant mechanical properties, also derived from the laboratory tests, are listed in Table 2.

Table 2: In-situ stress and geomechanical properties at the FORGE stimulation zone

Parameter	Value	Source
Vertical stress (σ_v)	25.56 (MPa/km)	Integration of density logs, Moore et al., 2020
Minimum horizontal principal stress (σ_h)	16.85 (MPa/km)	Reexamining DFIT tests of 16A(78)-32
Maximum horizontal principal stress (σ_H)	21.15 (MPa/km)	Constrained by image logs (Ye & Ghassemi, 2024)
Pore pressure (P_p)	9.79 (MPa/km)	Hydrostatic pressure, Moore et al., 2020
Friction angle	30° - 50°	Lab tests on FORGE cores (see Sec. 2)
Unconfined compressive strength	121 MPa	
Young's modulus	62 GPa	
Poisson's ratio	0.27	

3.2 Failure Criterion for Natural Fractures

In this theoretical analysis, a linear failure criterion (Mohr-Coulomb criterion) is used to assess the response of natural fractures to injection pressure. This criterion assumes that fracture slip is independent of the intermediate principal stress and occurs in the plane defined by the maximum principal stress (σ_1) – minimum principal stress (σ_3). Considering that Utah FORGE is likely situated in a normal faulting zone (Ye et al., 2022; Ye & Ghassemi, 2024), the σ_v - σ_h plane is assumed to be the failure plane (see Figure 4).

The linear failure criterion for the planes of weakness (e.g., natural fractures) is obtained by considering the normal and shear stresses acting on them:

$$\sigma_n = P_o - S_o \cos(2\theta) \quad (1)$$

$$\tau = S_o \sin(2\theta) \quad (2)$$

where $P_o = \frac{\sigma_1+\sigma_3}{2}$ and $S_o = \frac{\sigma_1-\sigma_3}{2}$ are the mean and deviatoric stress components, respectively. The angle θ represents the fracture angle with respect to the maximum principal stress, while β represents the fracture angle with respect to the minimum principal stress, where θ = 90° - β. In a normal faulting regime, β is equal to the dip angle.

Eqns. (1) and (2) are then substituted into a Mohr-Coulomb failure criterion for the fractures:

$$\tau_f = C + \sigma_n' \tan\phi' = C + \left(\sigma_n - P_p\right) \tan\phi' \quad (3)$$

where τ_f is the shear stress, σ_n' is the effective normal stress, σ_n is the normal stress, P_p is the pore pressure, and ϕ' is the friction angle of natural fractures. C is the cohesion, which is generally assumed to be very small and is considered to be zero for fractures.

Substitution of Eqs. (1) and (2) into Eq. (3) yields:

$$\sigma_1 - \sigma_3 = \frac{2(S_o+\sigma_3 \tan\phi')}{(1-\tan\phi' \cos\beta)\sin 2\beta} \quad (4)$$

According to the experimental results in Sec. 2, in this work we consider a broader range of friction angle values from 30º to 50º as a sensitivity analysis. Differentiating Eq. (4) with respect to β and setting it equal to zero yields (Jaeger et al., 2009):

$$\tan 2\beta_{crit} = -\cot\phi' \text{ or } \phi' = 2\beta_{crit} - \frac{\pi}{2} \quad (5)$$

Eq. (5) represents the least stable fracture orientation for a given friction angle. Applying the 30º-50º friction angle values to Eq. (5) shows that β_{crit} equals 60º-70º, aligning with the dip angles of fracture set 2 (south-striking, moderately dipping west) and fracture set 4 (east-striking, sub-vertical dipping south). This implies that shear slips are most likely to first occur on fracture set 4 during injection.

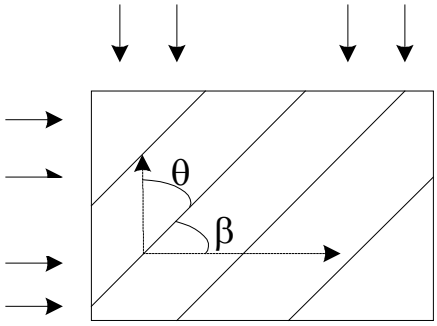

Figure 4: Conceptual model of fractures in the target stimulation zone, illustrating the definition of angles used in the analysis. At the FORGE site, which is characterized by normal faulting, σ_1 corresponds to σ_v, and σ_3 corresponds to σ_h. The angle θ represents the fracture angle with respect to the maximum principal stress, while β represents the fracture angle with respect to the minimum principal stress, where θ = 90° - β. In a normal faulting regime, β is equal to the dip angle.

3.3 Limiting Stress Conditions

The limiting value of the critical stress ratio, R, for a range of possible friction angles is determined in this section. This ratio is found by manipulation of Eq. (4) (Goodman, 1980; Pine & Batchelor, 1984):

$$R = \frac{\sigma_1'}{\sigma_3'} = \frac{1 + \tan\phi'(\sin 2\theta + \tan\phi' \cos 2\theta)^{-1}}{1 - \tan\phi'(\sin 2\theta + \tan\phi' \cos 2\theta)^{-1}} \quad (7)$$

It represents the stress condition required for limiting equilibrium of fractures in terms of their angle from the major principal stress and their friction angle. Plots of R with respect to θ for different friction angles ($\boldsymbol{\phi'}$) are shown in Figure 5, which demonstrates that as the friction angle increases the limiting value of R also increases. In a normal faulting regime, the vertical stress is the maximum principal stress, and the minimum horizontal stress is the minimum principal stress. The in-situ stress ratio value before fluid injection ($R_i = \sigma_v'/\sigma_h'$) for the estimates of the stress state at FORGE is 2.23 (see the blue horizontal line in Figure 5). As can be seen in Figure 5, the minimum of each curve represents the least stable fracture orientation. These least stable fracture orientations are 20º, 22.5º, 25º, 27.5º, and 30º for ϕ' = 50º, 45º, 40º, 35º, and 30º, respectively. Most of these least stable fracture orientations fall within a range close to fracture sets 2 and 4, particularly fracture set 4 (see Figure 5). This suggests that the natural fractures within fracture sets 2 and 4 are primarily near a critical state and might slip first following fluid injection. Additionally, the R values for each set of fractures are larger than the in-situ stress ratio (R_i), indicating that an increase in fluid pressure within the fractures is required to trigger fracture slip due to the fractures not being in critical state. In the following section, the critical pore pressure required to initiate fracture slip will be discussed within a theoretical framework based on the Mohr-Coulomb failure criterion.

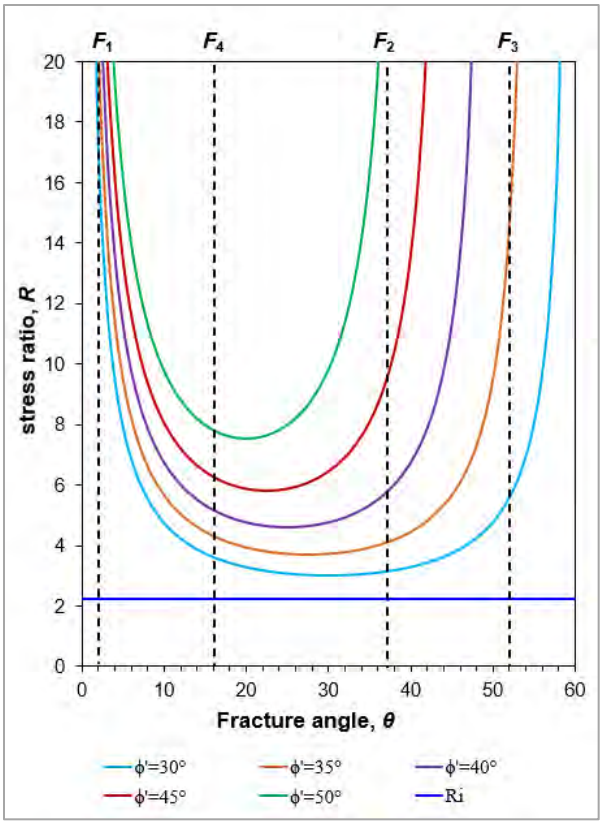

Figure 5: *R* Values for the range of friction angles chosen (ϕ'=30° - 50°). R_i represents the in-situ stress ratio at the FORGE site, which is the ratio of σ'_v/σ'_h. The four black-dashed lines from left to right indicate the four fracture sets at the FORGE site with dips of 88° (fracture set 1), 74° (fracture set 4), 53° (fracture set 2), and 38° (fracture set 3), respectively.

3.4 Critical Injection Pressure Required for Fracture Reactivation

Since the natural fractures at the toe of the stimulation well are not in a critical state (as illustrated in Figure 5), pressurized fluid injection is necessary to reactivate the fractures during hydraulic stimulation. It is important to determine the amount of fluid pressure needed to critically stress these fractures and induce slip. Upon stimulation of a reservoir, a unit increase in fluid pressure within a fracture will decrease the effective stress by the same amount, according to Terzaghi's definition of effective stress. For pre-existing or natural fractures, the critical injection pressure (P_c^{joint}) required to induce shearing must satisfy the following equation according to the Mohr-Coulomb criterion:

$$\tau_f = C + \left(\sigma_n - P_c^{joint}\right) tan\,\phi' \tag{8}$$

Substitution of Eqs. (1) and (2) into Eq. (8) yields:

$$P_c^{joint} = \frac{\sigma_1 + \sigma_3}{2} - \frac{\sigma_1 - \sigma_3}{2}\left(\frac{sin\,2\theta + cos\,2\theta\,tan\,\phi'}{tan\,\phi'}\right) + \frac{C}{tan\,\phi'} \tag{9}$$

The critical pore pressures required for the reactivation of the natural fractures in the FORGE reservoir (at a depth of 2.6 km) with different friction angles are shown in Figure 6. In Figure 6, all the curves of critical pore pressure decrease until a critical fracture orientation is reached, after

which they increase. It is evident that fractures oriented from θ = 15º to 35º (corresponding to dip angles β = 55º to 75º) are among the first to slip. This suggests that fracture sets 2 and 4 are likely to slip first during hydraulic stimulation. Additionally, for natural fractures with shallow dipping orientations (dip angles β < 20˚), the required pore pressure increases significantly.

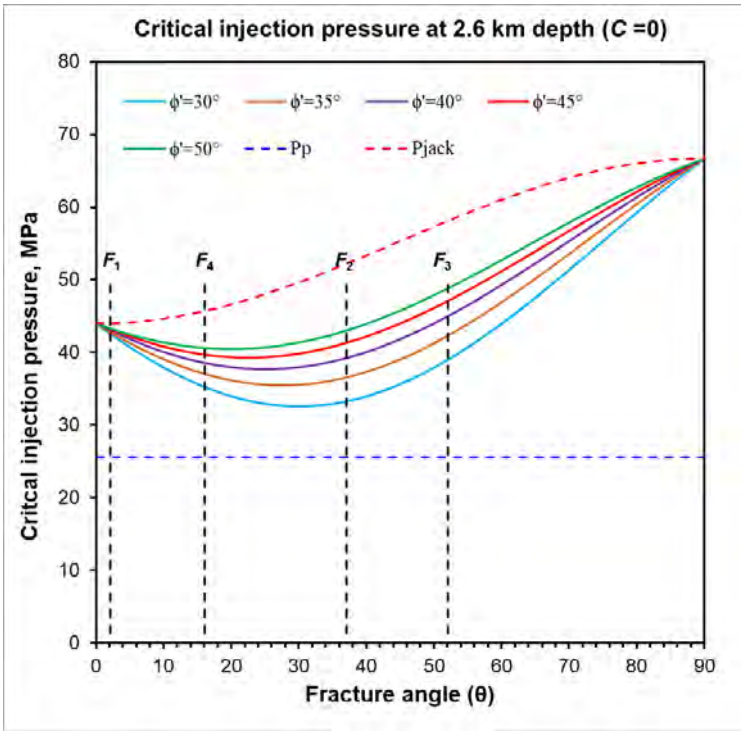

Figure 6: Critical injection pressures required for inducing shear slip and jacking on various fracture orientations and friction angles at a depth 2,609 m (the toe of stimulation well). In the plot, the four black-dashed lines indicate the four primary fracture sets at the FORGE site with dips of 88° (fracture set 1), 74° (fracture set 4), 53° (fracture set 2), and 38° (fracture set 3), respectively.

3.5 Critical Injection Pressure Required for Inducing Hydraulic Jacking

Pressurized fluid injection can also induce hydraulic jacking, which reopens natural fractures. Theoretically, for hydraulic jacking, the effective normal stress acting on the fracture becomes zero. Therefore, the critical fluid pressure required for hydraulic jacking (P_{jack}^{joint}) is given by the following equation:

$$P_{jack}^{joint} - \sigma_n - T = 0 \tag{10}$$

Substitution of Eqs. (1) and (2) into Eq. (10) yields:

$$P_{jack}^{joint} = \frac{\sigma_1 + \sigma_3}{2} - \frac{\sigma_1 - \sigma_3}{2} cos\, 2\theta + T \tag{11}$$

where T is the tensile strength of natural fractures, which can be assumed to be negligible.

From Eq. (11), it can be observed that the critical pressure for hydraulic jacking is not influenced by the friction angle of fractures. Additionally, when θ = 0º or 90º, and assuming that both cohesion

and tensile strength of natural fractures are negligible, P_{jack}^{joint} is equal to P_c^{joint} according to Eqs. (9) and (11), as illustrated in Figure 6.

In Figure 6, it is noticed that slip is generally initiated before jacking during injection. The critical pore pressure (P_c^{joint}) and the net fluid pressure ($P_p^+ = P_c^{joint} - P_p$) for the fracture sets 1, 2, 3 and 4 are reported in Table 3. The net fluid pressure is referred to the surface pressure required for fracture reactivation. The values in Table 3 are calculated at an injection depth of 2,609 m (the toe of stimulation well) where the pore pressure (P_p) is 25.54 MPa. In Table 3, we can see that fracture sets 2 and 4 require a relatively lower fluid pressure to be activated by shear stimulation. This is consistent with the predictions suggested by the above analysis of limiting stress conditions.

Table 3: Critical Pore Pressure ($\boldsymbol{P_c^{joint}}$) and net pore pressure ($\boldsymbol{P_p^+}$) in MPa required to reactivate the four sets of natural fractures for different friction angles □'□ at FORGE

	β = 88° (fracture set 1)		**β = 53° (fracture set 2)**		**β = 38° (fracture set 3)**		**β = 74° (fracture set 4)**	
ϕ'	P_c^{joint}	P_p^+	P_c^{joint}	P_p^+	P_c^{joint}	P_p^+	P_c^{joint}	P_p^+
30°	42.62	17.08	33.28	7.74	38.98	13.44	35.27	9.73
35°	42.86	17.32	36.60	11.06	42.33	16.79	37.10	11.56
40°	43.05	17.51	39.18	13.64	44.94	19.4	38.52	12.98
45°	43.20	17.66	41.28	15.74	47.05	21.51	39.67	14.13
50°	43.33	17.79	43.03	17.49	48.83	23.29	40.64	15.10

3.6 Fracture Growth and Shearing Migration

When non-horizontal fractures/faults slip, shear growth can occur upward or downward. One of the critical challenges in the development of an EGS system is to predict and control the growth of the stimulated fractures and ensure the appropriate connections of the injection well, the stimulated zone, and the production well. Hence, it is necessary to analyze the possible migration of fracture shearing under the reservoir conditions. The shearing migration of natural fractures during fluid injection can be predicted by considering the difference in the pressure increase per unit depth required for inducing shear slip above and below the injection point. If the pore pressure increment difference is positive, downward shear growth is expected since slip propagates downward where less pressure is required. On the other hand, if the pore pressure increment difference is negative, upward shear growth is likely the primary shearing mode. The analysis of shearing migration is a function of the variation of fracture properties and in-situ stress with depth. Indeed, a change in shear growth can occur at a critical depth if the stress gradient is non-linear. Therefore, the downward or upward shear growth can be expressed as (Pine & Batchelor, 1984):

$$G = \frac{dP_p^+}{dz} = \frac{1}{2}\left(\frac{d\sigma_1'}{dz} + \frac{d\sigma_3'}{dz}\right) - \frac{\sin 2\theta + \tan\phi' \cos 2\theta}{2\tan\phi'}\left(\frac{d\sigma_1'}{dz} - \frac{d\sigma_3'}{dz}\right) \quad (12)$$

where z is depth. Solving Eq. (12) for the critical fluid-pressure gradient (G), upward growth is predicted for positive values of G, while negative values of G suggest downward growth. The derivatives on the right-hand side of Eq. (12) are the gradient of the effective maximum principal stress ($\frac{d\sigma_1'}{dz}$) and the gradient of the minimum principal stress ($\frac{d\sigma_3'}{dz}$).

Plotting the critical pressure gradient (G) in Figure 7. It is noticed that the values of G for the four fracture sets are positive under the friction angles from 30º to 50º, indicating the upward shearing migration/growth.

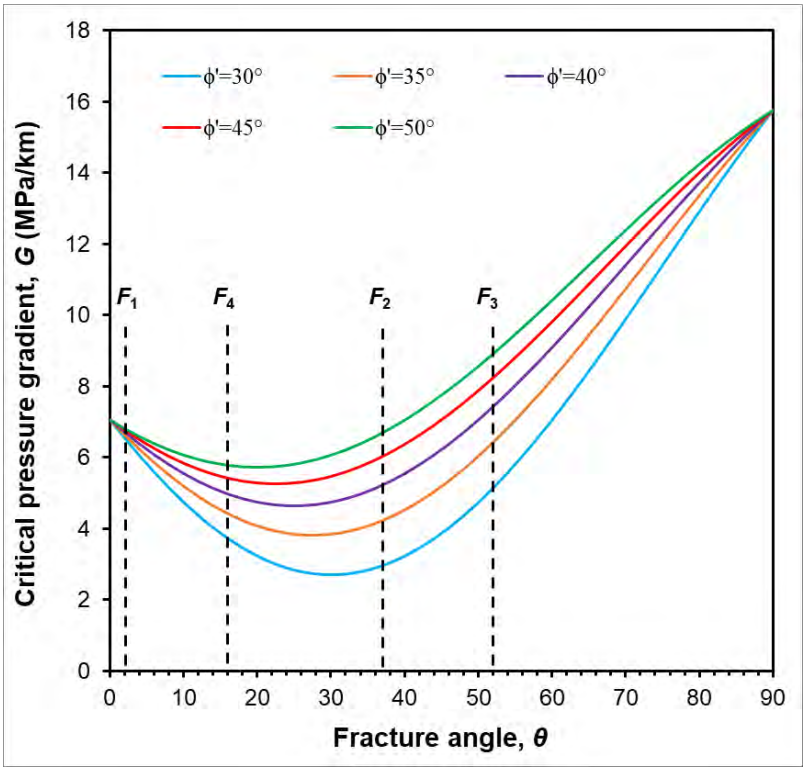

Figure 7: Critical fluid-pressure gradient for the four natural fractures various friction angles in FORGE site. In the plot, $G > 0$ indicates upward growth of fracture shearing. the four black-dashed lines indicate the four primary fracture sets at the FORGE site with dips of 88° (fracture set 1), 74° (fracture set 4), 53° (fracture set 2), and 38° (fracture set 3), respectively.

4. Discussion

Since April 2022, several hydraulic stimulations have been conducted at the toe of injection well 16A(78)-32, and a series of fluid circulation tests have been performed between injection well 16A(78)-32 and production well 16B(78)-32. These injection tests are accompanied by high-resolution seismic monitoring, providing an opportunity to analyze the Stimulated Reservoir Volume (SRV) and seismicity growth. Using seismicity data from the three-stage stimulation in April 2022 and four flow circulation tests in July 2023, we have plotted the seismic clusters observed during these tests, as shown in Figure 8. This analysis helps in understanding the spatial distribution and growth of seismic events, offering insights into fracture behavior and reservoir response to hydraulic stimulations and fluid circulation. The upward growth of the seismicity cloud induced by fluid injection suggests that fractures tend to propagate and/or shear upwards. Additionally, the complex geometry of these seismic clouds indicates the likely involvement of hydraulic fracture-natural fracture (HF-NF) interaction during hydraulic stimulation and fluid circulation. These observations from induced seismicity align well with the results of our theoretical analysis, suggesting that the presented analytical model can reliably predict the growth

of the SRV and seismicity, as well as estimate the net fluid pressure required to induce fracture slip.

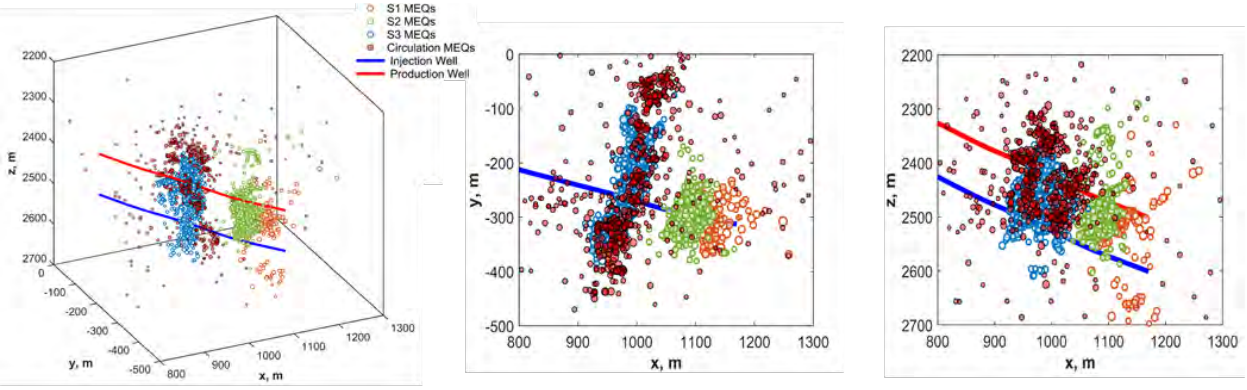

Figure 8: Seismic clusters observed during the three-stage stimulation in April 2022 and the four flow circulation tests in July 2023 conducted in the Utah FORGE reservoir. The inclined blue and red lines represent the deviated portions of the injection well and the production well within the FORGE reservoir, respectively. The blue, green, and red hollow circles represent the seismic events induced during the three-stage stimulations, while the red solid circles represent the seismic events induced during the fluid circulation tests.

It should be noted that the upward or downward shearing of pre-existing fractures depends on the gradients of the effective principal stresses, the friction angle, and the dip angle of the individual fracture. Therefore, spatial or temporal changes in the stress regime, due to continuous fluid injection and the associated cooling during the stimulation phase and later the production phase, might alter the slip tendency and shearing migration during hydraulic injection.

5. Conclusions

In this study, a series of laboratory experiments were conducted on FORGE reservoir rocks to characterize their mechanical properties, including the friction coefficient, Young's modulus, Poisson's ratio, and unconfined compressive strength (UCS). The experimental results, along with in-situ stress data and natural fracture data, were used to perform a theoretical analysis based on the linear Mohr-Coulomb failure criterion to evaluate the shearing behaviors of natural fractures in the FORGE reservoir. The critical stress analysis demonstrates that none of the four major fracture sets at FORGE reservoir are currently in a critical state, with fracture sets 2 and 4 being relatively less stable than fracture sets 1 and 3. Consequently, fracture sets 2 and 4 are likely to slip first during fluid injection. According to this theoretical analysis, the critical injection pressures required to induce fracture slip and jacking were estimated. Additionally, the analysis of the critical fluid-pressure gradient (G) suggests that upward shearing is likely the primary mode of shearing migration at FORGE. The predicted upward shearing migration is consistent with the growth of microseismic clouds observed during the stimulation and fluid circulation tests conducted in the FORGE reservoir, supporting the reliability of this model. The results of this analysis are expected to provide valuable insights into the design and operation of hydraulic stimulation and the mitigation of induced seismic risks at the Utah FORGE site.

Operation Strategy to Avoid Thermal Short-circuit in EGSs with Horizontal Wells

Qitao Zhang and Arash Dahi Taleghani

Department of Energy and Mineral Engineering, Pennsylvania State University, State College, 16801, USA

Keywords

Enhanced geothermal systems, Thermal short-circuit, Downhole flow control, Heat extraction efficiency, and Distributed temperature sensing.

ABSTRACT

Enhanced geothermal systems face a significant obstacle: thermal short-circuiting, where fluid flows through only a few fractures, limiting efficiency. This issue is particularly problematic for horizontal wells with multiple fractures. To address this challenge, we introduce a revolutionary temperature-sensitive flow management system. Equipped with real-time sensors and dynamic flow control devices, this innovative system optimizes injection and production across the lateral, effectively preventing thermal shortcuts. Utilizing this flow management system, operation strategies can be designed to determine when and where to adjust the injection and production rates within a twin-horizontal well Enhanced Geothermal System (EGS). Our numerical simulations demonstrate the system's impressive long-term impact. Over a 50-year period, it maintains a produced fluid temperature 40 K higher than uncontrolled systems, and thus the heat extraction efficiency can be increased significantly by simply applying the presented operation strategy. Our innovative approach has the potential to transform horizontal wells into high-performance EGS, unlocking a future of sustainable and efficient energy production.

1. Introduction

The Enhanced geothermal system (EGS) is a type of geothermal technology that utilizes hydraulic stimulation to improve fluid flow within deep, impermeable hot dry rock (HDR) formations. This method creates fractures in the rock, increasing the permeability and allowing for greater circulation of hot fluids. Consequently, EGS systems have the potential to extract significantly more heat compared to traditional geothermal systems, such as closed-loop systems. (Liu and Dahi Taleghani, 2023a; Liu and Dahi Taleghani, 2023b). However, thermal short-circuiting is a significant issue that can severely limit the efficiency and productivity of EGS reservoirs (Liu et al., 2020). It occurs when the injected fluid preferentially flows through a limited number of

fractures or high-permeability pathways within the reservoir, resulting in an inefficient heat exchange with the surrounding rock formation. The primary mechanism behind thermal short-circuiting is the development of localized cooling zones around these high-flow pathways. As the injected fluid, typically cooler than the reservoir rock, flows through these pathways, it absorbs heat from the adjacent rock, gradually decreasing the rock temperature in the vicinity of the flow paths. Over time, this localized cooling effect creates a thermal short-circuit, where a significant portion of the injected fluid flows through these cooled zones without effectively extracting heat from the bulk of the reservoir. Thermal short-circuiting can be exacerbated by several factors. Reservoirs with highly heterogeneous fracture networks or permeability fields are more susceptible, as the injected fluid tends to follow the path of least resistance, concentrating flow in a few high-permeability channels (Al Balushi et al., 2023a). Improper well spacing or configuration can also increase the likelihood, for instance, if the injection and production wells in a doublet system are too close together, allowing the injected fluid to preferentially flow through a direct pathway between them (Li et al., 2016). Additionally, the stress state and orientation of fractures within the reservoir can influence flow patterns and potentially promote thermal short-circuiting if the fractures are favorably aligned with the well trajectories (McLean and Espinoza, 2023).

Thermal short-circuiting has severe consequences for EGS operations. As the injected fluid bypasses a significant portion of the reservoir through the short-circuiting pathways, the amount of heat extracted from the rock formation is significantly reduced, leading to lower reservoir productivity and energy output. The rapid flow through these pathways can also cause premature thermal breakthroughs at the production well, where the injected fluid returns to the surface without sufficient heat extraction. Moreover, over time, the continuous injection of cooler fluid through the short-circuiting pathways can lead to progressive cooling of the reservoir, further reducing its thermal potential and lifespan. Recently, horizontal drilling or basically horizontal wells in the form of new drilling or repurposing existing wells (Santos et al., 2022) has been considered as a potential option to boost the efficiency of EGS, however, well configuration and multistage stimulations in parallel horizontal wells may increase the risk of thermal short-circuiting, significantly. Mitigating thermal short-circuiting is crucial for enhancing the efficiency and longevity of EGS reservoirs. Strategies such as optimizing well placement, stimulating additional fractures, and implementing advanced flow control techniques may help address this challenge and improve the overall performance of EGS systems with some limitations.

Before we present the potential application of flow control systems, we review some of the field observations regarding this problem. The inherent heterogeneity and anisotropy (unequal properties in different directions) of geothermal formations often cause the working fluid to concentrate in just a few fractures. Studies like those at Rosemanowes, UK (Parker, 1999) and Soultz, France (Tester et al., 2006) revealed how a single fracture can dominate fluid flow, carrying over half the injected fluid despite the presence of multiple potential pathways. This uneven distribution highlights the critical role of fracture conductivity in EGS projects. By controlling the conductivity of individual fractures, we can potentially mitigate the formation of dominant flow paths (plane-channeling) between injection and production wells. Unfortunately, current technologies lack the finesse to achieve truly uniform heat extraction from all fractures. This research aims to bridge that gap by exploring innovative methods, like Inflow and Injection Control Devices (ICDs) and real-time temperature monitoring, to manipulate flow within the reservoir and optimize heat extraction efficiency.

Even though operators hope to avoid thermal short-circuiting between horizontal wells in EGS, delaying or preventing early thermal breakthroughs. However, achieving uniform thermal flow between wells is challenging for two reasons. Firstly, the geometry of induced fractures is difficult to control underground. Secondly, the natural variations within rock formations make it nearly impossible to adjust the fluid flow for even heat extraction precisely. One solution we proposed before is tunable fracture conductivity, which can adjust the fracture conductivity according to the local temperature and thus temporarily seal preferential fracture flow pathways. (Al Balushi et al., 2023b; Zhang and Dahi Taleghani, 2023; Zhang and Dahi Taleghani 2024). However, these methods highly depend on the special agents, and their durability and actually performance in the field practice have not been tested. By contrast, in this research, we are presenting some techniques that have been widely used in the oil and gas industry. Our approach in this paper focuses on modifying the heat harvesting process, not the reservoir. We propose controlling flow injection and production based on real-time temperature measurements from the production well. In the oil and gas industry, inflow and injection control devices (ICDs) successfully manage flow across wellbore lengths. These versatile tools can be installed even in open-hole completions. ICDs restrict flow in highly permeable zones, promoting flow in less productive areas. This helps prevent bypassing valuable resources and improves fluid recovery. Similarly, ICDs can be adapted for geothermal systems, working independently of the fracture network or geological formations. Since they reside within the wellbore, they offer the advantage of being independent of geology or completion methods. Additionally, distributed temperature sensors (DTS) using fiber optics can reliably provide temperature data along the wellbore at various depths. It's important to note that this research is not endorsing specific products, but rather exploring potential advancements through adopting such technologies in the geothermal field.

This research investigates a novel subsurface flow management system designed to combat thermal short-circuiting, a longstanding challenge in enhanced geothermal systems (EGS). By strategically directing fluid flow between wells, this system has the potential to significantly improve heat extraction. The study unfolds in several parts: first, we introduce the system and its method for eliminating thermal short-circuits. Second, a numerical model specifically designed for EGS with horizontal wells is built, with the key capability of integrating the flow management system. Third, the system is incorporated into the EGS model to numerically explore its operational benefits. This research, by tackling thermal short-circuiting with this innovative approach, paves the way for substantial improvements in heat extraction, ultimately fostering a more efficient and sustainable future for geothermal energy.

2. Methodology

2.1 Mathematica model

Assuming the reservoir matrix has been fully saturated, then fluid flow in the reservoir matrix can be described by Darcy's law. The corresponding kinematic equation for the fluid flow is as follows:

$$\boldsymbol{u} = -\frac{k_m}{\mu_f}\left(\nabla p - \rho_f \boldsymbol{g}\nabla z\right) \tag{1}$$

where **u** is the vector of Darcy's seepage velocity in the reservoir matrix. k_m represents the permeability of the reservoir matrix. μ_f and ρ_f are the viscosity and density of working fluid, respectively. p is the reservoir pore pressure. ∇ represents the Hamiltonian operator which

calculates the gradient of a scalar. **g** represents the gravitational acceleration in the vertical direction and $\rho_f \mathbf{g}\nabla z$ represents the whole gravity terms.

The continuity equation for the fluid flow in the reservoir matrix can be expressed as follows:

$$\frac{\partial(\phi_m \rho_f)}{\partial t} + \nabla \cdot (\rho_f \boldsymbol{u}) = 0 \tag{2}$$

where ϕ_m denotes the porosity of the reservoir matrix.

For the fluid flow in discrete fractures, the kinematic equation can be expressed as follows:

$$\boldsymbol{u}_f = -\frac{k_f}{\mu_f}(\nabla_T p_f + \rho_f \boldsymbol{g} \nabla_T z) \tag{3}$$

where $\mathbf{u}_f$ is the vector of fluid velocity in discrete fractures. $\nabla_T p_f$ is the pressure gradient tangent to the fracture surface. k_f represents the permeability of fracture.

Heat transfer in EGS consists of heat conduction and heat convection. During production, convection plays a dominant role in heat extraction from EGS. Assuming the local equilibrium is achieved in the porous media, which means the temperature for the fluid at the rock surface equals the temperature of the rock, then the temperature distribution in the reservoir matrix can be calculated as follows:

$$(\rho c)_{\text{eff}} \frac{\partial T}{\partial t} + \rho_f c_f \boldsymbol{u} \cdot \nabla T - \nabla \cdot (\lambda_{\text{eff}} \nabla T) = 0 \tag{4}$$

where T is temperature. c_f is the heat capacity of the working fluid. λ_{eff} is the effective heat conductivity. Assuming the heat conduction in solid and fluid phases happens in parallel, then the effective heat conductivity is the weighted arithmetic of the heat conductivity of the solid phase and fluid phase.

Heat transfer in discrete fractures can be expressed as follows:

$$d_f (\rho c)_{\text{eff}} \frac{\partial T}{\partial t} + d_f \rho_f c_f \boldsymbol{u} \cdot \nabla_T T - \nabla_T \cdot (d_f \lambda_{\text{eff}} \nabla_T T) = 0 \tag{5}$$

Based on the mathematical models presented above, the operation of EGS can be simulated. In the next section, we are going to introduce the novel real-time downhole flow control system. We will simulate the EGS operated with such a system based on the mathematical models presented in this section.

2.2 Real-time Downhole Flow Control System

To prevent thermal short-circuiting between horizontal wells in EGS and boost heat extraction efficiency, we propose a real-time flow management system for intelligent fluid distribution. The presented flow management system for EGSs consists of two parts.

The first component of the flow management system comprises temperature sensors strategically placed within the production well. These sensors continuously transmit real-time data on downhole temperatures. This system utilizes distributed temperature sensors (DTS) installed within the production well, similar to those used in the oil & gas industry for downhole monitoring. DTS technology offers real-time (less than 60 seconds) and high-resolution (less than 1 meter) temperature data, allowing operators to identify hot and cool zones along the wellbore. This information is crucial for the second part of the flow management system, which is yet to be

revealed but will likely leverage this data to adjust fluid flow and prevent thermal short-circuiting. While previous geothermal projects primarily used DTS in vertical wells for monitoring purposes (Patterson et al., 2017), its application in horizontal EGS wells holds significant promise for detecting thermal short-circuiting in real-time. This combined approach has the potential to significantly improve heat extraction and pave the way for a more efficient and sustainable future of geothermal energy.

Secondly, the system utilizes Inflow and Injection Control Devices (ICDs) installed in the injection well and production well. Similar to their application in oil & gas for problems like water breakthroughs, ICDs can be adapted for geothermal use with minimal modifications. By analyzing the temperature data from the production well, operators can identify fractures or stages producing cooler water. This information allows them to precisely control fluid flow through these specific fracture flow pathways, ultimately limiting cold water production in the corresponding production well. This targeted approach prevents thermal short-circuiting and optimizes heat extraction efficiency.

Inefficient heat extraction plagues geothermal systems due to thermal short-circuiting, where water preferentially flows through some specific, highly conductive fractures. This bypasses untapped heat pockets and leads to early thermal breakthroughs. Our proposed flow management system tackles this challenge. Distributed temperature sensors (DTS) act as our downhole sentinels, pinpointing the problematic fracture by detecting its abnormally low temperature. In response, downhole inflow control devices (ICDs) strategically intervene, restricting flow through this "shortcut". This intervention fosters a more uniform temperature distribution across the reservoir, enabling balanced heat extraction from each zone. By eliminating the thermal shortcut and promoting even flow, our system significantly boosts heat extraction efficiency, maximizing the geothermal system's potential.

3. Numerical Implementation

Based on the aforementioned methodologies, the numerical model for the simulation of EGS operation with the real-time downhole flow control system is presented in this section. Figure 1 shows the 3-D geometry model and this model consists of (a) underburden and overburden layers for potential energy support; (2) a targeted layer for the heat extraction purpose as highlighted in red box ~ formation height is 150 m; (3) an injection horizontal well and a production horizontal well for fluid circulation ~ these two well are drilled parallelly and the well spacing is 400 m; (4) 11 induced fracture connecting the injection and production well ~ fracture spacing is equal, i.e., 100 m and fractures fully penetrate the geothermal formation. It is assumed that all fractures are fully propped and thus the thermal distressing effect has few impacts on fracture width. We also assume that the injection and production wells are completely cased and injected fluid circulates through the perforations. Detailed dimensions of the model can be found in Figure 1.

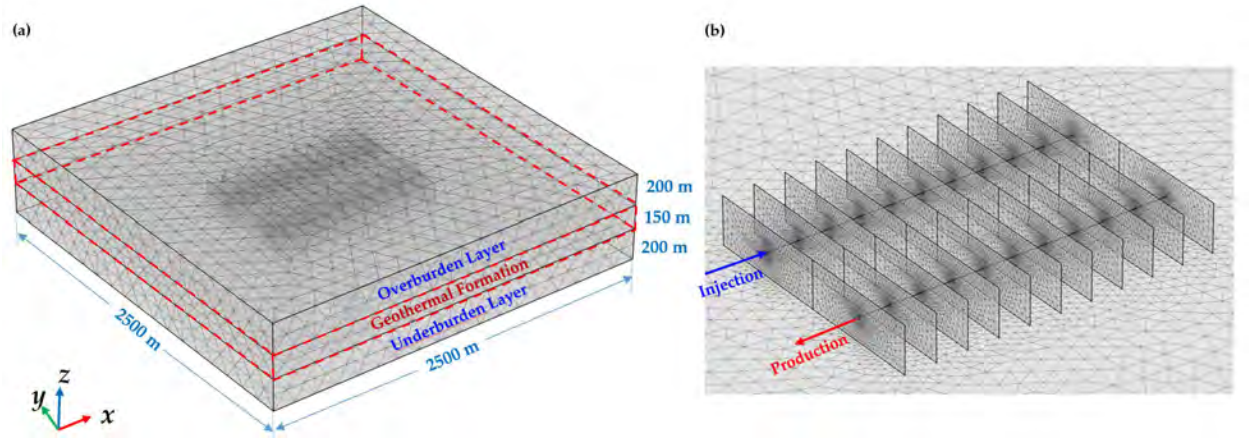

Figure 1: The 3-D geometry model and mesh generation.

The detailed parameters for the numerical simulation are listed in Table 1.

Table 1: Parameters for the simulation model

Parameter	Value	Unit
Size of the reservoir	2500×2500×550	m^3
Height of geothermal formation	150	m
Permeability of reservoir matrix	1	10^{-3} μm^2
Initial porosity of reservoir matrix	10	%
Initial porosity of fracture	20	%
Initial reservoir pressure	3.0×10^7	Pa
Initial reservoir temperature	473.15	K
Production rate	50	kg/s
Injection rate	50	kg/s
Injection temperature	313.15	K
Total calculation time	50	Year

Here, we assume that the hydraulic conductivities of each fracture are different, and distinct hydraulic conductivities in different fractures leave a great chance to form thermal shortcuts. The designed comparison of hydraulic conductivities among 11 fractures is shown in Figure 2. Fractures #2, #6, and #10 have higher hydraulic conductivity which can naturally accommodate more fluid flow through them.

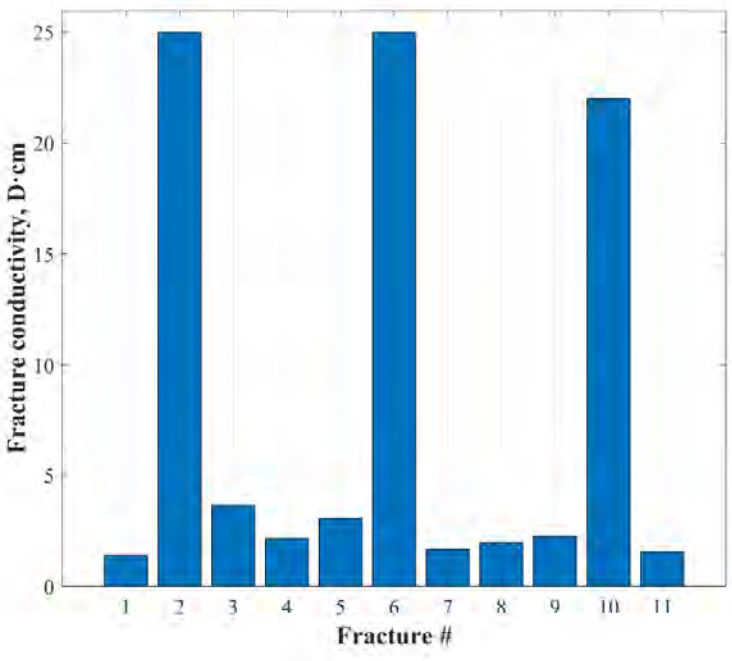

Figure 2: Distribution of fracture hydraulic conductivities in different fractures.

In this section, several simulation scenarios are designed for comparison, which are described as follows

- Case #1: No flow control in injection well or production well.
- Case #2: Flow control is implemented in both injection and production wells. The flow rate in each stage is calculated based on the produced fluid temperature at that stage as:

$$q_{\text{in}}^{a} = \frac{T_{\text{out}}^{a} - T_{\text{in}}}{\sum_{i=1}^{n}\left(T_{\text{out}}^{i} - T_{\text{in}}\right)} q_{\text{in,total}}, \; q_{\text{out}}^{a} = -q_{\text{in}}^{a}, \tag{6}$$

where $T_{\text{out}}{}^{a}$ is the produced fluid temperature from fracture #*a*. T_{in} is the injection temperature which is 313.15 K in this study. $q_{\text{in, total}}$ is the total injection rate. $q_{\text{in}}{}^{a}$ is the injection rate through fracture #*a*. $q_{\text{out}}{}^{a}$ is the production rate from fracture #*a*. *n* is the total fracture number, i.e., 11.

Based on the established numerical model and simulation scenarios, numerical simulations are conducted to investigate real-time flow rate adjustment using produced fluid temperature data.

4. Results and Discussions

Simulations reveal a stark contrast between scenarios with and without the proposed flow management system. Figure 3a depicts the temperature distribution within the fracture system after 50 years in a case without flow management (Case #1). The figure exposes the detrimental effects of thermal short-circuiting, particularly in stages #2, #6, and #10. where significantly cooler temperatures indicate bypassed heat. Conversely, Figure 3b showcases the temperature profile after 50 years in a case with the flow management system implemented (Case #2). The injection

and production rates are adjusted based on Eq. (5) after each time step during the numerical simulation. The figure convincingly demonstrates the system's effectiveness. Instead of concentrated hot zones, a more uniform and balanced temperature distribution is evident across all stages, signifying efficient heat extraction throughout the entire fracture system. This visualization underscores the significant improvement in overall heat extraction efficiency achieved by the proposed flow management system.

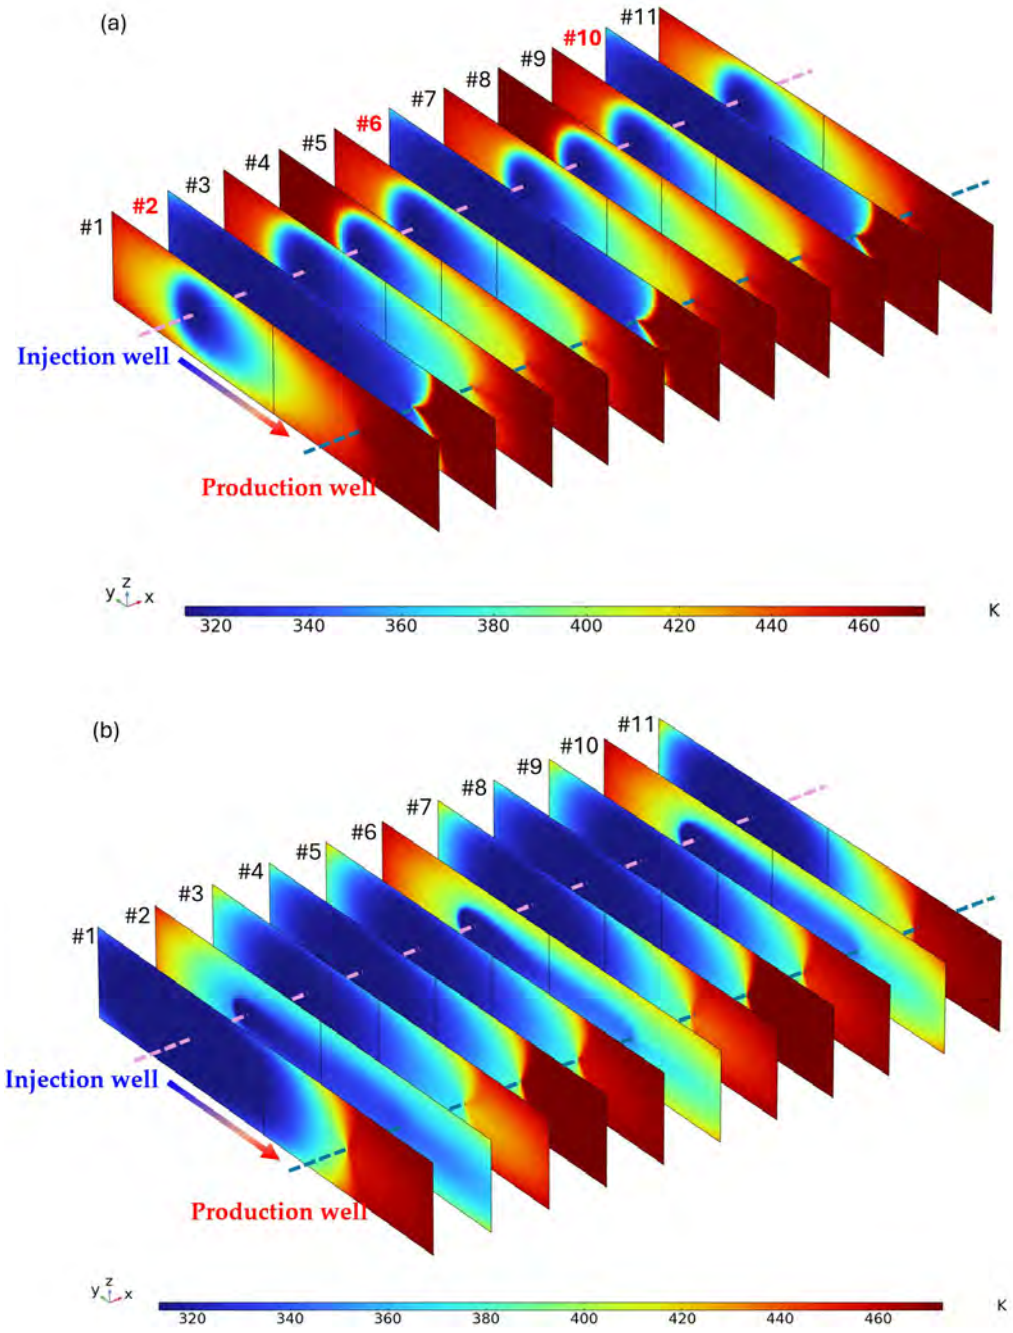

Figure 3: Distribution of fluid temperature distribution in the fracture system: (a) without flow control; (b) with proposed flow control.

Figure 4 shows the produced fluid temperature from different fractures over 50 years of operation. It could be seen that due to high hydraulic conductivities, fractures #2, #6, and #10 have larger decline rates regarding the temperature drop, which indicates a potential thermal short-circuit. However, given the installment of the real-time downhole flow control system, there are inflection points that appear on these 3 curves at around 3rd year of operation, which significantly delay the temperature drop in these fractures and thus prevent the thermal short-circuiting to get worse (The timing of inflection points is the time of early thermal breakthrough in these fractures). These inflection points are generated due to the adjustment of the injection rate and the production rate, which also suggests that the application of the flow management system can significantly enhance production efficiency.

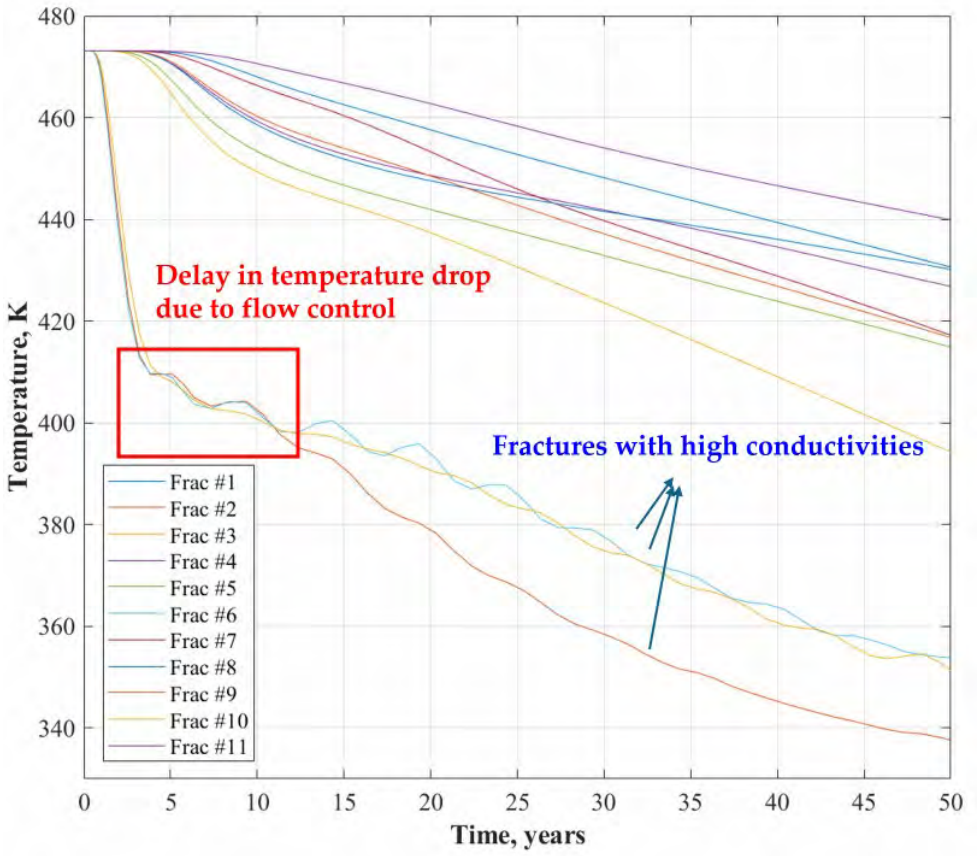

Figure 4: Comparison of temperature of produced fluid from different fractures over 50 years of operation.

Figure 5 shows a comparison of real-time injection and production rates in different fractures over 50 years of operation. At the beginning of the EGS operation, since there are 11 fractures that share 50 kg/s fluid circulation, each fracture has an initial circulation rate of 4.545 kg/s. After that, the ICDs adjust the flow rate in different fractures continuously. It could be seen that, since fractures #2, #6, and #10 have much larger hydraulic conductivities and lower local temperatures (see Figure 4), the installed valves in the injection well and production well are lowering the circulation rates through these fracture for the entire 50 years. After 50 years of operation, the circulation rate in fracture #2 declined from 4.545 kg/s to 1.248 kg/s, which is a 72.5% decline. By contrast, for those fractures that maintain high produced fluid temperature, the installed valves in the injection well and production well increase the circulation rates through these fractures for the entire 50 years.

For instance, after 50 years of operation, the flow rate in fracture #11 has increased by 44.3%, from 4.545 kg/s to 6.559 kg/s. This real-time management of flow rate across the system ensures that the geothermal system is operating in a highly efficient way.

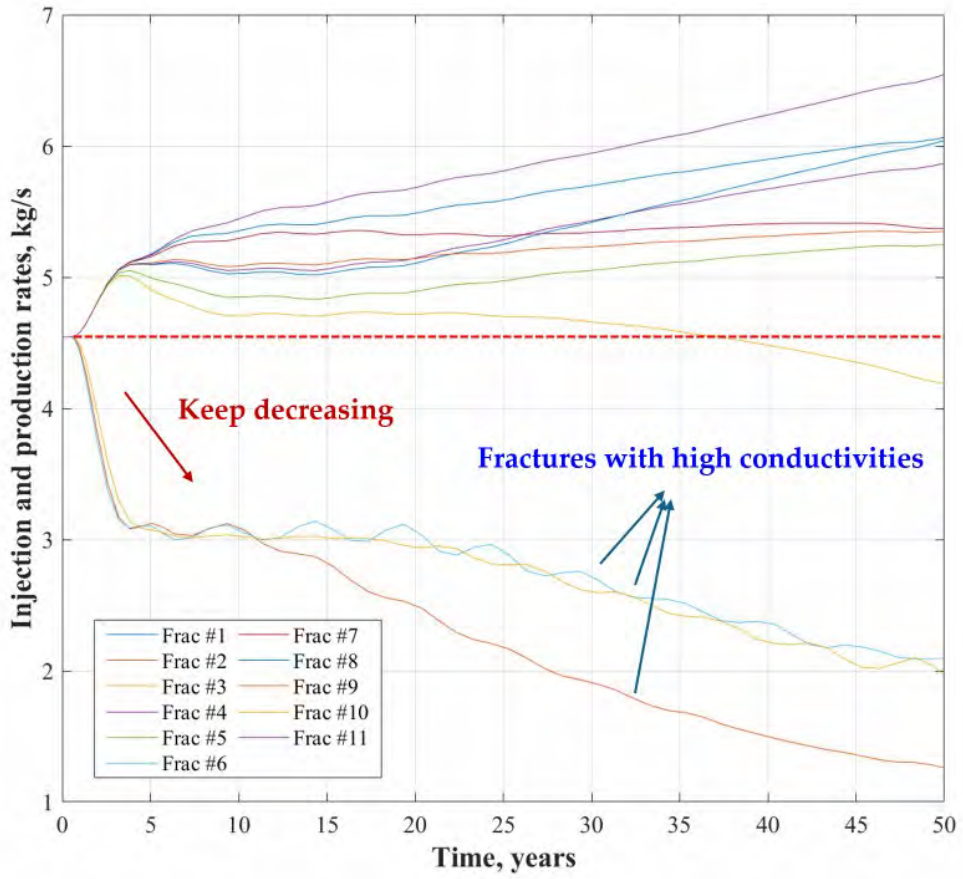

Figure 5: Comparison of real-time injection and production rates in different fractures over 50 years of operation.

Figure 6 shows a quantitative comparison of the overall temperature of produced fluid between cases 1 and 2. It can be seen from the figure that, when the ICDs are not installed, we are not able to control the fluid flow into the production well. The temperature of the produced fluid would keep decreasing from the beginning to the end. Over the 50 years of production, the temperature of the produced fluid in case 1 decreases by 30.18 K, from 473.15 K to 378.67 K. However, when the autonomous subsurface valves are installed in the geothermal system, the temperature of the produced fluid would be much higher than that in Case 1, decreasing from 473.15 K to 414.77 K. In other words, the application of a flow management system can effectively increase the temperature of the produced fluid. By utilizing the proposed flow management system, operators can expect a higher production temperature even after long-time production, and thus the effective operation time for the EGS can be effectively prolonged.

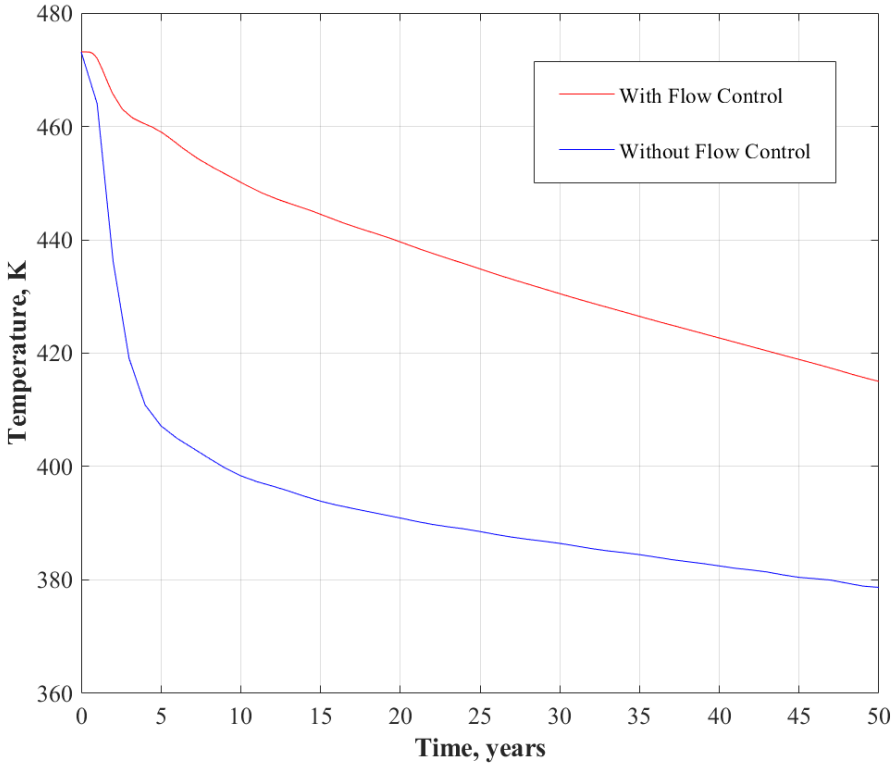

Figure 6: Comparison of overall produced fluid temperature over 50 years of operation.

5. Conclusion

This paper introduces a novel downhole flow management system for enhanced geothermal systems (EGS) utilizing horizontal wells to significantly improve heat extraction. These temperature-sensitive devices reside within the wellbore, dynamically adjusting injection rates in different sections based on the real-time temperature of the produced fluid. This targeted approach tackles the pervasive issue of thermal short-circuiting, where preferential flow paths exploit specific fractures, bypassing vast areas of untapped geothermal energy. We investigated the system's effectiveness in mitigating this challenge. By leveraging real-time downhole data, the system autonomously manages thermal shortcuts along the wellbore, restricting cold water injection into corresponding zones. Our numerical simulations demonstrate a substantial improvement in heat extraction: with constant pressure in the EGS, the produced fluid temperature can be about 40 K higher compared to a system without Inflow Control Devices (ICDs). The benefits of this system are even more pronounced in EGS with significant variations in fracture conductivity. This research provides valuable insights into the efficient management of fluid circulation within horizontal well EGS, paving the way for substantially increased heat extraction and a more sustainable future for geothermal energy.

ABSTRACT

Recent work in the Great Basin region of the western United States has made it possible to predict the depth of hydrothermal reservoirs (i.e., the depth at which heat is accumulated prior to ascent via hydrothermal upflow) identified through geochemistry and to contextualize the spatial patterns of these reservoir depths. Chemical geothermometers use the chemical and mineral constituents of hydrothermal fluids to predict the temperature at which fluids equilibrated with the host rocks at depth. Assuming that most of the Great Basin is dominated by conductive conditions until a vertically connected hydrothermal flow path is created (e.g., by faulting), geothermometers reflect the chemical and thermal conditions at the depth interval that the fluid has conductively equilibrated over a long period before a vertical conduit allows convective upflow. By pairing geothermometer temperature estimates with our recent three-dimensional temperature model of conductive heat flow in the Great Basin, we estimate the corresponding reservoir depths and construct a map of circulation depths.

The predicted depths from geothermometers have spatial patterns across the Great Basin that relate to patterns seen in other geologic and geophysical data. Deeper springs generally occur disproportionately in areas with higher strain rates and in basins. We posit that current elevated strain rates reflect patterns of historic deformation where ongoing tectonic activity maintains permeable pathways to deeper reservoirs, some of which are estimated to exceed 6 km depth. Basins, as expected, contain a disproportionate number of these deep systems, because the underlying aquifers are closer to the surface in basins, thus requiring less water pressure to reach the surface than in mountain ranges. Most springs estimated to have their source in a deep reservoir occur at places known to host a hydrothermal system; these refined depth estimates of the source

reservoir can help to better constrain the source depth for many known hydrothermal systems across the Great Basin.

1. Introduction

We extract depth estimates from chemical geothermometer estimates (hereafter, geothermometers) in the Great Basin using a recent three-dimensional conductive heat flow temperature model (Burns et al., 2024; DeAngelo and Burns, 2024). Geothermometers use the chemical and mineral constituents of hydrothermal fluids to predict the temperature at which these fluids equilibrated with the host rocks. Equilibration occurs whenever water spends sufficient time residing or flowing through a depth interval (e.g., permeable geologic layer), so the geothermometer represents the most recent equilibrium before rapid ascent of the water through a hydrothermal conduit (Kennedy et al., 2020); the term "rapid" only implies that travel time is fast relative to chemical reaction rates, so that the mineral content of the water still represents temperature and compositional conditions at the depth interval of the most recent equilibration. The reservoir depth estimates therefore represent an estimated depth of equilibration (i.e., the depth at which lateral flow is accumulated and starts its rapid ascent). The Burns et al. (2024) temperature model is a one-dimensional conductive heat flow model that uses a recent conductive heat flow map of the Great Basin (DeAngelo et al., 2023a) along with equations from Williams and DeAngelo (2011) that assume steady-state conditions, negligible convective heat flow, uniform constant radiogenic heat production with depth, and varying sedimentary unit thickness to estimate temperature between 0 and 7 km depth. The heat flow model (DeAngelo et al., 2023a) took steps to remove the influence of wells reflecting hydrothermal upflow and groundwater recharge, thus depicting only broad regional heat flow variations. This results in a temperature model that does not represent convective heat flow from hydrothermal systems or local effects from groundwater recharge; it depicts conductive conditions only with thermal gradients that are nearly linear within sedimentary units or underlying rock.

2. Methods

2.1 Geothermometer Data

Geothermometer temperatures for wells and springs in the Great Basin were obtained from the Nevada Bureau of Mines and Geology (Mlawsky and Ayling, 2020, Fig. 1). For each well or spring location, all available geothermometer temperatures were used to extract corresponding depths from the 2024 U.S. Geological Survey (USGS) three-dimensional temperature model of the Great Basin (Burns et al., 2024). Three geothermometers were present in the data, one cation and two silica geothermometers: the cation geothermometer Na-K-Ca (Fournier and Truesdell, 1973); and silica geothermometers: quartz and chalcedony (Fournier, 1977), though many of the wells and spring samples had only some or none of the geothermometers present. The geothermometers used the following equations:

Na-K-Ca: $$T = \frac{1647}{\log\left(\frac{Na}{K}\right) + \beta\left[\log\left(\frac{\sqrt{Ca}}{Na}\right)+2.06\right] + 2.47} - 273.15$$ Fournier and Truesdell (1973) (1)

Quartz (SiO_2): $$T = \frac{1309}{5.19 - \log\left(SiO_2\right)} - 273.15$$ Fournier (1977) (2)

Chalcedony (SiO_2): $$T = \frac{1032}{4.69 - \log\left(SiO_2\right)} - 273.15$$ Fournier (1977) (3)

Where T, Na, K, Ca, SiO_2, are temperature in °C, sodium concentration in mg/L, potassium concentration in mg/L, calcium concentration in mg/L, and silica concentration in mg/L, respectively. For the Na-K-Ca geothermometer, $\beta = 1/3$ if $\left[\log\left(\frac{\sqrt{Ca}}{Na}\right) + 2.06\right] < 0$, otherwise $\beta = 4/3$ unless the resulting temperature exceeds 100°C, in which case $\beta = 1/3$.

Different geothermometers produce valid results within different temperature ranges. Equations for silica geothermometers (e.g., quartz, chalcedony) presented in Fournier (1977) are described as relating silica content to temperature in the range of 0-250°C but further states: "*The quartz geothermometer probably works best in the temperature range 150-225°C"*. The Na-K-Ca geothermometer (Fournier and Truesdell, 1973) was developed using data ranging in temperature from 4-340°C, though Li (2000) recommends its use above 200°C. The maximum temperatures reported for the Na-K-Ca, quartz, and chalcedony geothermometers were 284°C, 243°C, and 234°C, respectively.

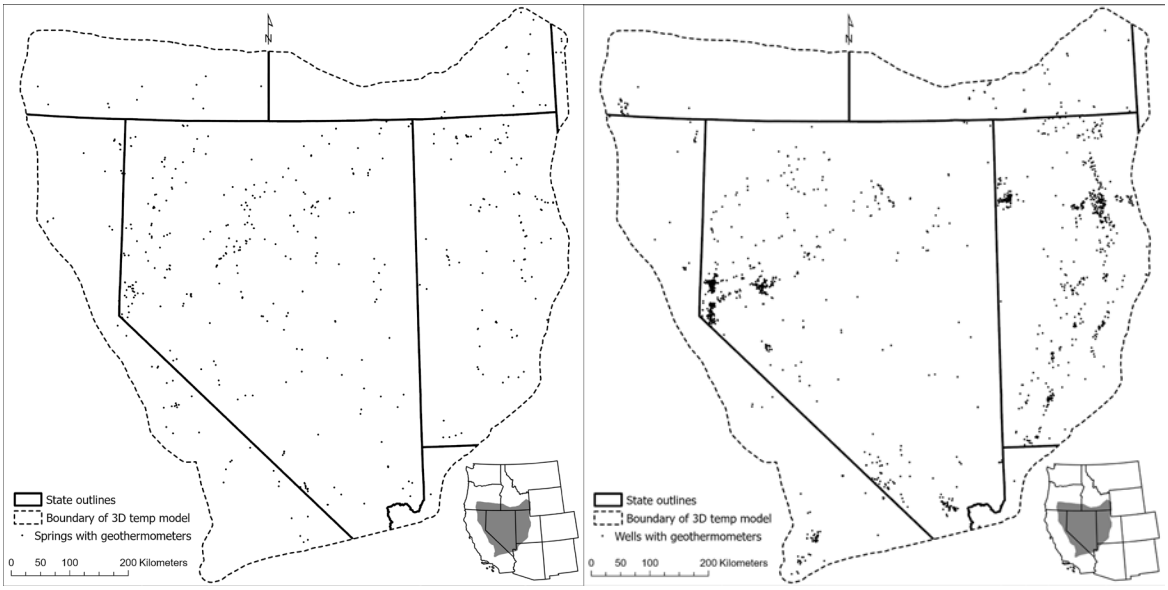

Figure 1: Distribution of springs (left) and wells (right) containing geothermometer temperatures with charge balance not exceeding ± 5% (Mlawsky and Ayling, 2020) shown above the boundary of the temperature model (Burns et al., 2024) and state outlines (U.S. Geological Survey, 2023b).

2.2 Estimation of Depth

Depth was estimated using the nearest thermal profile of Burns et al. (2024) by linearly interpolating depth proportionally between the two temperatures bracketing each geothermometer temperature. The Burns et al. (2024) model assumes conductive conditions only; it does not depict convective effects from known hydrothermal systems or groundwater flow. Associated depth estimates, therefore, assume a conductive gradient. The Burns et al. (2024) model estimates temperature up to 7 km depth; any geothermometers with a corresponding depth greater than 7 km were labeled as having a 7 km depth and can be assumed to be greater than 7 km depth.

2.3 Conceptual Model

For a spring at the surface to release water from a deep reservoir, there must be permeable pathways leading to that deep reservoir. These pathways must be maintained with new fractures

generated from faulting more quickly than they seal shut from mineral precipitation as fluids migrate through changing temperature, pressure, and compositional conditions. However, if a fracture pathway intersects shallower reservoirs, the water at the surface will be dominated by water from the shallower reservoirs with geothermometers reflecting the lower temperatures , even if hydraulic properties are the same. This is because flow path resistance is proportional to flowpath length (Darcy, 1856), with shorter flowpaths being the easier path. A spring discharging water from a deep reservoir must therefore have very few connections to shallower reservoirs along its path. There is likely some mixing along the way, but to have geochemical conditions reflecting a high temperature, most of the flow must have originated from a single deep horizon that equilibrated with the surrounding conductive temperature conditions at depth.

2.4 Histogram Maps

To visualize regional depth estimates, we plotted histograms (examples in Fig. 2) for 50 by 50 km cells in our study area depicting the count of nearby (within a radius reaching from the cell center to the corner) depth estimates for the different geothermometer types. Samples with a charge balance exceeding ± 5% are not considered valid for reliable geothermometer estimates and were therefore excluded (Nordstrom et al., 1989; Appelo and Postma, 2005). To account for geographic clustering of data, all well or spring observations in geographically clustered areas aside from the minimum, median, and maximum values within a 1 by 1 km cell were excluded.

The different styles of plots in Fig. 2 depict: A) the *raw* count with each plot showing a maximum of 20 records per bin; B) a *scaled* depiction where the maximum number of depicted records is equal to the size of the largest bin; and C) a *presence /absence* plot where a full color bar is given if any observations fall into the bin. These are included to offer visualizations that allow one to see where deeper reservoirs are predicted, even when there are relatively few observations. The individual histograms seen in Fig. 2 comprise the 50 by 50 km blocks in the histogram plots in subsequent figures. Colors in the histogram correspond to depth to make it easier for an observer to see where deeper depths were predicted.

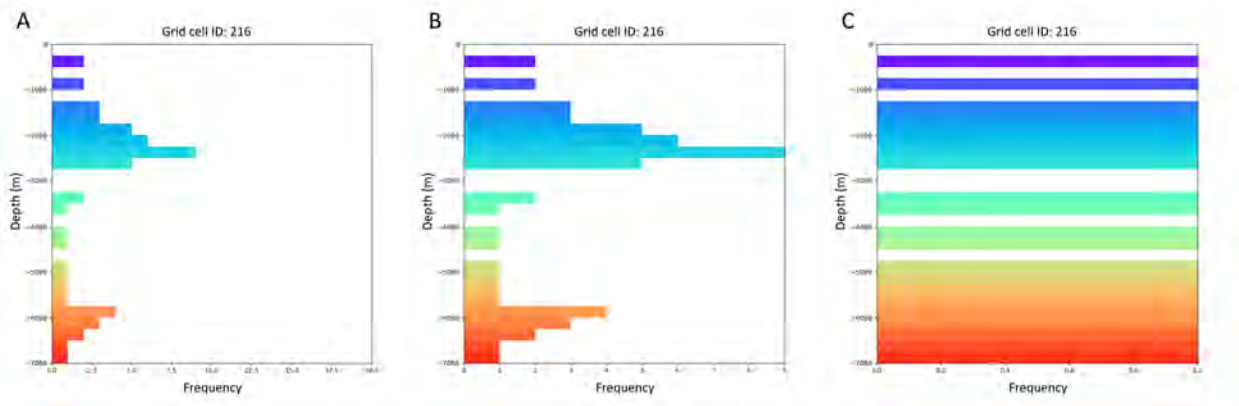

Figure 2: Example histograms for a single 50 km grid cell depicting the frequency of depth estimates based on geothermometers. These three histograms depict the same data and show, A) the raw counts, B) scaled to maximum to emphasize the local pattern, and C) presence/absence to emphasize depth intervals that may be permeable.

2.5 Comparison to Other Regional Maps

We compare geothermometer depth estimates to regional models for strain rate (Zeng, 2022), heat flow (DeAngelo et al., 2023a), and derivatives of elevation data that separate the local basin and range elevation signal from regional trends in elevation (DeAngelo et al. 2023b). We select the strain rate model (i.e., the second invariant of strain derived from geodetic observations) from Zeng et al. (2022) to examine how deeper geothermometer estimates correspond to rates of overall deformation under the hypothesis that elevated strain rates may be an indication of increased tectonism that could provide a continued connection to deeper reservoirs. We select the conductive heat flow from DeAngelo et al. (2023a) to see whether deeper geothermometer estimates fall disproportionately in areas of higher or lower heat flow. We select elevation trend from DeAngelo et al. (2023b) as a proxy for crustal thickness to test whether thermal springs with estimated deep sources occur disproportionately in areas with thinner crust. We also look at detrended elevation from DeAngelo et al. (2023b), which depicts elevation relative to the basin-range interface (generally with positive values in ranges and negative values in basins) to see whether deeper springs fall disproportionately in basins.

To understand whether deeper reservoir estimates preferentially fall in areas with disproportionately higher or lower values of the features mentioned above, we inspect the rank order of said features at locations of relatively deep springs. By isolating the rank order for features at only the deeper springs (deeper than 3 km using quartz estimates), we compare the distribution of rank values for deeper springs to the values from the entire study area. Proportionally higher ranks indicate preferentially higher values in features; likewise, proportionally lower ranks preferentially indicate lower feature values.

3. Results

Fig. 3 shows the combined counts of estimated depth from all declustered wells and springs at each 50 by 50 km cell (as illustrated in Fig. 2) across the study area to provide a visualization of where geothermometer estimates correspond to relatively deep source depths. The columns in Fig. 3 show the three different styles of histograms (raw, scaled, presence/absence); the rows show the three geothermometer types (Na-K-Ca, quartz, chalcedony). Most frequently, reservoir depths are in the range 0-2 km, as shown by blue histogram bars across most of the Great Basin in all visualizations in Fig. 3, but reservoir depths over 6 km are present over parts of the study area, shown by the warmer (i.e., redder) colors. Areas with deeper estimates suggest deep reservoirs and tend to be near northwest Nevada or along the Wasatch Front (i.e., areas known to host hydrothermal activity [Faulds et al., 2021]), with the greatest proportion in the northwest quadrant of Nevada and relatively few in the central Great Basin in the areas surrounding the Nevada-Utah border.

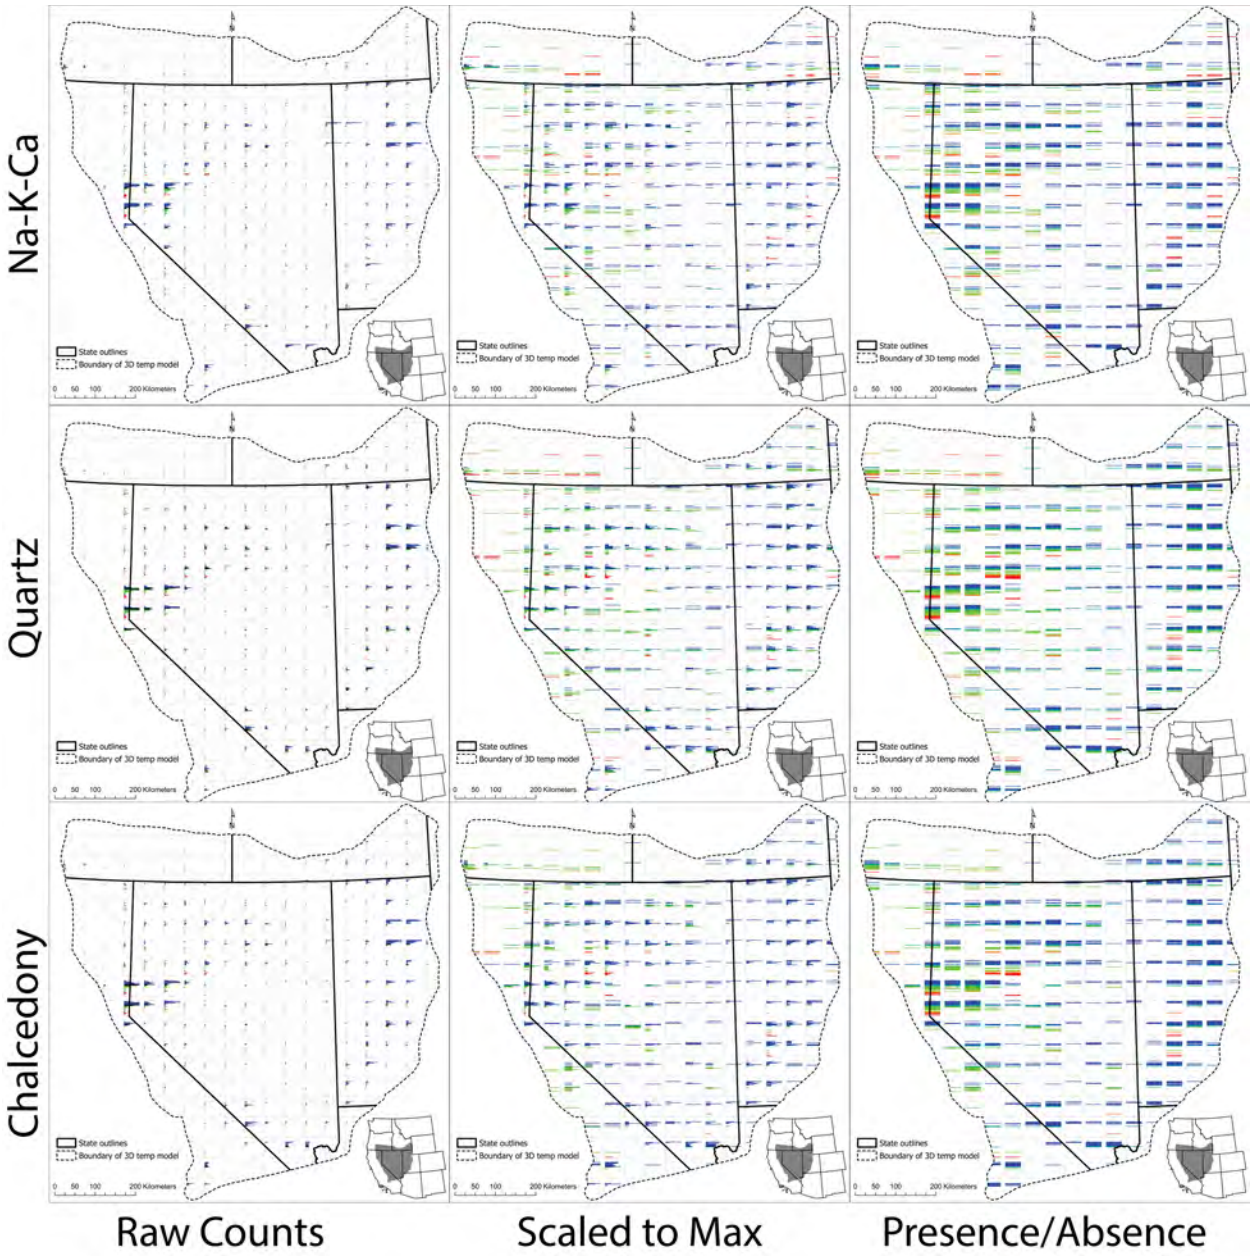

Figure 3: Histogram plots for the Na-K-Ca, quartz, and chalcedony geothermometers (rows from top to bottom), with raw, scaled, and presence/absence plotting styles (columns from left to right). All plots contain histograms showing the frequency of nearby depth values predicted from a combined data set of all declustered wells and springs with charge balance not exceeding ± 5%.

4. Discussion

Maps in Figs. 4A-C compare only springs (i.e., not wells) to known hydrothermal systems (Fig. 4A; Faulds et al., 2021), geodetic strain rate (Fig. 4B; Zeng, 2022), and detrended elevation (Fig. 4C; DeAngelo et al., 2023b). Most of the deeper springs (deeper than 3 km using quartz estimates with charge balance not exceeding ± 5%) are associated with known hydrothermal systems (Fig.

4A). These hydrothermal systems do not have reported values for estimated reservoir depths; however, extrapolating depths informed by the geothermometer estimates from the Burns et al., (2024) temperature model allows for a better understanding of the possible reservoir depths of known geothermal systems.

Fluids from deeper reservoirs (e.g., 6 km; Fig. 3) require permeable pathways to reach the shallow subsurface. The results presented in Figs. 4B and D suggest that active ongoing tectonic deformation in these areas correlates with maintaining these permeable pathways (Kennedy et al., 2020). The current strain rates reflect current deformation, but likely also reflect past deformation. Areas with deeper predicted reservoirs generally have been experiencing higher deformation rates relative to the larger study area, which may have been creating and maintaining sufficiently high permeability to outpace mineral precipitation in the pathways from deep reservoirs. Fig. 4D shows that deeper springs tend to be correlated with higher strain rates, as the blue line is higher than the 1:1 'Entire Great Basin' line throughout, with approximately 40% of deep springs being in areas in the top 80% of strain values. These deeper reservoirs must have some component of lateral flow, and perhaps they exist in horizontally permeable strata throughout the Great Basin (either primary or secondary permeability). Although the evidence shows springs with estimated depths deeper than 5 km depth in many areas across the Great Basin, we do not see this in all areas. We postulate strain rates are insufficiently high in most areas to regularly establish and maintain vertical conduits with geologic units at 6 km depth, and therefore, there may exist hidden reservoirs at this depth in other areas (i.e., the absence of evidence does not imply the evidence of absence), and future studies could strive to develop methods to identify deep reservoirs that are currently untapped by hydrothermal circulation.

DeAngelo et al. (2023b) describe how patterns in regional elevation trends are likely a good proxy for variations in crustal thickness in the Great Basin, and that heat flow and crustal thickness appear to be inversely related in much of the Great Basin, because thinner crust results in less insulation between the atmosphere and the hot interior of the Earth. We sought to discover whether thinner crust (~1 km thickness differences observed across the Great Basin [DeAngelo et al., 2023b]) might also be allowing more surface expressions like deeper thermal springs to manifest from reservoirs that exist at the same sea level in areas with thicker crust, simply because there is a shorter path to the surface. Fig. 4D shows no evidence of this; deeper springs do not appear to be correlated with thinner crust, as the orange line for crustal thickness mostly has little divergence from the 1:1 'Entire Great Basin' line. We next looked at detrended elevation to see whether these deeper springs fell disproportionately in areas above or below the range front. These deeper springs overwhelmingly tended to fall in areas with low detrended elevation values (i.e. basins, see Figs. 4C, D); this is to be expected, because springs emerge at the surface in basins far more frequently than in ranges because the underlying aquifers are closer to the surface in basins, thus requiring less water pressure to reach the surface than in mountain ranges. Fig. 4D also shows a curve for raw elevation (U.S. Geological Survey, 2023a), which falls between the crustal thickness and detrended elevation curves. This is likely because the elevation data contain a mixture of signals for both detrended elevation and regional elevation (reflection of crustal thickness), and springs correlate strongly with the signal from detrended elevation, causing a correlation magnitude with raw elevation to fall between that of crustal thickness and detrended elevation. Additionally, heat flow exhibited only a modest amount of correlation with deep springs (Fig. 4D).

The discussion herein has ignored possible confounding effects of volcanism. Strain conditions that create vertical paths for water upflow could also conceivably create conduits for magma upwelling. Studies have shown that modern volcanism correlates with hydrothermal favorability (Smith and Shaw, 1975; Williams and DeAngelo, 2008). Therefore, in some cases, upwelling magma might conceivably bias depth estimates made from geothermometers. As the northwest corner of the study area occupies the transition between the Great Basin and the Northwest Volcanic Province (Sherrod and Keith, 2018, Glen et al., 2004), we postulate that some of the deeper estimates are likely affected by rising magma; the same could be occurring in volcanic areas of eastern California. Hence, the associations we identify between estimated geothermometer depths and strain rate are broad trends rather than a complete explanation.

This paper is intended as a proof of concept to begin discussions about using geothermometers as a tool to estimate reservoir depths in the Great Basin. Future work could focus on better understanding the reliability of the various geothermometers based on whether minimum chemical concentrations should be present, whether pH should be within certain limits, whether other geothermometers should be generated to provide additional support, and other related considerations. Herein, the focus has been on the temperature estimates made from hydrothermal waters, but future efforts might also consider the chemistry of these fluids to answer questions like:

- Does the chemistry and/or mineralogy tell us anything about the reservoir itself?
- Can we compare this chemistry across regions to postulate whether these deep reservoirs extend for great distances?
- Does the water chemistry show evidence of magmatic degassing?

Understanding these questions could help to uncover whether deep reservoirs may exist laterally at a great scale throughout the Great Basin.

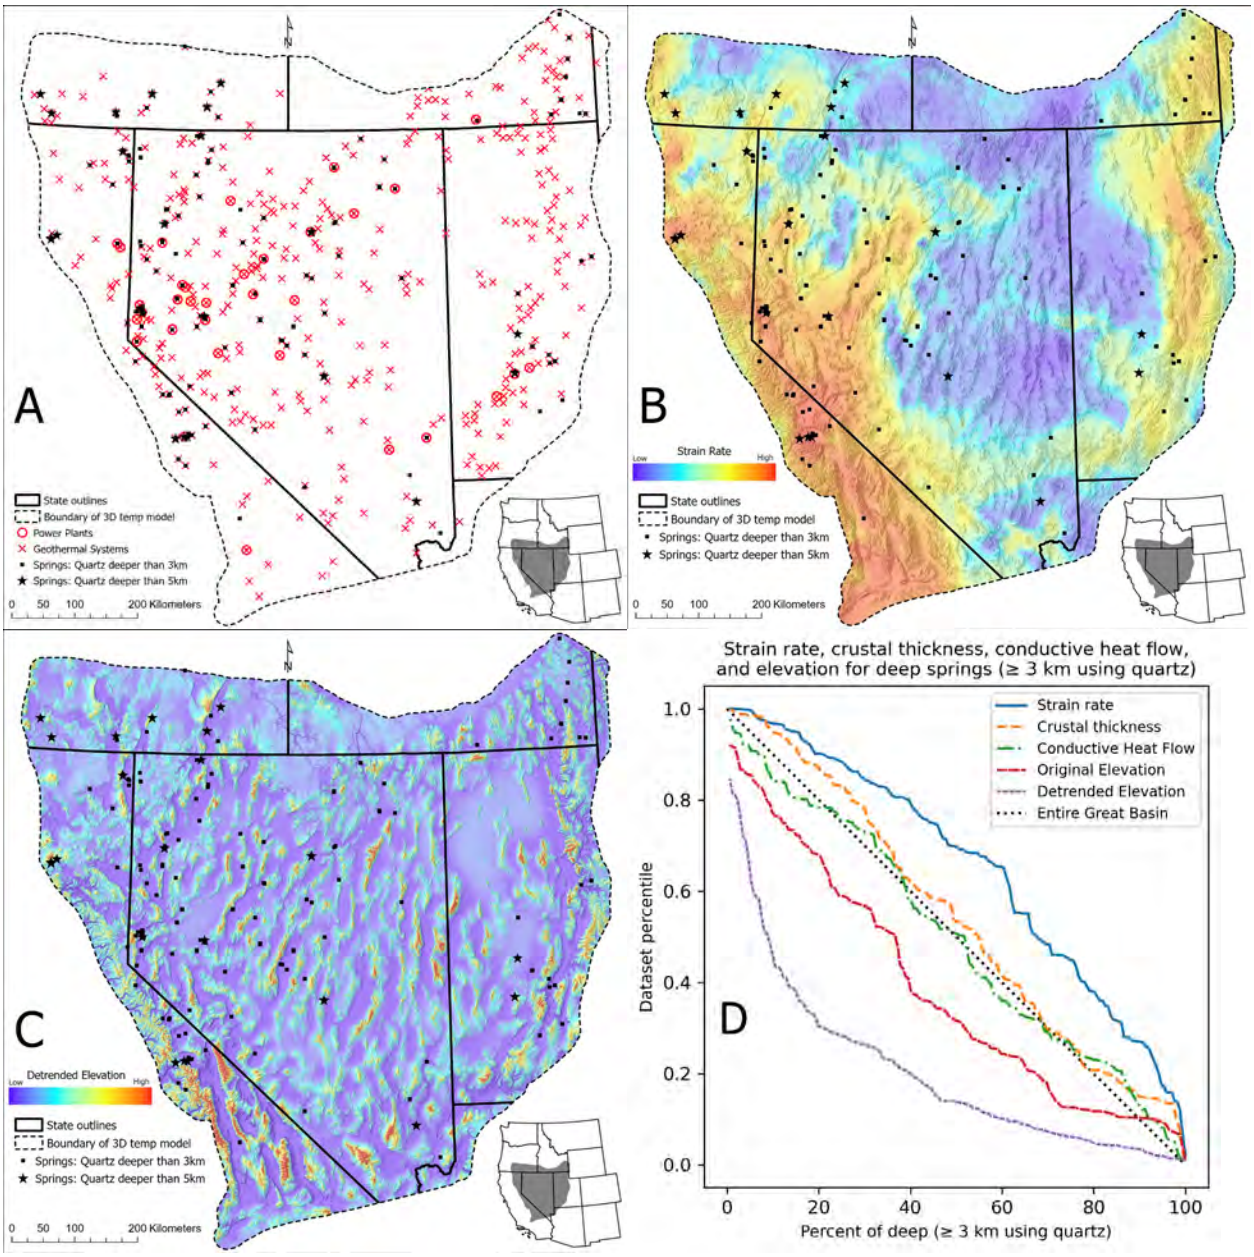

Figure 4: A) Springs with relatively deep (≥ 3 or ≥ 5 km) quartz geothermometer reservoir estimates overlain upon locations of known geothermal systems and power plants (Faulds et al., 2021). B) Strain rate (Zeng, 2022) with deep quartz springs plotted, C) Detrended elevation (DeAngelo et al., 2023b) with deep quartz springs plotted, D) Predictive skill for all features examined: the 1:1 "Entire Great Basin' line depicts values across the entire study area and the curves for features that depart from the 1:1 line show that deeper springs (≥ 3 km using quartz) have disproportionately high strain rate and low detrended elevation (i.e. basins). Hillshade for B) and C) is derived from USGS National Atlas (National Atlas of the United States, 2012).

5. Data Release

A USGS data release (DeAngelo and Burns, 2024) that supports this paper contains the well and spring data with estimated depths from all available geothermometers, including those with a

charge balance exceeding ± 5%; the data release also contains the georeferenced histogram plots shown in Fig. 3.

Stable isotopes, 18-Oxygen, The Geysers

ABSTRACT

The high-temperature reservoir (HTR) in the northwest Geysers inherently produces steam of varying quality, for example, higher volatile chlorides than the normal-temperature reservoir (NTR) in the central and southeast Geysers. HTR rocks from the northwest central Prati area (formerly Central California Power Agency) have distinct delta18-Oxygen (δ18-O) isotopic signatures compared to rocks of the NTR, but HTR rocks from the nearby Aidlin and High Valley areas have isotopic signatures like the rocks of the NTR. Reservoir metagraywackes of the NTR have silicate δ18-O values as low as +3 ‰, while anomalously high values in metagraywackes in productive portions of the central northwest Prati HTR typically range from +8 to +10 ‰. This δ18-O anomaly in the Prati portion of the NW Geysers reservoir is particularly striking given that is bounded to the SW (Aidlin) and the NE (High Valley) by blocks which produce steam of comparable pressure and temperature from similar depths, suggesting that the deep Prati reservoir is not hydrologically isolated even if it is isotopically distinct.

Many previous studies have concluded that the primary cause of isotopically “light” rock compositions in the main Geysers field was pervasive flushing of the permeable reservoir rock by meteoric waters with an average value of -8‰, while permeable reservoir rock in the Prati HTR has not been pervasively flushed and is therefore producing steam from boiled connate and / or magmatic waters with δ18-O values near 0‰. Some studies have suggested mechanisms by which water flushing of the Geysers reservoir could have reached far northwest into the HTR sections of Aidlin and High Valley without impacting the HTR in the Prati area. One key line of evidence for such models is the overall lower noncondensable gas (NCG) content of steam produced from Aidlin and High Valley versus Prati HTR sections. Although stable isotope systematics have always been considered as supporting evidence in such studies, detailed software-based mapping of rock 18-O data has not previously been done at The Geysers.

Whole-rock and steam condensate samples have been collected continuously during drilling and flow testing of new geothermal wells between 2018 and 2024, and these samples have added to the existing legacy data set of >1,000 silicate 18-O analyses. Sampling from a new step-out drilling program in the northwest Geysers has also significantly increased data density in both the NTR and HTR sections in this area. The entire Geysers δ18-O whole rock isotope catalogue (now ~1,400 δ18-O analyses) has been turned into an interpolated 3D model using the radial basis function in Leapfrog Energy software. Integration of this new isotopic model with fault mapping, micro-earthquake (MEQ) hypocenter alignments, and lithology data has allowed for new insights into the possible fault controls for meteoric water flushing in the Northwest Geysers and its impact on HTR steam quality. This isotope map has also been used to assist in the planning and targeting of new geothermal wells at The Geysers.

1. Introduction

1.1 Overview of Oxygen Isotopes Systematics

Regional scale δ18-O compositional mapping of silicate minerals was first recognized as a prospecting tool in mining geology where large, economic ore bodies are created by deep circulation of heated meteoric waters which cause hydrothermal alteration of magma bodies and surrounding country rock (e.g. Criss et al., 1991 and references therein). Criss et al. noted that steep δ18-O gradients and "bullseye" map patterns generally pointed towards the centers of such deposits. Since large hydrothermal ore bodies are essentially the rock record of extinct geothermal systems, many workers realized that the Oxygen and Deuterium (O / D) stable-isotope systematics of ore bodies could be applied to understanding active geothermal systems, including The Geysers in northern California. Craig (1963) noted that most geothermal systems worldwide are composed of boiling meteoric water. As a result, typical water / rock interactions in hydrothermal systems consist of isotopically light meteoric water causing initially isotopically heavy δ18-O values of unaltered rock to be depleted to values closer to zero ‰, though exact isotope values of both waters and rocks will vary by region. In the Geysers / Clear Lake region, unexchanged metagraywackes of the Franciscan Formation outside of the geothermal field have values as high as δ18-O +17‰ (Hulen and Moore, 1995), and meteoric waters have δ18-O values of -7 to -8‰ (White et al 1973). Inside the Geysers geothermal reservoir, steam-condensate samples have δ18-O values of +3.2 to -6.8‰ (Lowenstern and Janik, 2003; Geysers unpublished data), and δ18-O values in silicate-mineral samples from reservoir-depth metagraywacke and granitoid intrusions ("the felsite") range from +2 to +10‰ (Geysers unpublished data).

As this wide range of δ18-O silicate and δ18-O / D water values suggests, The Geysers reservoir is not contained in a single homogeneous body of uniformly exchanged rock, but rather contains notable vertical and lateral δ18-O isotopic gradients which have been extensively studied and published on over the last 40+ years with implications for not only conceptual understanding of reservoir emplacement and evolution but also practical understanding of exploration, development and extraction. For example, the SE to NW increase in rock δ18-O values was used to interpret the magnitude and direction of meteoric water flushing (Truesdell et al., 1987; Walters and Beall, 2002); abrupt lateral shifts from low to high rock δ18-O values were used to infer fault bounded reservoir compartments in the northwest Geysers (Walters et al., 1996); δ18-O rock isotopic gradients were correlated with primary and secondary mineralogy profiles of well bores that approach and penetrate the felsite pluton that intruded the central and southeast Geysers (Moore and Gunderson, 1995); anomalously high 18-O water and rock isotopes in the northwest Geysers

were used to identify and characterize a distinct HTR component in the CCPA / Prati area (Haizlip, 1985; Truesdell, 1991; Walters et al., 1992); fluid inclusion studies of 18-O / D isotopes were employed to help characterize the fluid in multiple generations of vein paragenesis (Moore and Gunderson, 1995; Jones et al., 2016); and correlations have been made between low isotopic exchange in the reservoir with poor steam quality, i.e. high NCG and high chloride content (Gunderson, 1989, Beall et al., 2007).

1.2 Novel Application

This paper is written in the context of all the above research, but it is focused on the utility of the Geysers rock δ18-O isotopic database itself as an applied science tool that leverages all the research cited above. The sheer sample size, areal extent and data density of the dataset makes it an ideal candidate for interpolation into a geo-referenced 3D mesh body. This was done using the radial basis function in Leapfrog Energy software, though any similar 3D interpolation tool on various industry-standard software platforms could have been employed to achieve similar results. The resulting data visualization does not supplant any of the conceptual models referenced above, but rather helps validate them and leverage them into an exploration and well- targeting tool by integration with other data sets in 3D model space. Calpine is now using subsurface variation in rock δ18-O values to develop targets for new wells, which is a novel application of stable isotope data at The Geysers.

1.3 High-Temperature Reservoir (HTR)

The Geysers vapor-dominated system primarily produces steam from the normal-temperature reservoir (NTR) at temperatures up to 240° C. Starting in the 1980s, deeper drilling in the northwest Geysers encountered steam temperatures of up to 346° C (Walters et al., 1988; Unocal unpublished reports), which contained varying NCG concentrations and high volatile chlorides. Today, Calpine's Resource team delineates the top of the high-temperature reservoir (HTR) when reservoir temperature reaches 260° C and temperature gradients switch from convective to conductive. Recent drilling in the northwest Geysers validates the ongoing use of these criteria (Calpine unpublished data). Although the NTR and the HTR have distinct temperatures and geochemical characteristics, they are nonetheless connected, with no hydrologic or structural boundary between them (Walters et al. 1996). In some areas of the field (e.g. Aidlin), HTR steam was utilized commercially, while in other parts of the field, some HTR steam was initially considered not economically viable, e.g. former CCPA areas 2 and 3 (Walters et al. 1996). Steam with the highest NCG content was consistently found in HTR rocks that were less isotopically exchanged (Walters and Beall 2002). The northwest Geysers Enhanced Geothermal System (EGS) demonstration project deepened existing wells in the former CCPA leases farther into the HTR and encountered reservoir temperatures of 400° C (Garcia et al., 2016). Whole-rock δ18-O values from reservoir metagraywacke samples taken from the productive EGS reservoir ranged from +10 to +12‰, which are comparable to cap rock values in the rest of The Geysers (Lutz et al., 2012). The Geysers EGS project showed that injection of tertiary-treated recycled water could reduce the NCG content of the steam by up to 90% (Garcia et al., 2016), which significantly improves its economic viability, but the fundamental underlying observation that the deep northwest central (Prati / CCPA) Geysers HTR has experienced no natural meteoric-water flushing remains true, irrespective of these injection derived benefits to the reservoir. Further discussion of injection impacts at The Geysers are beyond the scope of this paper but are summarized in Beall et al. (2007).

2. Methods

The data set used to create the 3D model described in this study contains ~1,400 unique samples (with more pending at the lab) and is a fully validated and quality-controlled compendium of all the rock isotope data from the Geysers and surrounding delineation wells, including much (if not all) of the rock isotope data used in the references cited in the introduction. Figure 2 is a summary histogram of all δ18-O rock isotope data with a bin size of 0.5‰.

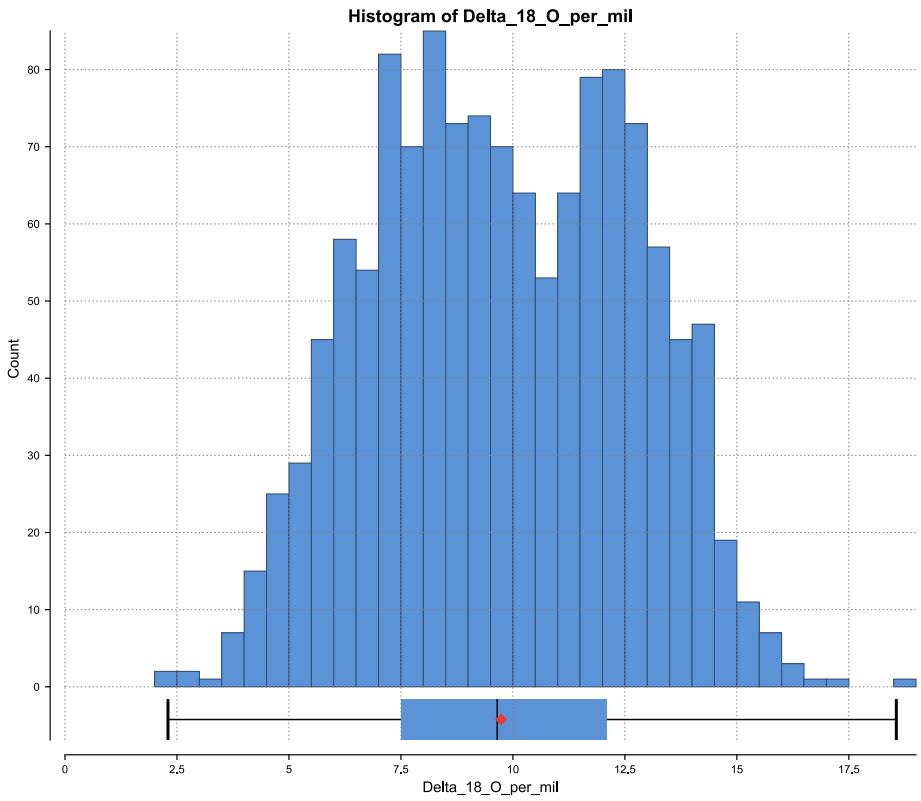

Figure 1: Histogram summarizing the entire δ18-O rock isotope database used to create the 3D rock isotope model described in this section. The catalogue was screened for anomalous values, and all georeferencing for each well's data set was cross checked against original well files and sampling notes.

Since 2019, ~300 new analyses have been completed, primarily on samples collected from new wells that Calpine has drilled at The Geysers. In 2021, 36 additional legacy samples were obtained from The EGI Geothermal Sample Laboratory in order to fill in some spatial gaps in the central and southeast Geysers. Rock isotope sampling has become part of Calpine's mud-logging and sampling standard operating procedure, including for recent drilling. Sample collection starts at ~2,000 feet (ft) measured depth in each newly drilled well and continues at ~500-ft intervals to total depth, hole conditions and rock type allowing. Only intervals logged as ≥80% graywacke or 100% felsite are considered for analysis. Samples are collected even in the shallow caprock to improve data density in the 3D model and to capture any isotopic variations that might occur in

the transition from caprock to the top of the steam reservoir. Steam-condensate samples are also collected for 18-O / D sampling at various stages during drilling and flow testing, but discussion of steam condensate isotopes is beyond the scope of this paper.

Samples were prepared following the same procedures that have been applied by various Geysers resource groups (multiple operating companies) since the mid 1990's, so that new data can be compared directly to historical data. Sample preparation procedures are described in Gunderson and Moore (1994) and bromine pentafluoride digestion of samples to extract oxygen from silicates is described in Clayton and Mayeda (1963). Analytical results in this paper are reported in delta notation relative to standard mean ocean water (SMOW). The Calpine Geysers Resource group and other previous resource groups have primarily employed the stable isotope lab at Southern Methodist University for the majority of the rock and water sample analyses continuously from the mid 1990's to the present.

3. Results

The primary utilities of the 3D rock isotope model are: 1) improved data visualization, 2) integration into existing conceptual models, and 3) application to well targeting. This section will give examples of each of these categories.

3.1 Data Visualization

Before discussing improved data visualization capabilities provided by this rock isotope 3D modeling effort, it should be said that using software interpolation to convert point clouds in the format (X,Y,Z + data) into body models is not a novel technique, nor is using various subsurface modeling software platforms to create map views and cross-sections of such data. Therefore, the intent here is to show that these well-established techniques have added value to a large and valuable Geysers legacy data set that was not previously utilized to its maximum potential. Previous renderings of the rock isotope data for The Geysers reservoir had been limited to plan view contour maps of average values from a wide range of reservoir depths shown at a single representative datum (e.g., Walters et al., 1996), or hand drafted cross sections which were time consuming to create and thus limited to one or two major section lines traversing the steam field per project (e.g. Garcia et al., 2015). Figure 2 is a series of map view depth slices of the rock isotope model focused on the northwest Geysers study area. This sequence of depth slices elucidates several features of the northwest Geysers reservoir that have long been understood (as discussed in section *3.2* below) but that have never been depicted in the context of detailed rock isotope maps at multiple elevations. Similarly, the cross section A-A' (Figure 3) shows the result of integrating the rock isotope model with fault data, well course locations plus "Top Steam" and "Top High Temperature Reservoir" interpreted surfaces (imported from the Geyser's SKUA GoCAD model and described in Hartline et al., (2016; 2019)). Beyond the obvious utility of generating cross sections at any view angle and refreshing on demand as new drilling data are added, this particular section view has provided several new insights. It has provided evidence that certain faults mapped at the surface penetrate to reservoir depths (see section *3.2* below) and also led to a significant re-targeting of one of the planned steam production wells in the area (see section *3.3* below).

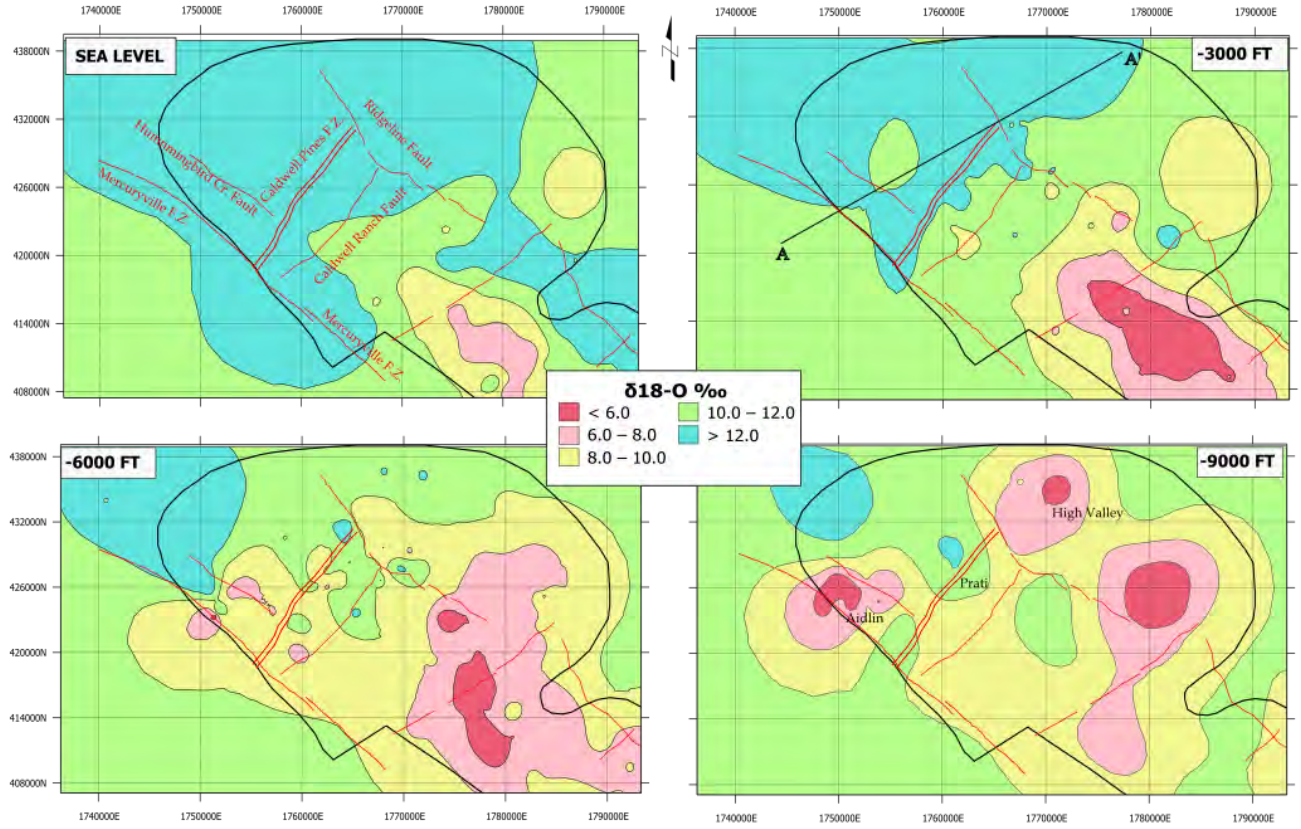

Figure 2: Figure 2. Map-view depth slices of 18-O rock isotope model in the northwest Geysers study area. The deep "lobes" of highly exchanged rock in the Aidlin and High Valley areas visible only in the slice at -9000 ft with respect to mean sea level (MSL) can only be accessed by drilling 10,000- to 12,000-ft' wells. The Prati / Caldwell Pines area (former CCPA leases) hosts normal temperature and high temperature steam reservoirs at depths from -3000 ft to -9000 ft MSL in rocks that are much less exchanged than any other reservoir rocks at The Geysers. Isotope values are contoured per the color key inset in center of figure. The Geysers reservoir limit is the solid black line, and surface fault traces are red lines. Labeling in the sea level map applies to all four views. The cross-section line for the subsequent figure is shown in the -3000 ft. map.

3.2 Comparison with Existing Conceptual Models

Previous published work referenced in Section *1.2* above has established the validity of using δ18O rock isotope data from silicates to assess the degree of water / rock interaction in the Geysers reservoir and has thus established isotopic exchange in reservoir rocks at The Geysers as a proxy for meteoric water flushing. This line of evidence has been used in the development of many conceptual models of The Geysers, some of which are summarized in Section *1.1* above and are too numerous to review here, so this discussion will instead focus on one example.

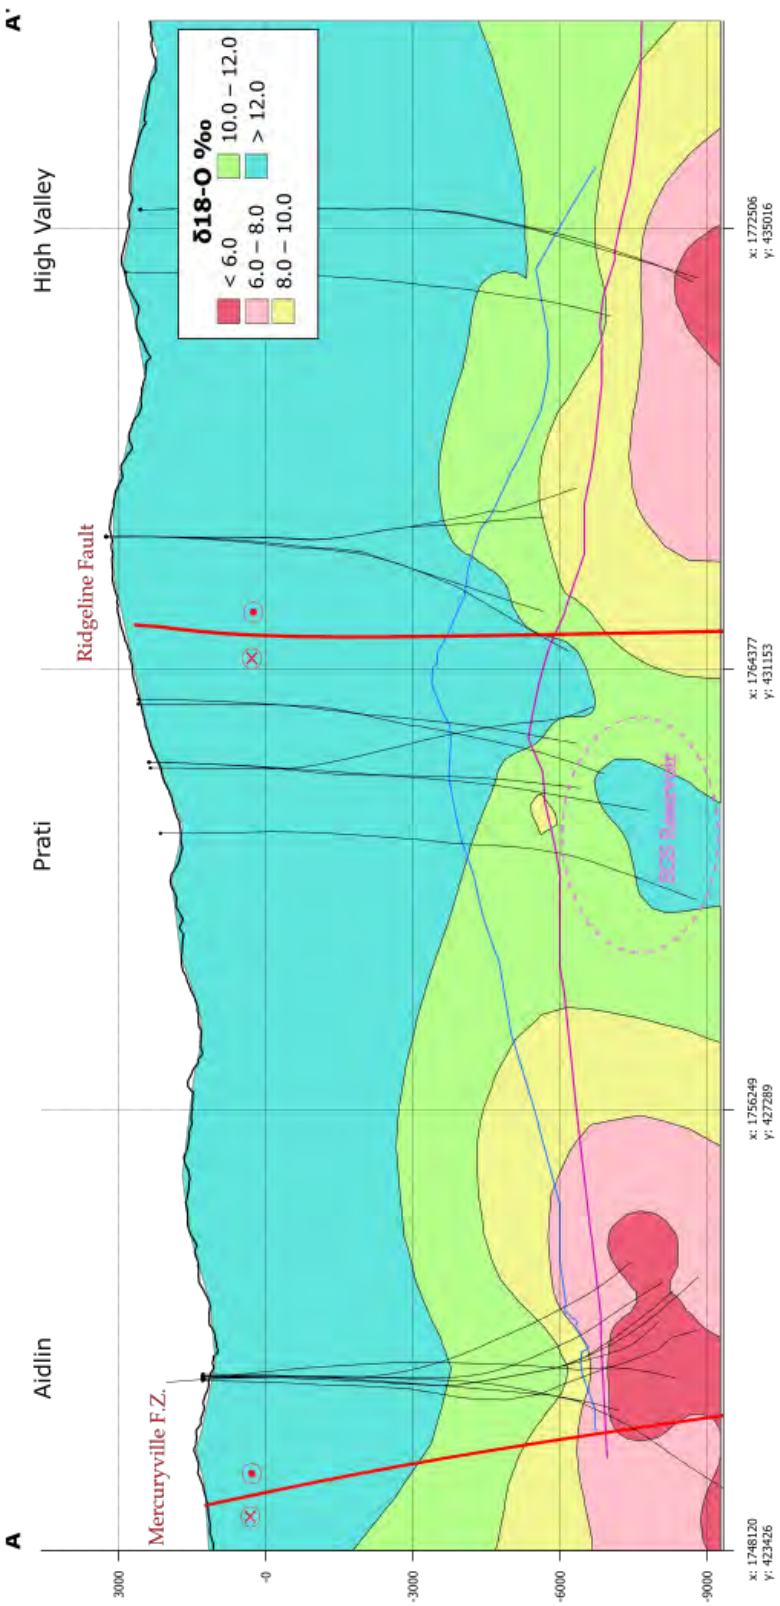

Figure 3: Cross section A-A' (southwest to northeast, see Figure 2 for location map). In this view, the 18-O stable isotope model is integrated with: a) The Geysers well course map (black lines – well names withheld), b) software projections of mapped surface faults into the subsurface (thick red lines) and interpreted surfaces "Top Steam" and "Top High Temperature Reservoir) imported from The Geysers SKUA GoCAD 3D model. This view emphasizes that the HTR of the northwest Geysers is broken into three distinct blocks: Aidlin, Prati (CCPA) and High Valley, where the two highly exchanged "lobes" of reservoir rock described in the -9000' MSL panel of Figure 2 clearly flank the less isotopically exchanged Prati block with abrupt lateral transitions on both sides. On the northeast side, this transition is spatially correlated with the Ridgeline Fault at depth. Although the Prati block of the HTR hosts many productive steam wells, NCG concentrations can exceed 60,000 ppmw, which has been correlated to the higher rock 18-O values, i.e. less meteoric water flushing.

3.2.1 Timing and Spatial Distribution of Meteoric Water Flushing

Beall et al. (2007) explained the pre-development initial condition distribution of NCG concentrations, which were lower in the southeast Geysers and higher in the northwest Geysers using a meteoric water flushing model. Their hypothesis detailed where meteoric water first entered the Geysers reservoir, and subsequent direction of flow. Figure 4A below illustrates this hypothesis. Because the southeast Geysers had the lowest initial NCG, the shallowest steam reservoir and nearby hot springs, this was the suggested entry point for the major water flushing event that occurred during a postulated tectonic breach of the reservoir and concurrent boil down from two phase into vapor dominated reservoir (see Moore and Gunderson 1995). The blue lines and arrows in Figure 4A depict the inferred SE to NW travel direction of the infiltrating water, which was determined by following the "troughs" in the NCG contours. Although Beall et al. did note that silicate δ18-O values indicative of pervasive water-rock exchange in the path of the hypothesized meteoric water flushing front were permissive of this interpretation, the isotope data were not presented in detail, nor were they plotted in map view. Figure 4B below is modified from Beall et al. 2007 figure and replaces the NCG contours with the δ18-O isotope contours at -9000 ft MSL derived from the new 3D model. Notably, the inferred meteoric water sinks from the 2007 map correspond to the deep areas of pervasive isotopic exchange in the Aidlin and High Valley reservoirs. Meanwhile, the gassier CCPA (Prati) contour block in 4A correlates to the 10‰ closed contour "island" seen in 4B.

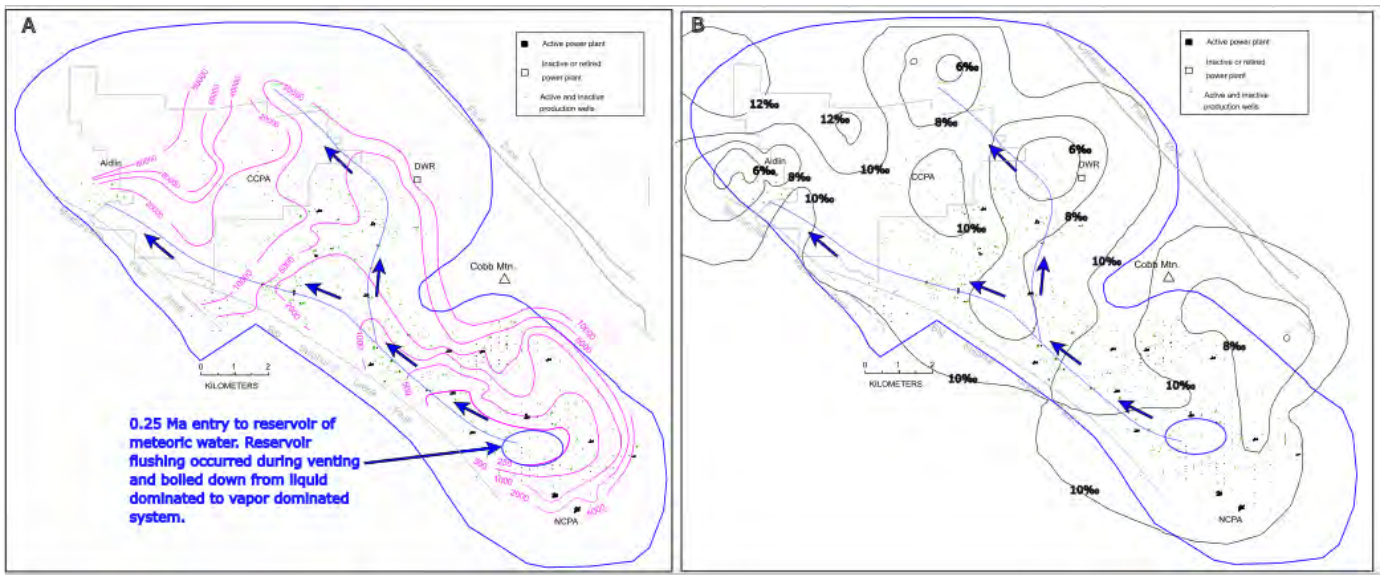

Figure 4: (modified after Beall et al., 2007) A. Conceptual model showing inferred entry of meteoric water into SE Geysers (blue oval) and interpreted path of water invasion and flushing of the steam reservoir from SE to NW, illustrated by blue lines and arrows. NCG concentrations are contoured in pink lines with values labeled in units of parts per million by weight (ppmw). B. Same as (A), but NCG contours replaced with silicate δ18-O values at -9000 ft MSL contoured in black lines with values labeled in ‰. The δ18-O contours show that the deep reservoir sections of Aidlin and High Valley have lower NCG and more isotopic exchange, while the Prati (CCPA) area has higher reservoir NCG and less isotopic exchange.

3.3 Example of Well Targeting Application

As part of Calpine's current step-out drilling program, thirteen new geothermal wells will be drilled utilizing four existing well pads. The northeast-most of these well pads is represented in the cross-section above (Figure 3). This pad is located on the northeast side of the Ridgeline fault, and has four existing wellbores, two drilled to the southwest and two drilled to the northeast. In the process of developing the 3D isotope model and integrating all the observations described above, it was noted that the two wells drilled to the northeast are reaching out towards the High Valley block of the reservoir, though their bottom hole locations are shallow with respect to the zone of maximum isotopic exchange depicted in core of this feature at ~9,000 ft MSL. In light of that observation, the original well targets planned from this pad were reconsidered as described below.

The following description references Figure 5 below for the northeast-most step-out well pad in Figure 3. The first well to be drilled on that pad was planned with a Geysers "standard" well trajectory with a kickoff point at ~3,000 ft MD and a directionally drilled section building to an inclination angle of 22° from vertical (pink line in figure). Although other factors were considered in the planning of this trajectory, it was determined that designing a different well that intersected with (and penetrated into) the modeled 10‰ isosurface at depth would improve the well prognosis by increasing the chance intersecting High Valley "type" steam, which is known to have lower NCG. The revised trajectory is shown by the black line in Figure 5. The final planned bottom hole location of this well is 1,500' deeper in true vertical depth (TVD) than the original planned trajectory.

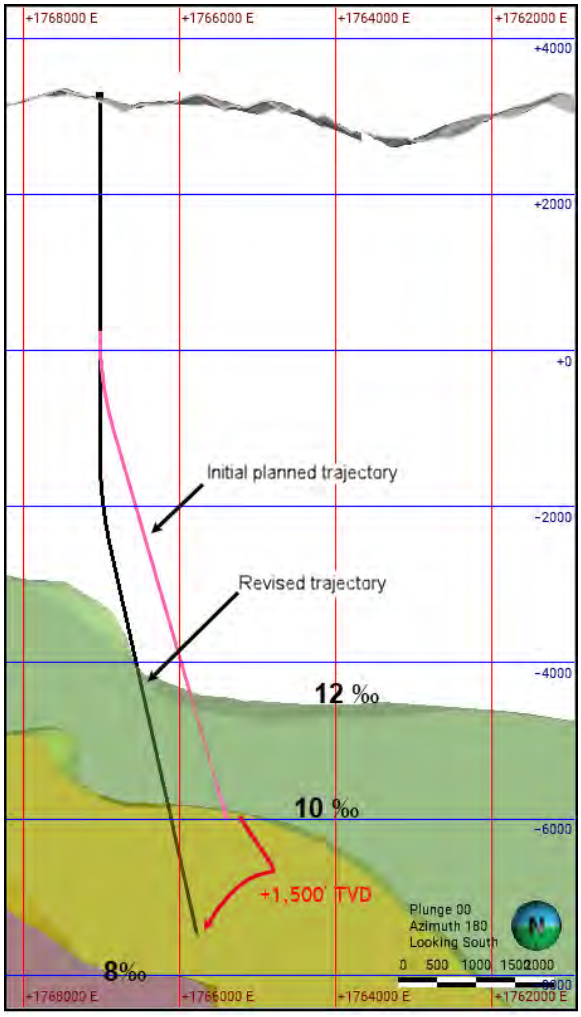

Figure 5: Cross sectional view of two planned well trajectories for Calpine's step out drilling program. The pink trajectory was planned using a "Geysers standard" well plan with a kick off point (KOP) of ~3,000 ft measured depth and a directional drilling program building to an angle of ~22° off vertical. Using the 3D rock isotope model as a guide, the well trajectory was redesigned (black line) to reach deeper into the more isotopically exchanged body of reservoir rock by using a deeper KOP and by limiting the build angle to ~18°.

Conclusions

The new δ18-Oxygen rock isotope 3D model of the Geysers reservoir was created by using software interpolation on a dataset of ~1,400 samples, which was composed of 1,000 + legacy data points and 300+ new analyses done since 2019 as part of Calpine's ongoing drilling program. The creation and use of this dataset has been done in the context of the extensive research that has already been completed on 18-Oxygen and Deuterium isotope systematics of geothermal systems in general, and of The Geysers specifically. Within that body of work are several dominant conceptual models based on integration of stable isotope data with structural data, steam condensate geochemistry, MEQ data, and operating company production and injection data. The

purpose of the present study is not to supplant any of those models, but rather to cross reference, validate, and possibly improve those models by leveraging the maximum value out of a previously underutilized dataset. This study has demonstrated that software integration has allowed Geysers rock isotope data to be incorporated into 3D model space and rapidly viewed in the context of other spatial data in ways commonly seen with potential fields in geophysical data. From that software platform, the isotope maps were also used to validate and expand upon the hypothesis of Beall et al.(2007) that meteoric water flushing started at an infiltration point in the southeast Geysers and moved deeper and to the northwest, eventually impacting the Aidlin and High Valley high temperature reservoir blocks. Finally, the isotope model has already been demonstrated to have value as a well planning tool, where an upcoming steam well trajectory in Calpine's step out drilling program was significantly changed in order to improve its chances of encountering a part of the deep high temperature reservoir where higher oxygen isotope exchange has previously been correlated with lower NCG concentrations in produced steam.

Acknowledgements

The authors wish to acknowledge Mark Waters and Joe Beall, both of whom have passed away. Their influence lives on at The Geysers. We also thank Ian Richards and John Robbins from the SMU stable isotope lab. Their consistent, quality work has been the backbone of decades worth of Geysers stable isotope research. The EGI Geothermal sample laboratory provided the authors with access to archived drill cuttings samples for isotope analysis with generous facilitation from Clay Jones and David Langton.

Silica scale, Low adhesion, Resin materials, Ab initio calculation, Quantum chemistry

ABSTRACT

Silica scaling results in flow rate reduction or improper performance in power generation. To preserve the power generation capacity, it is necessary to take measures to prevent silica adhesion. One of the issues is to improve the surface properties of the components by surface coating or applying alternative materials to metal.

In this work, *ab initio* calculation based on the quantum chemistry was applied to clarify the mechanism of silica adhesion and to predict the silica adhesion properties of the resin materials. The calculations have been performed for seven kinds of resin materials which contains polytetrafluoroethylene (PTFE), polyvinyl chloride (PVC), polybutylene terephthalate (PBT), polyethylene terephthalate (PET), sheet molding compound (SMC), polymethyl methacrylate (PMMA) and polycaprolactam (Nylon 6). According to the calculation results, it is found that the seven kinds of resin materials could be divided into two groups. The low silica adhesion group which contains PTFE, PVC, PMMA and Nylon 6, and the high silica adhesion group which contains PBT, PET and SMC.

Field tests for verification were performed with the same resin materials at one geothermal power plant in the northeast part of Japan. According to the field test results, the low silica adhesion group and the high silica adhesion group were in excellent agreement with the calculation results.

Therefore *ab initio* quantum chemical calculation is considered to be a powerful research methodology for predicting the adhesion properties between silica and the candidate resins. Furthermore, an efficient and effective screening method for low silica adhesion resin materials has been developed in this work.

1. Introduction

In order to realize the big goal of carbon neutral target in 2050, various renewable energies are attracting attention at this moment. In particular, geothermal power generation is a renewable energy that can generate power sustainably with almost zero CO_2 emissions, and is said to be a "baseload power source" that can generate power stably without being influenced by natural conditions such as weather, in contrast to other renewable energies, for example solar power and wind power (Imamura et al., 2016) .

In geothermal power plants, geothermal fluid is exploited for power generation. However, reduction of power generation due to silica scale is a serious issue which affects many geothermal projects. Once silica scale adheres to the inner surface of the pipes, valves or other parts on the brine line, such silica scaling results in flow rate reduction or improper performance. As the solutions to this issue, some new approaches have been proposed.

For example, one of the approaches is to predict the amount of generated silica scale for scheduling the maintenance works in order to preserve the power generation capacity (Jiang et al., 2023). Another one is to improve the surface properties of the components by surface coating, such as diamond like carbon (DLC) coat (Nakashima et al., 2022 and 2023).

DLC has been verified to be effective in reduction of silica adhesion and has been used as the surface coating for the blade of the turbines. On another hand, since the uniformity of the DLC surface coating has been reported to be very important, DLC is considered to be not suitable for some large parts on the brine line such as the inner surface of the pipes. Therefore, it is considered to be necessary to separate the materials for the surface coating based on the target and situation.

In this case, resin materials are expected to be a good choice. There are various kinds of resin materials in the world with wide range of properties (Ebbing and Gammon, 2016). The studies on the performance design and synthesis of the resin materials have been widely discussed. It is considered that some new alternative materials which are easy-to-install on geothermal field with high durability and low silica adhesion property could be found.

However, it is said to be such a tough problem because the experiments which take a lot of time and effort are required to verify the silica adhesion properties for the large number of resin materials. Hence, a new screening method for predicting the low silica adhesion resin materials would be necessary. As a solution to the issue, the *ab initio* calculations based on the quantum chemical approach has been applied in this work.

2. Methodologies for theoretical analysis

2.1 The frontier molecular orbital theory

The major process of silica adhesion is considered to be chemical phenomena. From the point of view of chemistry, the chemical properties of the materials are determined by the molecular orbital and the electronic state of the molecules. It is well known that a good approximation for reactivity could be found by analyzing the Highest Occupied Molecular Orbital (HOMO) and the Lowest Unoccupied Molecular Orbital (LUMO), based on the famous frontier molecular orbital theory which won the Nobel Prize in Chemistry (Fukui et al., 1952). The theory has been widely utilized

in many fields for resin material researches, for example to find suitable materials for the polymeric binders in lithium-ion batteries (Kanamura, 2003).

In the case of silica adhesion, the passage of the electrons from silica to the molecules of geothermal power plant equipment result in the adsorption reaction. It is considered that the resin molecules with low LUMO energies are predisposed to adsorb silica and the ones with high LUMO energies are not predisposed to adsorb silica. Therefore the LUMO energies of resins could be an important indicator for predicting the reactivity between silica and the candidate resin materials.

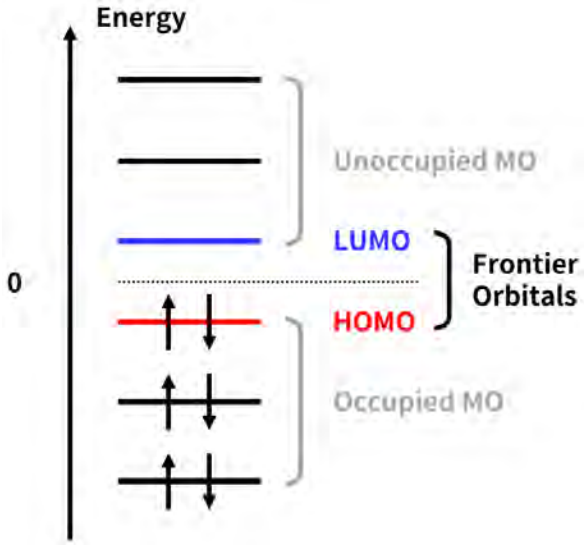

Figure 1: The overview of frontier molecular orbital theory.

2.2 Overview of the ab initio calculations

The theoretical analysis has been carried out following the procedure shown in Figure 2.

The initial structures for the resin molecules were built using the GaussView 6.0 program (Dennington et al., 2016).

Optimization calculations were composed of two processes, the optimization with the density function theory (DFT) method and the optimization with the molecular orbital (MO) method, in order to obtain reasonable structures with low calculation cost.

Molecular orbital calculations for the optimized structures were performed with the MO method, and the LUMO energies were estimated to evaluate the silica adhesion properties of the resins.

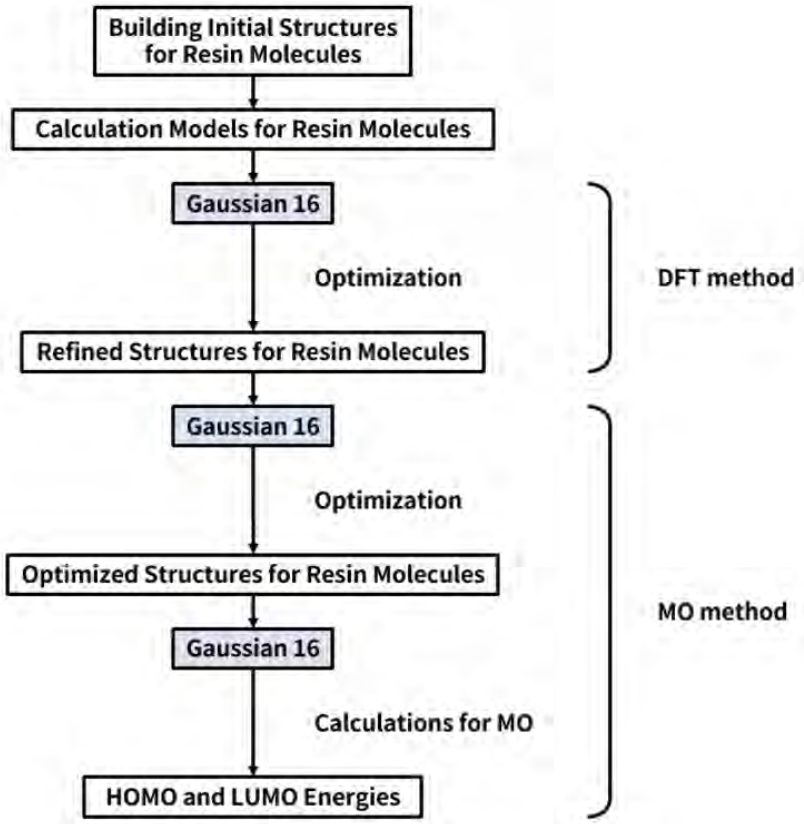

Figure 2: Flowchart of the theoretical analysis for estimating the LUMO energies to evaluate the silica adhesion properties of the resin molecules.

2.3 Optimization for the resin molecules

As described in section 2.2, the optimization calculations were composed of two processes.

The first-step optimizations were performed by the DFT method at B3LYP/6-31G level using the Gaussian 16 package (Frisch et al., 2016). Parallel computing was applied with 96 threads.

The second-step optimizations were performed by the Møller–Plesset (MP) perturbation theory, which is one of the commonly used MO method, at MP2/cc-pVDZ level using the Gaussian 16 package. It improves on the Hartree–Fock method by adding electron correlation effects by means of Rayleigh–Schrödinger perturbation theory (RS-PT) to second order (MP2) in this work.

2.4 Molecular orbital calculations for the resin molecules

Molecular orbital calculations were performed by the Møller–Plesset (MP) perturbation theory at MP2/cc-pVDZ level with the Merz-Singh-Kollman analysis using the Gaussian 16 package. The LUMO energy analysis were carried out based on the calculation results.

3. Methodologies for field test

3.1 Experimental apparatus

The field test was carried out by branching geothermal water from the reduction pit to the test section at one geothermal power plant in the northeast part of Japan.

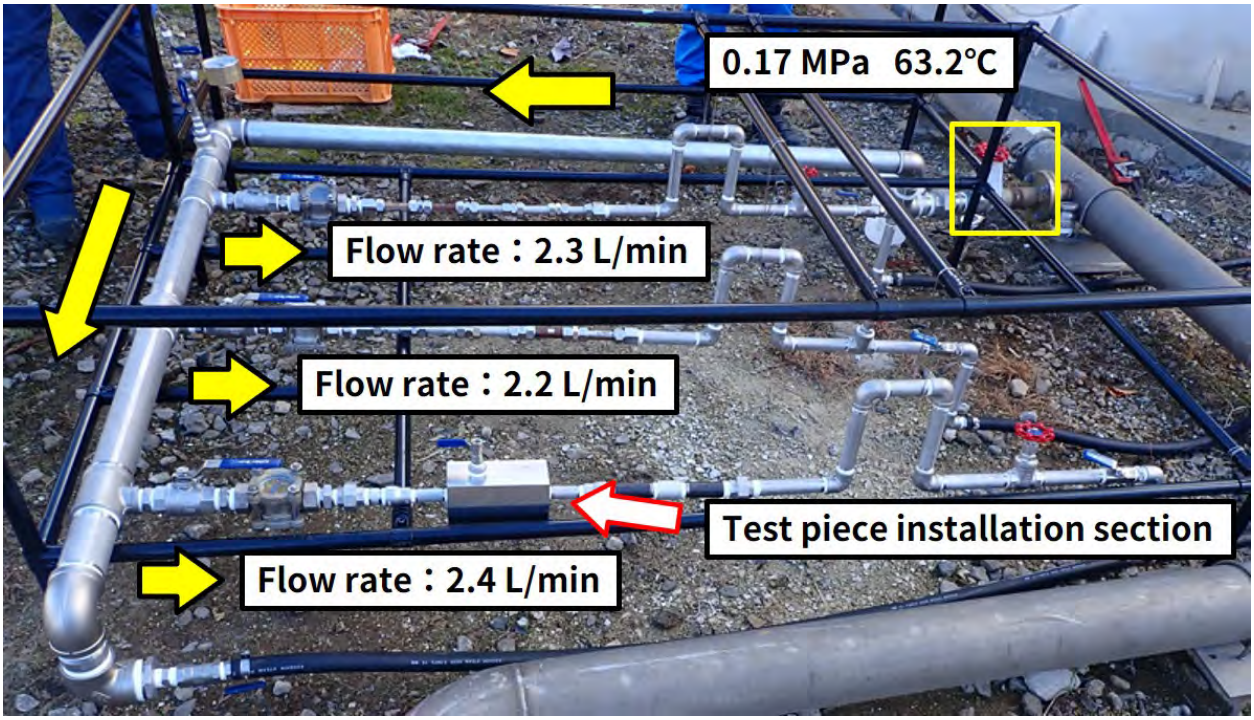

Figure 3: Experimental apparatus of the field test.

The schematic diagram of the flow test with the resin test pieces is shown in Figure 4. The main part of this apparatus was consisted of one routing line from the geothermal water pit, three test lines, and one resin test piece installation section. A ball valve and a pressure gauge for passing geothermal fluid through the routing line were installed, and three test lines were installed in the latter part as well. Field tests could be performed independently on each test line in parallel by providing ball valves at the upper and lower of them. In addition, the condition of geothermal fluid and the presence or absence of foreign matter contamination were confirmed by providing a sight glass at the upper part of each test line.

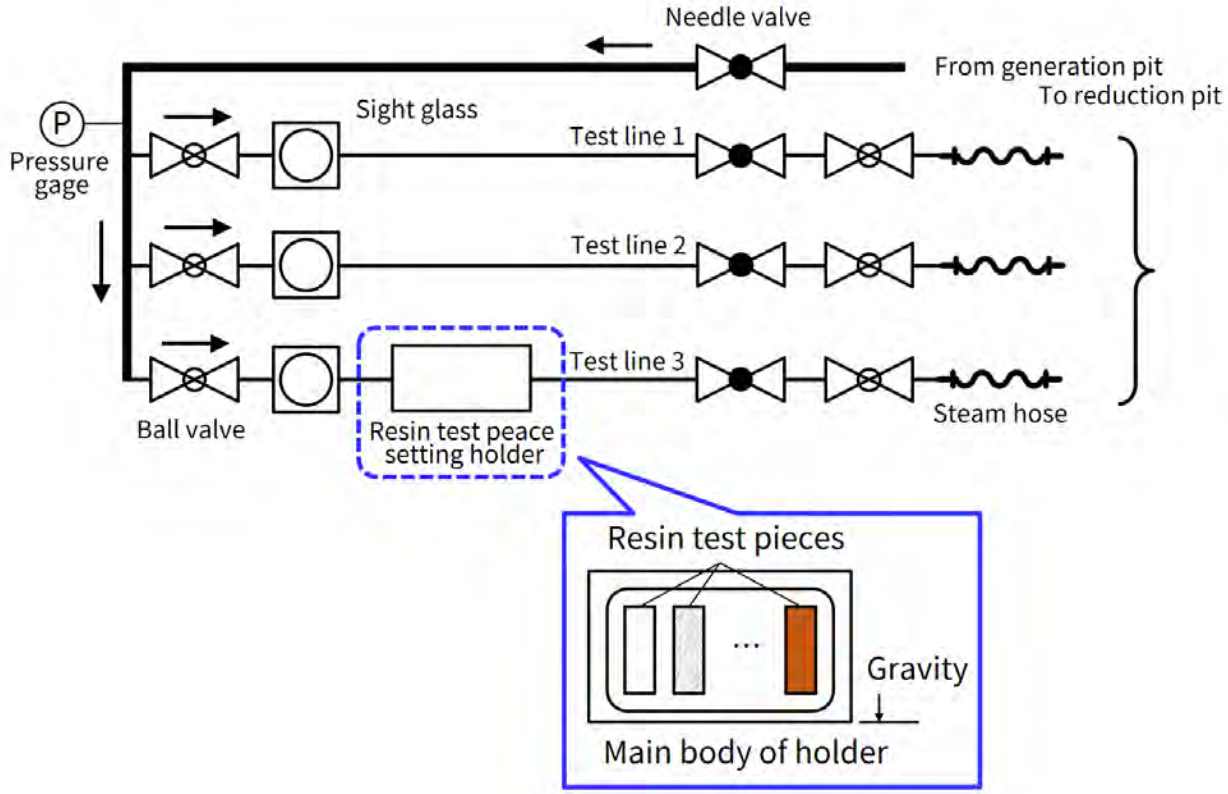

Figure 4: The schematic diagram of the local water flow test of the resin test piece.

Resin test pieces were mounted in the test piece installation holder of the test line 3. The resin test pieces were secured by screws to the inner side of the test piece installation holder in a vertical direction as shown in Figure 5, to prevent weight-impact deposition of the suspension in the geothermal fluid on the test pieces.

In addition, seven types of resin test pieces were installed, and the information of the resins is summarized in Table 1. All dimensions were in 40 mm × 10 mm × 3 mm, in order to make the impact of the shape of the test pieces on the fluidic flow uniform. At the latter stage of the test line, a needle valve for adjusting each flow rate was provided, and a steam hose was installed at the last stage, so that the geothermal fluid was returned to the pit.

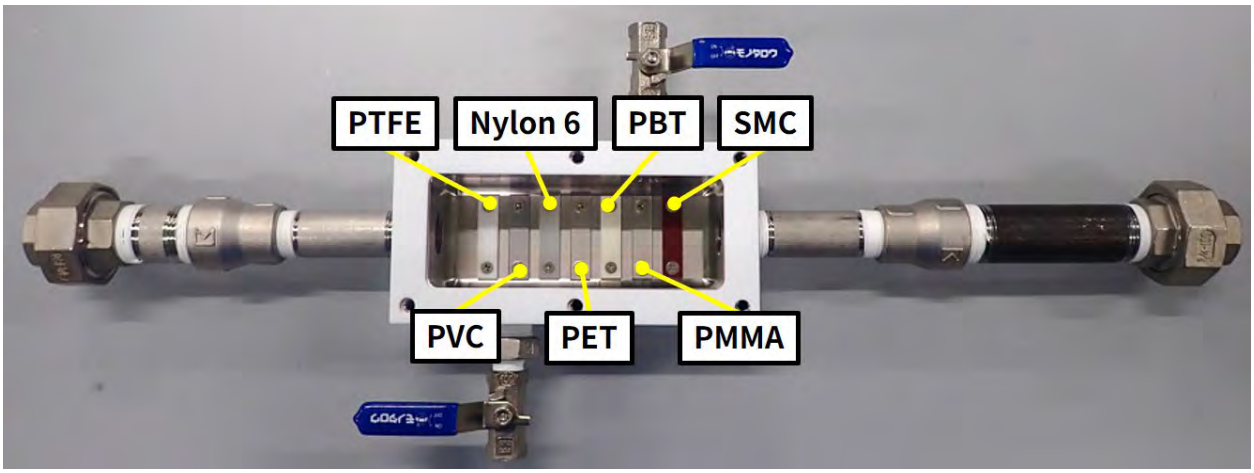

Figure 5: The inner side of the test piece installation holder.

Table 1: Summary of the information of the resins.

No.	Resin material	Glass ransition temperature [K]	Max allowable working temperature [K]	Melting point [K]	Density [g/cm^3]	Coefficient of water absorption [wt%] (24h)
1	PTFE	338	533	600	2.13 ～ 2.20	0.01
2	PVC	353	333	358	1.35 ～ 1.45	0.04 ～ 0.40
3	Nylon 6	323	413	498	1.13	1.10 ～ 1.90
4	PET	343	353	533	1.38	0.10 ～ 0.20
5	PBT	333	413	503	1.31 ～ 1.38	0.06 ～ 0.09
6	PMMA	343	363	378	1.18	0.20 ～ 0.40
7	SMC	353	423	—	1.65 ～ 2.60	0.05 ～ 0.50

3.2 Experimental method

Geothermal water of 63°C, 0.17 MPa and default flow rate 2.4 L/min was passed through the test line 3 on which the resin test pieces were installed for about 50 days. The flow rate measurement method was calculated by taking the water flow rate from the wastewater section (steam hose) of each test line into the graduated cylinder and using the water intake rate and time. Within this test period, flow rate adjustment was not performed, so that the natural flow rate attenuation due to silica adhesion was allowed. Resin test pieces to which silica adhered were subjected to ultrasonic cleaning and drying in a laboratory, and then subjected to elemental analysis by a SEM-EDX.

The sample preparation and SEM-EDX were performed following the procedure below.

(1) The samples are immersed in pure water for ultrasonic cleaning

(2) Dry in an auto dry desiccator for at least 24 hours.

(3) Compositional analyses are performed on five randomly selected sites in SEM-EDX.

(4) Calculate the ratio of adhered substance/substrate at each point and compare it with the average value.

(5) When the ratio of adhered substance/substrate was large, it was judged that many scales with strong adhesion force remained.

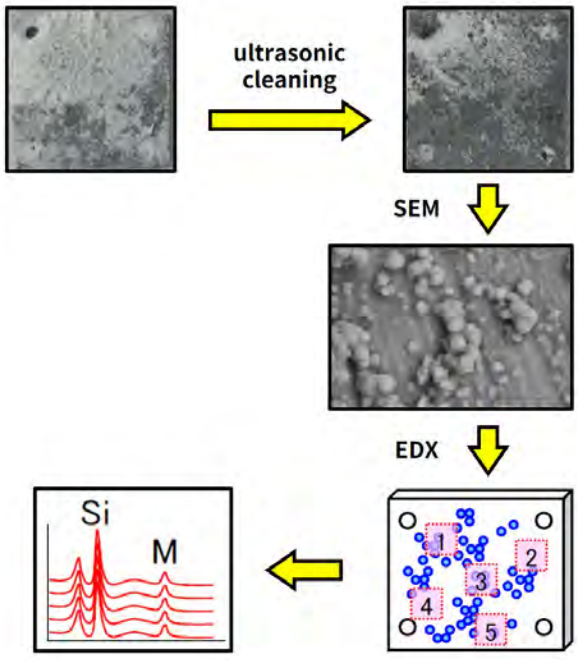

Figure 6: The procedure of sample preparation and SEM-EDX.

4. Results and discussions

The optimization calculation as mentioned in section 2.3 have been performed for seven kinds of resin materials which contains polytetrafluoroethylene (PTFE), polyvinyl chloride (PVC), polybutylene terephthalate (PBT), polyethylene terephthalate (PET), sheet molding compound (SMC), polymethyl methacrylate (PMMA) and polycaprolactam (Nylon 6). The structure refinement were carried out and the structure of the resin molecules were obtained theoretically as shown in Figure 7, Figure 8 , Figure 9, Figure 10, Figure 11, Figure 12 and Figure 13.

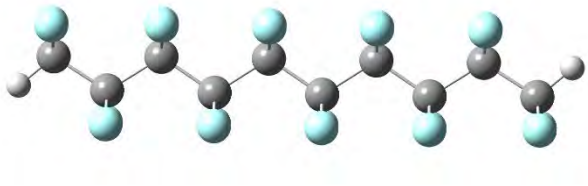

Figure 7: The Structure of PTFE molecule.

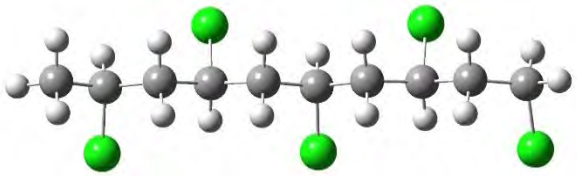

Figure 8: The Structure of PVC molecule.

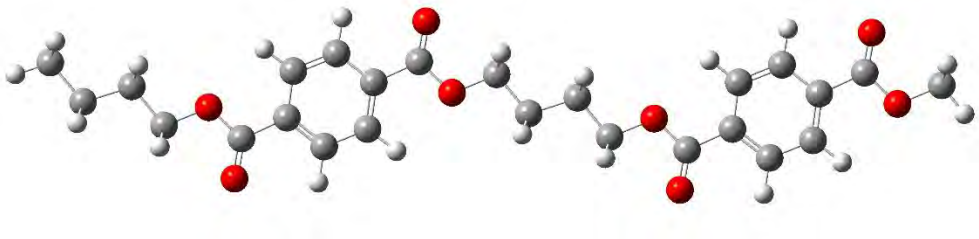

Figure 9: The Structure of PBT molecule.

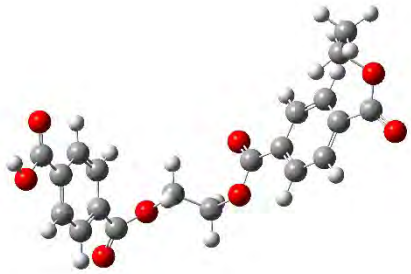

Figure 10: The Structure of PET molecule.

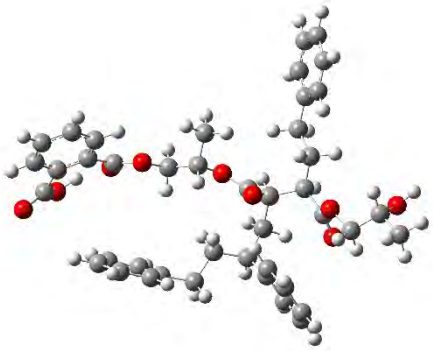

Figure 11: The Structure of SMC molecule.

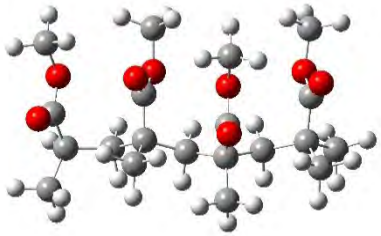

Figure 12: The Structure of PMMA molecule.

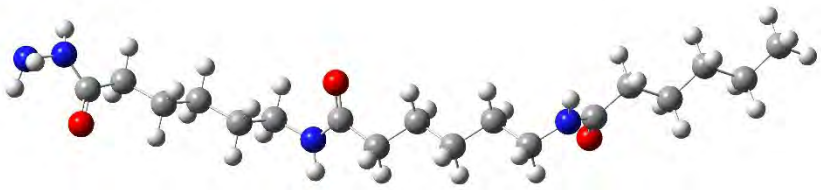

Figure 13: The Structure of Nylon 6 molecule.

The molecular orbital calculations for the seven kinds of resins were performed and the LUMO energies, which are considered to be the important indicator for predicting the reactivity between candidate resin materials and silica have been estimated. The calculation results are summarized as shown in Figure 14.

The LUMO and HOMO energies of some resins such as PTFE, have been reported by other experiment groups in past studies (Choi et al., 2015). The LUMO and HOMO energies of PTFE is reported to be about 3 eV and -15 eV. On the other hand, in this work the LUMO and HOMO energies of PTFE were estimated to be 3.49 eV and -13.90 eV. Thus, the calculation result is considered to be reasonable.

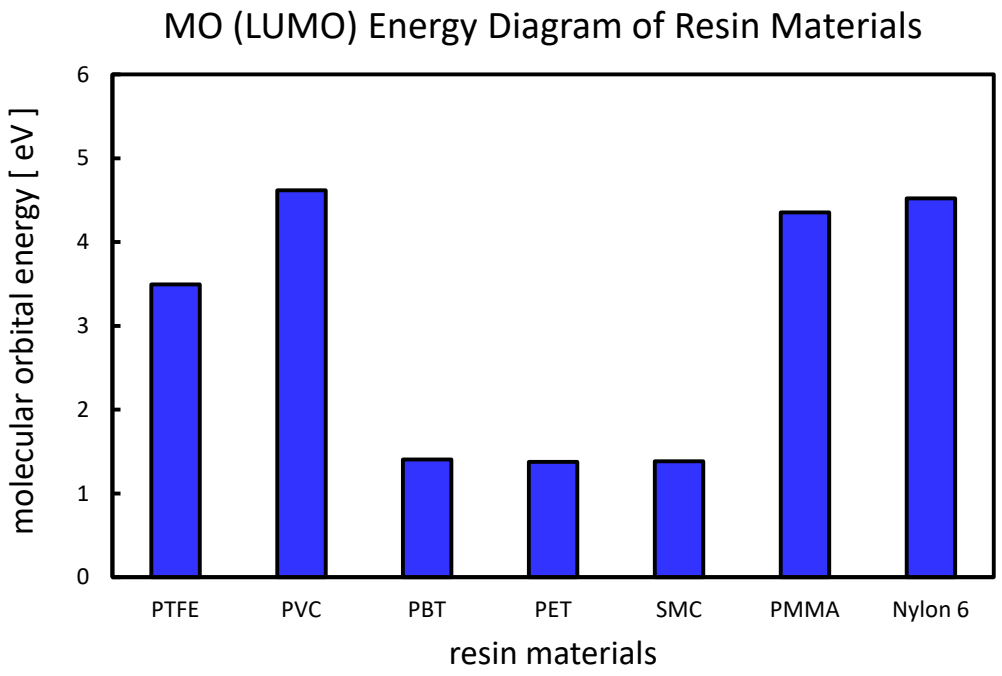

Figure 14: The calculation results of LUMO energies for the resin.

As mentioned in section 2.1, it is considered that the resin molecules with lower LUMO energies are predisposed to adsorb silica and the resin molecules with higher LUMO energies are not predisposed to adsorb silica. From the calculation results, it is found that the seven kinds of resins could be divided to one low silica adhesion group (PTFE, PVC, PMMA and Nylon 6) and one high silica adhesion group (PBT, SMC and PET).

The field test for verification were carried out as mentioned in section 3.1 and 3.2. The state of the test pieces before ultrasonic cleaning and after ultrasonic cleaning is shown in Figure 15. The appearance of silica adhesion seems to be the same as the calculation results. The analysis by SEM-EDX were also performed as shown in Figure 16.

The appearance of silica adhesion seems to be the same as the calculation results.

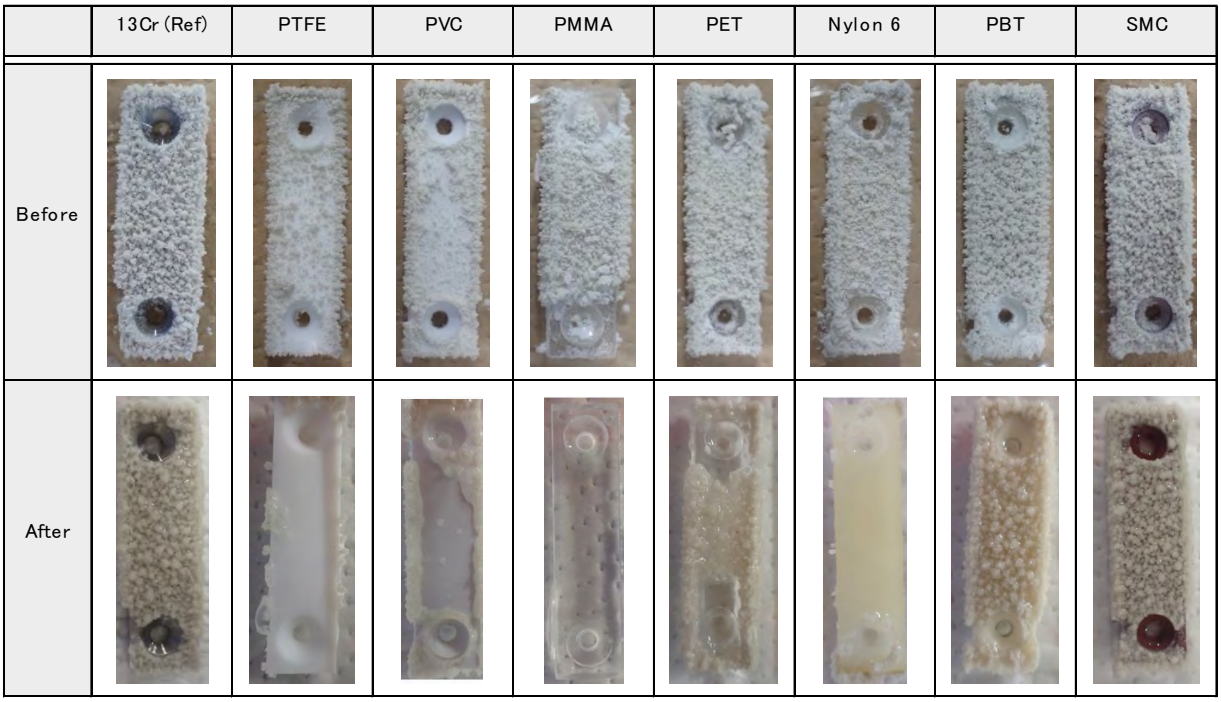

Figure 15: The state of the test pieces before ultrasonic cleaning and after ultrasonic cleaning.

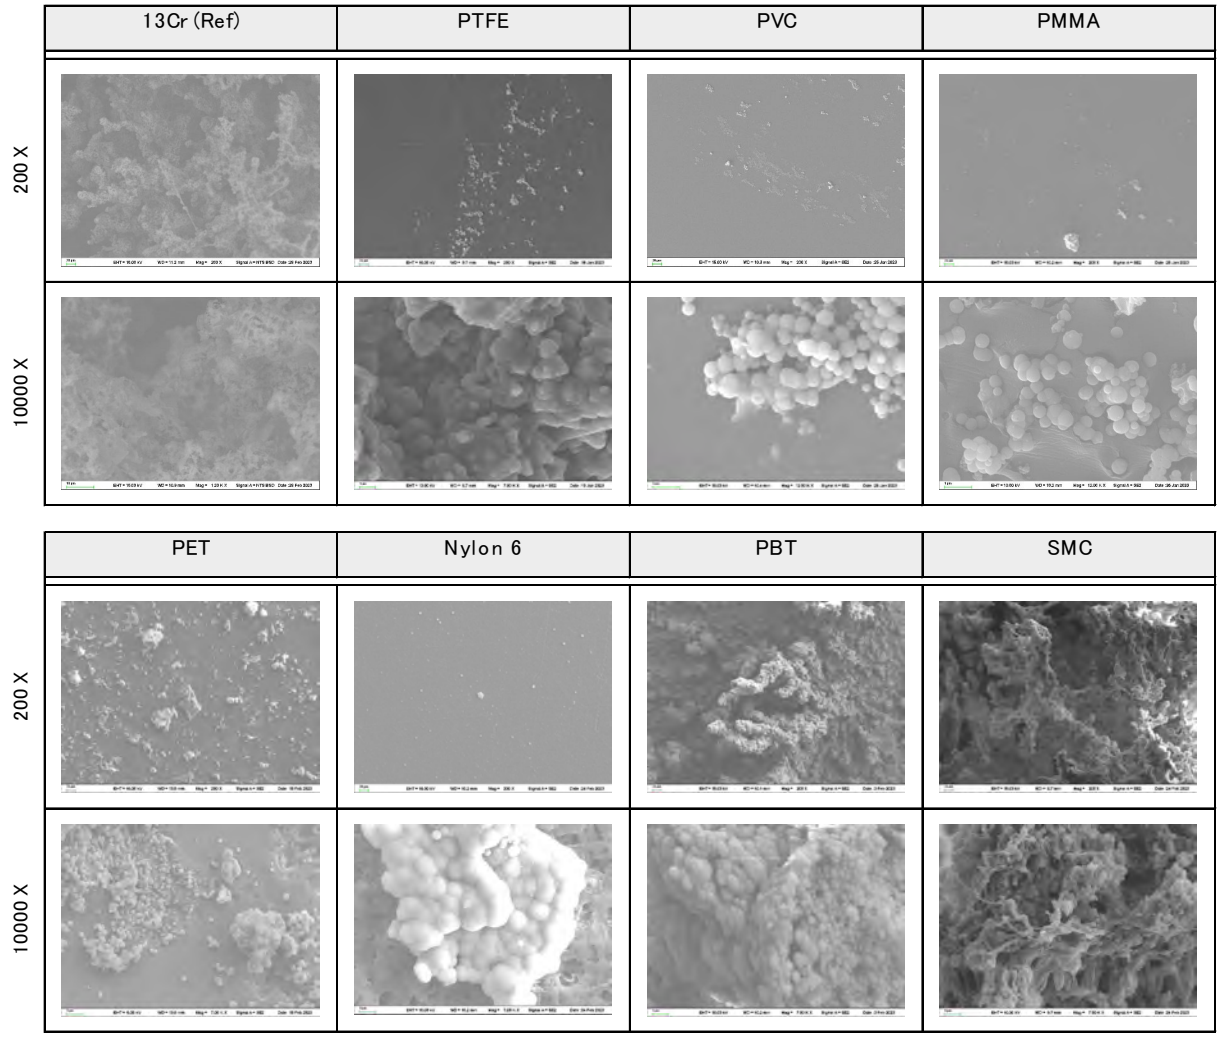

Figure 16: The observation results of SEM-EDX.

Furthermore, the ratio of adhered substance/substrate estimated from the SEM-EDX results were summarized with the calculation results as shown in Figure 17. It is found that the calculation results of the silica adhesion properties agrees with the field test results very well. The low silica adhesion group and the low silica adhesion group were revealed as predicted.

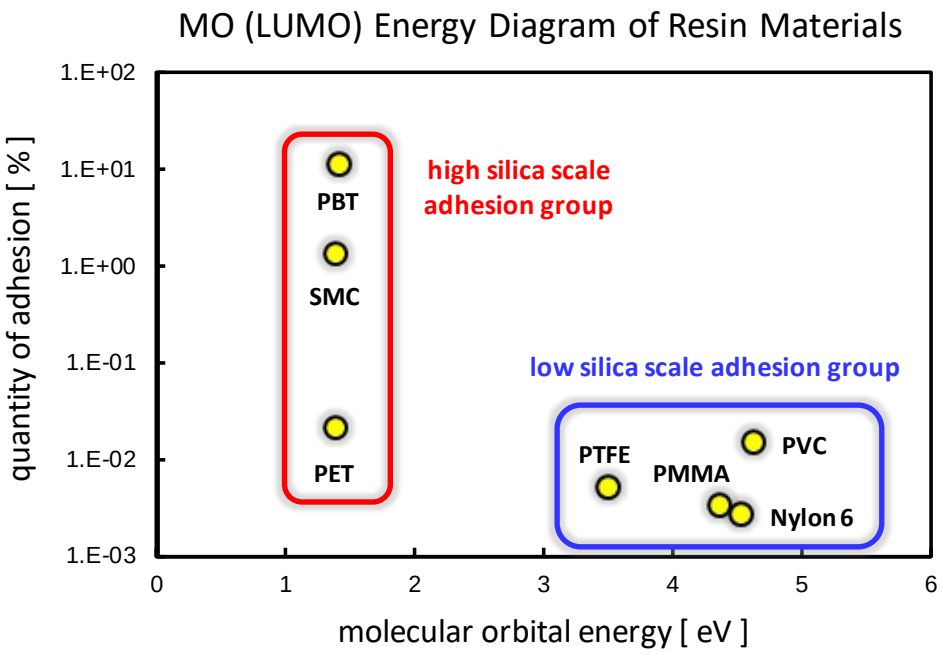

Figure 17: Summary of the calculation results and the field test results.

5. Conclusions

In the present work, to clarify the mechanism of silica adhesion and to predict the silica adhesion properties of the resin materials, *ab initio* calculation based on the quantum chemistry has been introduced. The calculations as well as the field tests have been performed for seven kinds of resin materials which contains PTFE, PVC, PBT, PET, SMC, PMMA and Nylon 6.

As a result of comparing the silica adhesion properties of the resins predicted by the calculations with the field test results, it is found that the field test results were in excellent agreement with the calculation results. The seven kinds of resins could be divided to one low silica adhesion group and one high silica adhesion group, which reveals that the silica adhesion properties of the resins could be predicted non-empirically with theoretical approach.

According to our results, *ab initio* quantum chemical calculation is considered to be a powerful research methodology for predicting the reactivity between candidate resin materials and silica. Furthermore, an efficient and effective screening method for low silica adhesion resin materials has been developed in this work. By utilizing this screening method, considering the strength and heat resistance of resin materials, it would be possible to quickly find the resin materials suitable for geothermal power plants. It is expected that the low silica adhesion resin materials for production lines and injection lines, or lining injection well as coating materials, could greatly contribute to the preservation of the power generation capacity.

ABSTRACT

Thermal energy storage at large scale has significant potential for large scale clean energy deployment. However, it is necessary to understand and address the challenges (Dobson et al., 2023) associated with high temperature reservoir thermal energy storage (HT-RTES). Lessons learned from the previous demonstrations identify insufficient site characterization, thermal short-circuiting, lack of available heat, scaling, corrosion, and biofouling as key factors affecting the performance of HT-RTES. The objective of this paper is to develop reactive transport modeling strategies to understand the geochemical processes associated with HT-RTES in high-saline reservoirs by evaluating the significance of changes in temperature, pressure, mineralogy, and porosity of the formation during the HT-RTES operation. The results from the model will also evaluate the retrograde solubility of minerals, changes in permeability, and changes in redox conditions during the HT-RTES operation.

For this study, an isolated injection-production well doublet is used for injecting hot and cold fluids during the seasonal cycle. During summer, brine at 75 °C is surface heated to 140 °C and injected into the reservoir with 15% porosity. Produced brine from the heat-exchanger at 60 °C is injected back into the cold well during winter. Reactive transport simulations are carried out using TOUGHREACT-EOS7(Dobson et al., 2004; Sonnenthal et al., 2021) for 5 years of cyclic RTES operation. Representative geochemical data were obtained from the depleted Leopoldshafen oil field of Leopoldshafen around the DeepStor site (Banks et al., 2021).

After a five-year operational period, the model estimates a 1.5% increase in the porosity in the vicinity of the hot wells. Near the cold wells, there is a negligible decrease in porosity, roughly

0.1%, within the same duration. These observations imply that dissolution of minerals is more prominent near the hot well because of the increase in temperature and the injection of slightly acidic brine, while mineral precipitation tends to occur near the cold well where the temperature falls. Iron minerals such as goethite show dissolution near the hot wells and precipitation in the relatively colder brine slightly away from the hot well. Also, changes in permeability have been evaluated using a cubic law of porosity-permeability correlation. There is no significant interference of hot and cold plumes, which indicates that thermal short-circuiting has not occurred under the simulated operating conditions. Future work will include a modeling scenario under strong oxidizing conditions such as presence of dissolved oxygen in the injection brine, which can better quantify the possibility of corrosion and scaling due to air intrusion.

1. Introduction

As the shift from fossil fuels to Variable Renewable Energy (VRE) technologies gains momentum for electricity generation and heating, the need for energy storage becomes more critical. While numerous energy storage systems are being developed to manage short-term needs, the significant seasonal fluctuations in VRE output and energy demand pose a greater challenge. Seasonal energy storage technologies, capable of transferring energy from periods of surplus such as summer to times of deficit like winter, are emerging as a vital solution. High-temperature reservoir thermal energy storage (HT-RTES) is being considered as a viable option for long-duration energy storage. This method allows the storage of surplus thermal energy in permeable geological formations like aquifers or depleted hydrocarbon fields over several months. While RTES demonstrates significant promise for geothermal energy applications at moderate temperatures (Fleuchaus et al., 2020), concerns about its long-term viability arise due to potential issues such as corrosion, scaling, and well clogging due to changes in geochemistry during the operation (Dobson et al., 2023) when shifting to higher temperatures.

This study aims to establish a method for assessing the impact of hydrogeochemical processes on RTES through the application of reactive transport modeling. The specific goals are 1) construct a numerical model for analyzing the reactive-transport processes relevant to RTES systems, 2) examine the geochemical factors which can impact system performance or diminished efficiency during cyclical operations, 3) determine the rates at which mineral precipitation and dissolution occur, and 4) assess alterations in porosity and permeability.

In terms of formation water chemistry, the DeepStor site at the Karlsruhe Institute of Technology (Germany) is used in this simulation. Notable research papers evaluating the potential of the DeepStor site for geothermal use include those by Banks et al. (2021), Frey et al. (2022), Bremer et al. (2022), Nitschke et al. (2023), Stober et al. (2023), Schill et al., (2024), and Stricker et al. (2024). Banks et al. (2021) conducted a preliminary geochemical evaluation, identifying potential risks such as mineral scaling and structural damage in the reservoir due to reactive transport processes, with a particular emphasis on reduced porosity around the thermal wells. The study utilized a model based on equilibrium thermodynamics to simulate the dissolution and precipitation of minerals. However, equilibrium thermodynamics may not yield precise predictions for the rates of mineral dissolution and precipitation. To enhance the accuracy of modeling results, it is important to incorporate reaction kinetics. Nitschke et al. (2023) conducted an analysis of brine-rock interactions and scaling potential, employing the MulT_predict geothermometer to analyze the chemical system's temperature control. The study identified key scaling minerals such as iron hydroxides, calcite, celestite, and barite, noting distinct scaling mechanisms during both

the testing phase with open pond storage and the operational phase with a two-well system for cyclic storage and production. However, the study did not integrate transport processes, which could impact the geochemical processes related to brine-rock interaction during cyclic RTES operations.

This study aims to bridge current knowledge gaps by evaluating the DeepStor site for RTES through a reactive-transport modeling approach.

2. Methodology

2.1 Geologic and Hydraulic Setting at DeepStor site

The DeepStor site is situated at KIT Campus North, nestled within the central portion of the Upper Rhine Graben (URG), a key segment of the European Cenozoic Rift System. This region is known for Germany's most significant temperature anomaly, reaching approximately 170°C at 3,000 meters depth (Baillieux et al., 2013). Over 2,000 meters of sediment have accumulated at the DeepStor location, predominantly under shallow marine conditions, leading to substantial marl deposits interspersed with layers of sand. The targeted strata for DeepStor, the calcareous fine-grained sandstones of the Niederrödern and Froidefontaine Formations, are found at depths of approximately 800 and 1,300 meters, respectively (Bremer et al., 2022). These sandstone layers reach thicknesses of up to 10 meters and exhibit subsurface temperatures between 70-90°C. The hydrologic and thermal characteristics of the sandstones in the Meletta beds from the Froidefontaine Formations have been described by Banks et al. (2021) and Stricker et al. (2024). These properties have been employed while setting up simulations in the current study. To generalize the approach, the site-specific and rather limited thickness of the sandstone layer of the Niederrödern and Froidefontaine Formations has been increased to a thickness of 220 m. In the first approach, the vertical temperature gradient has been neglected. Also, precipitation of minerals during the surface heating and cooling processes are not considered in this study.

Table 1: Hydrologic and thermal properties of the units used in modeling, adapted from Banks et al. (2021) and Stricker et al. (2024).

Unit	Porosity	Permeability (m^2)	Thermal Conductivity ($Wm^{-1}K^{-1}$)	Grain Heat Capacity (J/kg/°C)	Grain Density (kg/m^3)
Sandstone	0.15	6.6×10^{-14}	2.50	850	2680
Caprock	0.01	2.1×10^{-18}	1.50	964	2630

2.2. Numerical modeling approach

Reactive transport modeling was performed using TOUGHREACT V4 (Sonnenthal et al., 2021). The Equation of State module (EOS7) used for the modeling considers aqueous phases not as mixtures of water and salt but as mixtures of water and brine. The salinity of the aqueous phase is described by means of the brine mass fraction, and density and viscosity are interpolated from the values for the water and brine endmembers. The brine is modeled as NaCl solution. The model does not account for changes in enthalpy due to salinity. Fluid flow within this system are governed

by Darcy's law, as described by Pruess et al. (1999), while heat transfer is facilitated by both conduction and convection, incorporating both sensible and latent heat changes.
In the liquid phase, aqueous species are transported and interact with the solid and gas phases. The chemical transport equations use total dissolved concentrations, including primary species and their secondary aqueous counterparts (Sonnenthal et al., 2021). The kinetics of mineral dissolution and precipitation are based on the Transition State Theory, following the work of Steefel and Lasaga (1994) and Xu and Pruess (2001), expressed as follows:

$$r_n = \pm A_n k_n \left(1 - \Omega_n^{\theta}\right)^{\eta} \quad \text{n = 1…N}_q \tag{1}$$

where k_n is the rate constant (moles/mineral surface area/time), A_n is the specific reactive surface area/kg of H_2O, Ω_n is the ratio of the activity product (Q) divided by the equilibrium constant (K). A positive value of r_n indicates mineral dissolution and a negative value indicates mineral precipitation.
Permeability changes are calculated from porosity change using ratios of permeabilities calculated from the Carman-Kozeny relation (Bear, 1972) as follows:

$$k = k_i \frac{(1-\phi_i)^2}{(1-\phi)^2} \left(\frac{\phi}{\phi_i}\right)^3 \tag{2}$$

ϕ_i and k_i denotes initial porosity and initial permeability respectively.

2.3. Griding and RTES parameters

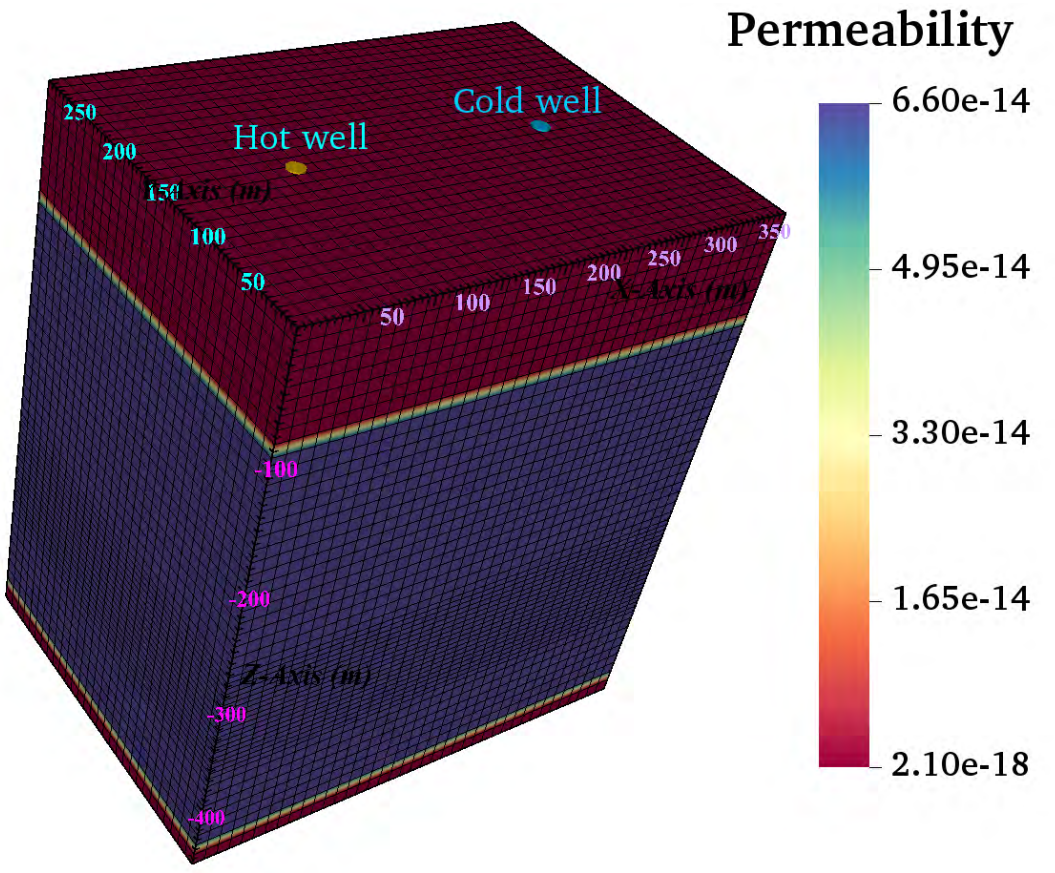

Figure 1: 3-D gridding of the mesh with initial permeability.

A finely discretized three-dimensional grid has been developed, tailored to the characteristics of the storage rock formations. The initial permeability for both the Niederrödern and Froidefontaine Formations has been uniformly set across the grid, with increased resolution near the injection zones as shown in Figure 1. The constructed mesh omits the overlaying strata up to a depth of 1000 meters, focusing exclusively on the Niederrödern and Froidefontaine Formations to optimize computational efficiency. The grid incorporates site-specific vertical pressure gradients to establish initial pressure conditions, maintaining a constant temperature profile. At the base level of the grid (Z=0 meters) represents the pressure conditions found at 1 kilometer depth at the actual site location. To avoid the thermal short-circuiting during injection and extraction processes, hot and cold wells are positioned 200 meters apart (Figure 1), each with a 50-meter screen segment, operating at a flow rate of 5 kg/s. In first run a steady state simulation is performed to obtain hydrostatic pressure conditions, and the results form this run is used as boundary condition in second run to simulate undisturbed natural state conditions with throughflow of mass and heat. In third run, the operational cycle begins with the injection of hot brine at 140°C into the hot well for six months during the summer, while the cold well simultaneously produces at the same rate. For the following six months, brine at 60°C is injected into the cold well, with the hot well producing at an equivalent rate. The study simulates this cyclic procedure over a period of five years.

2.3. Mineralogy and brine chemistry

For the reactive transport simulations, the mineral compositions and proportions are informed by Banks et al. (2021) and comprise primary minerals such as quartz, calcite, dolomite, albite, muscovite, microcline, annite, clinochlore, and kaolinite. Additionally, secondary minerals such as goethite, hematite, and ferrihydrite have been incorporated into the model. The mineral kinetic rate parameters are adapted from Palandri and Kharaka (2004).

The brine chemistry or fluid composition (Table 2) at Meletta Beds of Froidefontaine Formation in the Leopoldshafen field is reported by on Banks et al. (2021). Al^{3+} is calculated by assuming equilibrium with albite. The brine is further speciated for near steady state concentrations with minerals at 75°C using the thermodynamic database from Blanc et al. (2007). The steady-state brine chemistry is also speciated at 60°C and 140°C to align the temperatures of injection fluids in cold and hot wells respectively.

First scope calculations have been conducted accounting for a DeepStor type system consisting of a doublet with a warm and a cold leg. The calculations adopt the DeepStor strategy assuming the wells to be separated not to exchange thermal energies in the underground. These conceptual models intend to demonstrate the possible influence of hydrochemistry on thermal storage systems.

Table 2: Brine speciation calculated to mimic near steady-state brine composition with minerals at 75°C and 140°C. Al^{3+} is estimated by equilibrating the solution with albite using Blanc et al. (2012).

Primary Species	Speciated concentration at 75°C (molal)	Speciated concentration at 140°C (molal)
pH	7.24	6.53
Ca^{2+}	9.250×10^{-02}	9.249×10^{-02}
Fe^{2+}	1.207×10^{-05}	1.207×10^{-05}
Mg^{2+}	3.348×10^{-02}	3.349×10^{-02}
Na^{+}	1.647×10^{-00}	1.647×10^{-00}
K^{+}	1.557×10^{-02}	1.557×10^{-02}
Cl^{-}	1.907×10^{-00}	1.908×10^{-00}
HCO_3^{-}	2.310×10^{-04}	2.311×10^{-04}
SO_4^{2-}	5.166×10^{-03}	5.166×10^{-03}
Al^{3+}	1.734×10^{-8}	1.738×10^{-8}
$SiO_2(aq)$	5.822×10^{-04}	5.823×10^{-04}
$O_2(aq)$	3.153×10^{-63}	3.154×10^{-63}

3. Results and discussion

3.1. Evolution of temperature during seasonal operation

Figure 2 illustrates the temperature variations in the hot and cold wells after 5 years of seasonal operations. The spatial distribution of thermal energy across the XZ-plane at Y=145 m is depicted, highlighting the thermal dynamics around the wells. The cold well is injected with brine at 60°C, resulting in a cooler region surrounding them. Conversely, the hot well receives heated brine at 140°C, which then propagates outward, eventually encountering and mixing with the native colder brine, creating a cooler thermal front further from the well.

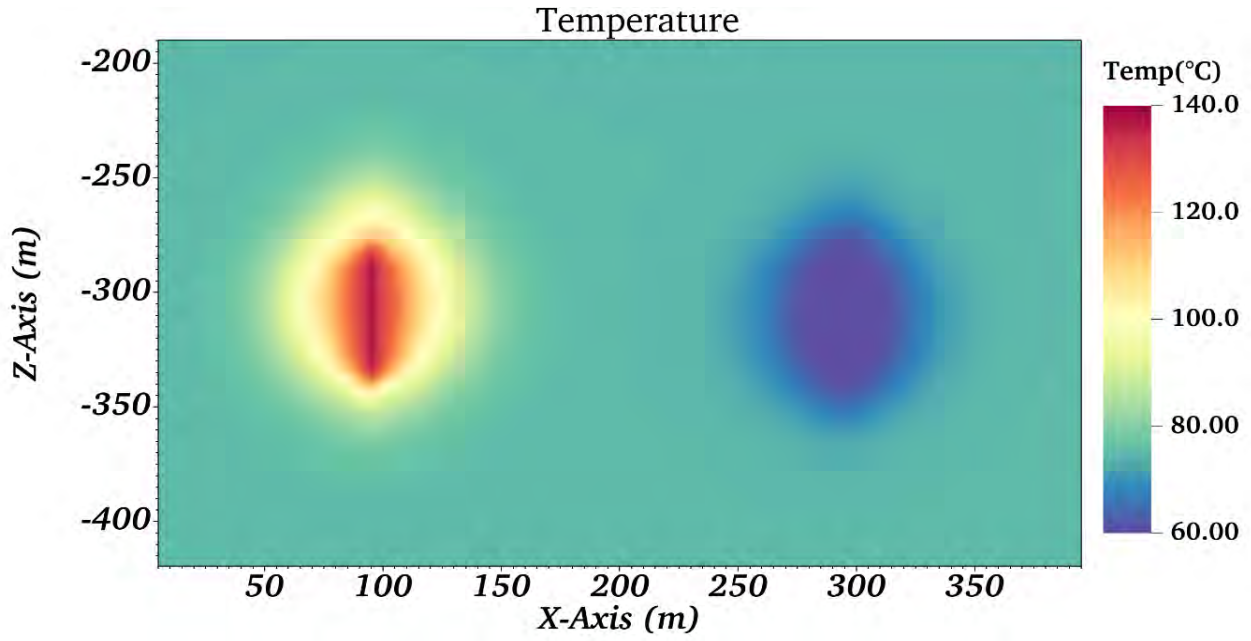

Figure 2: Variation of temperature at a hot and a cold well after 5 years of seasonal injection and production cycles.

3.2. pH and concentrations of iron species

Variations in pH and the concentrations of iron species (Fe^{2+} and Fe^{3+}) serve as significant indicators of the extent to which brine chemistry can influence mineral dissolution and precipitation, as well as the redox potential for iron oxidation, which are critical factors in the formation of scale and the occurrence of corrosion. In Figure 3, the pH levels around the hot and cold wells are depicted, indicating an increase in pH to about 7.5 near the cold well and a decrease to approximately 6.4 around the hot well. These pH shifts can be ascribed to the water-rock interactions and the temperature-dependent changes in the activity coefficient of H^+ associated with change in dissociation constant of water.

Figures 4 and 5 show the concentrations of ferrous (Fe^{2+}) and ferric (Fe^{3+}) ions respectively, with a notable increase in iron species concentrations around the hot wells relative to the cold wells. Plotting individual ferrous and ferric ion concentrations instead of total concentrations provides insight into the oxidizing or reducing conditions that may result in the precipitation of iron-containing minerals. This situation could pose a risk of corrosion to the well bore and tubing. The marked contrast between the concentrations of Fe^{2+} and Fe^{3+} suggests that the current model does not incorporate the effects of oxygen intrusion or potent oxidizing conditions. In oxidizing environments, there would likely be a greater conversion of Fe^{2+} to Fe^{3+}, which in turn could amplify the risk of precipitation of Fe (III) minerals such as goethite. At this point, the study doesn't consider intrusion of oxygen at the surface.

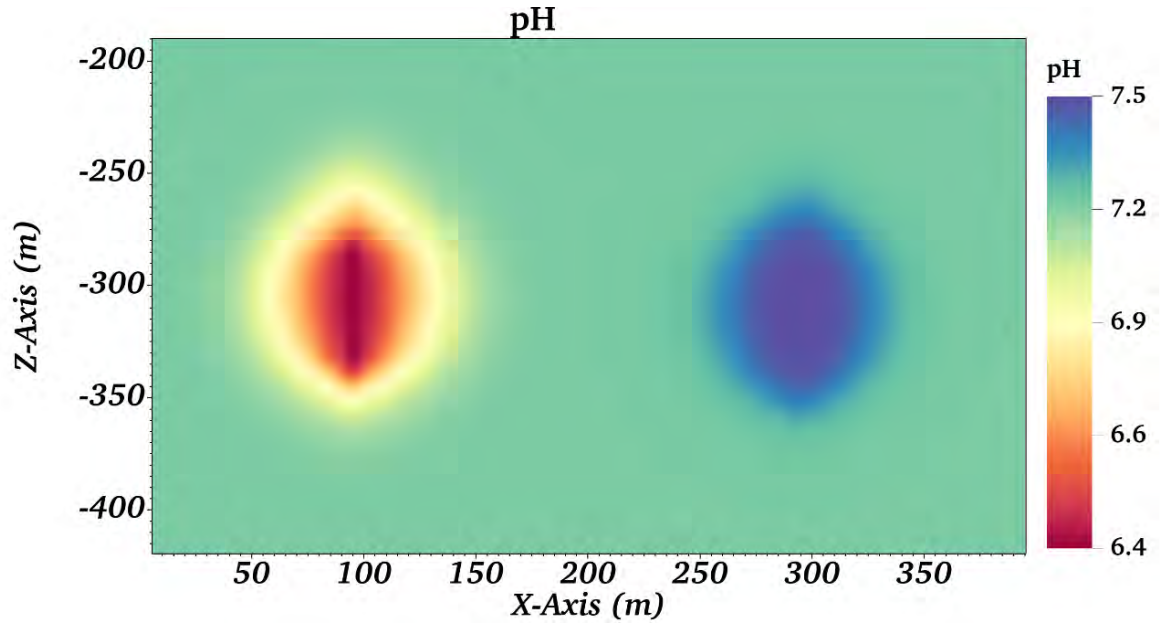

Figure 3: pH distribution in the XZ-plane (Y=145 m) after 5 years of seasonal injection and production cycles.

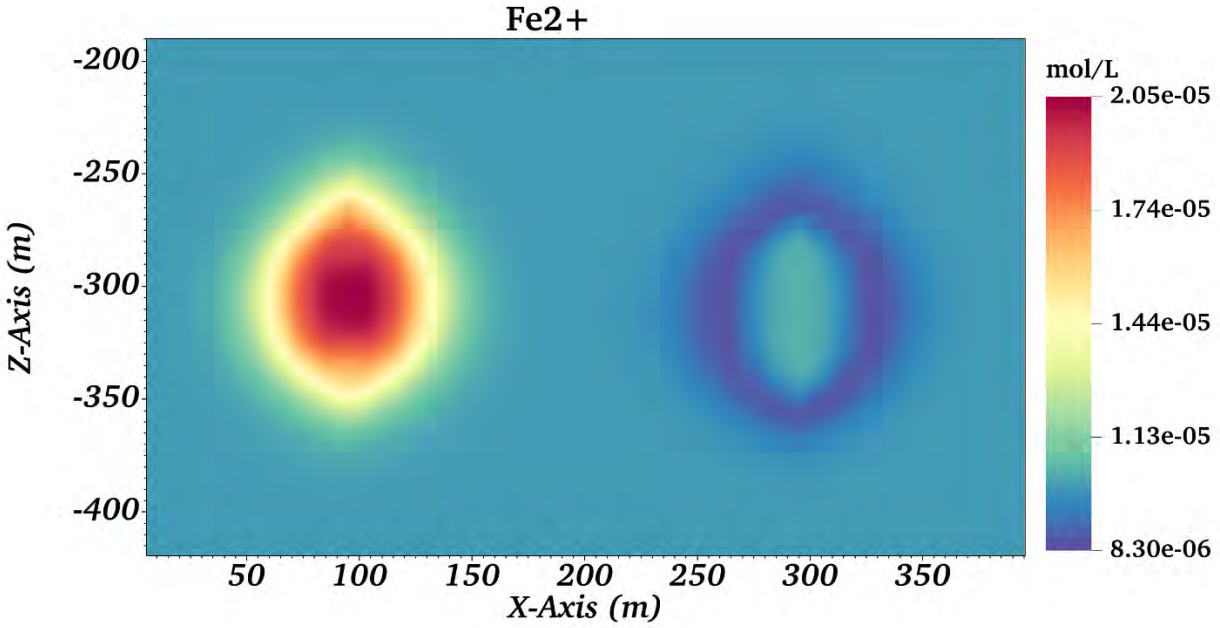

Figure 4: Concentration (mol/L) of Fe^{2+} in the XZ-plane (Y=145 m) after 5 years of seasonal injection and production cycles.

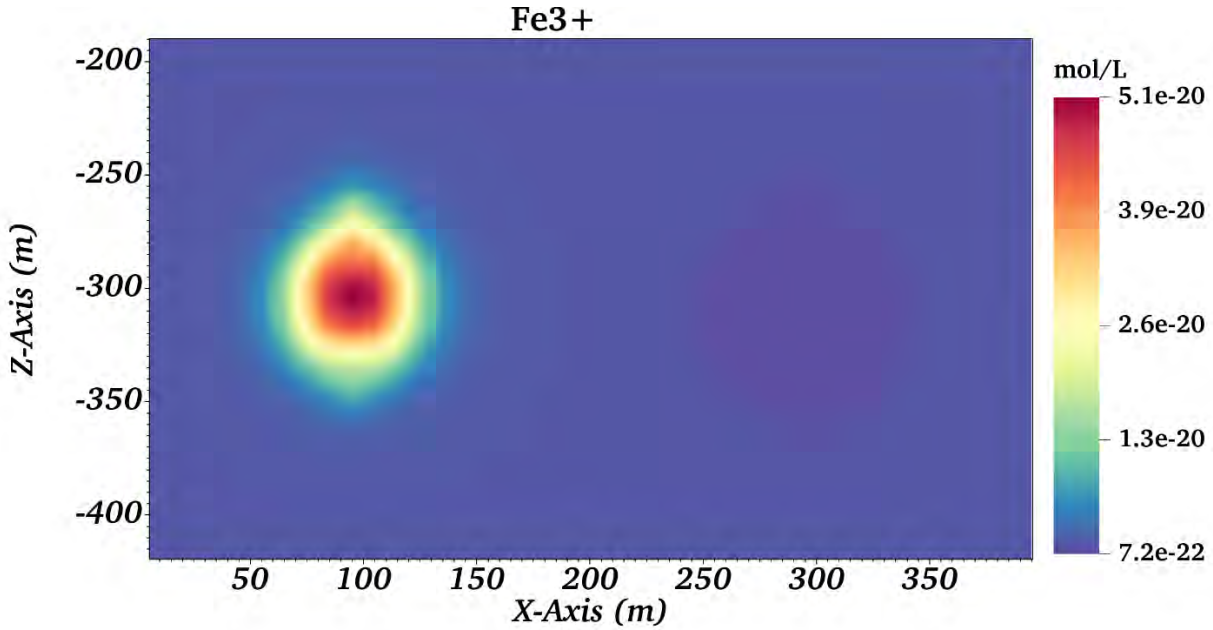

Figure 5: Concentration (mol/L) of Fe^{3+} in the XZ-plane (Y=145 m) after 5 years of seasonal injection and production cycles.

3.3. Changes in mineralogy

3.3.1. Changes in calcite and dolomite

Changes in calcite and dolomite in terms of volume fraction of total minerals are plotted in Figure 6 and 7, respectively. The model forecasts the dissolution of calcite near the hot well, likely due to the mildly acidic characteristics of the injected brine when subjected to elevated temperatures. However, the formation of dolomite is predicted in the areas adjacent to the hot well. Near the cold well, the situation reverses with calcite forming and dolomite dissolving. It is important to note that the mineralogical alterations of calcite and dolomite near the cold well are approximately an order of magnitude less compared to those near the hot well.

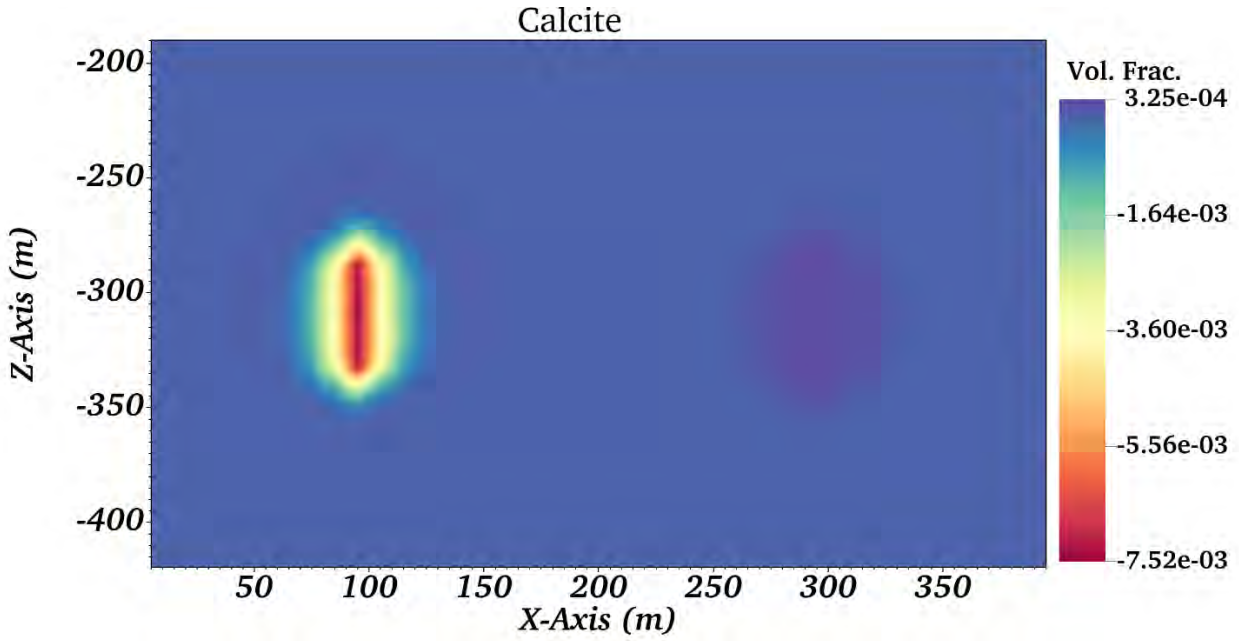

Figure 6: Calcite changes (volume fraction) in the XZ-plane (Y=145 m) after 5 years. A negative value on color bar indicates dissolution whereas a positive value indicates precipitation.

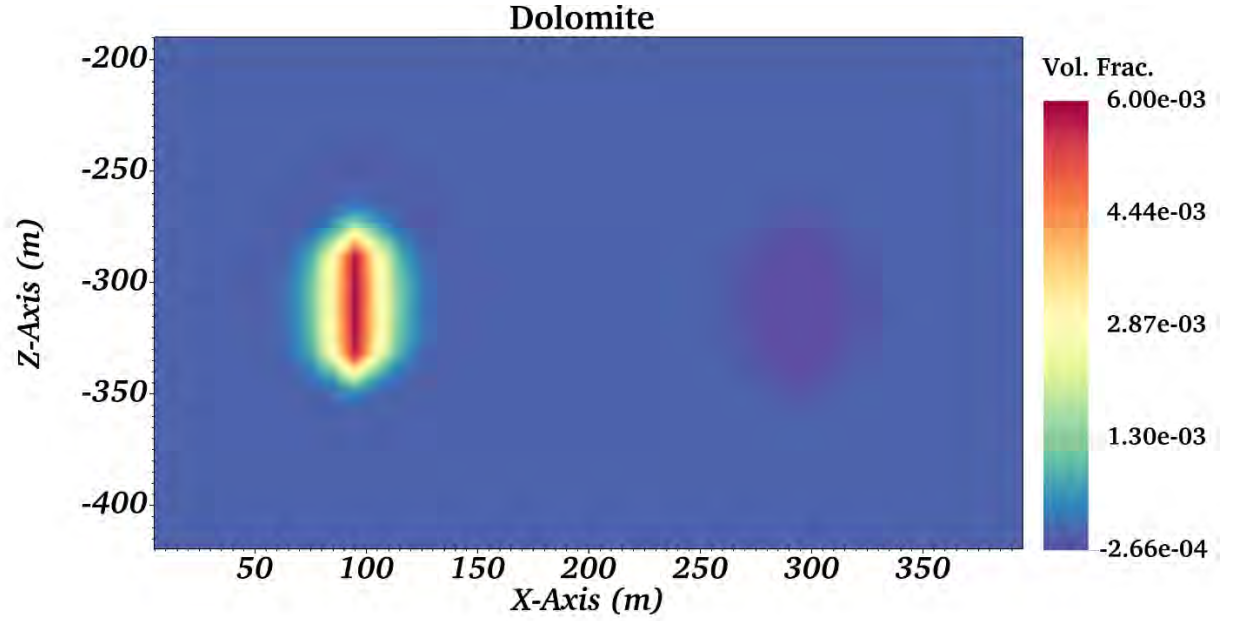

Figure 7: Dolomite changes (volume fraction) in the XZ-plane (Y=145 m) after 5 years of seasonal injection and production cycles.

3.3.2. Changes in quartz and microcline

Figures 8 and 9 illustrate that quartz and microcline undergo dissolution in proximity to the hot well, while precipitation of these minerals near the cold wells is observed to be substantially lower, with the rate of precipitation being about 20 and 50 times smaller in magnitude relative to the dissolution rates.

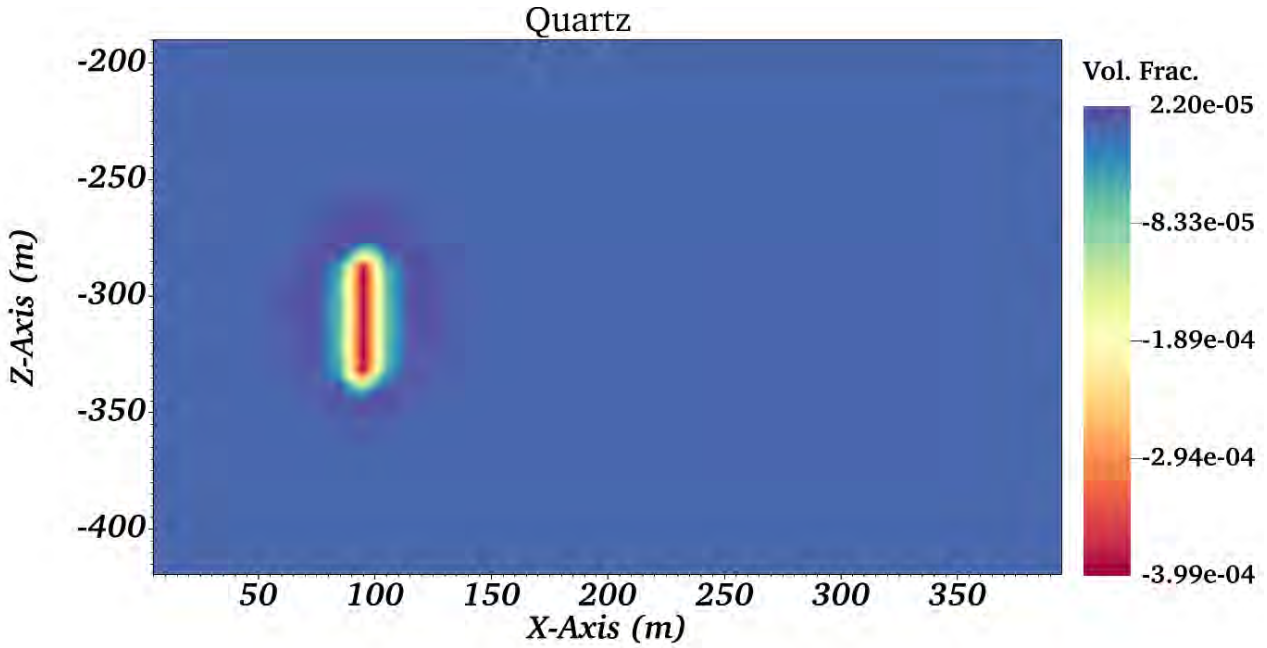

Figure 8: Changes in quartz (volume fraction) in the XZ-plane (Y=145 m) after 5 years of seasonal injection and production cycles.

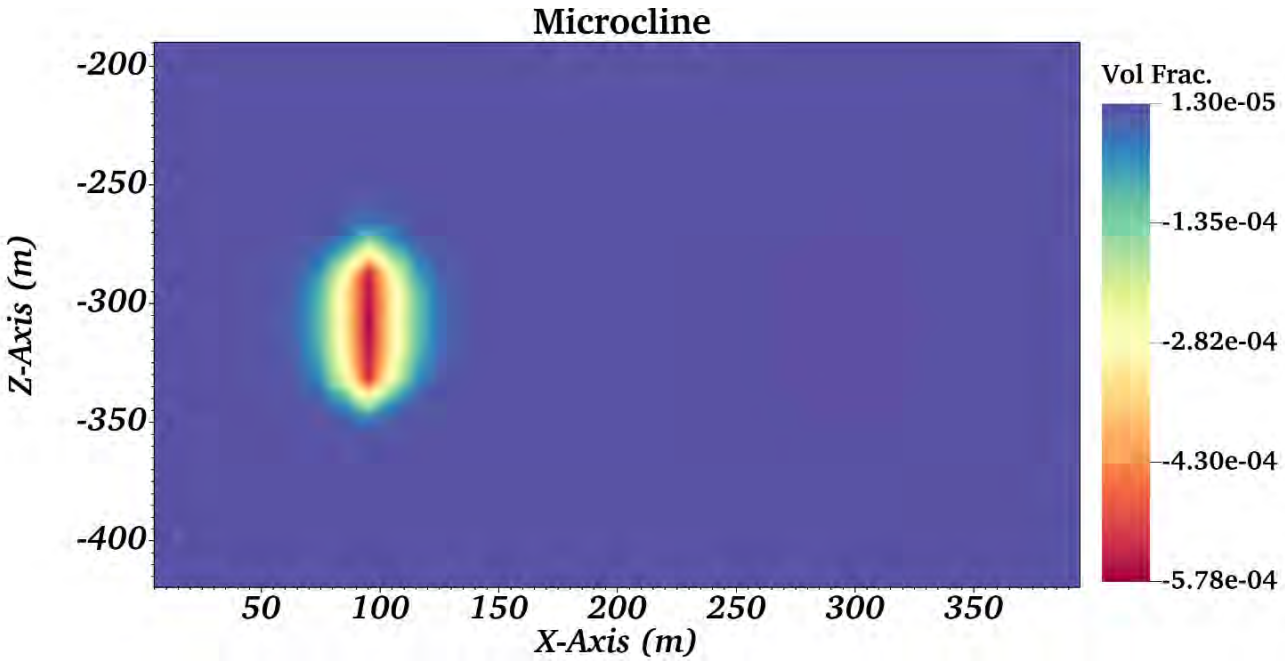

Figure 9: Changes in microcline (volume fraction) in the XZ-plane (Y=145 m) after 5 years of seasonal injection and production cycles.

3.3.3. Changes in goethite and hematite

In Figure 10, it is observed that goethite dissolves near the wellbore where the temperature is around 140°C. However, at a distance from the wellbore where the temperature drops, goethite precipitation occurs, matching the scale of dissolution seen in the warmer region. The precipitation of hematite (Figure 11) near the hot well is observed to be roughly 15 times less in magnitude

compared to the changes in goethite. Neither of the iron minerals, hematite and goethite, exhibit significant changes in the vicinity of the cold wells.

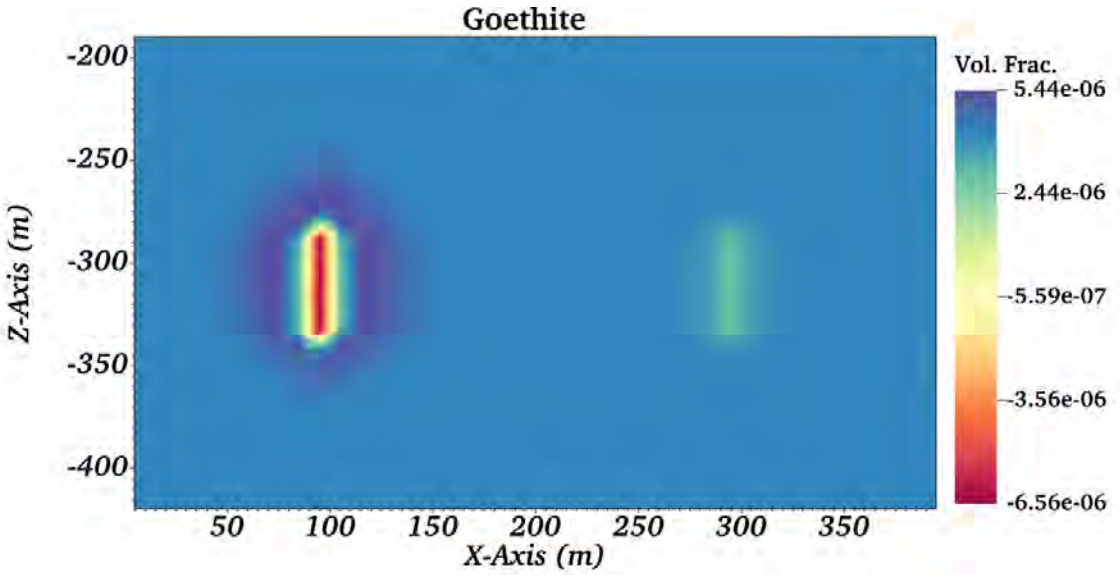

Figure 10: Changes in goethite (volume fraction) in the XZ-plane (Y=145 m) after 5 years of seasonal injection and production cycles.

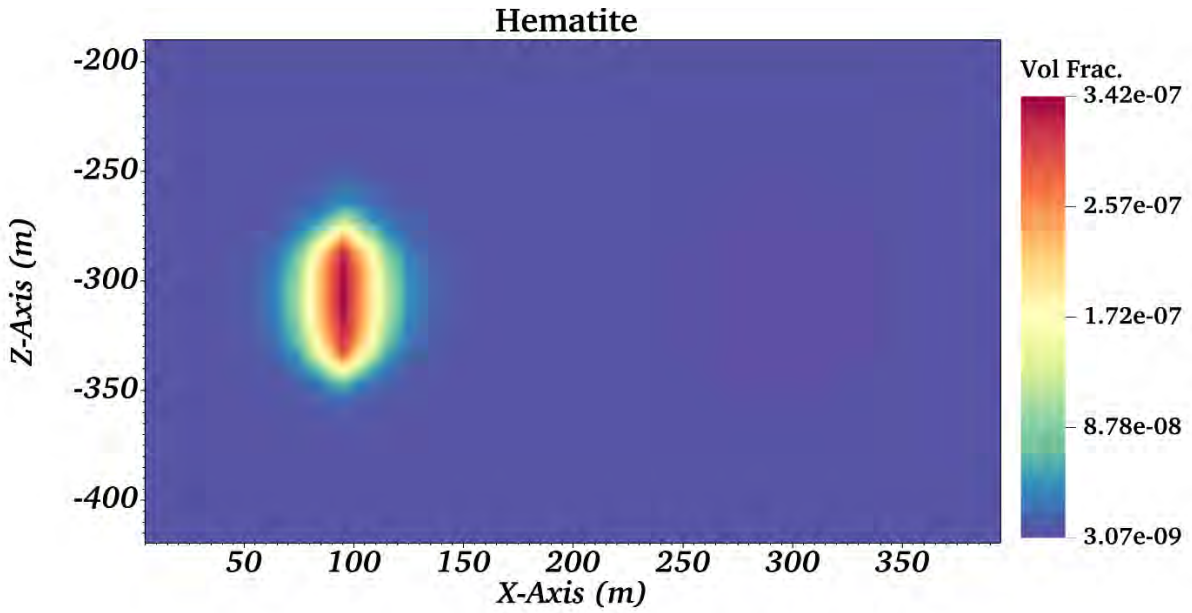

Figure 11: Changes in hematite (volume fraction) in the XZ-plane (Y=145 m) after 5 years of seasonal injection and production cycles.

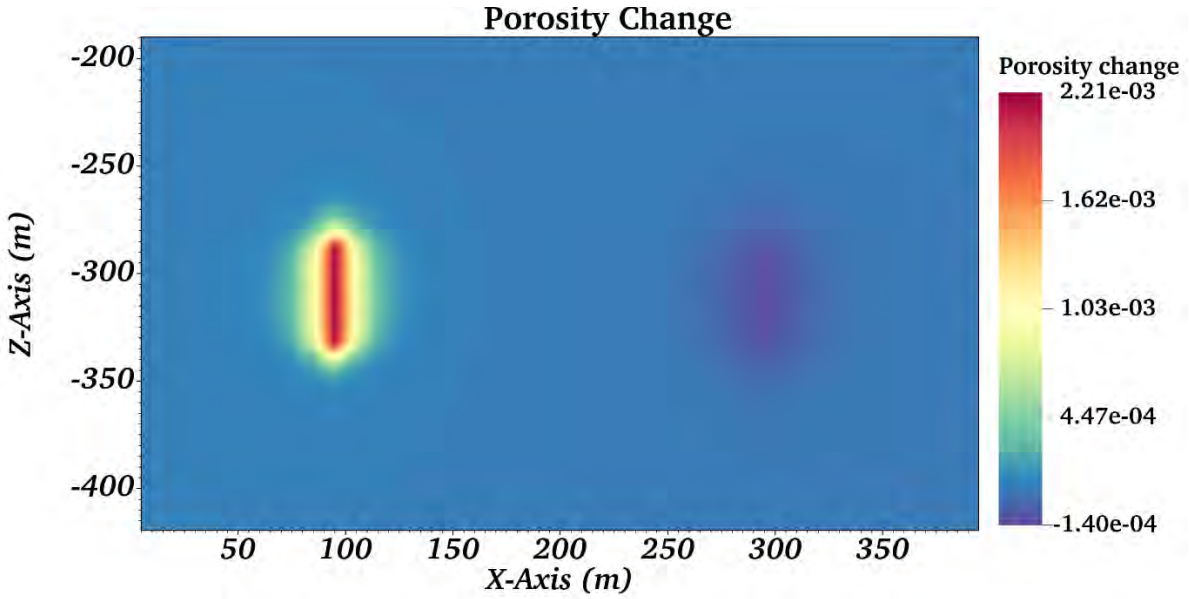

Figure 12: Changes in porosity in the XZ-plane (Y=145 m) after 5 years of seasonal injection and production cycles.

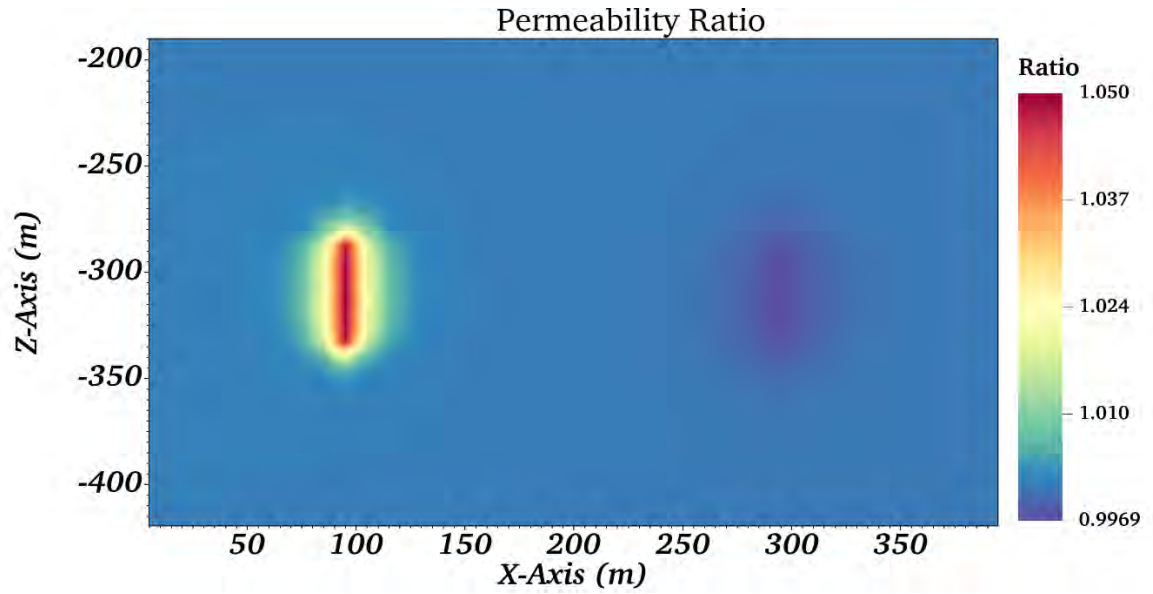

Figure 13: Permeability ratio in the XZ-plane (Y=145 m) after 5 years of seasonal injection and production cycles.

3.4. Changes in porosity and permeability

Figure 12 illustrates the overall variations in porosity attributed to the dissolution and precipitation of minerals. The modeling indicates an increase in porosity of around 1.5% in the area surrounding the hot well, while a decrease of approximately 0.1% in porosity is predicted near the cold well. The enhanced porosity observed near the hot well can be linked to the dissolution of calcite, quartz, and microcline, with calcite undergoing the most significant amount of dissolution among these minerals. The amount of dolomite that precipitates near the hot well is not as substantial as the combined dissolution of these minerals, which leads to a net increase in porosity. This augmented

porosity adjacent to the hot well may improve the efficacy of the injection process for long-term storage, and the minimal decrease in porosity near the cold well is considered to have little impact. Figure 13 depicts the permeability ratio, which is calculated as the current permeability divided by the initial permeability. This ratio is derived from changes in porosity, using a cubic law for the calculation.

4. Conclusions and future work

The conceptual model integrates operational conditions, hydrogeologic attributes, and mineralogical data to simulate outcomes such as heat distribution, the likelihood of thermal short-circuiting, and variations in pH, brine composition, mineralogy, porosity, and permeability. The conclusions drawn from this study reveal that, over a five-year period, the operation of the RTES system within the established operational and reservoir parameters carries no significant risk. Results from the reactive transport modeling can guide the optimization of operational practices to enhance the effectiveness of thermal energy storage and reduce the incidence of operational failures owing to corrosion and scaling, which stem from retrograde solubility and the precipitation of iron minerals. Additionally, the findings from this study can be utilized to develop preventative measures to circumvent these issues, thereby promoting the sustainability of long-term reservoir thermal energy storage.

Future directions for this research will account for a refined geometrical setting and will include modeling scenarios with strong oxidizing conditions, like the presence of dissolved oxygen, to better quantify the potential for corrosion and scaling resulting from air intrusion. Also, it will be necessary to refine the grid resolution around the well to millimeter-scale accuracy to more precisely quantify the precipitation of iron hydroxides on the well screen. Also, a detailed wellbore simulation can be integrated with the reservoir simulation to better quantify the mineralogical changes at well screens.

Inhibition of Iron Sulfide to Prevent Brine Pump Capacity Decline

Fritz Earwin Monterozo

Nalco Water, An Ecolab Company

Keywords

Brine pump, mineral scaling, and iron sulfide

ABSTRACT

In geothermal systems, iron sulfide can be considered as one of the most challenging scales because of the impacts of the deposits formed. This type of scale is usually intermixed with amorphous silica and metal silicates, which in turn, forms tenacious and hard deposits that can be observed in both surface and subsurface facilities. In one case in the Philippines, deposition of iron sulfide along the brine reinjection system negatively impacts the capacity of the brine pump. Aside from scaling along the pipelines, iron sulfide deposition was also observed inside the pump casing which causes the rapid decline of pump capacity. Without operable pumps, the plant is forced to shutdown and do manual cleaning to regain normal operations. A new inhibition program was studied based on existing cases of Nalco Water and check if the same principle can show positive impact on this type of application. The goal of the inhibition program is to preserve the capacity of the brine pump by minimizing scaling. This will maintain existing or reduce (or to some extent, eliminate) brine dumping rate. The trial was conducted from Oct. 19, 2023, and ended on Feb. 19, 2024. Nalco Water silica inhibitor blend was used targeting metal silicates/sulfides/oxides and amorphous silica. The Nalco program has started under an existing dumping condition. It can be observed that before the new inhibition program, the brine dumping rate increases steeply over time. The Nalco program was able to slow down the steep increase of the dumping rate. This was further demonstrated after the silencer cleaning where it can be observed that the brine dumping rate was consistently controlled for 1 month. Aside from brine dumping data, monomeric silica levels were also monitored during the trial. Comparing to the baseline, monomeric silica retention increased during the trial which is a good indicator of lesser scaling potential. Silica may not be visible in the XRF or XRD analyses because the sample was limited to the brine pump internals only. It is possible that the conditions inside the brine pump are not conducive to silica scaling, and thus scaling involving silica might be observed upstream or downstream of the brine pump. Aside from quantitative measurements, qualitative observations were also made during the trial. It is worth noting that during an outage where the brine pump was put out of service, no manual

barring was done to restart the pump. This was a good indication of the benefits of the chemical program in comparison to the previous experiences of the site.

1. Introduction

Mineral scaling in different geothermal systems is known to be a considerable limiting factor in achieving operational efficiency. It can occur at any location in a geothermal power station where temperature, pressure, pH or velocity changes, thereby affecting component concentrations that lead to scaling (Jamero et. al., 2018). Aside from amorphous silica and its derivatives, metal sulfide scaling in geothermal surface facilities can drastically reduce the output of the power plant. The formed hard and tenacious scales can reduce pipeline internal diameter which has severe adverse consequences on both operational and economic considerations (Andritsos & Karabelas, 1995).

Iron sulfide is one of the most common metal sulfide scales found in geothermal systems. It can be considered as the most abundant component in sulfide-rich scales. Observed iron sulfide scales in geothermal can exist in various forms. Geothermal wells in Paris Basin have large concentration of dissolved sulfide which forms mackinawite, pyrite and pyrrhotite (Criaud & Fouillac, 1989). A two-phase pipeline in the Philippines showed formation of pyrite and pyrrhotite co-depositing with magnetite and hematite (Jamero et. al., 2018). Another crystalline phase identified and observed in a geothermal facility in the US is troilite (Gallup et al., 1990). Among the crystalline phases observed, pyrite can be considered as the most stable phase. At relatively high temperatures conditions of 200 ℃ and above, pyrite and pyrrhotite are the dominating structures while other metastable sulfide phases can exist at lower temperatures and atmospheric conditions (Taylor, 1980).

Like mineral scaling in general, iron sulfide scaling is affected by both thermodynamic and kinetic considerations. Factors like flow velocity, pH and concentration of scale-inducing species (supersaturation) have strong influence on the scaling potential.

1.1 Factors Affecting Iron Sulfide Formation

According to the study of Andritsos & Karabelas (1995), aside from saturation conditions, pH, flow velocity and temperature have varying effects on the deposition behavior of iron sulfide. In terms of pH, the observed deposition behavior (assuming constant species concentration, temperature, salinity and velocity), resembles a “bell” shape curve with peak at pH 6.2.

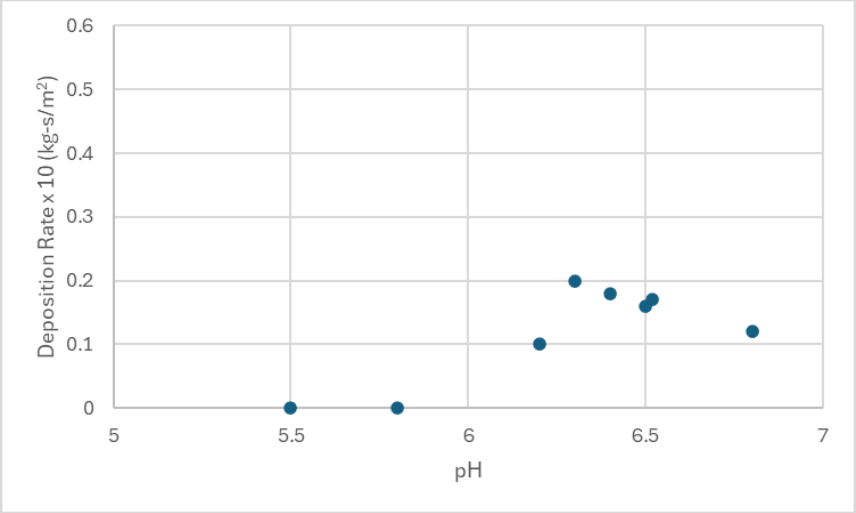

Figure 1. Effect of pH on deposition rate of iron sulfide. Reference: Andritsos & Karabelas, 1995)

Flow velocity has a considerable impact on deposition rate at fixed pH value. It can be generally observed that increasing velocity also increases the deposition tendency of iron sulfide. However, there is no direct impact on the morphology of the developed scales, having larger or smaller crystal structure (Andritsos and Karabelas, 1991). For temperature, a retrograde solubility curve of iron sulfide deposition was observed. An increase in temperature significantly increased the deposit formation rate. Unlike other sulfides where temperature has an impact on the pH range of deposition, this was not observed specifically for iron sulfides.

1.2 Geothermal Brine Pump Deposition

A geothermal site in the Philippines experiences brine pump capacity decline due to mineral scaling. Without enough capacity, diversion of the brine to the reinjection system can be challenging. To maintain the level inside the separator vessel, dumping of brine to collection ponds is being done. In worst case, production wells are being shut or throttled to manage limited reinjection capacity.

The nature of the deposition was studied by getting actual samples from pump casing and impeller. Figure 2 shows the actual scale samples obtained and analyzed.

The XRD was performed on: Dried at 105 °C

Iron Sulfide (Pyrite) - FeS2

Some amorphous material present.

Figure 3. XRF and XRD analyses of the scale samples obtained from the brine pump.

The primary identity of the scale is iron sulfide (pyrite), which explains the general dark gray color of the scale. This type of scale was also observed in other geothermal facilities like Leyte, typically from mixing an acidic well which carries the iron ions and a neutral well which causes the increase in prevailing pH (Jamero et al., 2018). Analysis of the brine that passes through the brine pump shows pH around 6.4. Based on Andritsos & Karabelas (1995) and as confirmed with our site experiences, pH is considered as the main driving factor of iron sulfide scaling. The pH of the brine is within the pH range of 6 to 6.8 at which this scale is expected to precipitate. Concentration of scale-forming ions is also an important factor to consider, especially for systems that we are expecting an influx of iron.

2. Methodology

From a similar site experience on addressing iron sulfide scaling, the same program principle was proposed. The program focuses on addressing the metal-based scales and preventing potential metal silicate formation both in the brine pump internals and downstream pipeline. This may help maintain the overall capacity of the pump.

In this case, a combination of metal silicate/sulfide/oxide inhibitor blend was used alongside with a silica inhibitor. These chemistries were blended on-site into a single product and dosed upstream of the brine pump. The details of the chemical program are summarized below:

Chemical	Function	Target Dosage (based on brine chemistry)
GEO981	Minimizes monomeric silica deposition by crystal structure modification and colloidal silica dispersion.	5 ppm
GEO962 and GEO939	Inhibition of metal silicates/sulfides/oxides to prevent further co-deposition with amorphous silica forming much harder scales.	10 ppm

The proposed program was applied for a period of 4 months. Brine dumping rate was the main key performance indicator involved. Ideally, the program should maintain the initial dumping rate to say the inhibition performance is favorable.

3. Results

For the trial, the key indicators that were agreed upon were reduction in the increase of dumping rate, which ultimately will have an impact on the actual time in-between cleaning of the brine pump. To gain additional data during the trial, monomeric silica was also measured. Scaling coupons were also installed both upstream and downstream of the brine pump.

The trial started on Oct. 19, 2023, with a target 4-month run which was to end on Feb. 19, 2024. During the testing, several outages were encountered which affected the trial. One was from Nov. 9 to Nov. 17 due to dosing pump issues, and the other one was from Dec. 5 to Dec. 17 for silencer dump cleaning.

Figure 4 shows the brine dumping trend from September 15, 2023 to January 22, 2024, along with level-control valve (LCV) positions during this period.

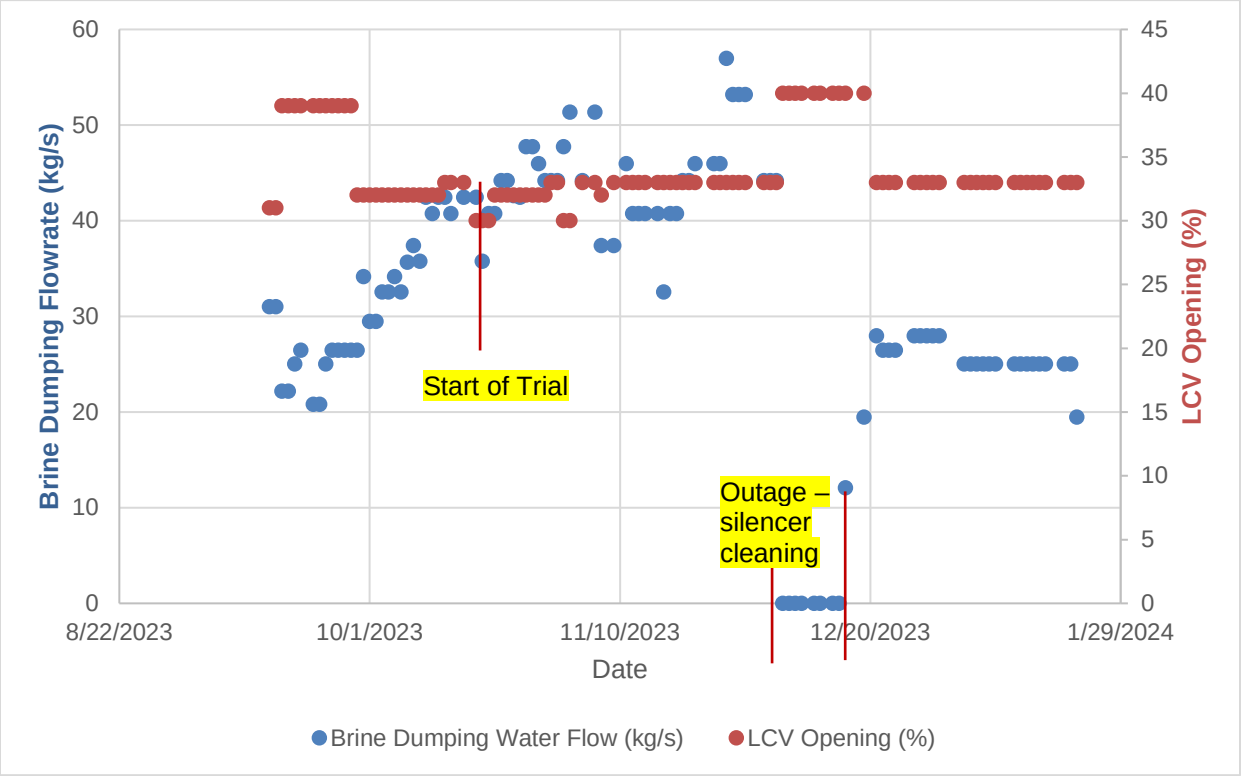

Figure 4. Brine dumping rate before and during the trial.

The test program started under an existing dumping condition. It can be observed that before the new inhibition program, the brine dumping rate was increasing steeply over time. The proposed program was able to slow down the steep increase of the dumping rate. This was further demonstrated after the silencer cleaning, where it was observed that the brine dumping rate was consistently controlled for 1 month.

Aside from brine dumping data, monomeric silica levels were also monitored during the trial.

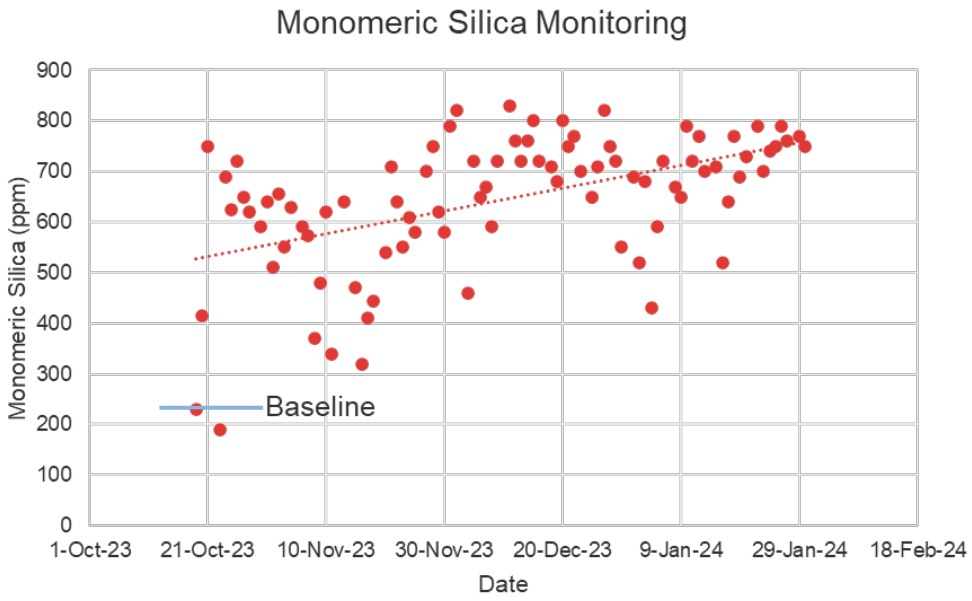

Figure 5. Monomeric silica levels along the brine pump line

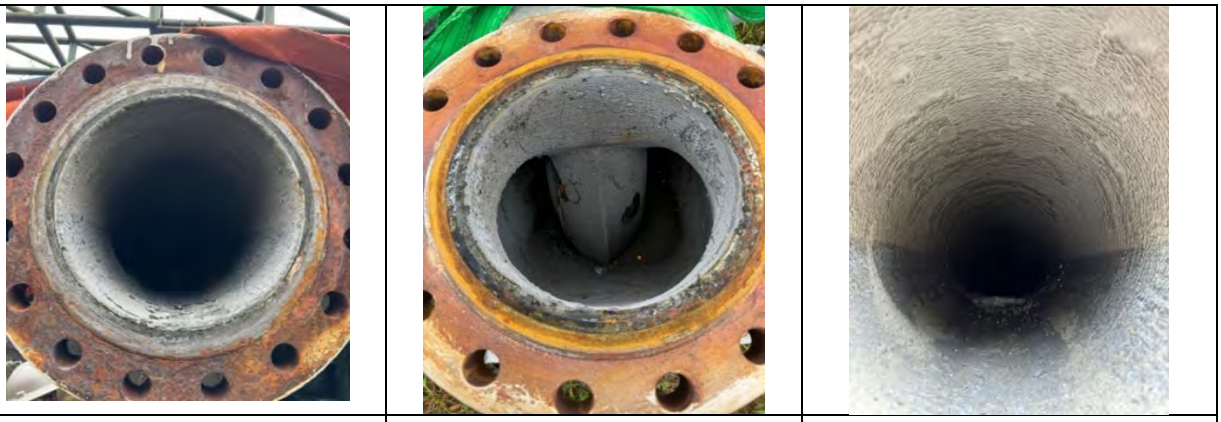
Comparing to the baseline, monomeric silica retention increased during the trial which is a good indicator of decreasing scaling potential. Silica may not be visible in the XRF or XRD analyses because the sample was limited to the brine pump internals only. It is possible that the conditions inside the brine pump were not conducive to silica scaling, and thus scaling involving silica might have been occurring upstream or downstream of the brine pump.

Scale coupons were also used to monitor the progress of the trial, but the data can be considered as inconclusive since there was an outage during one of the observation periods. Here is the summary of the measurements:

Treatment	Days Inserted	Initial Weight (g)	Final Weight (g)	% Increase	Remarks
Baseline 1 (BP-B)	15	25.2	27.9	10.7	Inserted without BP-B cleaning
Baseline 2 (BP-A)	31	27.3	28.5	4.4	Started clean
Treatment Program	33	27.2	28.8	5.9	Inserted without BP-A cleaning; with 9 days outage

Aside from quantitative measurements, qualitative observations were also made during the trial. It is worth noting that during an outage where the brine pump was put out of service, no manual barring was done to restart the pump. This was a good indication of the benefits of the chemical program in comparison to the previous experiences by the site.



Upstream	Brine Pump Internal	Downstream

Figure 6. Brine pump inspection after the 4-month trial run.

According to the studies done by Andritsos and Karabelas (1995), the brine condition is favorable for the formation of iron sulfide. It can be considered that saturation conditions as well as pH are the main driving factors for the deposition. In comparison to the dosing behavior along the lines and inside the brine pump, it was observed that iron sulfides where mainly deposited inside the brine pump, and a combination of iron sulfides and amorphous silica scaling was present on the upstream and downstream pipelines. The hypothesis is that iron sulfide deposition is more pronounced inside the brine pump due to turbulence. The turbulent nature of the flow enhances particle interaction and increases agglomeration (Afkhami et al., 2019).

4. Conclusions and Recommendations

The condition inside the brine pump as well as the brine characteristics are contributing factors to the deposition of iron sulfide. General dispersion and inhibition were considered for the selection of a suitable treatment program. Quantitative and qualitative results show that the new program used for scale inhibition in the brine pump line is promising. The positive impacts of the program were observed firsthand. These are related to maintaining the dumping rate prior to the start of the program and obvious differences like elimination of manual barring to restart the pumps.

Ideal scenarios for the conduct of the program are the following:

1. The dosing program should ideally start with a clean system – to be able to fully demonstrate the inhibition capabilities. Pre-existing scales usually serve as seed for other scales so this can have an impact on the parameters being measured.

2. Brine dumping should be eliminated prior to the start of the dosing program. This will help to clearly demonstrate the benefits of having a preventive approach.

3. A brine sampling point should be available downstream of the brine pump. This will capture the true monomeric silica retention and clarify the relation to scaling downstream of the system.

4. Scale coupons should be installed on a clean system prior to the start of the program.

In relation to item 2, there was an observation of soft white deposits at the dump area of the silencer. Based on initial XRF results, these are purely amorphous silica. Compared to previous deposition behavior, these white deposits are easier to clean and do not form hard deposits. However, the deposition rate is faster compared to the conditions before. This can be attributed to the further concentration of silica downstream of the silencer which forces the inhibitor-colloidal silica bonds to be unstable. The result is precipitation of amorphous silica instead of complexing with metal ions. This leads to a strong recommendation that the inhibitor program should be dosed in systems where we will not expect re-concentration (exposure to atmosphere/flashing) and drastic temperature reduction that will increase the silica saturation index beyond an allowable range.

Low-adhesion coating, Silica scale, Diamond like Carbon

ABSTRACT

Silica scale accumulation on the inner surface of pipes such as heat exchanger causes power reduction or frequent maintenance to remove it. This problem is caused by blocking fluid flow due to scale accumulation. This work aimed to reduce silica accumulation by using Diamond-Like Carbon (DLC) coating. DLC is a carbon-based amorphous thin film that consists of a diamond structure and graphite structure and a low-adhesion performance against silica scale was confirmed in previous our studies. However, DLC is generally coated to outer surface due to limitation of deposition method. In this study, new coating method specialized for an inner surface has been developed, and its chemical structure was evaluated by X-ray Analysis Fine Structure (XAFS) and Elastic Recoil Detection Analysis (ERDA). As a result of chemical structure, a half-length of pipe in 500 mm received the DLC coating, while the other side was coated with a polymer-like carbon (PLC). Furthermore, geothermal brine was flowed in the coated pipes to validate the effect on silica scale accumulation. The accumulated silica morphology and accumulated amount was observed by Scanning Electron Microscope and Energy Dispersive X-ray microanalyzer. On the non-coated surface, silica scale completely covered the inner surface of pipes. The DLC-coated surface also accumulated silica. However, the silica peeled off by itself during observation, and eventually the amount of silica on the DLC surface reduced to 3% of the accumulation for the non-coated surface.

1. Introduction

Geothermal power plants produce renewable energy and they emit only 1 – 3 % CO_2 compared to emissions from fossil-fired thermal power plants [1],[2]. Additionally, geothermal power plants provide stable electricity supply in contrast to the other renewable power sources such as solar and wind power which fluctuate depending on time and weather [2]. However, geothermal brine contains a certain amount of dissolved silica, which precipitates and accumulates on the inner surfaces of pipes in heat exchangers.

Figure 1 shows examples of scale accumulation on the inner surface of the pipes in the shell and tube type heat exchanger. The silica accumulation eventually reduces the power generation because the accumulated silica blocks the geothermal-brine flow paths. Chemical and physical combined methods for removal of accumulated silica (such as fluorine acid washing and water jets) are routinely adopted to mitigate this issue [3]. However, power plants are typically shut down for these operations. Therefore, a method to suppress silica adhesion without power plant shutdowns is required. In a previous study, Nakashima et al. reported that diamond-like carbon (DLC) coatings could reduce silica adhesion to 2% of levels without coatings (compared with 13% Chromium steel) based on silica adhesion testing which imitates silica accumulation experimentally [4]. Therefore, the use of DLC coatings could be effective in suppressing the silica adhesion without power plant shutdowns. DLC is a carbon-based amorphous thin film with diamond- and graphite-like structures with sp^3 and sp^2 hybridization state, respectively [5]. DLC can be categorized as hydrogen-free and hydrogen-containing DLC; these are designated as amorphous carbon (a-C) or tetrahedral amorphous carbon (ta-C) (depending on the sp^3 fraction) and a-C:H, respectively. The ta-C coatings are excellent hard materials which provide anti-wear properties. The a-C:H coatings are generally deposited by chemical vapor deposition (CVD), resulting in lower hardness. However, it is a suitable coating method for complex shapes. DLC coating is generally applied to outer surfaces due to limitations of coating methods. The physical vapor deposition (PVD) method is a kind of sputter process, therefore, surfaces hidden from the coating source (such as inner surface of the pipes) have difficulty getting deposition. Figure 2 shows the schematic illustration of inner surface deposition. The CVD method also needs to generate plasma for deposition, however inner surface is narrow and plasma is hard to get into that space. Therefore, there were few research about DLC coatings on inner surface of pipes and evaluation of it against silica accumulation. In this study, a new coating method was developed specifically for the inner surfaces of pipes. The PVD and CVD methods require putting the surfaces to which we want to apply the coatings inside a vacuum chamber. The new coating method treats the pipes as the vacuum chamber, and we could generate the plasma needed for CVD deposition inside the pipes, and DLC could be deposited on the inner surface of the pipes. Then, chemical structure of DLC on the pipes was evaluated, and it was exposed to geothermal brine to validate the suppression of silica accumulation.

2. Experimental procedure

2.1 Test materials and DLC coating procedure

In this study, stainless steel (AISI 304, SUS304 in JIS) pipes, which is generally used in the corrosive environment, was adapted for coating substrate. The outer diameter, thickness, and length of pipes were 19.05, 1.65, 500 mm, respectively. This pipes diameter and thickness is same as that in a heat exchanger adapted in the binary geothermal power plant. Additionally, in order to evaluate the chemical structure and composition of DLC coating, 10 × 10 × t1 plate substrate consist of stainless steel (AISI420, SUS420J1 in JIS). This plate substrate was buff finished to Ra 0.01μm for chemical structure evaluation. Figure 3 shows schematic illustration of the DLC coating equipment. There are 3 jigs to connect steel pipes or quartz pipes, and it has spaces to contain the plate substrate (10 × 10 × t1). Therefore, both tip and midpoint of pipes were able to be evaluated. Since DLC coating requires to apply a bias voltage to pipes, quartz pipes were adopted for the electrical insulation. Bottom jig was connected to gas supply and top jig was connected to vacuum pump. In order to generate plasma in DLC coating process, pressure adjustment was implemented by flow rate of gases and vacuum pump adjustment. The 3 jigs (top, midpoint and bottom) were used for the chemical structure evaluation of top, midpoint and bottom positions. However, the midpoint jig was removed in the DLC coating process for the scaling test at site to apply the DLC coating to 500 mm pipes which was suitable in the scaling test. The deposition conditions for the chemical structure evaluation and the scaling test were same.

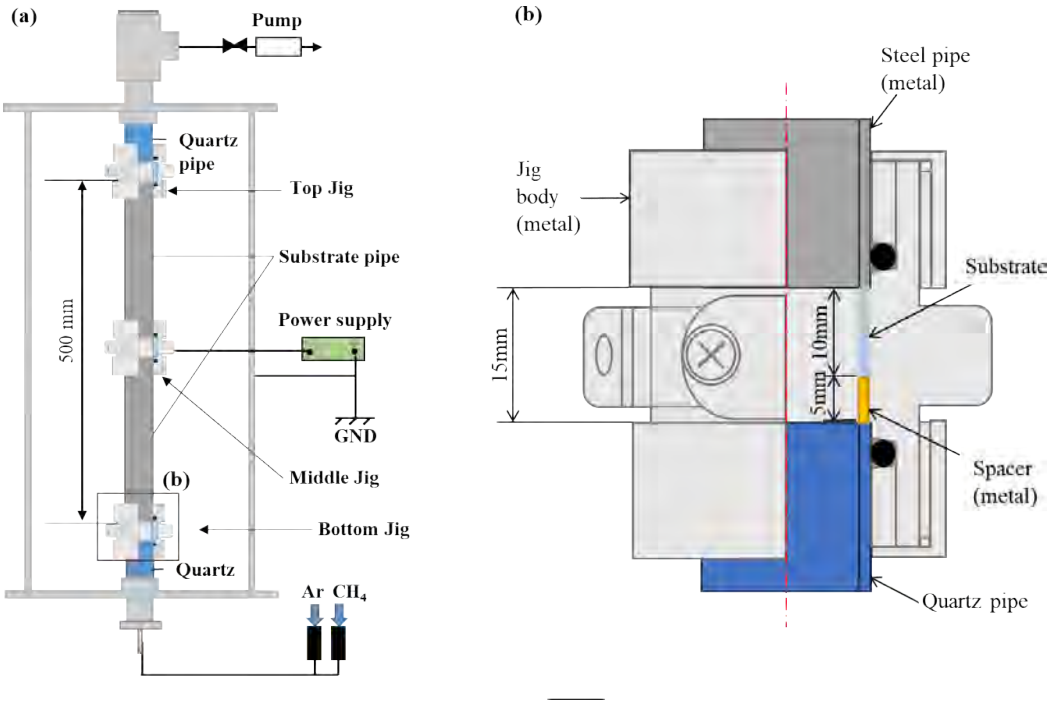

Figure 3: Schematic illustration of coating equipment (a) overview of coating equipment, (b) details of bottom jig[6]

Table 1 shows the deposition condition of DLC coatings. Bias voltage was applied as pulse direct current with a duty ratio of 0.75% to avoid the temperature increase during coating process. Ar gas was adopted as to generate plasma, and CH4 was adopted as carbon source of DLC coating. The back pressure of exhaust gas was set as 33 Pa, it was adjusted to generate plasma. Before the DLC coating process, plasma cleaning was applied to remove contamination or oxidation layer on the inner surface of pipe by exposing that surface under Ar gas plasma.

Table 1 Deposition conditions of DLC coating

Average Voltage		-840	V
Duty rate		0.075	%
Deposition time		80	min
Pressure		33	Pa
Gas flow	Ar	75	sccm
	CH_4	18.5	sccm

2.2 Analysis methods used to measure DLC coating properties

In order to measure the sp^2 bond fraction on the outermost surface, X-ray analysis of the fine structure (XAFS, Aichi synchrotron BL7U) was conducted. Highly oriented pyrolytic graphite (HOPG) was employed as a reference with 100% sp^2 binding, and the sp^2 bond fraction ($sp^2/(sp^2+sp^3)$) of the DLC coating was calculated by comparing the spectrum regions by utilizing the π^* orbitals in sp^2 bonds at 285.4 eV in the HOPG and DLC coatings[7]. XAFS can be employed to measure the sp^2 fraction at different depths depending on the type of electron yield. It was previously mentioned that the auger electron yield (AEY) comes from 0–2 nm depth and that the total electron yield (TEY) comes from 0–50 nm depth51). Therefore, the sp^2 bond fraction calculated from the AEY was defined as that of the outermost surface structure of the DLC coating, and the fraction obtained from the TEY was defined as that of the bulk structure.
In order to measure the depth profile of the hydrogen amount, high-resolution elastic recoil detection analysis (HR-ERDA, HRBS500) was performed with 480 keV N+ ion input, and recoiled H+ ions were detected. The hydrogen amount was calculated from the reference DLC coating, for which the hydrogen amount was already known.

2.3 Scaling test at site

In order to confirm the suppression of silica accumulation at DLC coating on the inner surface of pipes, non-coated and DLC coated pipes was exposed under actual geothermal brine at the actual geothermal plant. The geothermal brine was branched from the hot brine line at the geothermal binary plant and led to the test section. Figure 4 shows test section. Non-coated and coated pipe was connected in series, and geothermal brine was flowed through the pipes with 0.65t/hr for 75 days.

After the test, both non-coated and DLC coated pipes were cut and the silica accumulation morphology was evaluated using Scanning electron microscopy (SEM) to confirm the difference of silica accumulation between non-coated and DLC coated pipes.

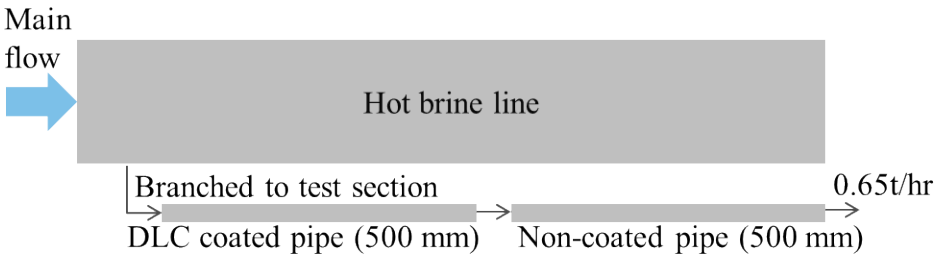

Figure 4: Test section of scaling test

In addition, scale suppression effect was confirmed by comparing the accumulated amount of scale on the coated and non-coated pipes. The accumulated amount of scale was defined as following.

$$A = \frac{Si}{M}$$

where A, Si, M are accumulated silica amount, detected Si atom amount [wt%], and detected atoms derived from coating or substrate amount, respectively. Therefore, summation of the amount of Fe, Cr, C is used for M. The accumulated amount of scale on the coating was calculated from A of the coating divided by that of non-coated one.

3. Results

3.1 DLC coating on the inner surface of pipes

Figure 5 shows coating equipment for pipes in process and appearance of plate substrate after deposition set inside of jig at (a) 0 mm (bottom), (b) 250 mm (midpoint) (c) 500 mm (top). Plasma light was evident at both ends of the pipe, and it is thought that plasma was generated and coating deposition occurred over the entire length of pipe. Points (a), (b), (c) had colored areas where coating deposited. DLC coating has generally black color derived from carbon. Therefore, these colors of substrate were caused by interference color depending on the thickness of coating. Figure 6 shows appearance of DLC coating on 500 mm pipe. Each position of the inner surface of pipe got black colored, indicating that entire surface of pipe got deposited with coating. However, the color of the coating was different from plate substrate, as shown in Figure 5. The inner surface of pipes shown in Figure 6 had no color gradation. In contrast, the plate substrate as shown in Figure 5 had color gradation on the substrate, and it was not of a black color. Therefore, the color change in the plate substrate was caused by thickness difference, since the jig shape was different from the pipe, and the plasma state was also different from that of the pipe. In contrast to the black color at the inner surface of pipe at (a), (b), (c), the substrates at these positions showed brownish black, greenish black, and black, respectively. It is thought that the chemical structures were different at each position. Therefore, in order to differentiate the chemical structure of coatings deposited on the inner surface of pipe, XAFS and ERDA analysis was performed on the plate substrates.

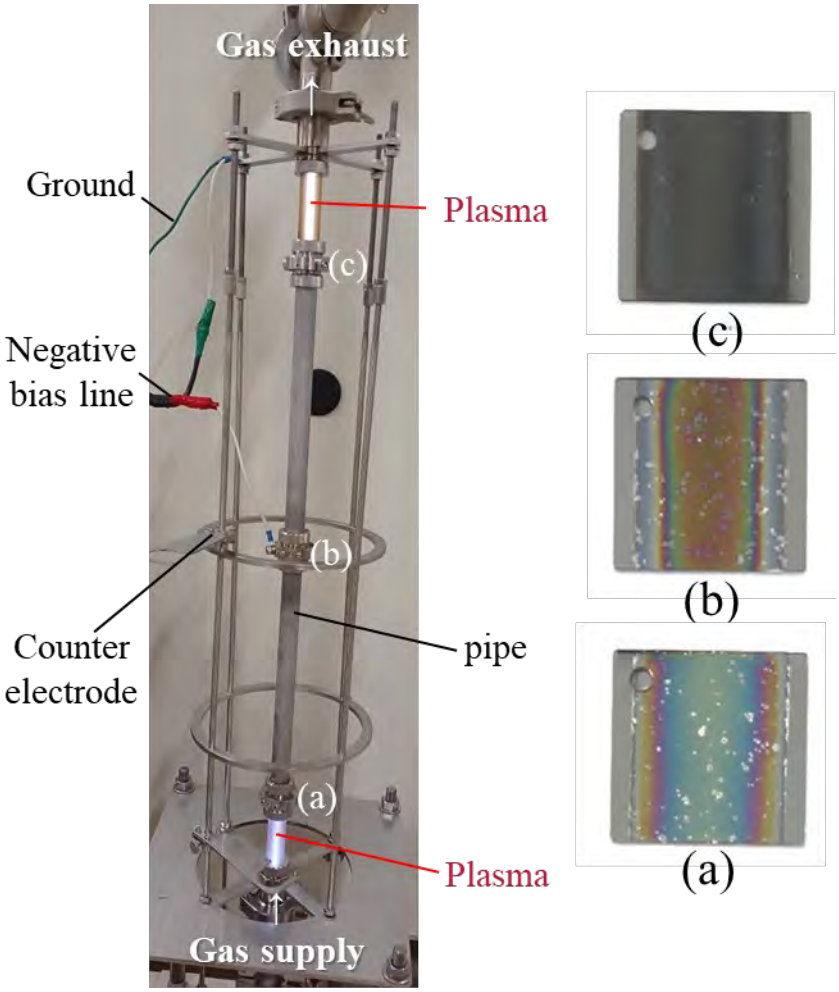

Figure 5: Coating equipment in deposition process, appearance of plate substrate after deposition set inside of jig at (a) 0 mm (bottom), (b) 250 mm (midpoint) (c) 500 mm (top)

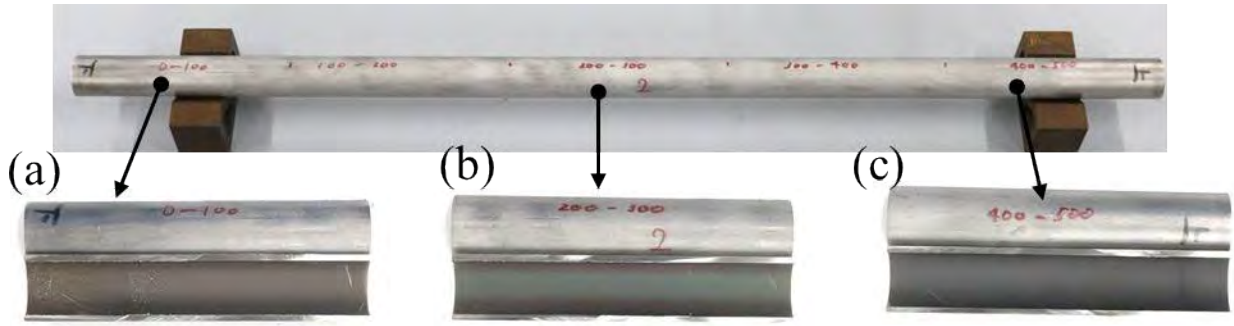

Figure 6: Appearance of DLC coating on 500 mm pipe from gas supply at (a)0 – 100 mm, (b) 200-300, (c) 400 – 500 mm

Figure 7 shows spectrum of XAFS with the analysis of outermost surface in 0 – 2 nm. The XAFS spectrum describes peaks derived from π, σ bonding of carbon atoms which represent the sp^2 and sp^3 hybridization state of DLC coatings. Our previous study [4] indicated that a low sp^2 fraction (described as peak area of $sp^2/(sp^2+sp^3)$ in the XAFS spectrum) could reduce silica adsorption energy and eventually suppress the amount of accumulated silica. Therefore, the sp^2 fraction was analyzed at 0, 250, 500 mm from the gas supply position. DLC is an amorphous coating, which indicates that the XAFS spectrum should have broad peaks. Therefore, the XAFS spectrum at the (b) 250 mm and (c) 500 mm positions indicated the presence of DLC coatings. However, the

XAFS spectrum at the (a) 0 mm position had multiple peaks in the σ bonding region. These multiple peaks are characteristic of graphite [7], and it indicated that little of the coating at (a) was in an amorphous state. Therefore, the area of 0 -100 mm from the tip of pipe was coated with polymer-like carbon (PLC) rather than the DLC coating. However, at least the area of 300 – 500 mm was coated with DLC coating.

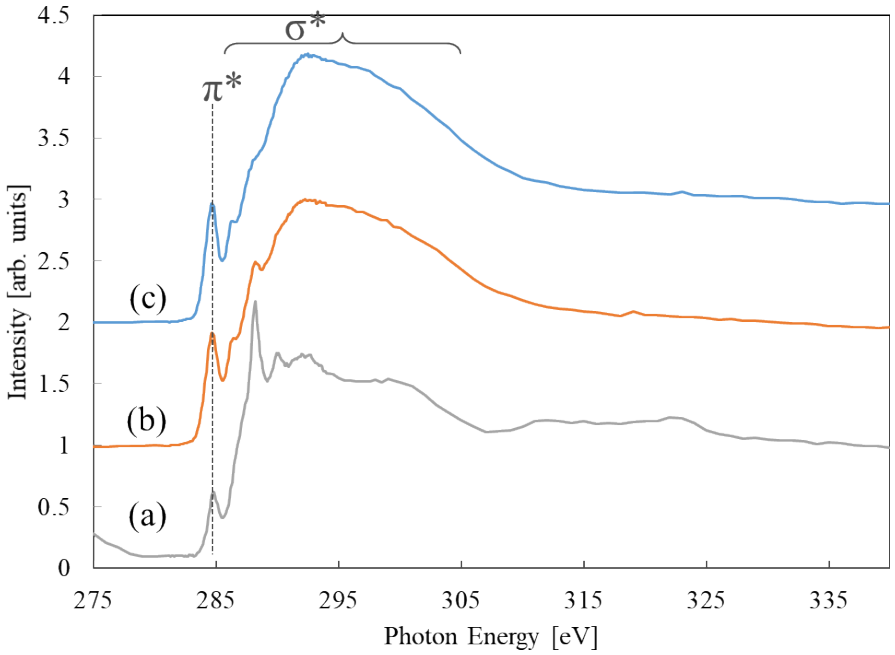

Figure 7: XAFS spectrum of plate substrate set in the position of (a) 0 mm, (b) 250 mm, (c) 500 mm

Figure 8 shows hydrogen content distribution from surface of coating by ERDA analysis. Our previous studies indicated that higher hydrogen content could suppress silica accumulation [8]. Each position (a) – (c) had hydrogen distribution at depth and a different trend in the outermost surface around 0 – 5 nm. At the outermost surface, hydrogen content is higher in order of (a) 0 mm, (c) 500 mm, (b) 250 mm. Therefore, (c) 500 mm had a lower-adherence DLC coating than the other positions since that position had highest hydrogen content in DLC. In this coating method, the chemical structures of the coatings were quite different depending on the position along the pipe length. (a) was polymer-like carbon (PLC) coating as indicated by XAFS analysis. Therefore, (a):PLC had higher hydrogen content than (b),(c):DLC [5]. Conventional coating method has enough space to contain the coating gas, however, inner pipe coating method had less space to contain the coating gases (CH_4) than conventional one, as illustrated in Figure 3. Therefore, coating gas was consumed along with the length of pipe, and much amount of hydrogen derived from CH_4 were in (c) than (b) position. Therefore, I inferred that hydrogen content results in order of (a), (c), (b).

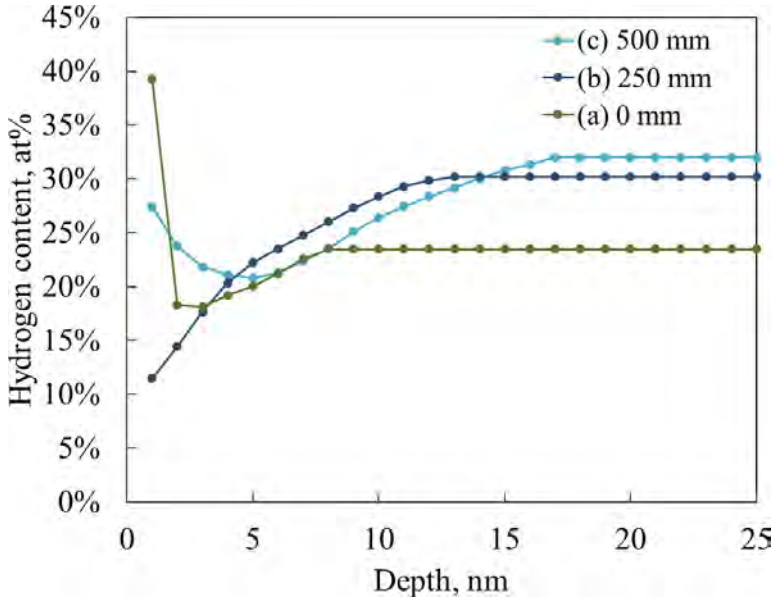

Figure 8: Hydrogen content distribution from surface of coating at (a) 0mm, (b)250mm, (c)500 mm

3.2 Scale accumulation on the inner surface of pipes

In order to confirm that the suppression effect of accumulated scale at the DLC coating depends on its chemical structure, accumulated scale morphology was observed by SEM-EDX for non-coated and several positions of coated pipes corresponding to chemical structure analyses of the previous section. Figure 9 shows accumulated scale morphology on the inner surface of SUS304 pipe. Scale covered the entire surface. Its morphology was made of cohesive spheres, which is characteristic of amorphous silica[9]. Table 2 shows chemical composition of accumulated scale on the inner surface of SUS304 pipe. Si and O atoms were mainly detected, and Al, Ca, Ca, Na atoms were also detected. Few Fe atoms which derived from substrate were detected. Therefore, it is thought that the accumulated scale was mainly made from amorphous silica.

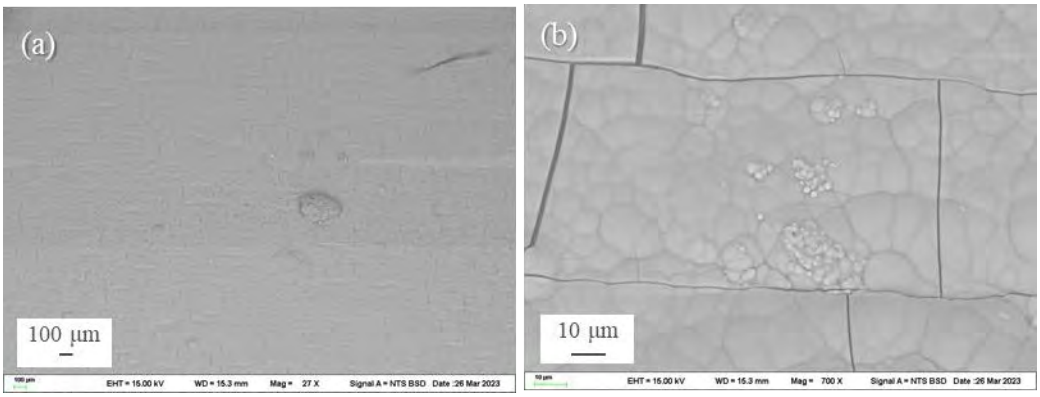

Figure 9: SEM image on the inner surface of SUS304 pipe.

Table 2: Chemical composition of accumulated scale on the inner surface of SUS304 pipe

Chemical composition [wt%]							
C	O	Na	Al	Si	K	Ca	Fe
1.72	53.45	1.26	6.24	31.41	1.40	3.91	0.61

Figure 10 shows SEM images of accumulated scale morphology on the inner surface of coated pipe. Each position of pipe accumulated scale with cohesive sphere morphology; therefore it is thought that the scale accumulation consisted mainly of amorphous silica. At the (b) position, which had DLC coating with a hydrogen content 11 at% at the outermost surface, the surface got covered entirely with accumulated scale. In contrast, at the (a) position, which had a polymer-like carbon coating with hydrogen content of 39 at% at the outermost surface, the scale partly peeled off. At the (c) position, which had DLC coating with hydrogen content of 27 at% at the outermost surface, the accumulated scale peeled off almost the entire surface. Figure 11 shows the accumulated scale amount at the surface of coated pipe. The reference amount for 100% accumulated scale is that of uncoated SUS304 pipe. However, DLC coating was partly peeled off. Therefore, the effectiveness of scale suppression was in the following order: (c), (a), (b). Moreover, DLC coating with higher hydrogen content at (c) could attain a level of 0.5 % of scale accumulation compared with SUS304. In our previous study [4],[8], DLC coating with high hydrogen content could reduce the accumulated silica amount. Therefore, the (c) position, at which the DLC coating had the highest hydrogen content could reduce more scale accumulation than the other positions.

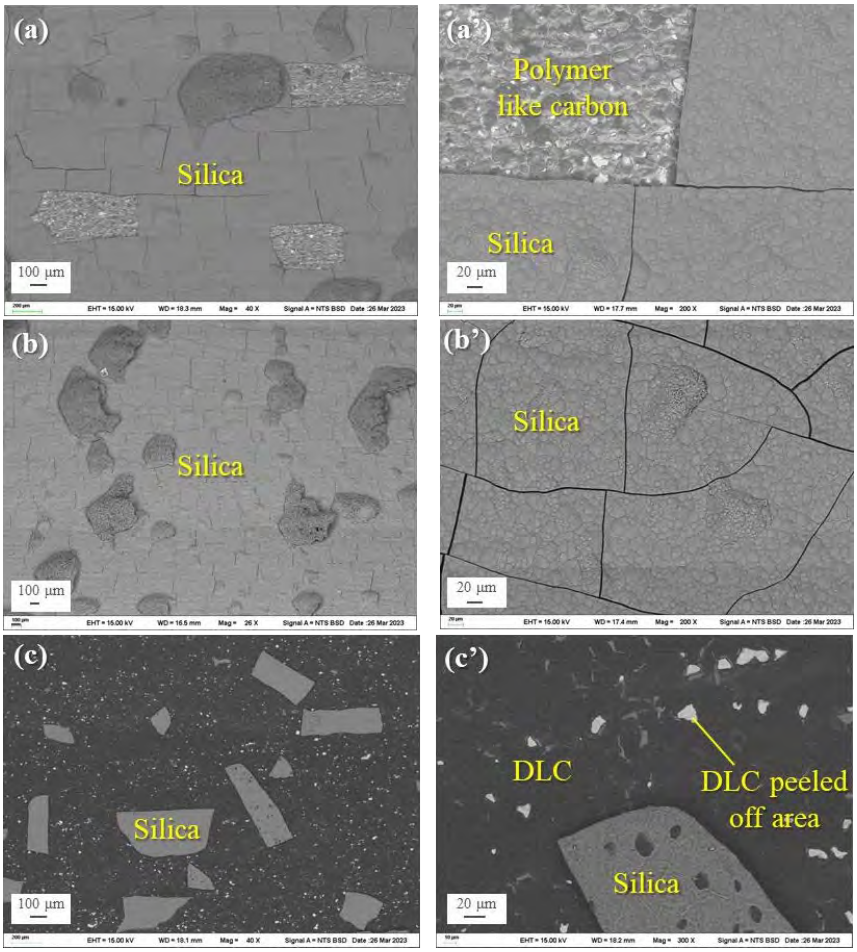

Figure 10: SEM image on the inner surface of coated pipe
(a)(a')0 - 100 mm, (b)(b') 200 – 300 mm, (c)(c') 400 – 500 mm

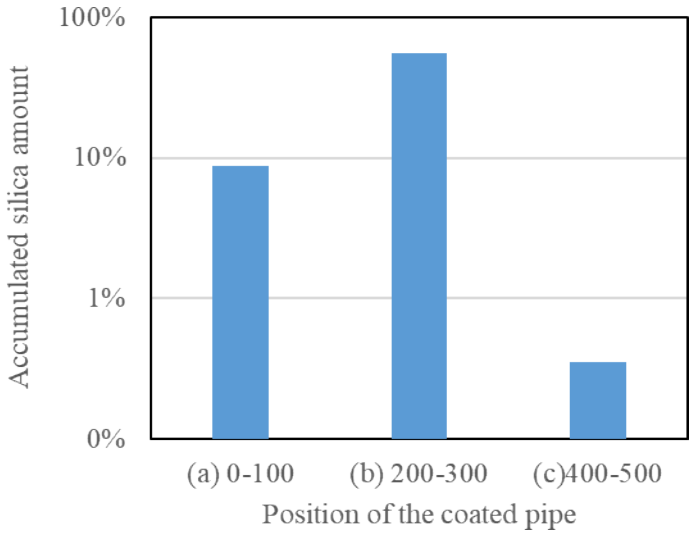

Figure 11: Accumulated scale amount at the surface.

4. Discussion

4.1 Suppression mechanism of silica scale accumulation by DLC coating

In order to discuss the suppression mechanism of scale accumulation by DLC coating, accumulated scale morphology was additionally observed. Figure 12 shows accumulated scale and DLC-coated surface comparison on the inner surface of DLC-coated pipe at the position of 400 – 500mm, which had highest suppression effect against the scale. SEM image of (a) and (b) is the corresponding surface with peeled-off scale and DLC coating, as described in the illustration. The white dotted line in the (a) and (b) images indicates the corresponding area. At the DLC-coated surface, there were many rough surface with polygonal shapes. It is thought that these polygonal shapes derived from grains of austenite in the SUS304. There was no silica inside of the grains; however on the groove located at the border of grains, accumulated silica remained. Figure 13 shows the surface of scale corresponding to the grooves shown on the DLC-coated surface. There is flat surface in the peeled scale at locations corresponding to the grooves, indicating that scale in the grooves got fractured, and the scale eventually peeled off. Therefore, it is thought that adhesion force between the DLC and scale was weak. However, when grooves derived from the substrate surface worked as anchor for the scale, then silica scale adhered at that area. Figure 14 shows the visual appearance of inner surface of the DLC-coated pipe at (c) 400-500mm after scale test. At this part of coated pipe before the SEM observation, there was silica scale entirely on the surface; however, it was peeled off after the SEM observation. It is indicated that the accumulated silica adhered to the coated surface through the groove area as Figure 13, and scale was already peeled off on almost the entire surface. Therefore, it is inferred that a small impact by vacuum during SEM observation caused scale removal.

5. Conclusion

In order to suppress silica accumulation on the inner surface of pipes used for heat exchangers, a new deposition method of DLC coating for the pipes was developed, and the scale suppression effect was evaluated through field testing at a geothermal power plant. The new deposition method could deposit DLC coating on the inner surface of pipes by using the pipes themselves as vacuum chambers. Moreover, some positions along the pipe had high hydrogen content in the DLC coating, which was expected to suppress scale accumulation, and was able to suppress accumulated scale amount dramatically compared with stainless steel pipe. Therefore, it is believed that DLC coating is potentially applicable as a new method to reduce silica scale on geothermal turbine blades. The evaluation results are as follows.

- Pipe with an inner diameter of 16 mm and a length of 500 mm was used for the inner surface coating substrate, and coating was deposited along the entire length of the pipe. Polymer-like carbon coating was deposited at 0 mm from the tip of the pipe, and DLC coating was deposited at 250 and 500 mm, as distinguished by XAFS analysis.
- DLC coating at the 250-mm and 500-mm positions had hydrogen contents of 11% and 27%, respectively. The higher hydrogen content at 500 mm was expected to have higher suppression effect for scale accumulation.
- Based on the amount of amorphous silica scale that accumulated during the field test, the DLC coating at 500 mm could reduce the amount of accumulated silica to 0.5 % of the amount observed with non-coated pipe made from SUS304.

ABSTRACT

Amorphous aluminosilicate scales are a common occurrence within infrastructure at many geothermal fields around the world, often resulting in the unexpected fouling of surface infrastructure and injectivity decline in geothermal reinjection wells. Amorphous aluminosilicate scales often form under conditions at which pure amorphous silica scales would not be expected. Such conditions include temperatures significantly higher than that predicted for amorphous silica polymerisation and extreme low pH, such as the formation of blockages in sulfuric acid injection quills. Additionally, the formation of aluminosilicate scale does not share the kinetic limitations displayed by its pure amorphous silica counterpart, having been observed to nucleate quasi-instantaneously both in the laboratory and in the field. Given these unique characteristics, a novel formation mechanism triggered by the precipitation of aluminium (oxy)hydroxide was tested in laboratory experiments, leading to a simple predictive tool for the occurrence of aluminosilicate scales. These results and tool are then compared to examples of and formation conditions of aluminosilicate scales within geothermal power stations at 3 separate geothermal fields. These examples include a rapidly formed aluminosilicate material deposited en masse during a binary plant excursion, leading to the first reported observation of the aluminium (oxy)hydroxide mineral, boehmite, in a geothermal scale,

1. Introduction

The purpose of this paper is to highlight the formation mechanism of many amorphous aluminosilicate scales encountered within the geothermal industry, and a means to predict their occurrence. This report is primarily aimed at assisting geothermal infrastructure operators identify risk areas and likely causes of apparently anomalous aluminosilicate scaling where pure

amorphous scaling is not anticipated. The formation mechanism discussed here (Newton, 2020) is also relevant to natural hydrothermal settings under conditions of significant physico-chemical disequilibrium, such as during boiling events within hydrothermal veins and mixing zones where downflowing near-surface derived acidic sulphate fluids interact with up flowing neutral pH geothermal waters. However, the focus of this report is scaling affecting the industrial utilization of geothermal resources including direct use for heating, and particularly power generation scenarios. It should be noted, however, that many of these physico-chemical scenarios are also often analogous to those occurring within natural hydrothermal systems.

Aqueous Al is typically undersaturated with respect to boehmite in the deep production zones of geothermal reservoirs, with aqueous Al concentration instead being controlled by the solubility of stable aluminosilicate mineral phases such as felspars and clay minerals. Unlike crystalline aluminosilicate minerals, amorphous aluminosilicate materials produced under rapid changes in fluid chemistry and temperature during which boehmite becomes supersaturated are instead quasi-stable. Although these quasi-stable aluminosilicate solid phases are not well preserved in the geologic record within extinct hydrothermal systems, these amorphous aluminosilicate materials are of primary significance within the comparatively short time spans relevant to human use of a geothermal resource.

The experimentally tested observation that the supersaturation of Al with respect to boehmite in presence of aqueous silica triggers the quasi-instantaneous formation of amorphous aluminosilicate material (Newton, 2020) has resulted in the development of a relatively simple excel-based tool to predict the onset of amorphous aluminosilicate scaling. This tool calculates boehmite saturation concentration and based on input values of fluid temperature and pH, and then compares this to the measured Al concentration as Al^{3+} (due to Al concentration typically being stated in terms of this species in laboratory analytical reports). Similar to the calculation of a silica saturation index (SSI) (Fournier, 1986), this tool yields a boehmite saturation index (BSI), which can be used to predict the onset of amorphous aluminosilicate scale deposition. Analogous with SSI, BSI is simply the concentration of aqueous Al divided by the solubility of Al with respect to boehmite. This tool also calculates SSI, however it uses a somewhat more sophisticated method after Fleming and Crerar (1982), rather than that of Fournier (1986) or Gunnarsson and Arnórsson (2000), in that it also takes pH into account for the amorphous silica solubility calculation.

At a pH of ~6 and above the Si/Al ratio of amorphous aluminosilicate scales are 3 and above, and more commonly between 5 and 10 (Gallup, 1997; Newton, 2020). The Si/Al mole ratio of the scale appears to be largely influenced by aging of the scale and its deposition rate (Newton et al.,2018, Newton, 2020), with the initially deposited amorphous aluminosilicate scale gradually taking up silica brine as it ages (Newton et al., 2018; Newton, 2020). Amorphous aluminosilicate scales also take up cations, such as Na^{+}, K^{+}, and Ca^{2+}. This as a result a of tetrahedrally coordinated Al^{3+} being substituted for Si^{4+} in the tetrahedral silica lattice, which imparts a charge imbalance. This imbalance is neutralised via the incorporation of positively charged metal cations (Gallup, 1997; Newton, 2020).

Aluminosilicate scales formed below a pH of ~6 have a Si/Al mole ratio below 3, commonly close to 1.0, and do not incorporate cations, such as Na^{+}, K^{+}, and Ca^{2+} into their short-range structure. This is likely due, depending on Si/Al mole ratio of the material, to Al being either entirely octahedrally coordinated, or partially octahedrally coordinated, with any tetrahedrally coordinated Al being so in a different manner to aluminosilicate scales produced under near neutral conditions

(Exley and Birchall, 1993: Doucet et al., 2001a; Strekopytov and Exley, 2006; Tokoro et al., 2014; Leiviska et al., 2014; Beardmore et al., 2016).

Such geothermal scales have not been discussed elsewhere in the geothermal literature to the knowledge of the author. However, these materials appear to be readily formed where acidic fluids mix with near neutral pH geothermal brine. Examples include zones where diluted sulfuric acid mixes with hot geothermal brine within brine acid dosing static mixers, and where acidic steam condensate mixes with neutral pH brine within binary plant heat exchangers and interconnect pipes. These scales are often combined with antimony, and occasionally arsenic sulphides. Although such materials appear to have received little recognition within the geothermal literature, they are likely the higher temperature analogue to some well-studied low Si/Al mole ratio aluminosilicate materials produced at lower temperatures. These include allophane like materials deposited by some acidic low temperature freshwater springs (Childs et al., 1990; Newton, 2020), and artificially produced hydroxyaluminosilicate (HAS) materials, also produced at near ambient conditions (Exley and Birchall, 1993: Doucet et al., 2001a; Strekopytov and Exley, 2006; Tokoro et al., 2014; Leiviska et al., 2014; Beardmore et al., 2016).

2. **Methodology**

2.1 Scale Sampling and Analysis

Scales sampled from geothermal fields A and B were analysed for bulk (qualitative) elemental composition in the field via a handheld Olympus Vanta X-ray fluorescence (XRF) analyser. Scales from geothermal field C were analysed at the University of Waikato for bulk (quantitative) composition via Bruker WDXRF S8 Tiger XRF analyser, and mineral phase composition and structure with a Panalytical Empyrean X-ray diffractometer (XRD). Handheld XRF analyser results are reported as elemental ratios as the analyser was not calibrated for rock samples. Nonetheless, results for samples which have been analysed via both handheld and quantitative XRF were found to be very close for the elements of interest (Si, Al, Na, K, Ca). Scales from all three geothermal fields were examined via Scanning Electron Microscopy (SEM) using Energy-Dispersive X-ray Spectroscopy (EDS) at the University of Auckland.

2.2 Silica Solubility (SSI) Calculation

A full description of the method after Fleming and Crerar (1982) used to calculate SSI by the scaling model used in this study is beyond the scope of this report, however an overview of the calculation is provided below.

$$S = K_C{}' \left[1 + \frac{10^{pH}\, K_B\, K_w}{\gamma_{H_3(OH)_4^-}}\right] \quad (1)$$

Where S, K_c', K_B, K_w, and γ are the total equilibrium solubility of silica in water (molal), silica solubility product constant (at neutral pH), silicic acid dissociation constant, water dissociation constant, and the activity coefficient of the silicic acid ion. In the scale prediction tool discussed

in this report, the total equilibrium solubility of silica is calculated from input values of temperature and pH only, with the constants given above calculated within the tool from empirically derived data.

This the solubility values derived from this tool are in very close agreement with more commonly used simpler solubility calculations, such as that of Fournier (1986) (equation 2) below a pH of approximately 8.5, above which the singly ionized silicic acid anion increasingly contributes to the total solubility of amorphous silica in water.

$$t = -42.196 + 0.28831(C) - 3.6685 \times 10^{-4}(C^2) + 3.1665 \times 10^{-7}(C^3) + 77.034(logC) \quad (2)$$

Where t and C are temperature in ºC and silica concentration in mg/kg, respectively.

2.3 Aluminium (oxy)hydroxide Solubility (BSI) Calculation

Boehmite solubility is calculated using the solubility product constants (K_{spB}) (infinite dilution) obtained for boehmite by Bénezeth et al. (2001) (Table 1). Although the K_{spB} utilized are for a solution state of infinite dilution, in practice the calculated solubility values obtained from them provide an excellent match, both experimentally and from field observations for the low Al concentration dilute chloride fluids encountered within geothermal systems used for power generation. This approximation has the advantage of greatly simplifying the use of this scale prediction tool.

For completeness it should also be noted that there is a phase transition of the solid crystalline aluminium (oxy)hydroxide phases against which the solubility of Al in water is referenced l within the temperature range of this scaling tool. The phase transition of gibbsite (Al-hydroxide) to boehmite (Al-oxyhydroxide) occurs above approximately 80ºC (Wefers and Misra, 1987; Palmer and Wesolowski, 1992). This phase boundary, however, has no meaningful consequence for rapidly polymerised Al-(oxy)hydroxide structures which then proceed to rapidly react with silica under typical geothermal conditions. This is due to amorphous Al-(oxy)hydroxide being more soluble than crystalline Al (oxy)hydroxide. However, in near-neutral solutions, the solubility curve of gibbsite/boehmite very closely approaches the precipitation onset condition (Okada et al., 2002). Therefore, this simplified model of boehmite solubility is used here to estimate Al-(oxy)hydroxide precipitation-onset conditions, which has proven to be effective in practice, both in laboratory experiments and in the field.

The calculation of boehmite solubility and hence BSI is achieved by solving the solubility equilibria (equations 3 to 7) below using the solubility product constants for the relevant species and temperature in Table 1. For temperatures which fall between values referenced in Table 1, K_{spB} is estimated via linear interpolation.

$$AlOOH_{(s)} + 3H^+ \overset{K_{sB0}}{\longleftrightarrow} Al^{3+} + 2H_2O \quad (3)$$

$$AlOOH_{(s)} + 2H^+ \overset{K_{sB1}}{\longleftrightarrow} Al(OH)^{2+} + H_2O \quad (4)$$

$$AlOOH_{(s)} + H^+ \overset{K_{sB2}}{\longleftrightarrow} Al(OH)_2^+ \quad (5)$$

$$AlOOH_{(s)} + H_2O \overset{K_{sB3}}{\longleftrightarrow} Al(OH)_3^0 \quad (6)$$

$$AlOOH_{(s)} + 2H_2O \overset{K_{sB4}}{\longleftrightarrow} Al(OH)_4^- \quad (7)$$

Table 1. Solubility product constants (K_{spB}) for boehmite at infinite dilution (Bénézeth et al., 2001) used by the aluminosilicate scale prediction tool used in this report.

	Al^{3+}	$Al(OH)^{2+}$	$Al(OH)_2^+$	$Al(OH)_3$	$Al(OH)_4^-$
T °C	log K_{sB0}	log K_{sB1}	log K_{sB2}	log K_{sB3}	log K_{sB3}
0	9.43	3.58	-2.80	-7.83	-16.41
25	7.64	2.69	-3.09	-7.72	-15.14
50	6.03	1.83	-3.17	-7.60	-14.32
75	4.65	1.09	-2.24	-7.90	-13.62
100	3.46	0.46	-3.30	-7.49	-13.02
125	2.42	-0.09	-3.36	-7.38	-12.50
150	1.49	-0.59	-3.40	-7.27	-12.06
175	0.68	-1.03	-3.41	-7.16	-11.69
200	-0.06	-1.42	-3.48	-7.06	-11.40
225	-0.07	-1.77	-3.52	-6.95	-11.18
250	-1.31	-2.09	-3.55	-6.84	-11.05
275	-1.85	-2.38	-3.58	-6.73	-11.01
300	-2.35	-2.64	-3.60	-6.62	-11.07

Due to the simplifying assumptions discussed above, only temperature (to determine the appropriate K_{spB}) and pH (to obtain $x[H^+]$ for each equilibrium reaction calculation) are required as inputs for this scale prediction tool. The results of each equilibrium equation are then summed to obtain total Al (molar) and then converted to ppm (as Al^{3+}) for easy comparison with brine laboratory chemistry analyses. Measured Al^{3+} from laboratory analyses is then divided by calculated equilibrium Al concentration with respect boehmite to yield a BSI value.

3. Results and Discussion

3.1 Geothermal Field A: Amorphous aluminosilicate scaling induced by brine-acid dosing

The power station at geothermal field A consists of a two-stage turbine with a direct contact condenser. The deep reservoir temperature and pH of this geothermal field is ~290°C and 6.8 (pH calculated via the geochemical calculation program WATCH), respectively. Reservoir silica and

aqueous aluminium concentrations are ~680ppm (as SiO_2) and 1.5ppm (in terms of Al^{3+}), respectively. HP steam and brine are separated at ~190°C, with LP steam and brine being subsequently separated at ~130°C. HP brine is dosed with diluted sulfuric acid to mitigate silica scaling within a static mixer (Figure 1 and 2), located in the HP brine line between the HP and LP steam separators. The 98% v/v concentration sulfuric acid is prediluted using a side stream of HP brine via a tantalum quill housed in a removeable spool (Figure 2) in the 3" side stream pipeline.

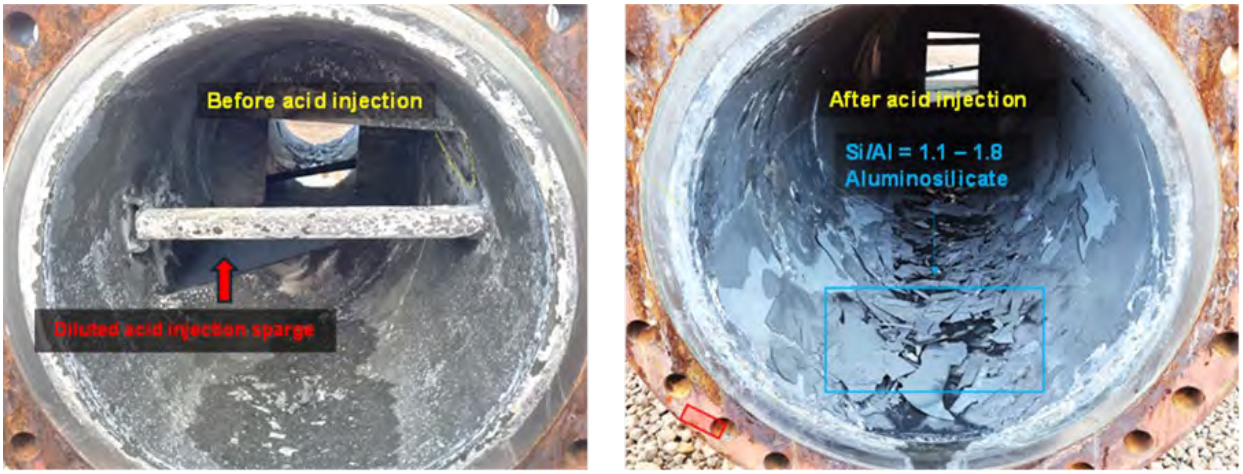

Figure 1: Acid static mixer from geothermal field A. There is minimal scaling prior to acid injection, which consists of a <1mm think extremely hard glassy material. Scaling post acid addition is voluminous downstream of the dilute acid injection sparge bar. The Si/Al mole ratio of this scale ranges between 1.0 and 2.0 for the aluminosilicate component of the scale. The dark colour of the scale is imparted by sulfides which begin being deposited approximately 2 metres downstream of the dosing sparge. Calculated SSI and BSI prior to acid addition are 0.84 and 0.33, respectively. SSI and BSI post acid addition are 0.92 and 300.48, respectively.

Aluminosilicate scale was found to be deposited immediately downstream of the acid dosing point within the static mixer at geothermal field A, accompanied by sulfides. (Figure 1). This scale was very aluminium-rich, with a Si/Al mole ratio ranging between 1.0 and 2.0; Aluminosilicate scale was also found to be deposited immediately adjacent to acid injection points both within the main acid static mixer (Figure 2) and within the brine dilution line opposite the neat acid injection quill (Figure 3). Surprisingly, aluminosilicate scale was also found inside and partially blocking the neat acid injection quill (Figure 4). The aluminosilicate scale deposited within the main static mixer is compositionally zoned, which appears to be correlated with degree of acid mixing with the main brine flow. Areas closest to where the center of the diluted acid plume from the sparge nozzles impinges on the static mixer wall and fins possess the lowest Si/Al mole ratios, ranging between 1.0 and 2.0. Further from the center of the acid plume, Si/Al increases in the deposited material up nearly 6 (Figure 2). Even further from the inferred acid plume the scaling drops to near zero, with the mixer wall appearing the same as that upstream of the acid mixer sparge.

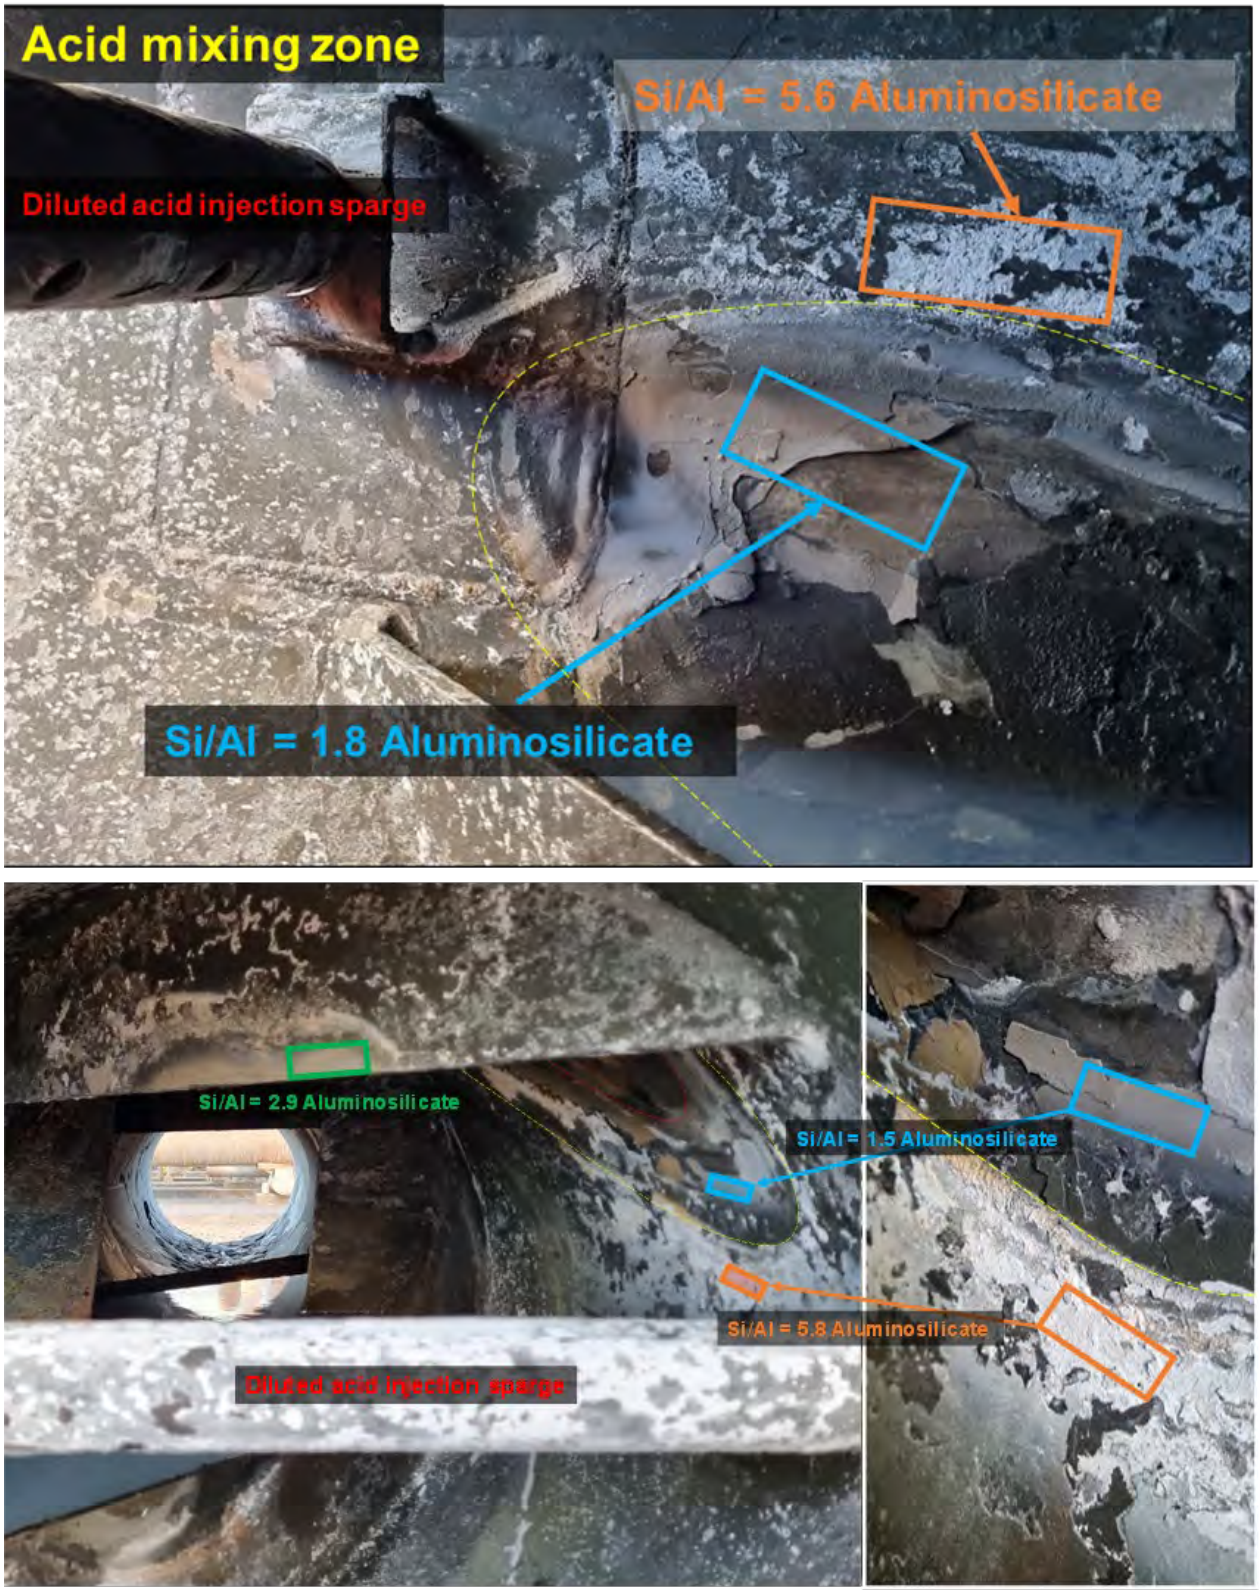

Figure 2. Compositionally zoned aluminosilicate scales deposited in the acid-brine mixing zone within the acid static mixer of geothermal field A. The Si/Al mole ratio reported for each zone is the average of several analyses.

Calculated SSI before acid dosing of the HP brine is calculated to be 0.84, and post acid dosing it is 0.92 (Figure 4). This indicates that there should be no risk of silica scaling, post acid dosing in the HP line, both due to the low pH and SSI remaining below 1.0. Conversely BSI increases precipitously from 0.33 pre acid dosing to 300.48 post acid dosing (Figure 5). As predicted by the BSI tool, this coincides with the immediate appearance of aluminosilicate scale. This occur within both the main brine-acid static mixer, and surprisingly in the likely turbulent mixing zone surrounding the neat sulfuric acid injection quill, and within the tantalum acid injection quill (Figure 4).

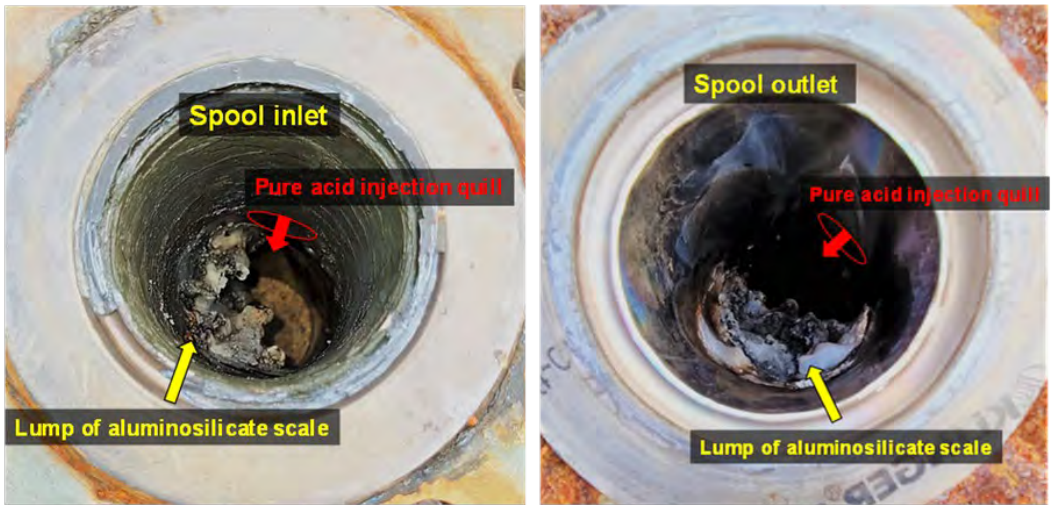

Figure 3. Amorphous aluminosilicate scale buildup surrounding a sulfuric acid (98% v/v) injection quill within the dosing spool at geothermal field A. The scale occurs as a large, isolated build up localised on the 3" pipe wall opposite the tantalum dosing quill. No scale is visible downstream of the of the dosing quill, which is likely due to the extreme acidic conditions in the ~1% v/v sulfuric acid-brine mixture.

Figure 4. Tantalum acid injection quill partly obstructed by aluminosilicate scale (Si/Al = 5.7).

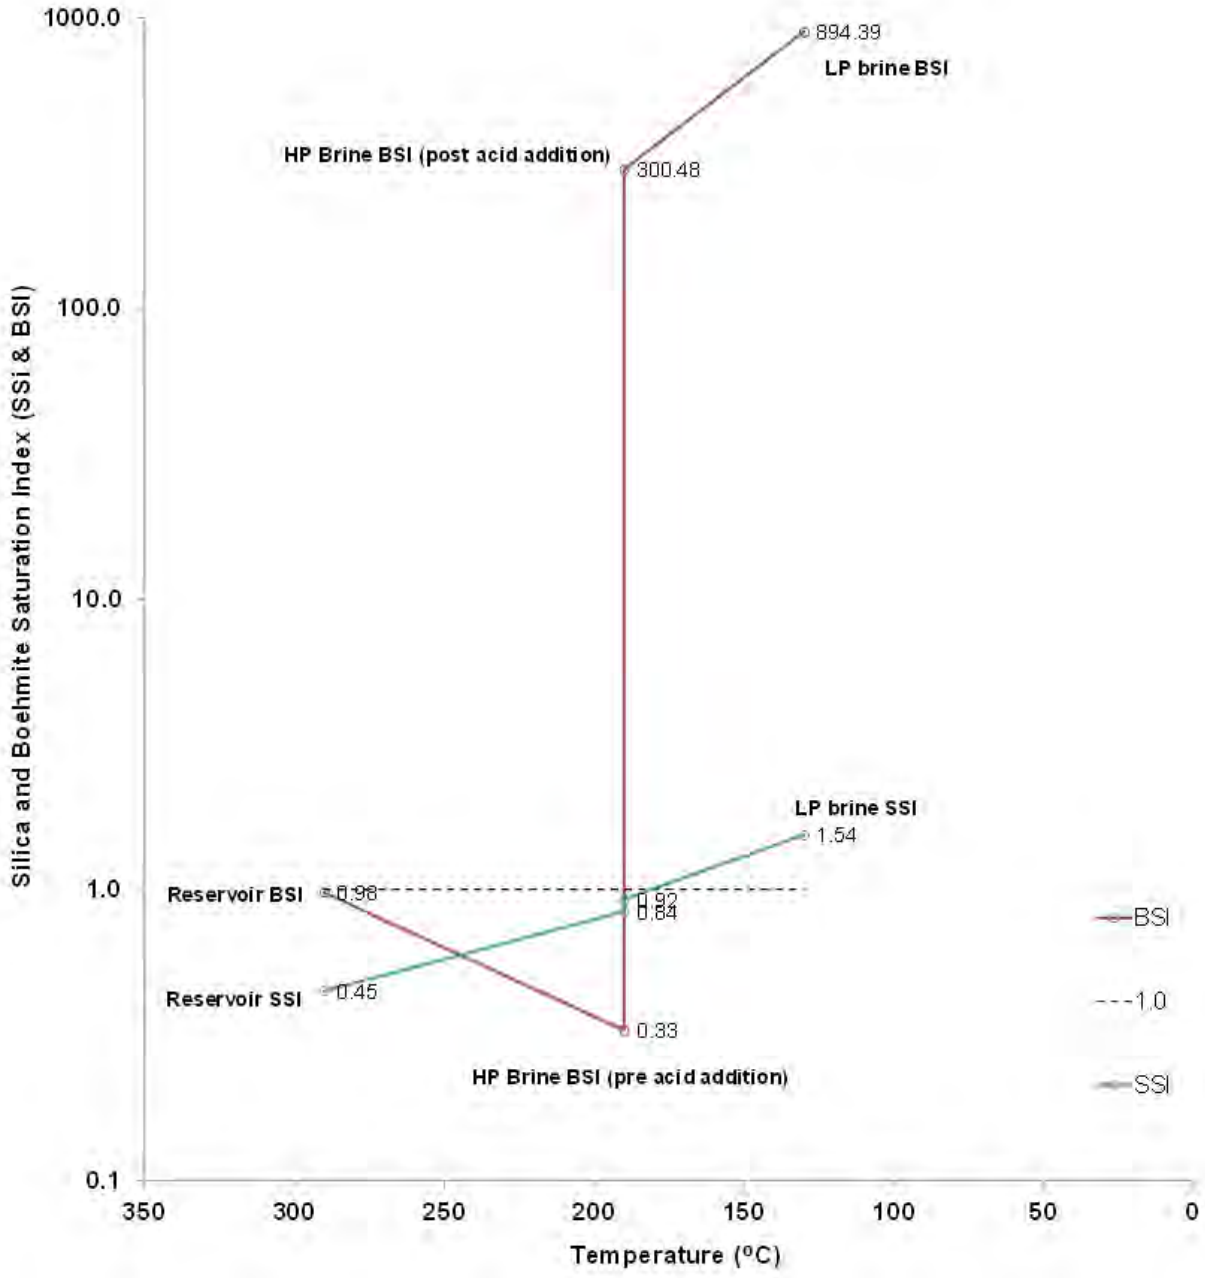

Figure 5. Calculated SSI and BSI path for the produced brine at geothermal field A from the reservoir feed zone, through the HP steam-brine separator, acid dosing plant, and finally the LP steam-separator.

3.2 Geothermal Field B: Amorphous aluminosilicate scaling coinciding with cooling and brine-acidic steam condensate mixing

The power station at geothermal field B consists of a binary Ormat Energy Converter (OEC) unit which makes use of both brine (220°C and pH 6.65) and steam condensate (200°C and pH 5.0) in separate heat exchangers, the outlet fluids are then mixed prior to reinjection, yielding a fluid with a temperature of 135°C, pH of 5.5, aqueous silica (as SiO_2) concentration of 780ppm and Al (as Al^{3+}) of 0.75 ppm. At the brine-condensate mixing point, a voluminous black and relatively soft scale is formed. This scale is an approximately 50:50 mixture (by mass) of stibnite and aluminosilicate scale (Figure 6).

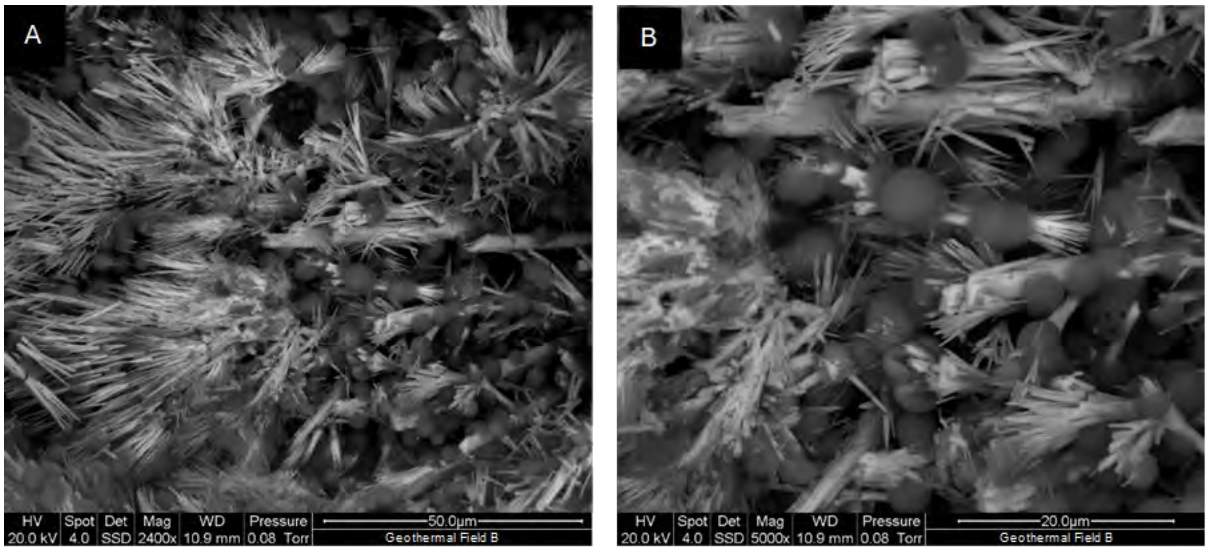

Figure 6. SEM images of the scale formed at the OEC outlet brine-condensate mixing point at power station of geothermal field B. This scale is composed of a mixture of stibnite (long radiating fibers) and aluminosilicate scale (spheres suspended within the scale). A: SEM image of the combined stibnite/aluminosilicate scale at 2400x magnification. The brightest grey-white hued radiating needles are stibnite, with the darker spheroids comprising aluminosilicate material. The brightness of the stibnite is due to the SEM instrument being operated in backscatter mode, with the larger/heavier antimony nuclei causing a greater proportion of emitted electrons to be scattered back toward the electron detector than that of the lighter elements comprising the aluminosilicate spheroids. B: A: SEM image of the combined stibnite/aluminosilicate scale at 5000x magnification. The greater magnification in this image provides a better view of the aluminosilicate spheroids within the loose stibnite matrix of the scale. The aluminosilicate spheroids were found to have a Si/Al mole ratio of 1.0 in all 3 EDS measurements.

Although the SSI at OEC brine outlet is 1.65 (Figure 7), pure amorphous silica is unlikely due to the rapid transit of the heat exchanger and consequent insufficient time for pure amorphous silica polymerisation to occur (Rothbaum et al., 1979). This assumption was confirmed by no pure amorphous silica scale being observed in the OEC brine outlet line, with only some thin, hard aluminosilicate scale being found. SSI is reduced at the brine-condensate mixing point due to brine dilution with the steam condensate. The chance for pure silica scaling is further reduced due to the low pH caused by mixing of the near-neutral pH brine with the acidic condensate retarding silica polymerisation (Brown, 2011). Conversely, BSI rises from approximately 1 at the brine heat

exchanger inlet to over 140 at the brine-condensate mixing point, indicating the strong possibility of aluminosilicate scale to form here. Dilution by the acidic steam condensate has a relatively minor effect on BSI due to the exponential relationship between boehmite solubility and both pH and temperature (Figure 8). As predicted by this tool, this significant increase in BSI at the steam condensate-brine mixing point is again associated with the deposition of aluminosilicate scale where pure amorphous silica would not be expected to occur.

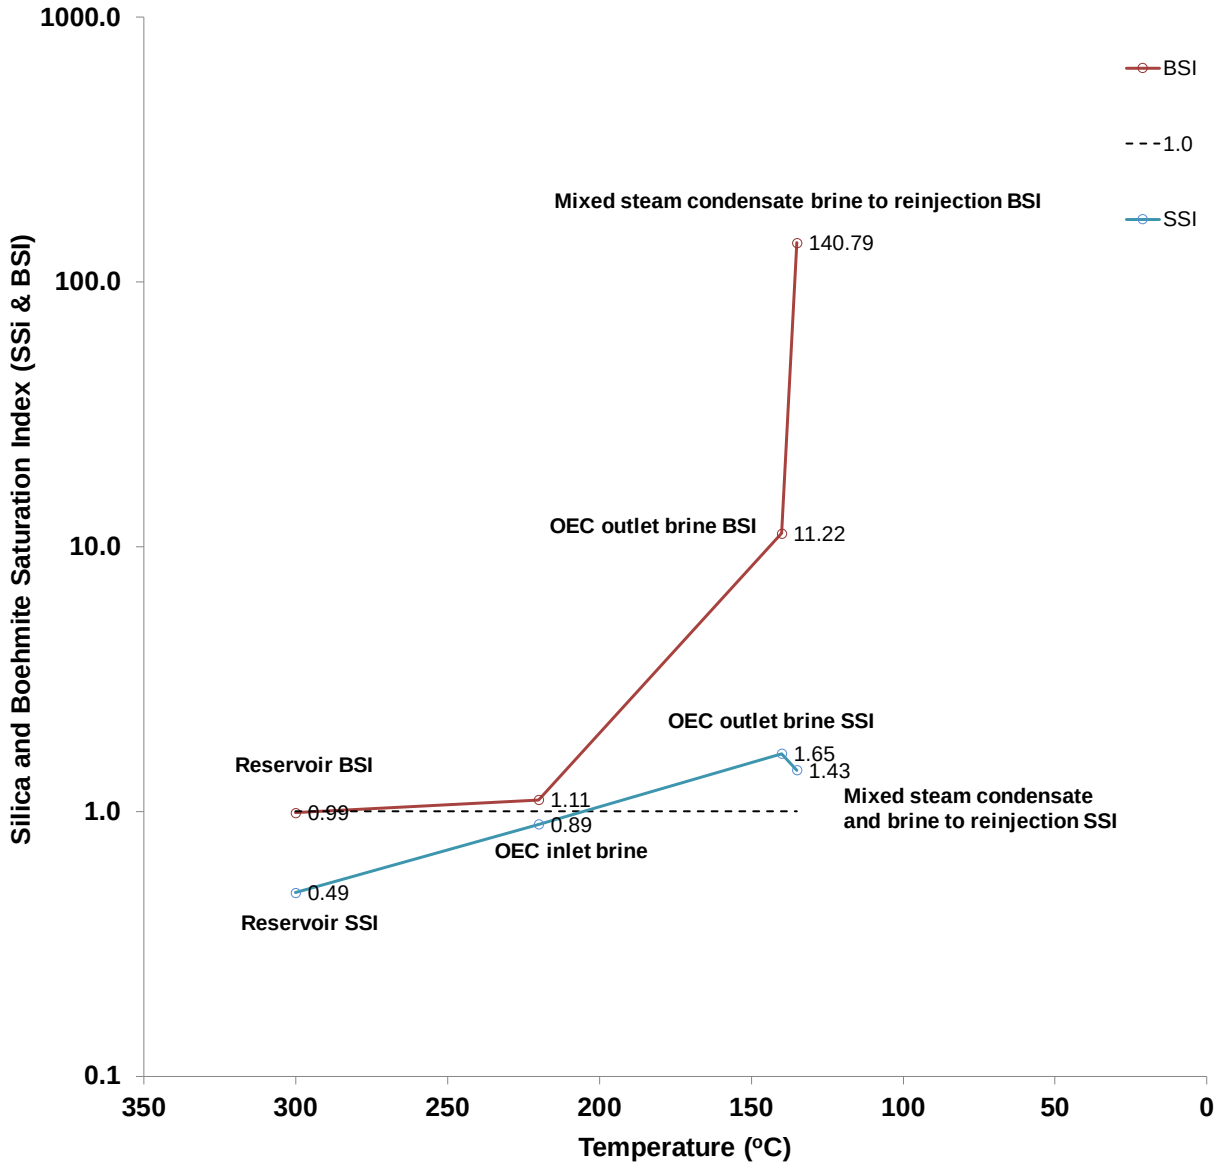

Figure 7. Calculated SSI and BSI path for the produced brine at geothermal field B from the reservoir feed zone, through the OEC brine heat exchanger to the steam condensate-brine mixing point/reinjection.

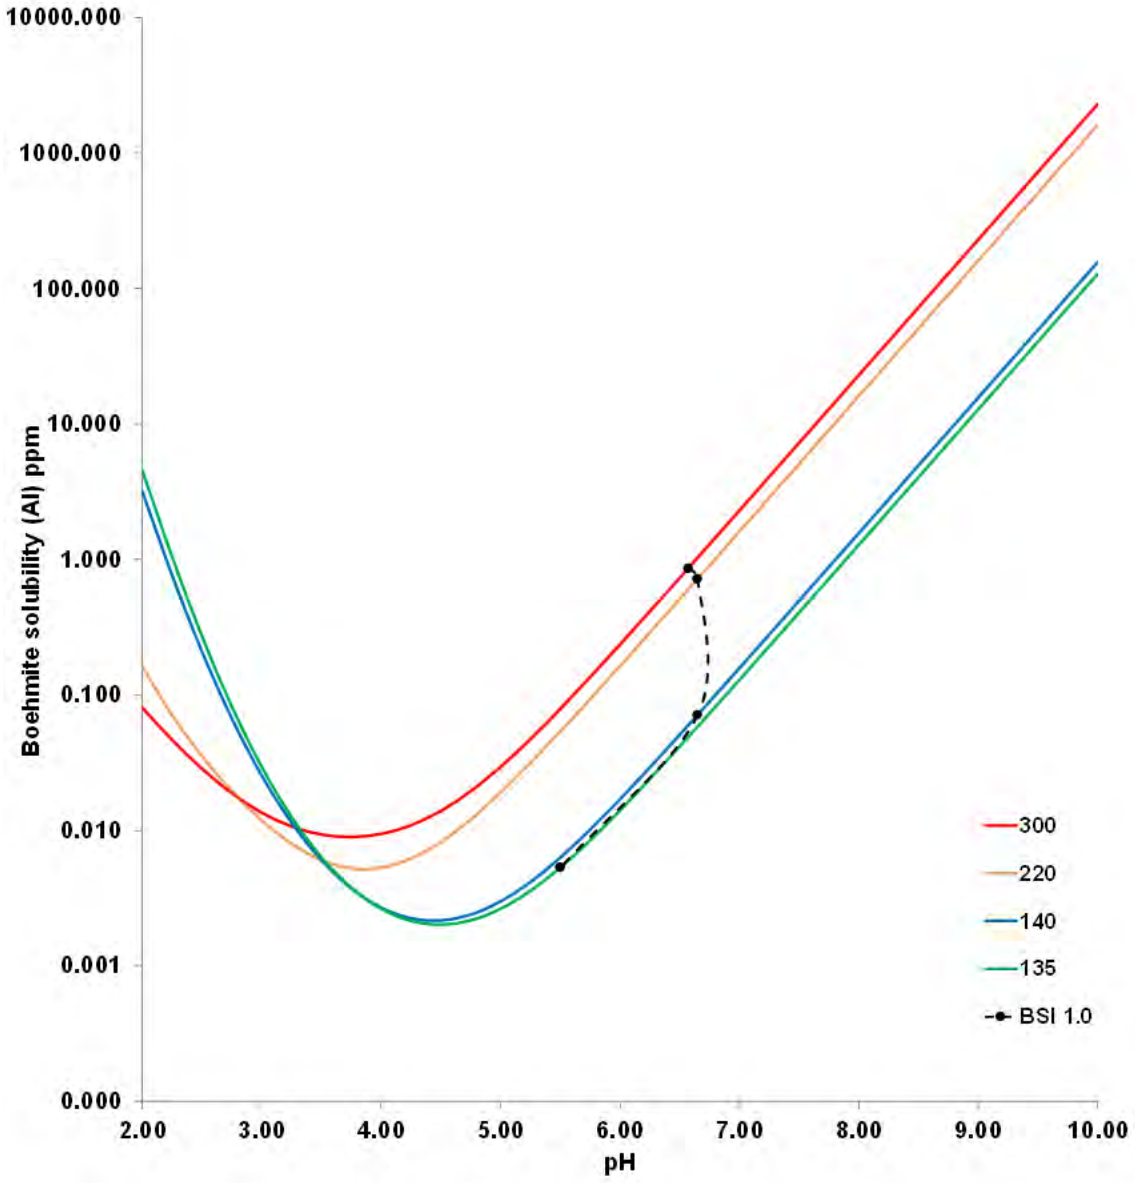

Figure 8. Dashed black line: Boehmite solubility path (BSI 1.0) as a function of temperature and pH at geothermal field B from the reservoir feed zone, through the OEC brine heat exchanger to the steam condensate-brine mixing point/reinjection. Solid colour lines: Boehmite solubility curves as a function of pH at each temperature through the OEC unit at geothermal field B.

The potential for the nucleation of the aluminosilicate scale being induced by the precipitation of stibnite does not appear likely due to the clear separation between the phases that can be seen in Figure 6. Conversely, the aluminosilicate spheroids deposited at the steam condensate-brine mixing point may be supporting the growth of the stibnite needles. This possibility is indicated by the scale becoming progressively aluminosilicate rich toward the fluid-facing scale surface, with

the stibnite needles being longer and more developed with depth closer to the basal, pipe wall adjacent, layers of the scale.

3.3 Geothermal field C: Amorphous aluminosilicate scale from steam condensate + brine mixing and from neutral pH brine during a process excursion

The power station at geothermal field C consists of an OEC unit which makes use of both brine (195^{o}C and pH 6.55) steam (195^{o}C), and a mixture of brine and steam condensate through separate heat exchangers. The inlet temperature and pH of the mixed fluid used by the 3rd heat exchanger is 180^{o}C and pH 5.5, respectively, with an outlet temperature of 140^{o}C. Aqueous silica (as SiO2) concentration is 820ppm at the inlet of the brine heat exchanger (stage 1), and 660 at the inlet of the mixed steam condensate-brine heat exchanger (stage 2). Al (as Al3+) concentration is approximately 1.0ppm at the at the inlet of the brine heat exchanger (stage 1), and 0.85 at the inlet of the mixed steam condensate-brine heat exchanger (stage 2).

Within the stage 2 heat exchanger a light brown aluminosilicate scale with a Si/Al mole ratio of between 1.2 and 3.0 is formed within the tubes and on the tube bundle face of the heat exchanger (Figure 9). The SSI within this heat exchanger ranges between 0.8 at the vessel inlet and 1.14 at the vessel outlet (Figure 10). Meanwhile, BSI ranges between 0.99 prior to mixing of the stage 1 outlet brine with steam condensate, to 36.92 post mixing/the stage 2 heat exchanger inlet, and finally 134.92 at the stage 2 vessel outlet (Figure 10). Although pure amorphous silica is slightly over saturated by the time the steam condensate-brine mixture exits the stage 2 heat exchanger, pure amorphous silica scaling is unlikely. This is due to both the rapid transit of the fluid though the heat exchanger and consequent insufficient time for pure amorphous silica polymerisation to occur (Rothbaum et al., 1979), and the relatively low pH of the fluid which retards polymerisation of aqueous silica (Brown, 2011). Conversely, BSI rapidly increases from just under 1.0 just prior to the steam condensate-brine mixing point to over 130 at the stage 2 heat exchanger exit. This sudden supersaturation of Al with respect to boehmite again coincides with the sudden appearance of aluminosilicate scales. It should be noted that some very thin, hard and glassy aluminosilicate scales do also form upstream of the stage 2 heat exchanger, however the accumulation rates are very slow, unlike for the stage 2 heat exchanger, which requires regular mechanical cleaning.

Interestingly, the aluminosilicate scale with the stage 2 heat exchanger appears to rapidly undergo a change in composition following deposition, with Si/Al ratio dropping from 3.0 at the fluid facing surface of the scale (Figure 9) to approximately 1.4 less than a micrometre below the surface of the scale. This change in composition is accompanied by a change in apparent structure of the scale, with the aluminosilicate material appearing to convert to something which looks very much like a clay mineral in SEM images (Figure 9). None the less it is X-ray amorphous (Figure 11), and therefore does not possess any crystalline structure, and is therefore not a mineral, clay or otherwise. This material does however display the characteristic lowered peak intensity and intensity maximum shifted to ~25^{o} 2θ CuKα of other amorphous aluminosilicate scales, compared to the greater peak intensity and intensity maximum located at ~22^{o} 2θ CuKα of pure amorphous silica (Newton, 2020).

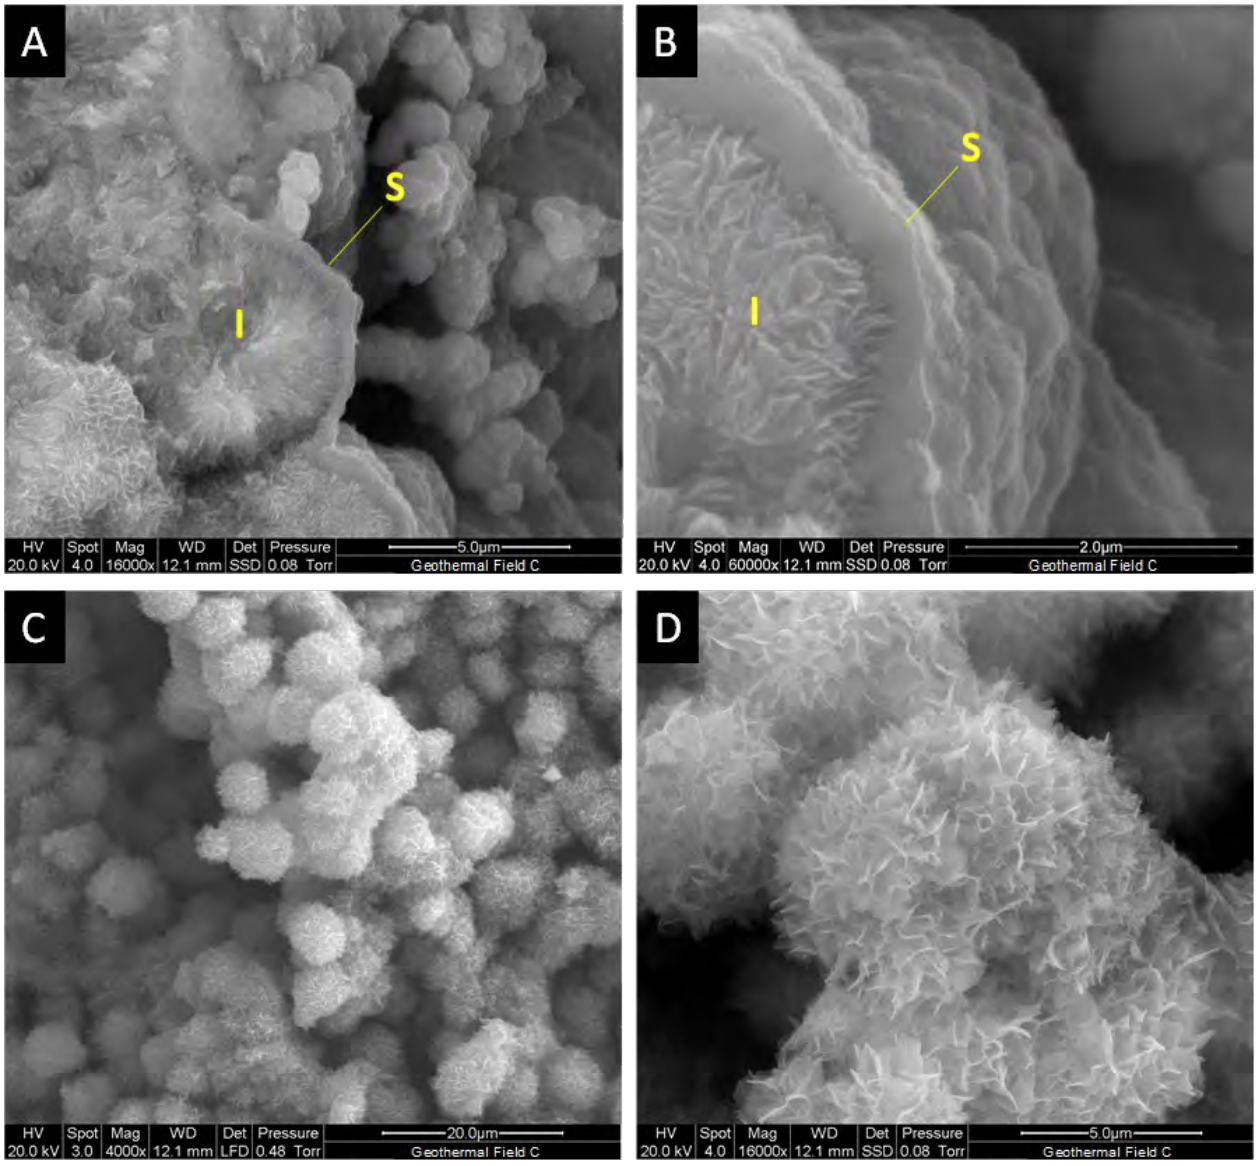

Figure 9. SEM images of aluminosilicate scale deposited within the geothermal field C stage 2 heat exchanger. A: Cross-sectional view of the top fluid-facing surface of the scale. "S" indicates the surface 'rind' of the scale, which has a Si/Al mole ratio of 3.0 and does not appear to incorporate Na, Ka, or Ca into its short-range structure. "I" indicates the interior of the scale spheroidal structure, which has a Si/Al mole ratio of 1.4 and similarly does not appear to incorporate Na, Ka, or Ca into its structure. B: Magnified view of the surface and interior of the top-fluid facing scale surface shown in image A. C: Cross-sectional view of the deeper interior of the stage 2 heat exchanger a scale. This material has a Si/Al ratio of between 1.2 and 1.4, with the Si/Al ratio of most EDS analyses clustering closer to 1.4. D: Magnified view of the spheroidal structures visible in image C.

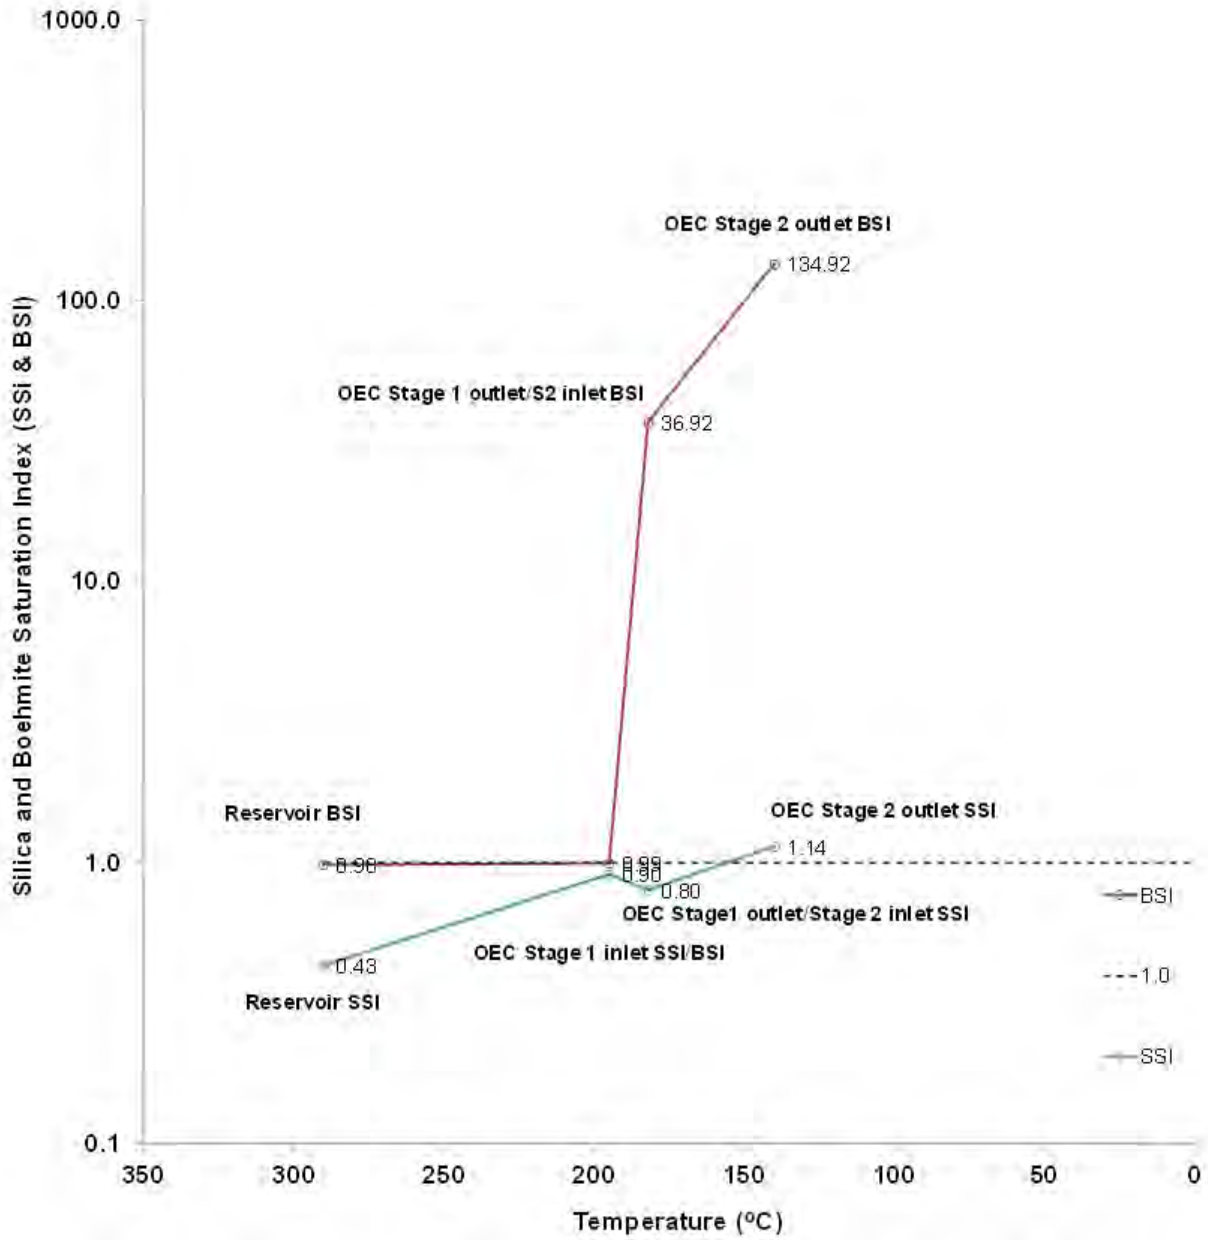

Figure 10. Calculated SSI and BSI path for the geothermal fluid at geothermal field B from the reservoir feed zone and through both OEC brine/steam condensate + brine mixture heat exchangers.

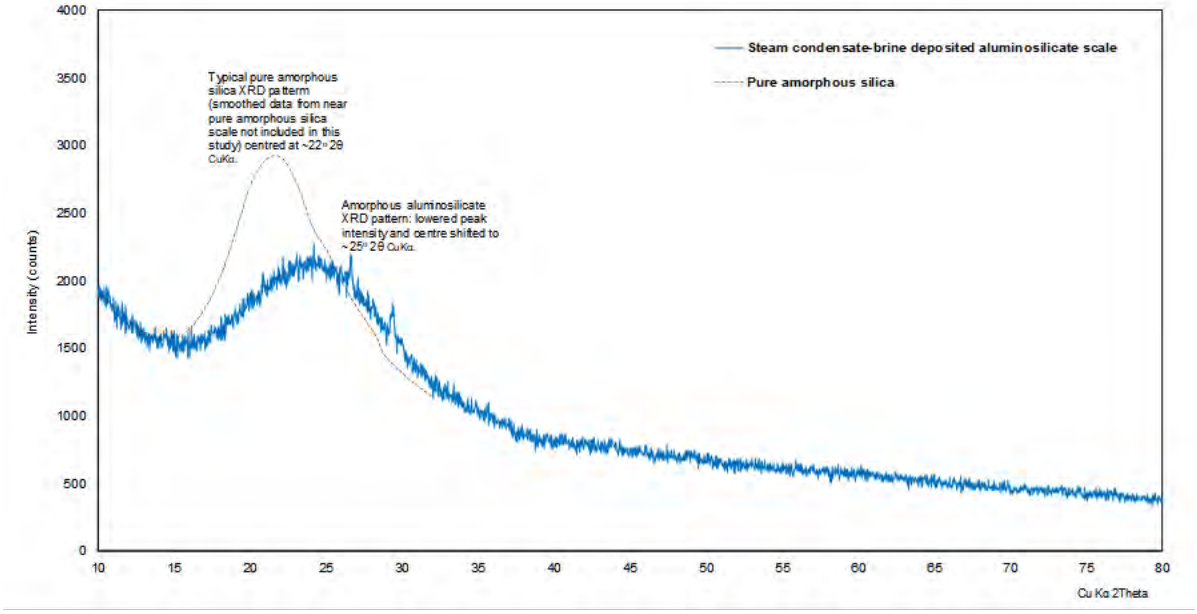

Figure 11. Geothermal field C stage 2 heat exchanger aluminosilicate scale XRD pattern.

A process excursion within the stage 1 heat exchanger also led to the rapid formation of an aluminosilicate scale. In contrast to the examples given above, this scale was formed at neutral pH and was likely caused by a local drop in brine temperature. This process excursion consisted of the rapid blockage of the first pass tubes of the stage 1 brine heat exchanger with debris from upstream in the brine line during a plant start up (Figure 12).

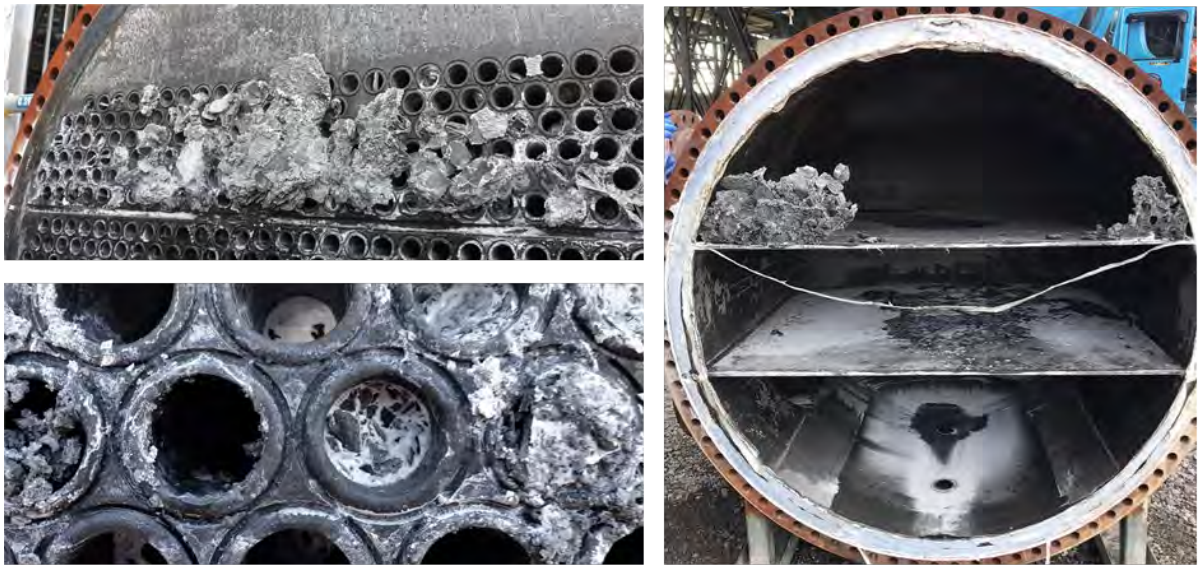

Figure 12. Scale material blocking the tubes and tube face of the stage 1 brine heat exchanger at geothermal field C.

These dark coloured debris were subsequently ‘cemented’ with a white aluminosilicate material (Figure 12), which was actively being produced until the unit was shut down for cleaning approximately 8 weeks following the inception of the incident. The deposition of the white aluminosilicate cement resulted in the gradual increase in pressure differential (dP) of approximate 3 bar across the heat exchanger over time as it built up. The mechanism inferred to be the cause of the precipitation of the white aluminosilicate cement is localised reduction in brine temperature caused by boiling induced by the pressure drop. As the blockage occurred at the inlet of the heat exchanger, the brine was still very close to saturation temperature following steam separation, so that only a small pressure drop is necessary to induce boiling.

Figure 13. White aluminosilicate powder located downstream of the tube blockages. Top image: Middle divider plate. Bottom left image: Endcap drain. Bottom right image: Middle divider plate edge close-up view.

The material which formed the white ‘cement’ was also found as a white powder mantling horizontal surfaces within the heat exchanger. (Figure 13) immediately downstream of the first-pass tubes. This powder has a Si/Al mole ratio of 4.3 (Table 2) and does incorporate cations such as Na+ and K+ to balance the negative charge induced by Al substituting for Si in the short-range structure of the scale (Table 2). Structurally, this material appears to be like other aluminosilicate scales, with the characteristic lowered XRD pattern peak intensity and intensity maximum shifted to ~25º 2θ CuKα (Figure 14), compared to the greater peak intensity and intensity maximum located at ~22º 2θ CuKα of pure amorphous silica Newton (2020). A significant difference

between this material and the other largely amorphous aluminosilicate scales is the presence of the aluminium oxyhydroxide phase, boehmite (Fig. 14).

Table 2. Compositional comparison between stage 1 heat exchanger white powder and rapidly precipitated synthetic aluminosilicate produced in lab experiments (80F02, Newton, 2020). Ratios calculated on a mole basis.

Material	Si/Al	(Na+K+2Ca)/Al	$(K/Na_{(scale)})/(K/Na_{(brine)})$
White aluminosilicate powder	4.3	0.75	7.45
Synthetic aluminosilicate	3.6	0.78	7.29

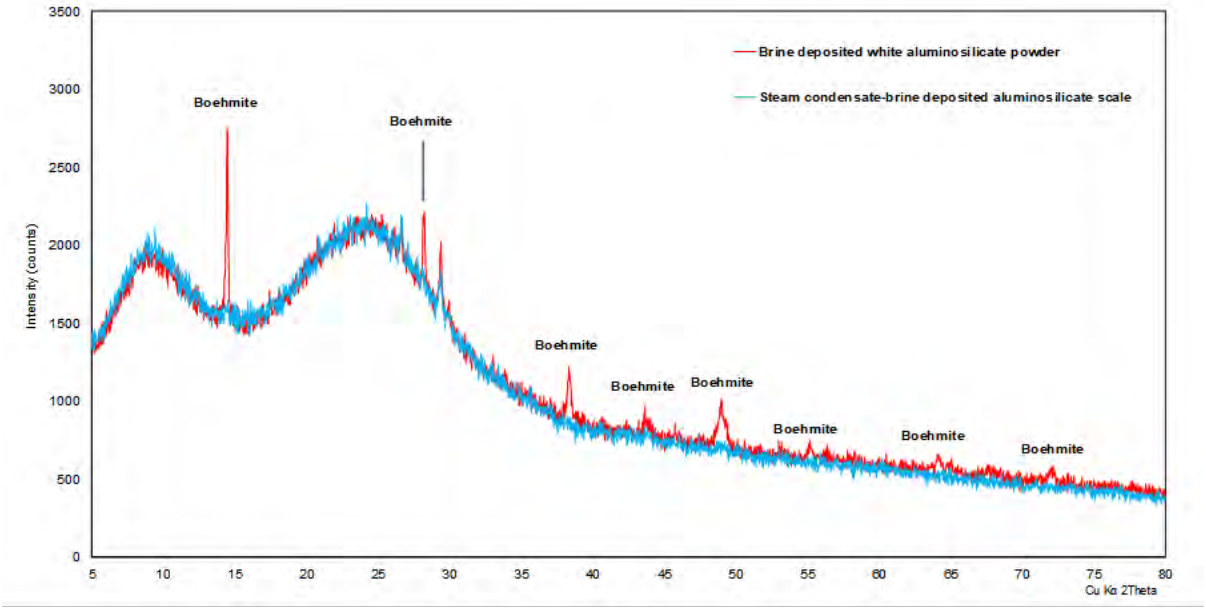

Figure 14. Comparison of geothermal field C stage one heat exchanger white powder XRD pattern (red trace) with that of the stage 2 heat exchanger aluminosilicate scale (blue trace). Boehmite diffraction peaks in the red trace are labelled as 'Boehmite" in black.

As the white aluminosilicate powder was being rapidly formed right up until the heat exchanger was shut down and opened up for cleaning, this material is likely very 'young'. Potentially only formed between several seconds and several hours before the unit was shut down.

The stage one heat exchanger white aluminosilicate powder was likely being rapidly formed right up until the heat exchanger was shut down and opened up for cleaning. This is indicated by its loose fine texture and improbable extended residence on the smooth surface of the heat exchanger divider plate amidst the high velocity and turbulence of the brine's direction change between the 1st and 2nd heat exchanger passes. This in turn suggests this material is likely very 'young', potentially only formed between several seconds and several hours before the unit was shut down, and still retains some of the structure from its initial formation. Consequently, it still contains boehmite, which has not been fully consumed by silica (boehmite is not stable in aqueous silica-

rich environments). A similar phenomenon was observed by Yokoyama et al. (1999) in aluminium-containing silica scales from Hachobaru geothermal power station in Kyushu, Japan. Within this material, the recently deposited scale was found to contain a significant portion of octahedrally coordinated Al, which was rapidly converted to tetrahedral coordination deeper within the same deposit.

Additionally, the composition and probable short-range structure of the white aluminosilicate powder closely resemble those of rapidly precipitated synthetic geothermal aluminosilicate produced under temperature, pH, and compositionally controlled laboratory experiments (Newton, 2020) (Table 2). The compositional similarities also extend to the $K/Na_{scale}/K/Na_{brine}$ ratio of the materials. This cation enrichment value has been found to typically be in the range of 4 to 6 in nearly all scales formed at neutral pH analysed by the author (Newton, 2020). In experiments where synthetic aluminosilicate scales were formed, the rapid precipitation of synthetic aluminosilicate was triggered by the supersaturation of aqueous Al with respect to boehmite, independent of silica concentration in the test brines (Newton, 2020).

The brine entering the stage 1 heat exchanger is very close to boehmite saturation, with a BSI of 0.99. A small reduction in localised temperature by, for example 5ºC, induced by flashing is enough to increase the BSI to 1.2, and therefore the production of boehmite and hence aluminosilicate scale would be predicted by the BSI/aluminosilicate tool. Given the notable boehmite content in the stage 1 heat exchanger aluminosilicate powder, its rapid precipitation, and the silica-undersaturated formation conditions (SSI ~0.87), it is highly plausible that the chemical mechanism identified in the synthetic aluminosilicate experiment led to the formation of stage 1 heat exchanger aluminosilicate powder.

4. Conclusion

Four instances of amorphous aluminosilicate scaling formed under a variety of physico-chemical conditions at three different geothermal fields were compared against a tool developed to predict their formation. This tool is based on laboratory experiments Newton (2020) which indicated that the supersaturation of aluminium with respect to boehmite in the presence of dissolved silica results in the quasi-instantaneous formation of amorphous aluminosilicate material. In each of the four instances of amorphous aluminosilicate scaling studied, the BSI calculated by the aluminosilicate scaling ‘prediction’ tool indicated that aluminosilicate scaling was likely, while SSI calculations indicated that siliceous scales were not likely. This tool therefore shows promise for future use in anticipating otherwise unexpected silica scales in geothermal fluid handling equipment. Anticipation of potential aluminosilicate scaling allows for planning for mitigation ahead of time where required to prevent unplanned and expensive shutdowns. Examples of aluminosilicate scaling which may result in unexpected plant maintenance are fouling of brine acid injection systems and binary station heat exchangers. Therefore, the ability to anticipate geothermal aluminosilicate scaling is valuable, both during the plant design stage, and for troubleshooting problems once equipment is in operation.

ABSTRACT

The Upper Rhine Graben (URG) benefits from an extensive geothermal history with several industrial projects on stream since the beginning of the 21st century. Several deep wells have demonstrated that hydrothermal brines circulate inside a complex network of natural fractures developed in the Triassic sandstones and the altered granitic basement with temperatures up to about 210°C and Li concentrations up to 210 mg/L. More recently, scientific studies have revealed that geothermal lithium could be extracted from this brine. The opportunity for lithium extraction combined with a low CO_2 emission heat gave a second life to the geothermal exploration in the URG. A better knowledge of lithium sources will be based on mineralogical and geochemical characterization of the potential reservoir rocks. Representative samples were collected, i.e., several facies from the base to the top of the Triassic and Permian sandstones and granites of Hercynian basement from quarries in Vosges mountains as well as from deep wells. Micro-analytical techniques were correlated to petrological and geochemical data to discuss the Li resource circulations at the regional scale. Further investigations in other samples of the URG will be compared to attempt to upscale the Li rich rocks assessment at the regional scale and elucidate the Li enrichment in the brines.

1. Introduction

In the 1970s, the discovery of lithium concentrations until 400 ppm in the Salton Sea geothermal field in California attracted curiosity of researchers among the world (Werner, 1970). In the Upper Rhine Graben (URG), a first geochemical analysis of geothermal fluid from the Cronenbourg geothermal exploration borehole near Strasbourg, reveals high lithium levels of 210 ppm (Pauwels et al., 1993). The URG presents unique geological conditions, characterized by elevated geothermal gradient and brines upflow along major faults associated to regional thermal anomalies

that make it an ideal region for geothermal exploitation (Baillieux et al., 2013; Pribnow and Schellschmidt, 2000). Over the year, several reservoirs have been investigated for geothermal projects. Projects with the highest flowrate targeted fracture and fault zones in the granitic basement, while projects targeting the sandstones reservoir remain with lower flowrate (Vidal and Genter, 2018). Today, five high-temperature geothermal plants operate in Alsace (France), in Palatinate and in Baden-Württemberg (Germany), producing heat and power, with lithium concentrations in the deep geothermal brines ranging from 166 to 203 ppm (Bosia et al., 2021; Sanjuan et al., 2016) (Figure 1). Similar Li concentrations were analyzed in the brines from deep geothermal wells recently drilled in the granite basement at Vendenheim (Sanjuan et al., 2021) and Illkirch, in Alsace (Bosia et al., 2021). This ongoing research and development highlights the potential of geothermal lithium as a sustainable energy resource. In this framework, the GLITER project (Integrative multiscale investigation of heat and lithium source and pathways in Deep Geothermal System in a rift context: Focus on the Upper Rhine Graben), cofunded by the French National Research Agency, investigates, among other things the Li sources and Li fluid concentration processes in the URG. A petrological and geochemical characterisation is conducted on the selected samples of sandstones, and granite of the URG from deep wells, quarries and outcrops in order to determine the major Li-carrier minerals and correlate them to fluids concentration at the regional scale.

A geothermal well, named VDH, from the Strasbourg area is presented in this study. Cuttings from several facies of Triassic and Permian sandstones as well as Carboniferous granitic basement intersected below 3.5 km depth were sampled. These formations reached temperature above 200°C in VDH well and were affected by several hydrothermal events. The well intersected permeable fracture and fault zones that channelize deep circulations in both sandstones and granite. The circulating geothermal brine in VDH well has a high Li content between 162 and 200 ppm and a Total Dissolved Solids around 100 g/L. The Li range observed is explained by different sampling methods under different conditions, with production tests carried out on the early and late development stages of the well and having timelines ranging from few days to several weeks of circulations.

The preliminary results of the mineralogical and geochemical studies conducted on these samples are compared to existing literature, but also other analyses acquired in the framework of the GLITER ANR project; core samples at the sediments-basement interface from the EPS1 well at Soultz-sous-Forêts as well as sandstones samples from Adamswiller and Rothbach quarries in the western border of the URG (Figure 1). By synthesising these data, the goal of the project is to elucidate where the brines are enriched in depth and how they make it possible to mobilize the lithium available in the rock formations.

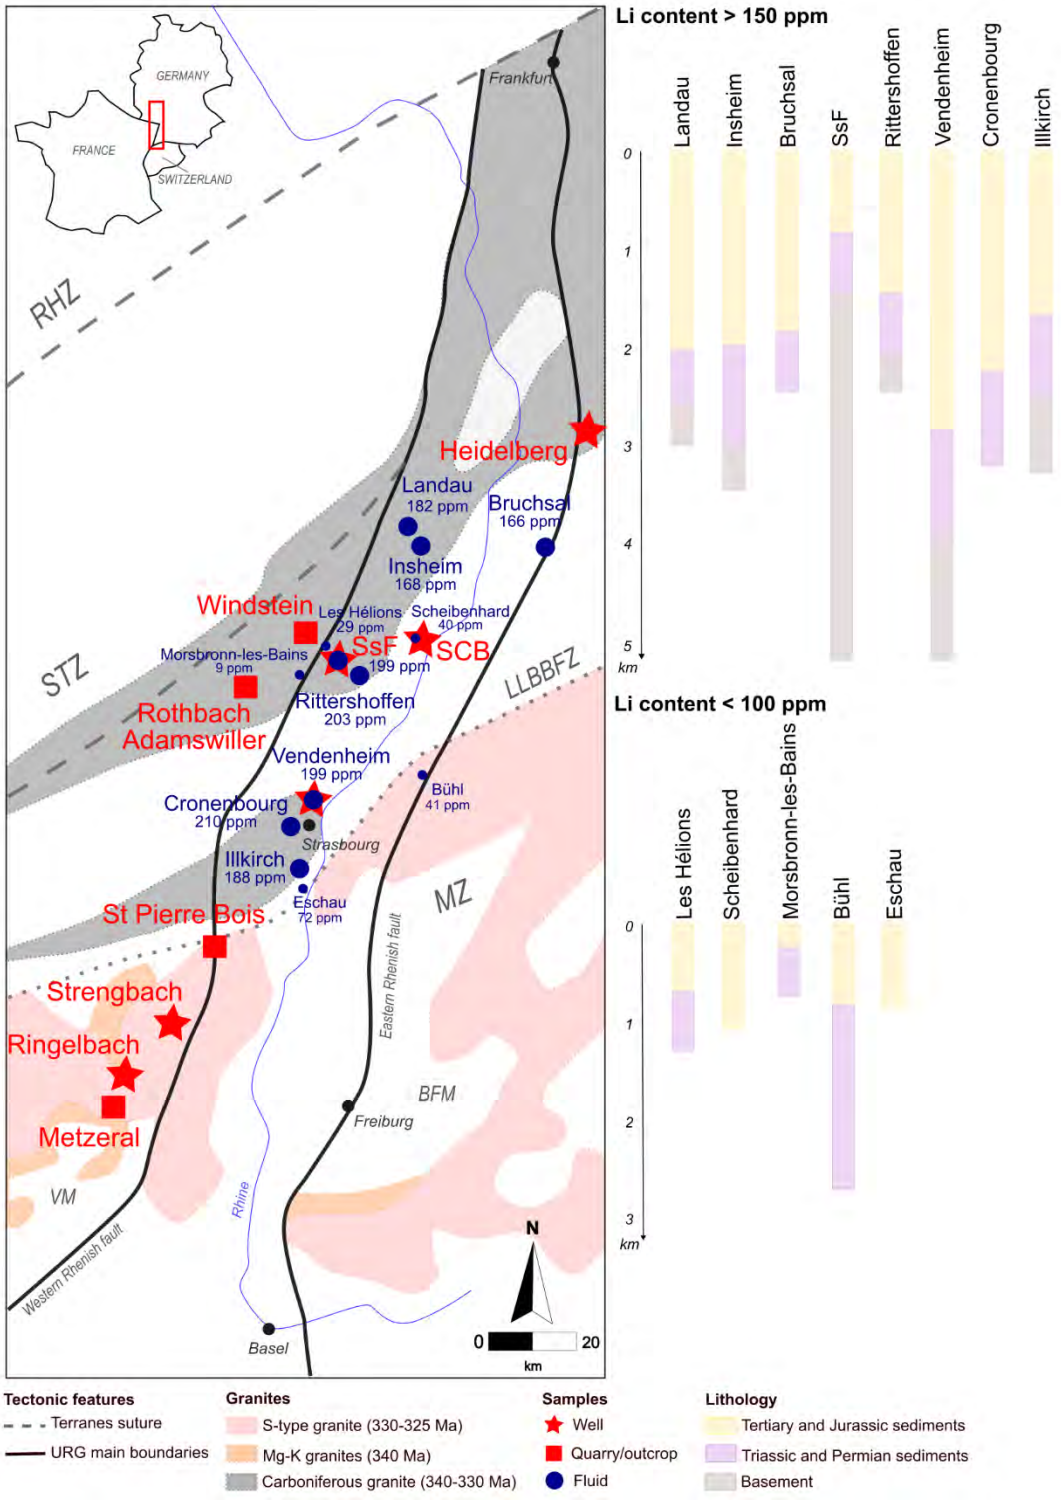

Figure 1: Map of Li distribution in fluids of the URG superimposed to the granite and granitoids emplacement. Li contents in fluids are from (Bosia et al., 2021; Pauwels et al., 1993; Sanjuan et al., 2016). Granites emplacement are extrapolated from the geological map and interpretative signature of the basement from Edel and Schulmann (2009). RHZ = Rhenohercynian zone, STZ = Saxothuringian zone, MZ Moldanubian zone, LLBBFZ = Lalaye-Lubine fault zone, VM = Vosges Mountains, BFM = Black Forest Mountains

2. Sampling and methodology

Cuttings were sampled in representative formations intersected by the VDH well at Vendenheim: Voltzia sandstones in the Upper Buntsandstein, Vosgian sandstones in the Middle Buntsandstein, Permian sandstones, the hydrothermalized granitic basement. The goal was to conduct analysis on fresh and fractured and altered levels to compare the impact of alteration on Li resource. In EPS-1 well at Soultz-sous-Forêts, Permian sandstones as well as the first few hundred meters of biotite-amphibole granite described in Dezayes and Lerouge (2019) were sampled. Voltzia sandstones were sampled from Adamswiller quarry while Vosgian sandstones are from Rothbach quarry. Other rock samples identified on Figure 1 will be presented in further studies to correlate the results of this paper.

For VDH well, mineral phases were identified by binocular (Figure 2) and quantified using X-ray diffraction on bulk rock and Rietveld refinement (Figure 3). XRD were performed on powder mounts using a D8 Advance Brucker AXS diffractometer (CuKα, from 2° to 70°2θ with a step-scan 0.02° increments per second, counting time 1s per increment, 30 mA, 40 kV) at IC2MP laboratory at the University of Poitiers. Then, bulk rock geochemistry was analyzed by Multi Collector Inductively Coupled Plasma Mass Spectrometer from major and trace elements in cuttings samples of representative formations.

In all samples from wells and quarries, analyses of major elements (^{23}Na, ^{24}Mg, ^{27}Al, ^{29}Si, ^{39}K, ^{48}Ti, ^{56}Fe) and lithium (^{7}Li) in minerals were performed using a UVl laser-ablation microsampler CETAC® Excite (193 nm) coupled to an Agilent triple quadrupole plasma mass spectrometer at the French Geological Survey laboratory in Orléans (France), according to the laser configuration of Monnié et al. (2018). Ablation spots 35 μm in diameter were performed at 8 Hz frequency with energy of ~6 J/cm^2 for quartz and ~4 J/cm^2 for other silicates. Analysis time for each spot was 60 s, including 20 s of background measurement with the laser off and 40 s of analysis time with the laser on. Quantification was performed with Glitter® software. All data were calibrated against the external standard NIST SRM 612 (Pearce et al., 1997), and the internal standard of the Si value in the mineral.

3. Results

3.1 VDH deep well from Strasbourg area

The Voltzia sandstones are micaceous sandstones presenting a very low matrix porosity and permeable levels associated to fractures. Fracture filling of the all Permo-Triassic sequence intersected is mainly barite (Figure 2). Li measurements on illite and muscovite range between 30 and 50 ppm (Table 1).

The Vosgian sandstones are quartz-rich sandstones with heterogeneous porosity mainly due to variation of grain size and occurrences of fractures. Li average content of illite is higher (127±57 ppm) than in the Voltzia sandstones (Table 1). Li contents of scarce biotite (143 ppm) and chlorite (317 ppm) are also higher than that measured in the Voltzia sandstones (13 and 96 ppm respectively. However, the bulk rock geochemistry reveals similar Li content of 20-25 ppm in the Triassic sequence (Figure 3).

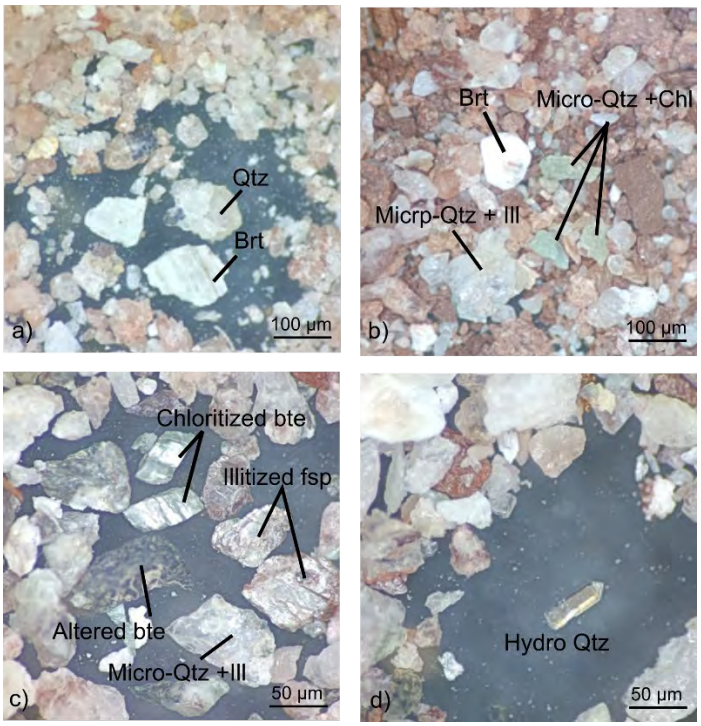

Figure 2: Mineralogical observations of cuttings samples in (a) Vosgian sandstones (b) Permian sandstones (c) altered granitic basement (d) fault zone in granitic basement. Qtz = quartz, Hydro Qtz = hydrothermal quartz, Bte = biotite, Brt = barite, Chl = chlorite, Fsp = felspar, Ill = illite

The Permian sandstones contain a low clay ratio similar to Voltzia sandstones. However, the Li content of the bulk rock ranges between 65 and 75 ppm, the highest values measured in the well. The Li content in minerals was not yet measured in the sample. It would be relevant as a major permeable fracture zone was intersected in this formation.

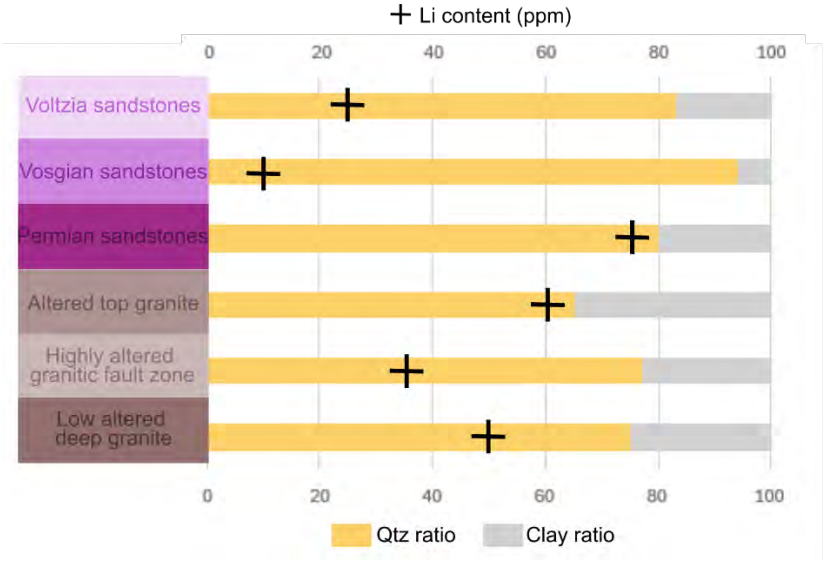

Figure 3: Clays and quartz ratio (in %) estimated from XRD as well as distribution of Li content (in ppm) measured in bulk rock. Clays include muscovite, illitic minerals (illite and illite-smectite mixed layers), biotite and chlorite.

Table 1: Li contents (in ppm) measured in minerals by laser ablation. Bte = biotite, Chl = chlorite, Ill = illite and illite-smectite mixed layers), Qtz = magmatic quartz, Amp = amphibole, ave = average, sd = standard deviation

Lithology	Sample	Bte		Chl		Ill		Qtz		Amp	
		ave	*sd*	ave	*sd*	ave	*sd*	ave	*sd*	ave	*sd*
Voltzia sandstones	VDH well	13	*6*	96	*28*	39	*8*	-	-	-	-
	Adamswiller quarry	~320		-	-	321	*541*	-	-	-	-
Vosgian sandstones	VDH well	143	*3*	317	*86*	127	*57*	14	*8*	-	-
	Rothbach quarry	-	-	-	-	109	*143*	-	-	-	-
Permian sandstones	EPS1 well	-	-	-	-	219	*339*	-	-	-	-
Altered top granite	VDH well	105	*32*	439	*67*	108	*48*	47	*83*	67	*39*
	EPS1 well	501	*124*	504	*103*	55	*5*	10	*2*	10	*3*

In the Hercynian basement, petrographic observations provide evidence of biotite, amphibole, quartz, feldspars, chlorite, illite, carbonates in cuttings of granite, suggesting that it consists of a biotite-amphibole granite affected by an intense weathering marked by the abundance of clay minerals including illite, chlorite, and the presence of hydrothermal microquartz and carbonates (Figure 2).

The Li contents of bulk rock vary considering the grade of alteration. The whole Li content is around 50-60 ppm in zones where chlorite and residual biotite prevail, and around 30-35 ppm in zones where illite, carbonates and hydrothermal quartz are dominant (Figure 3). The Li contents of minerals vary a lot: 105±32 ppm in altered biotite, 67±39 ppm in amphibole, 439±67 ppm in chlorite or chloritized biotite, 108±48 ppm in illitic minerals (Table 1). Quartz analyzed with laser ablation in granite is mainly magmatic one (47±83 ppm) as hydrothermal quartz in fault zone is more difficult to target.

3.2 Additional work on EPS1 deep well from Soultz-sous-Forêts

Core samples in Permian sandstones intersected by EPS1 well indicate very heterogeneous Li content of detrital micas ranging between 3 and 1444 ppm.

Some samples from the first few hundred meters of biotite-amphibole granite present preserved magmatic biotite showing high Li content (501±124 ppm) compared to amphibole (10±3 ppm). Chlorite associated to the diffuse propylitic alteration observed in the less altered samples shows similar high Li content (504±103 ppm) to that of biotite. In the most intense altered samples, illite in fractures (55 ±5 ppm) and in the granite wallrock (<40 ppm) has significantly lower Li contents than ferromagnesian minerals. It is noteworthy that hydrothermal quartz fills in fractures exhibits high Li content (353±152 ppm) compared to magmatic quartz (10±2 ppm).

3.3 Sandstone quarries

Voltzia sandstones from Adamswiller quarry exhibit a large range of Li concentrations in illitic minerals (1-2247 ppm, median = 86 ppm) and contain scarce biotite flakes (around 320 ppm). Vosgian sandstones from Rothbach quarry present a large range of Li concentrations in illitic minerals too (1-717 ppm, median = 62 ppm).

4. Discussion

In sandstones, illitic minerals with minor detrital chlorite, muscovite, and biotite are the primary Li-carrier minerals. Micro-analytical measurements on cuttings samples are likely less reliable than those on rock materials. Analyses of clays and mica in sandstones show a wide range of Li contents, suggesting significant heterogeneity in the sources. One mica flake can present a very high Li content, while a neighboring one may have a very low content. The overall Li content of Middle Buntsandstein sandstones, ranging from 20-25 ppm, is consistent with literature values: 20-40 ppm from a deep well in Bruchsal (Kölbel et al., 2023) and 13-17 ppm from a quarry in the Black Forest (Orywall et al., 2017). The highest Li content in Permian sandstones up to 70 ppm, or even 80 ppm in Bruchsal (Kölbel et al., 2023), might be due to a proximal source of dismantled granitic bedrock in the Permian basin, whereas the Middle Buntsandstein's extensive fluviatile context transported weathering products over several thousand kilometers.

The granite intersected in the VDH well from the Strasbourg area consists of biotite-amphibole granite. The first few hundred meters show intense alteration, with at least two stages identified: 1) diffuse propylitic alteration marked by biotite chloritization, and 2) fracture wallrock alteration associated with hydrothermal circulations, marked by prevalent matrix illitization, carbonate fills in fractures, and hydrothermal quartz fills in permeable levels. The Hercynian basement intersected by the VDH well is similar in terms of magmatic rock and alterations to that intersected at Soultz, aged from Carboniferous (330-340 Ma) (Genter, 1989).

In the VDH well, the granitic basement shows heterogeneous Li distribution mainly due to the type and intensity of alteration. The highest whole-rock Li contents correspond to zones where propylitic alteration (biotite chloritization) prevails and residual primary magmatic biotite remains. Lower values are found in fractured zones affected by matrix illitization and carbonate and quartz fills in fractures. These results are consistent with bulk rock data from Soultz; 25 ppm for illitized facies vs 37 ppm for facies dominated by propylitic alteration (Genter, 1989). High Li contents in biotite and chlorite and low ones in illite, measured in VDH and EPS1 wells, are similar to findings by Dugamin et al. (2024). The high Li contents measured in hydrothermal quartz in the EPS1 well and some quartz spots in the Strasbourg well confirm data from Dugamin et al. (2024) (623-1043 ppm). These high Li contents were also identified in a major fault outcropping in the St Pierre Bois quarry on the western shoulder of the URG (Dezayes et al., 2021).

These preliminary results, correlated with existing literature, suggest that ferromagnesian primary minerals of the Carboniferous granitic basement could be a possible source of lithium. The dissolution of Li-bearing ferromagnesian minerals during brine circulations in fracture and fault zones could lead to brine Li-enrichment (Figure 4). Simple seawater evaporation during the Triassic cannot explain the Li content observed in present-day fluid (Dugamin et al., 2024). Li resources migrate in the Permo-Triassic and Carboniferous reservoir rocks through fracture and fault networks where water-rock interactions are intense.

The decrease in Li contents from the propylitic alteration to an intense hydrothermal alteration (illite-carbonates-quartz) and the Li content in hydrothermal quartz suggest lithium mobilization from the granite into the hydrothermal fluids. This underscores the need for further analysis of other granite types in the URG, such as Mg-K granite or biotite-muscovite S-type granite (Tabaud et al., 2015). The latter are peraluminous granites known as sources of Li, and understanding

differentiation processes during granitic intrusion and granitoid emplacement could help elucidate Li distribution at a regional scale (Figure 1).

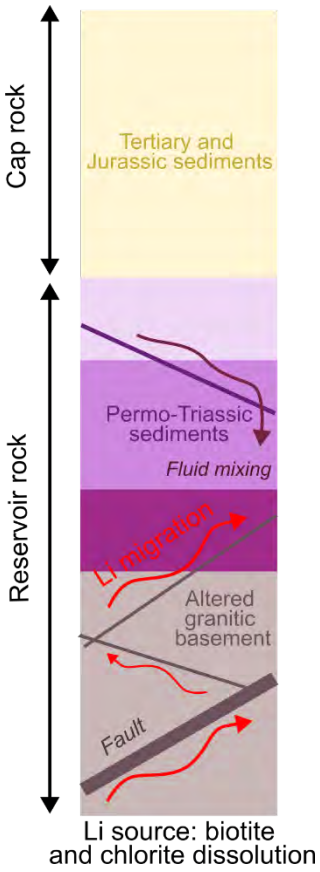

Figure 4: Conceptual model of the geothermal lithium play in the URG

5. Concluding remarks and perspectives

These preliminary results highlight the high-level content in ferromagnesians minerals from the Carboniferous granite making them potential sources of lithium during brine's enrichment. When the brine suffers disequilibrium and precipitate it can lead to Li-rich newly formed quartz. As the Permo-Triassic rocks result from granite's dismantling, the sedimentation context and grade of alteration of the minerals will impact the Li distribution in the reservoir rocks. The Li content of the reservoir rocks associated to an illite-facies is lower than a biotite-chlorite-facies.

The lithium behavior in alteration processes is only partially understood due to the lack of data on the lithium distribution in fresh minerals and their alteration products. Further analysis will be conducted in different sites and rock formations of the URG to strengthen the understanding of lithium enrichment in brines.

Geothermal exploration, structural controls, Great Basin, Nevada, favorable structural settings, geophysical data

ABSTRACT

The northeastern part of the Reese River basin situated ~15 km southeast of Battle Mountain, Nevada, scored highly in the Nevada geothermal play fairway analysis (PFA) for hosting potential hidden geothermal systems. This site (also referred to as Argenta Rise) was therefore chosen for detailed study in the INGENIOUS project (INnovative Geothermal Exploration through Novel Investigations Of Undiscovered Systems). The high PFA scores resulted primarily from favorable structural settings (e.g., fault intersections and pull aparts) with relatively high slip rates on Quaternary faults. The INGENIOUS project is utilizing additional parameters and more rigorous analytical techniques to further advance exploration at this site. This includes integration of geological (e.g., Quaternary fault mapping) and new geophysical datasets (e.g., gravity, magnetics, MT data, and five reprocessed seismic reflection profiles) to build a structural model and to identify specific favorable sites for potential geothermal upwellings. Two-meter temperature surveys were also conducted in the area (139 measurements).

This part of north-central Nevada is characterized by systems of intersecting northerly and ENE-striking faults within the broader Humboldt structural zone, a poorly understood belt of ENE-striking faults and relatively high heat flow extending across northern Nevada. Kinematic analysis of exposed fault surfaces shows that ENE-striking faults have accommodated sinistral-normal slip,

and normal slip characterizes N- to NNE-striking faults. Northeastern Reese River Valley lies within a broad left step between major ENE-striking fault zones on the northern flanks of the Argenta Rim and Shoshone Range and thus corresponds to a broad pull-apart in the ENE-striking sinistral-normal fault system. Notably, the nearby Beowawe geothermal system in Whirlwind Valley (with abundant sinter, hot springs, and a geothermal power plant) occupies a fault intersection in a relatively small left step in a major ENE-striking sinistral-normal fault and may serve as an analogue for a potential hidden system in northeastern Reese River Valley. Existing geological maps, high-resolution lidar, and seismic reflection data demonstrate that northeastern Reese River Valley is structurally complex with multiple intersections between the ENE- and N- to NNE-striking fault systems. Some of these fault intersections correspond to low resistivity anomalies, magnetic lows, and/or very subtle 2-m temperature anomalies, which may indicate hidden geothermal upwellings. Three-dimensional modeling and temperature-gradient drilling are planned to further evaluate these sites for geothermal activity.

1. Introduction

The primary goal of the INGENIOUS project is to accelerate discoveries of new, commercially viable hidden geothermal systems in the Great Basin region of the Basin and Range province in the western USA, while substantially reducing the exploration and development risks for all geothermal resources (Ayling et al., 2022, Faulds and Richards, 2023). The Great Basin region is a world-class geothermal province with >1200 MWe of installed nameplate capacity from ~28 geothermal systems (e.g., Muntean et al., 2021; Figure 1). However, studies indicate far greater potential for conventional hydrothermal systems in the region (Williams et al., 2009; U.S. Department of Energy, 2019), but most of these resources are hidden or blind (Coolbaugh et al., 2007a).

Most geothermal systems in the Great Basin region, especially those ≥120°C, reside along normal faults in complex interaction zones, such as fault terminations, fault intersections, step-overs or relay ramps, accommodation zones, displacement transfer zones at the ends of strike-slip faults, and releasing bends or pull-aparts in strike-slip faults (Curewitz and Karson, 1997; Faulds and Hinz, 2015; Faulds et al., 2021a; Figure 1). These fault interaction zones contain higher fault and fracture densities, more permeable fault breccia in lieu of impermeable clay gouge, and typically correspond to critically stressed areas (Faulds and Hinz, 2015; Siler et al., 2018; Siler, 2023a, b). These characteristics lead to enhanced permeability and promote long-term fluid flow (Micklethwaite and Cox, 2004).

Because most systems in this region are controlled by Quaternary normal faults (Bell and Ramelli, 2007), they generally reside near the margins of actively subsiding basins, which can lead to development of blind or hidden systems. Fault-hosted upwelling fluids commonly flow into permeable sediments in the basin without emerging directly along the surface trace of the reservoir-hosting fault(s). Geothermal outflow may therefore surface kilometers away from the deeper source or remain *hidden* (or blind) with no surface manifestations (Richards and Blackwell, 2002).

Thus, techniques are needed to identify and characterize structural settings associated with increased permeability and relatively high potential to host a hidden system. The discovery of the McGinness Hills hidden system in central Nevada, which is currently the largest producing system in Nevada (~150 MWe; Figure 1; Nordquist and Delwiche, 2013), suggests that many such systems

are yet to be discovered in the region and that some of these hidden systems may be capable of becoming large producers.

The technical challenge is to develop methodologies to locate such systems with minimal risk. The geothermal play fairway concept is one approach to reduce this risk, and it has been applied to evaluate undeveloped and potential hidden systems in various settings in the conterminous western U.S. (Faulds et al., 2015a; 2015b; 2018; 2019; Forson et al., 2016; Shervais et al., 2016; Siler et al., 2017; Craig, 2018; Craig et al., 2021). In Nevada, play fairway analysis was applied to a 96,000-km^2 study area (Figure 1) and resulted in the discovery of new hidden systems in Gabbs Valley and Granite Springs Valley (Faulds et al., 2021b, c; Craig et al., 2021).

However, geothermal play fairway analysis is a relatively 'youthful' methodology, and previous play fairway projects encountered challenges such as how to objectively estimate relative weights for input datasets, incomplete datasets, lack of key datasets, and limited numbers of training sites (Faulds et al., 2020). More broadly, the geothermal community has recently made major achievements on multiple fronts, including play fairway analysis (e.g., Faulds et al., 2015a, 2018, 2021b, c; Shervais et al., 2016; Siler et al., 2017; Wannamaker et al., 2017), 3D and conceptual modeling (e.g., Siler et al., 2019; Craig et al., 2021), resource capacity estimation, feature engineering (Hart-Wagoner et al., 2023), machine learning (e.g., Smith et al., 2023), the application of advanced geostatistics, and value-of-information (VOI) analysis to identify prospective geothermal resources and reduce exploration risk. However, these techniques have yet to be integrated together into a holistic, practical, best-practices workflow for a broad region.

The INGENIOUS project aims to fully integrate these techniques for the entire Great Basin region to develop a comprehensive exploration workflow toolkit that includes predictive geothermal play fairway maps at both regional- and local-scales, updated regional geological and geophysical data compilations, detailed 3D maps and conceptual models of four individual prospects, software tools to facilitate practical use of our refined exploration workflows, and ultimately a Developers' Playbook for the entire region (e.g., Ayling et al., 2022). The study area encompasses 494,269 km^2, including most of Nevada, western Utah, southern Idaho, southeastern Oregon, and easternmost California (Figure 1). Building on geothermal play fairway efforts in central Nevada (Faulds et al., 2015a, b, 2021b, c), NE California/NW Nevada (Siler et al., 2017), and western Utah (Wannamaker et al., 2017), we have expanded these study areas to the broader Great Basin region and have generated preliminary geothermal potential maps of this region (Figure 1; Hart-Wagoner et al., 2023, 2024).

Concurrently, we moved several promising blind prospects forward with detailed geological and geophysical analyses to be followed by thermal-gradient hole drilling (Faulds and Richards, 2023). The detailed study sites for the INGENIOUS project extend from northwestern Nevada into southwestern Utah (Figure 1). Our first detailed study site in Granite Springs Valley in western Nevada was initially identified in the Nevada play fairway analysis project in which detailed studies and temperature-gradient drilling documented an apparent hidden geothermal system (Faulds et al., 2019, 2021b). The INGENIOUS project extended this analysis by developing a 3D conceptual model and potentially locating the primary zone of upwelling (Kraal et al., 2023). Lessons learned from the regional and local-scale analyses in the Nevada play fairway project guided our strategy in locating and defining the next two detailed sites in northeastern Reese River Valley and the Buffalo Valley/Jersey Summit area, both in north-central Nevada. Selection of the fourth detailed study site at Lund North in southwestern Utah built on all prior experiences in this

and previous related projects. The three new detailed study sites (northeastern Reese River Valley, Buffalo Valley/Jersey Summit, and Lund North) cover areas not previously addressed with detailed studies in the Nevada play fairway analysis or in other projects.

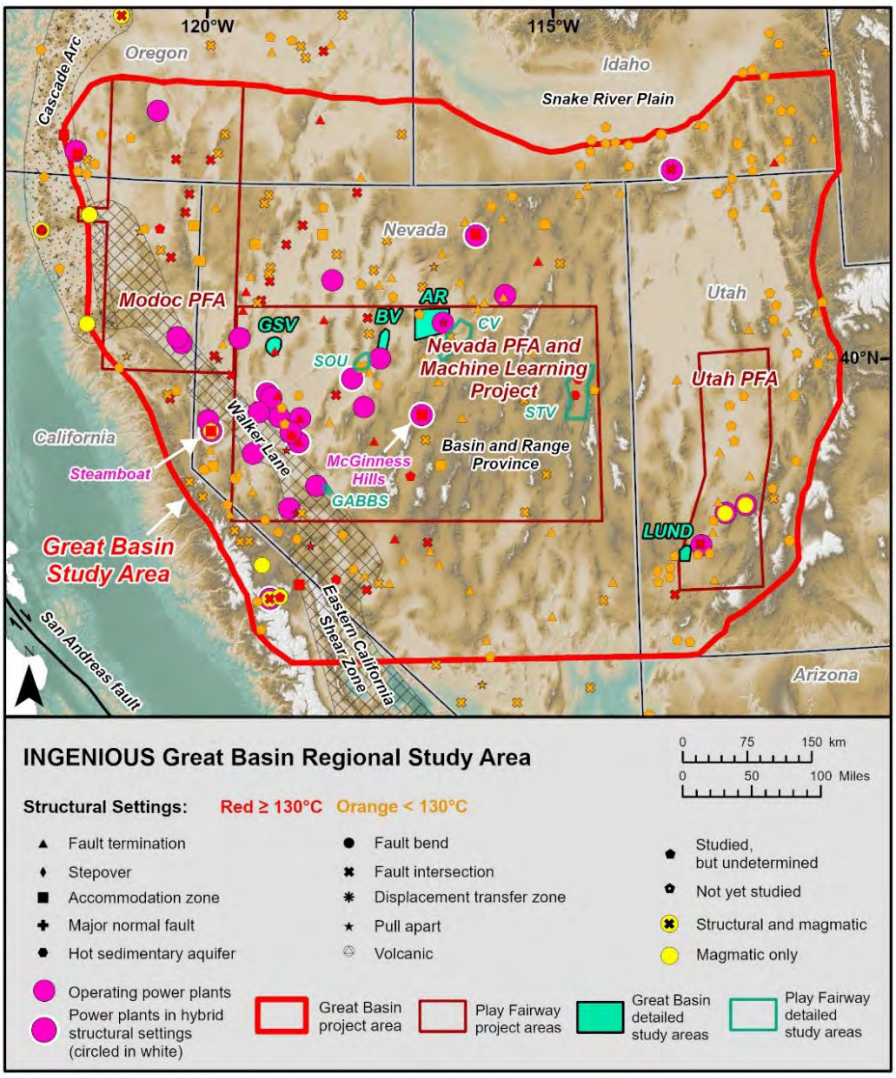

Figure 1: Great Basin study area for INGENIOUS project, with locations of known geothermal systems, identified structural settings, previous play fairway analysis (PFA) projects (Modoc, Nevada, and Utah), and detailed study areas for both the INGENIOUS project (Granite Springs Valley-GSV; Argenta Rise-AR [northern Reese River Valley], Buffalo Valley/Jersey Summit-BV, and Lund, Utah-LUND) and Nevada PFA (Crescent Valley-CV; SE Gabbs Valley-GABBS; Sou Hills-SOU; and Steptoe Valley-STV). Base map is from the ArcGIS online map server (Esri, 2024)

This paper provides a progress report on detailed geological and geophysical investigations of the study site in northeastern Reese River Valley known as Argenta Rise. First, we provide an overview of the area and then describe the detailed geological and geophysical analyses, followed by a brief discussion of the implications for potential hidden systems and planned temperature-gradient drilling in the area. We focus on the structural framework of the area, particularly the possible influence of the geometry and kinematics of complex intersecting fault zones on potential geothermal activity in prospective sites for hidden geothermal systems.

2. Northeastern Reese River Valley (Argenta Rise)

2.1 Regional Setting

The study area lies within the northeastern part of the Reese River Valley ~15 km southeast of Battle Mountain in north-central Nevada (Figure 2). It largely occupies a broad basin bounded to the southeast by the northern Shoshone Range, to the east by the Argenta Rim, and to the west by the Battle Mountain Range. This area was chosen for detailed analysis in the INGENIOUS project, because it scored highly in the Nevada geothermal play fairway analysis for hosting potential hidden geothermal systems. The high play fairway scores resulted primarily from the presence of favorable structural settings (e.g., fault intersections and pull aparts) with relatively high slip rates on Quaternary faults. We informally refer to this area as Argenta Rise due to its proximity to Argenta Rim directly to the east and slightly elevated topography relative to lower parts of Reese River Valley in the Battle Mountain area.

Northeastern Reese River Valley lies within a broad region of northern Nevada extending from near Reno to the Idaho border characterized by high heat flow and east-northeast-striking fault zones that disrupt the typical more northerly trending structural grain of the Great Basin region. This zone of faulting and high heat flow has been referred to as the Humboldt structural zone (Rowan and Wetlaufer, 1981). Several major geothermal fields in northern Nevada, including Bradys, Desert Peak, Beowawe, and Tuscarora reside within the Humboldt structural zone. From west to east, major east-northeast- to north-northeast-striking faults in the Humboldt structural zone include the Olinghouse fault (Sturmer and Faulds, 2018), faults along the northern margin of the Carson Sink, Midas trough, Argenta Rim and Northern Shoshone Range faults in the Argenta Rise study area (Figure 2), and Malpais fault near Beowawe (Struhsacker, 1980; Benoit and Stock, 1993; Watt et al., 2007). These east-northeast-striking normal faults intersect and are kinematically linked to the more common north- to north-northeast-striking normal faults in the Great Basin region and are generally presumed to accommodate sinistral normal slip. However, few detailed studies have documented the kinematics along these faults (Sturmer and Faulds, 2018). The Humboldt structural zone is oriented nearly orthogonal to the Walker Lane in the western Great Basin, which corresponds to a zone of dextral shear accommodating ~25% of the motion between the North American and Pacific plates (e.g., Hammond and Thatcher, 2004; Faulds and Henry, 2008).

The western margin of the northern Nevada rift cuts across northeastern Reese River Valley. The northern Nevada rift is a long, narrow, north-northwest-trending alignment of middle Miocene volcanic and hypabyssal rocks and epithermal gold-silver and mercury deposits formed during west-southwest to east-northeast extension (Zoback, 1989; Zoback et al., 1994; Wallace and John, 1998). It formed ~16 Ma to 14 Ma (Zoback et al., 1994). Mafic, mantle-derived magmas were emplaced along a deep-seated, north-northwest-trending fracture system that cut Paleozoic, middle Tertiary, and early Miocene formations.

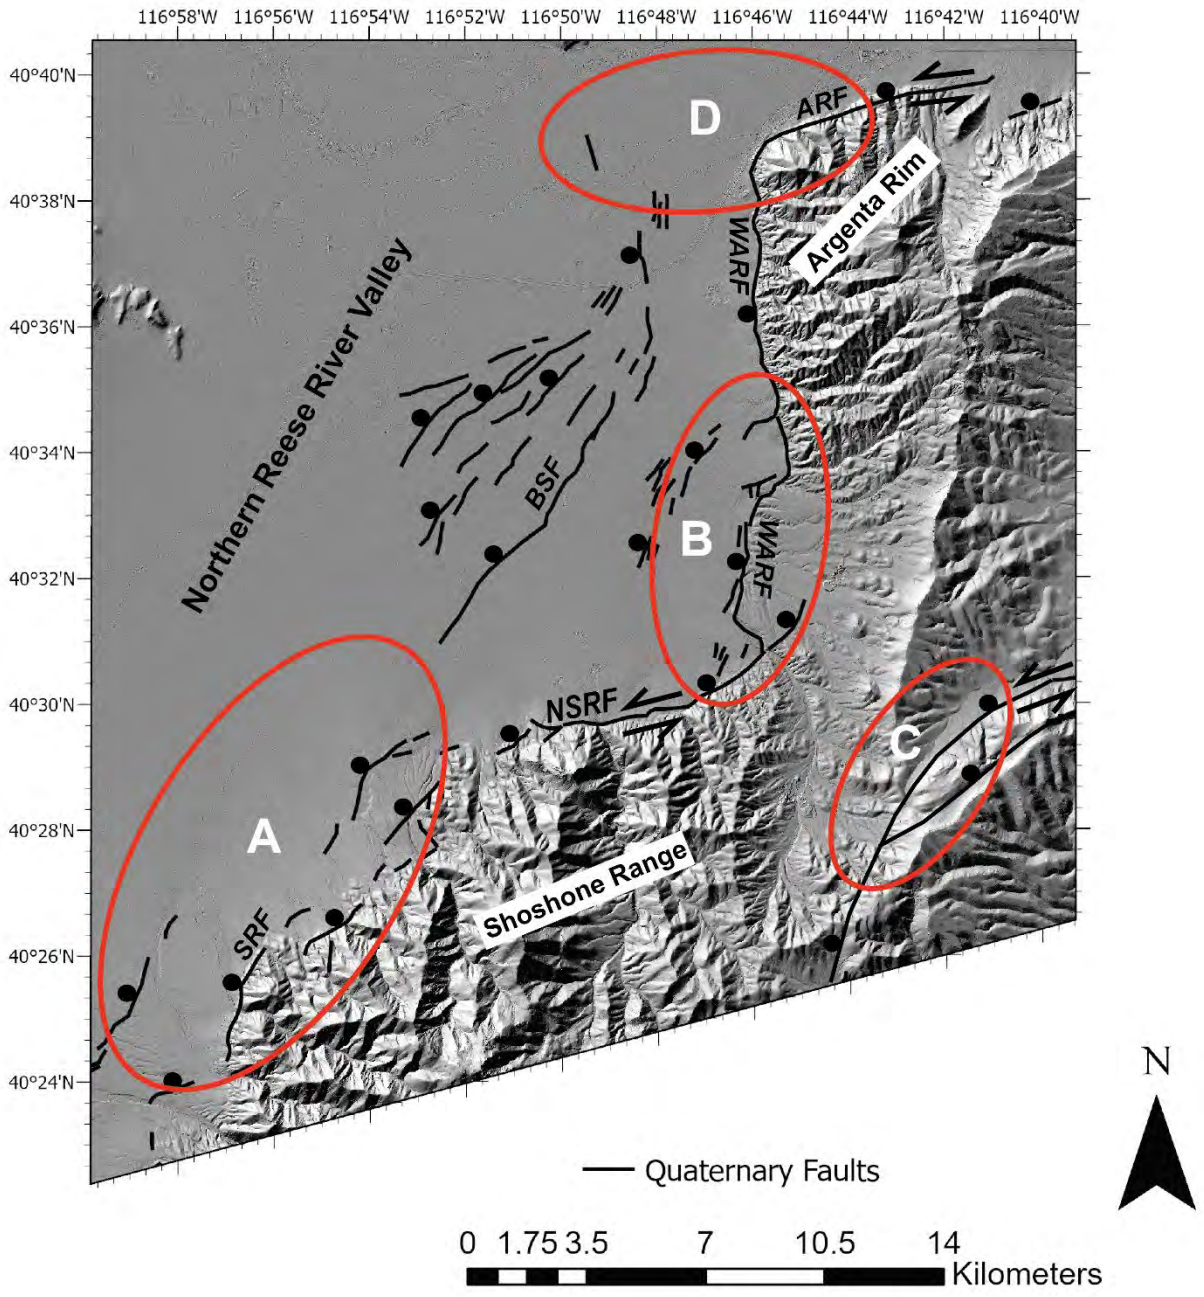

Figure 2: DEM hill-shade (U.S. Geological Survey, 2024) of the study area in northeastern Reese River Valley, also known as Argenta Rise. Quaternary faults are shown as black lines, with balls on downthrown sides and arrows indicating sinistral component of motion on ENE-striking faults. Individual favorable structural settings within the broader study area are outlined by red ellipses and labeled with letters. A, displacement transfer zone and fault intersection; B, fault intersection, pull apart, and step-overs; C, small pull apart and fault intersection; D, fault intersection. Major faults: ARF, Argenta Rim fault; BSF, Bateman Spring fault; NSRF, Northern Shoshone Range fault; SRF, Shoshone Range fault; WARF, West Argenta Rim fault.

2.2 Stratigraphic and Structural Framework

The bedrock stratigraphy of the Argenta Rise study area is characterized by Paleozoic rocks that are overlain by Tertiary volcanic rocks and Miocene to Quaternary basin-fill sediments (John and Wrucke, 2003; Gilluly and Gates, 1965; Ramelli et al., 2001). Formations of both the upper and lower plate of the Roberts Mountains thrust are present at Argenta Rise. The upper plate formations include the Ordovician Valmy Formation, the Silurian Elder Sandstone, and the Devonian Slaven Chert. The lower plate formations include the Shwin Formation and the Roberts Mountains Limestone. The western flank of the northern Shoshone Range is dominated by the upper plate of the Roberts Mountains thrust, with less extensive units of the lower plate present as windows in the thrust sheets (Gilluly and Gates, 1965; John and Wrucke, 2003).

A package of Cenozoic sedimentary and volcanic units unconformably overlie the Paleozoic sedimentary units of the Roberts Mountain allochthon. The volcanic units are extensive and range in age and composition. The oldest Cenozoic unit within the study area is the Caetano Tuff, a 33.8 Ma rhyolitic ash-flow tuff (John et al., 2008; Colgan et al., 2014). The tuff is widespread to the south and southeast of the study area, but the unit is only locally exposed within the study area. Overlying the Caetano Tuff and the Paleozoic section is a package of middle Miocene volcanic rocks that range in composition from basalt to dacite. These rocks are associated with the northern Nevada rift and are extensive in the eastern part of the study area, capping the Argenta Rim. Intruding the Paleozoic basement rock in the western part of Argenta Rim is a swarm of north-northwest-striking basaltic dikes that are potential feeder dikes to associated basalt flows. The Quaternary geology of the northern part of the Reese River basin has been mapped extensively (House et al., 2000; Ramelli et al., 2001, 2017). The ages of the Quaternary units range from Pleistocene to Holocene, with depositional environments including alluvial fan, alluvial flat, fluvial, and eolian deposits.

The structural framework of the study area is dominated by gently to moderately tilted Cenozoic fault blocks and associated half graben basins typical of the Basin and Range province. The northeastern part of the Reese River basin lies adjacent to the northern flank of the Shoshone Range and western margin of the Argenta Rim (Figure 2). The northern Shoshone Range is a north-northeast-trending, east-tilted fault block, and Argenta Rim is a southeast-tilted fault block (John and Wrucke, 2003). The study area is situated in a broad left step between the east-northeast-striking, north-dipping Argenta Rim fault on the north flank of Argenta Rim, and the east-northeast-striking, north-dipping fault that bounds the north end of the Shoshone Range (here referred to as the Northern Shoshone Range fault; Figure 2). These east-northeast striking faults are linked by a north-northwest-striking, west-dipping, fault zone that bounds the western flank of the Argenta Rim and is here referred to as the West Argenta Rim fault. Major fault intersections reside at the northern and southern ends of the West Argenta Rim fault with the Argenta Rim and Northern Shoshone Range faults, respectively. This area forms a broad pull apart between east-northeast-striking sinistral-normal faults. This favorable setting for geothermal activity was noted in the Nevada play fairway project (Faulds et al., 2015a). Notably, the nearby Beowawe geothermal system (with abundant sinter, hot springs, and a geothermal power plant) occupies a fault intersection in an apparent left step (or small pull apart) in the Malpais fault, a major east-northeast-striking sinistral-normal fault (Zoback 1979; Struhsacker 1980; Watt et al., 2007; Figure 7), and may serve as an analogue for a potential hidden system in the Argenta Rise area.

Quaternary fault scarps permeate the northeastern part of the Reese River basin (Figure 2) and commonly cut Holocene alluvial fan deposits. Paleoseismic studies along the northern Shoshone Range noted scarps with progressively greater offset across progressively older surfaces, indicating multiple deformational events. At least two paleoseismic events took place along this fault zone in the past 10,000 years (Wesnousky et al., 2005). The most recent event occurred ~3,317 years B.P. and resulted in 0.4 m of offset. From this, a slip rate of 0.1 mm/yr was calculated. In Whirlwind Valley directly to the east, which contains the Beowawe geothermal system and operating power plant, Quaternary scarps also cut Holocene fan deposits. The paleoseismic events along these faults have a recurrence interval of ~10,000 years (Wesnousky et al., 2005). The most recent event occurred ~7,450 years B.P. and resulted in 0.7 m of vertical offset, which yields a slip rate of 0.09 mm/yr.

3. Methods and Results

The INGENIOUS project has integrated geological and geophysical datasets to build a structural model and to identify specific favorable sites for potential geothermal upwelling. We have also conducted a 2-meter temperature survey.

3.1 Geological Studies

Geologic studies have included compilation of preexisting geological mapping, analysis of high-resolution lidar, and kinematic analysis of fault surfaces. We concluded that existing geologic mapping in the area was adequate for geothermal investigations and development of detailed models, if supplemented by analysis of lidar to locate and analyze (e.g., recency and slip rates) Quaternary faults. Kinematic analysis of exposed fault surfaces (Figure 3) showed that east-northeast-striking faults have accommodated sinistral-normal slip, and normal slip characterizes north- to north-northeast-striking faults. This is an important finding, as east-northeast-striking faults are common in north-central Nevada and intimately linked to arrays of northerly striking faults, but slip along these faults has rarely been characterized. Knowledge of the fault kinematics can help in defining the location and type of favorable structural settings and ultimately in modeling slip and dilation tendency and potential geothermal upwellings in 3D.

Analysis of lidar and field reconnaissance showed that major Quaternary faults in the study area, have several fault interaction zones that are conducive to geothermal activity. This includes major intersections between the West Argenta Rim fault and both the Northern Shoshone Range and Argenta Rim faults and a major step-over (relay ramp) near the southern end of the West Argenta Rim fault (Figure 2; areas B and D). In addition, the Northern Shoshone Range fault has several small steps and also intersects a major north-northeast-striking west-dipping fault on the west flank of the Shoshone Range (Figure 2, area A), which continues south of the study area for tens of kilometers and is here referred to as the Shoshone Range fault.

A 2-meter temperature survey with 139 measurements was completed across the area but did not identify any definitive thermal anomalies (Figure 4). Two very subtle anomalies were found but are either isolated to a single station or below the typical detection limit. Therefore, the shallow temperature survey at Argenta Rise was inconclusive. However, the two very small anomalies may suggest a hidden geothermal resource, which is possibly masked by a shallow cool aquifer or is relatively deep compared to other systems in the region that have yielded definitive shallow thermal anomalies (e.g., Coolbaugh et al., 2007b).

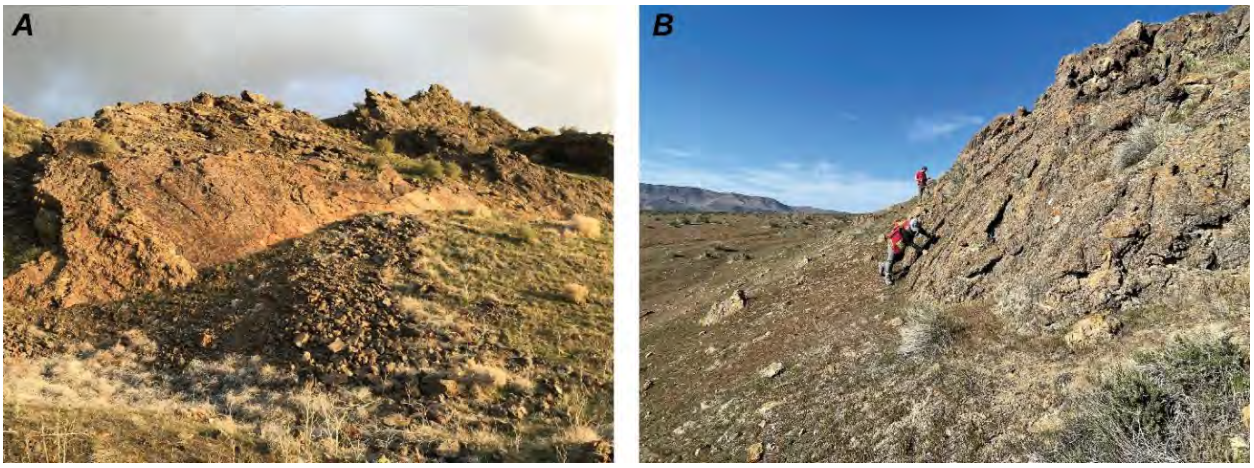

Figure 3: A. Well-exposed fault surface along the Argenta Rim fault, a major ENE-striking, N-dipping fault on north side of Argenta Rim. Fault surface is ~10-15 m in height. Kinematic indicators (e.g., fault striae, corrugations, and Riedel shears) indicate sinistral-normal displacement. B. N-striking, W-dipping fault on west flank of Argenta Rim (West Argenta Rim fault), with dip-slip normal displacement. Photos taken by James Faulds.

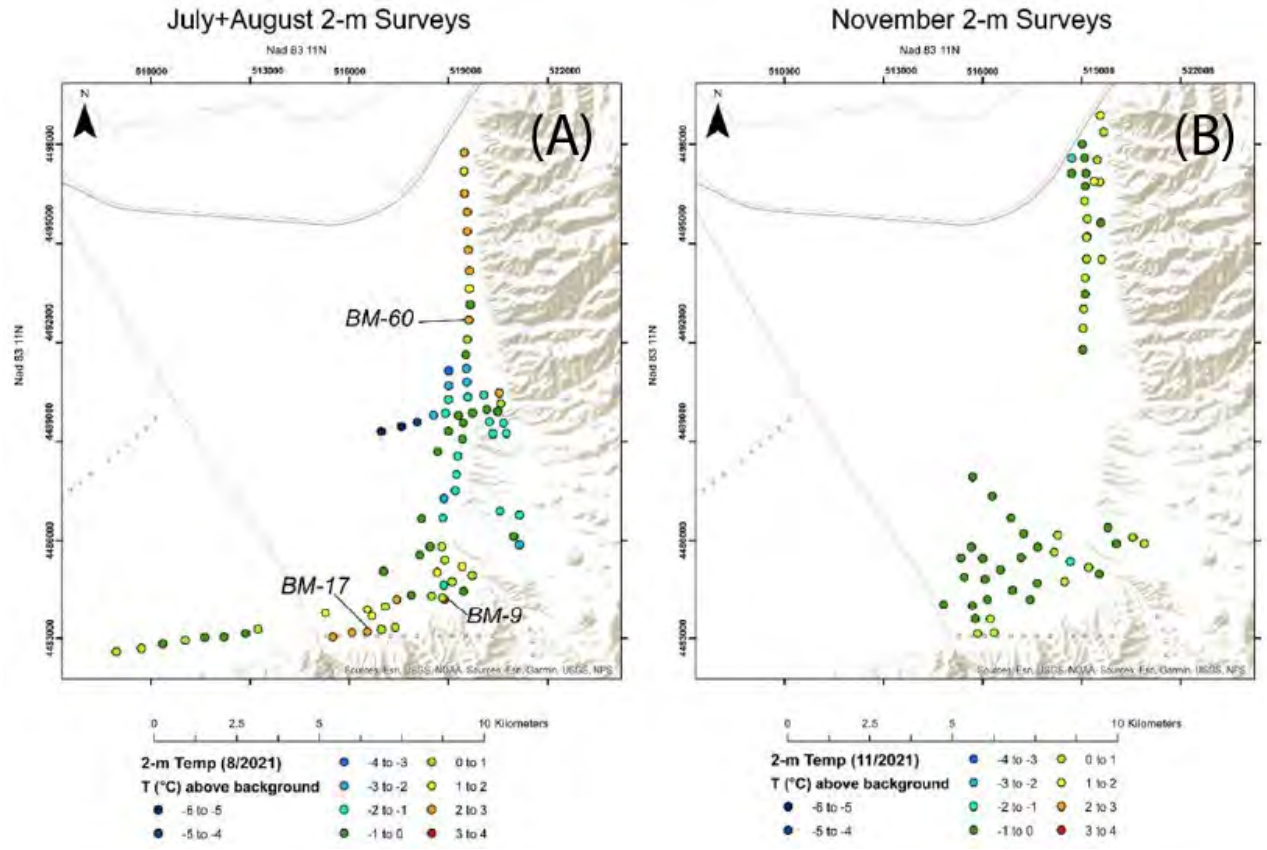

Figure 4: Shallow (2-meter) temperature surveys of the Argenta Rise study area. (A) Survey from July and August 2021. (B) Survey from November 2021. DEM hillshade is from U.S Geological Survey (2024).

3.2 Geophysical Investigations

New geophysical surveys for the Argenta Rise area in the INGENIOUS project have included gravity, magnetic, and MT data acquisitions, which were carried out by the U.S. Geological Survey (Earney et al., 2022, 2023, 2024). Data acquisitions included 1,207 gravity stations, ~70 line-km of magnetic profiles, 43 MT stations, and numerous rock property samples and outcrop measurements (254 hand samples collected for density, 76 outcrop magnetic susceptibility measurements, and 17 paleomagnetic cores taken from two sites) to help constrain potential field model rock properties (Figure 5). New gravity and magnetic grids were generated, and geophysically inferred structural mapping was derived from the gravity and magnetic datasets (Figures 6 and 7). A depth-to-basement inversion model was also developed from the new gravity compilation. Finally, a new 3D resistivity model was developed for the area based on the 43 MT stations. The MT slice at 500 m below sea level or ~2 km depth shows low resistivity anomalies occupying favorable structural settings (e.g., fault intersections and pull aparts) along the northern range-front fault of the Shoshone Range (Figure 8). Details of these datasets and resulting interpretations are reported in an accompanying paper in this volume (Earney et al., 2024).

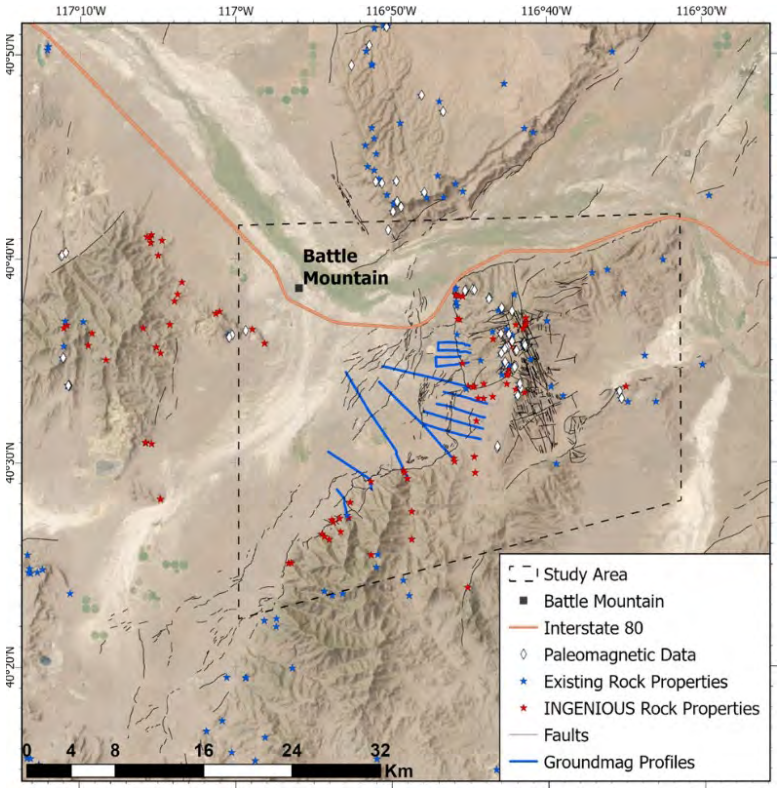

Figure 5: Ground magnetic, rock property, and paleomagnetic field data collection at Argenta Rise. Base map is from the ArcGIS online map server (Esri, 2024).

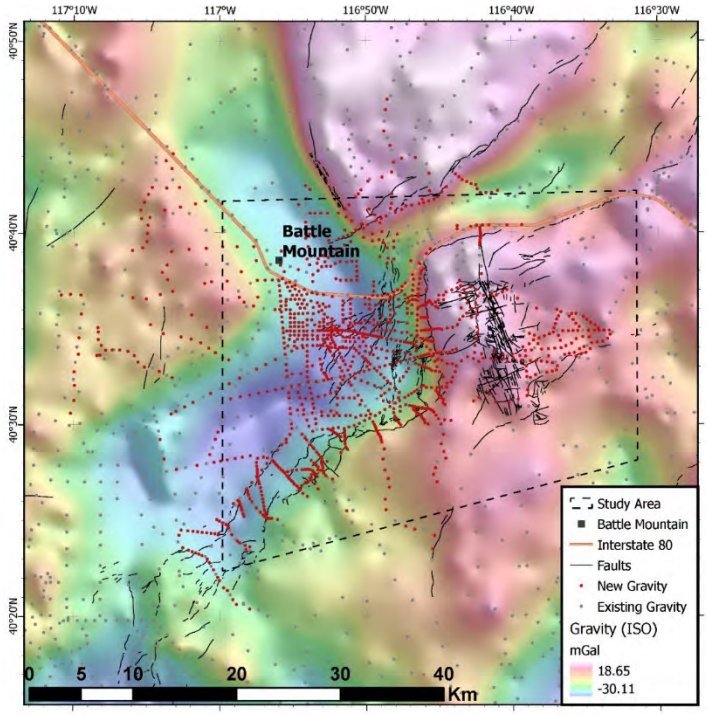

Figure 6: Isostatic gravity grid of the Argenta Rise area based on new and re-reduced existing data. Gravity station coverage includes existing (gray) and new field data (red). Quaternary faults compiled in this project are shown in black.

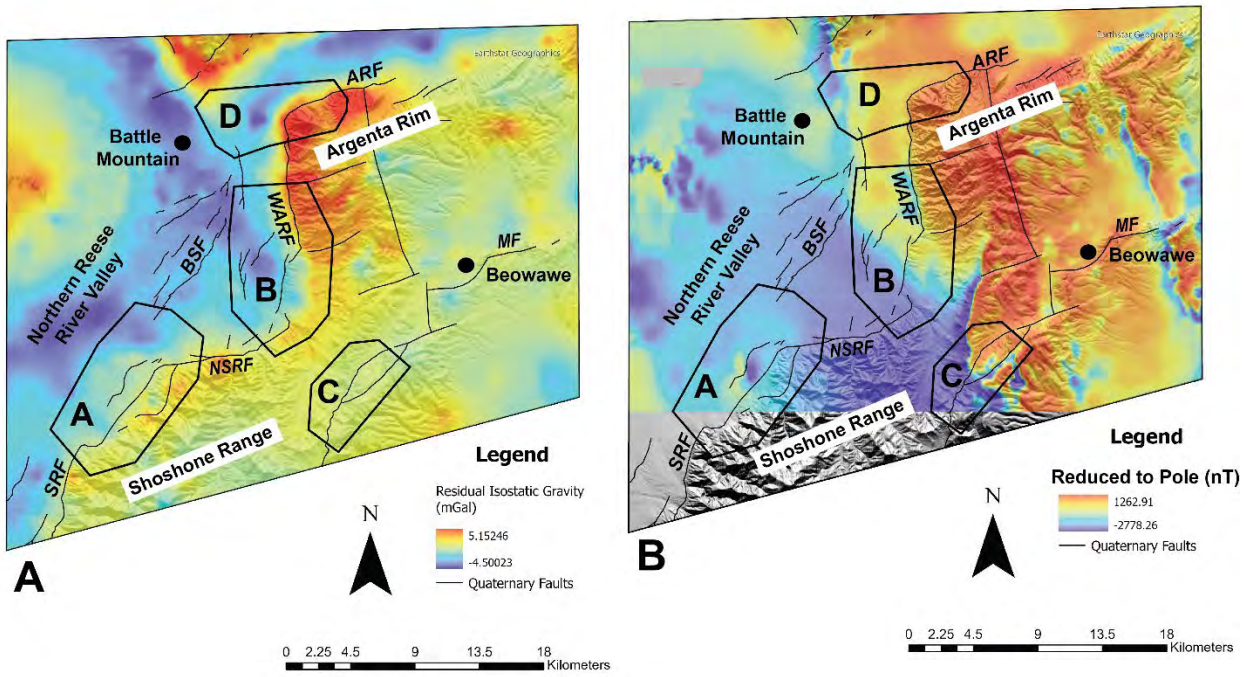

Figure 7: A. Preliminary isostatic residual gravity map for the Argenta Rise area. B. Preliminary magnetic anomaly map (reduced to pole). Black polygons outline the local-scale, individual favorable structural settings identified in this area based on both the geological and geophysical data (see text for discussion), with letters corresponding to those shown on Figures 2 and 8. MF, Malpais fault; see Figure 2 for explanation of other fault labels. DEM hillshade is from U.S Geological Survey (2024).

The rights to interpret six preexisting 2D seismic reflection profiles in the Argenta Rise area were purchased from Seismic Exchange, Inc. Based on the original quality of these profiles, we determined that it would be cost-effective to reprocess the profiles. Pre-stack depth migration (PSDM) results produced through the reprocessing showed substantial improvement for all profiles. A number of coherent reflection events can be tracked, and faulting is also indicated by offsets in some of these reflection events. This improvement in the processed results is related to careful unraveling of the source and geophone coordinates, the application of advanced tomographic refraction statics analysis, and the application of state-of-the-art pre-stack migration velocity analysis.

The reprocessed seismic reflection profiles and revised depth-to-basement horizon estimates for these profiles, based on their gravity inversion models, were interpreted for faults and stratigraphic horizons. Multiple faults were readily interpretable and correlate with major gravity gradients and faults mapped at the surface. Several faults were also noted that are concealed and have not ruptured the surface. This includes a major east-dipping fault on the west side of the northern Reese River basin, which corresponds to a major gravity gradient in that area. In addition, the proprietary seismic reflection data generally indicate that the northern Reese River basin is gently tilted toward the east (data not shown).

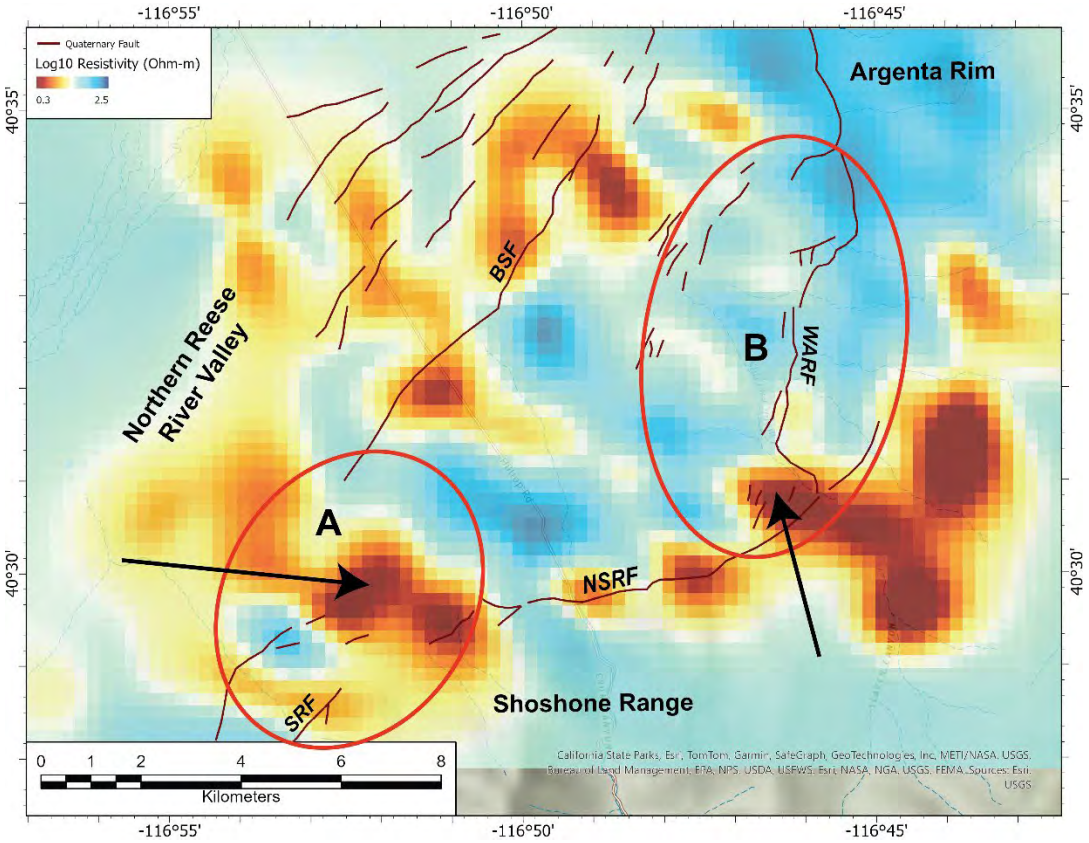

Figure 8: MT grid for the Argenta Rise site at 500 m below sea level or ~2 km depth. Low resistivity anomalies can indicate the presence of clay caps and/or geothermal reservoirs. Red ellipses highlight two favorable structural settings that are marked by low resistivity anomalies (red arrows), with letters corresponding to those shown in Figures 2 and 7. See Figure 2 for explanation of fault labels.

4. Discussion

The geological and geophysical datasets indicate a complex system of intersecting east-northeast-striking sinistral normal and north- to north-northeast-striking normal faults within the northeastern part of the Reese River basin (Argenta Rise area). This pattern of faulting is evident in surface geological data, including relatively abundant Quaternary fault scarps, and also in gravity, magnetic, and MT data. Reprocessed seismic reflection data also show these faults, with major faults imaged on the reflection profiles generally corresponding to gravity and/or magnetic gradients as well as, in many cases, to surface fault scarps.

The Argenta Rise study area occupies a large left step in a system of east-northeast-striking sinistral normal faults and thus represents a broad pull apart. However, this area covers many tens of square kilometers, and thus is impractical due to its size for an economical geothermal drilling program. It is therefore critical to vector into the most prospective parts of this area to reduce the risks in drilling. Three favorable structural settings for geothermal activity have been identified in the northeastern part of the Reese River basin. A fourth setting was defined directly to the east (Figures 2 and 7). Most of these settings lie within the broader favorable structural area noted in the Nevada play fairway project. Identifying additional prospective areas at a finer scale reflects the natural progression from regional- to local-scale exploration, as demonstrated in other detailed studies in the region (McConville et al., 2017; Faulds et al., 2019; Craig et al., 2021).

The newly identified favorable structural settings include three hybrid settings and a fault bend (Figures 2, 7, and 8). Structural setting A is a hybrid of several favorable settings, including a left step in the east-northeast-striking Northern Shoshone Range fault, a possible left step in a northeast-striking intrabasinal fault (Bateman Spring fault), an intersection between the Bateman Spring and Northern Shoshone Range faults, and a displacement transfer zone at the apparent western terminus of the Northern Shoshone Range fault. The displacement transfer zone contains a discrete elliptically shaped, north-trending magnetic low (Figure 7B) and a low resistivity anomaly (Figure 8). Structural setting B (Figures 2, 7, and 8) is also a hybrid of several favorable settings, including a left step in the north-striking West Argenta Rim normal fault and fault intersections between the West Argenta Rim fault and both an obscure intrabasinal east-north-northeast-striking fault and the east-northeast-striking Northern Shoshone Range fault. This setting is part of the broad pull apart between east-northeast-striking sinistral-normal faults. It is marked by large gravity gradients that correspond to mapped Quaternary faults (Figure 7A) and a low resistivity anomaly in its southern reaches (Figure 8). Additionally, there are two anomalous magnetic lows along the western range front of Argenta Rim (Figure 7B). Structural setting C (Figures 2 and 7) lies just to the southeast of our primary study area in the northeastern Reese River basin and is a fault bend in an east-northeast-striking to a north-northeast-striking fault zone. The orientation of this fault bend relative to a regional west-northwest-trending extension direction makes it optimally oriented for dilation and enhanced permeability. The fault bend is also associated with minor magnetic lows along the mapped fault trace. Structural setting D is a hybrid of two favorable settings, including a possible left step in the east-northeast-striking sinistral-normal Argenta Rim fault and a fault intersection between the Argenta Rim fault and northerly striking West Argenta Rim normal fault. This setting encompasses large gravity and magnetic gradients marking concealed faults. Proposed temperature-gradient drilling, planned for late 2024, will focus on structural settings A and B (Figures 2, 7, and 8).

Geothermal Resource and Opportunities Assessment of Colorado

Emilie Gentry, Joe Batir

Teverra

Keywords

Colorado geothermal, resource assessment

ABSTRACT

Colorado has a long history of mining and hydrocarbon production as well as recent developments of wind and solar energy. Additionally, hot springs and thermal wells exist across the state, suggesting potential for geothermal resources. Previously, limited studies aimed to characterize these individual geothermal sites, with plans for local development. The statewide geothermal resource has been generally known and mapped in the state in past years, but there is significantly more data now available, which means resource understanding can be improved through a new resource assessment. Additionally, no recent public studies have examined the best pathway for economic development of these resources in Colorado that could substantially assist the energy needs of the state.

As part of a larger geothermal resource study for the state of Colorado, an initiative by the Colorado Energy and Carbon Management Commission (ECMC), Teverra completed a thermal resource evaluation with new data and produced new geothermal resource maps. In addition to evaluating the geothermal resource in Colorado, the study also examined utilization opportunities given the determined resource potential.

The geothermal resource across the state was examined for electricity production, direct use, and geothermal heat pump applications. There are several prominent sedimentary basins with significant development that may be an opportunity for well repurposing, which is also examined. There is resource with temperatures 100-175 °C throughout the state at depths that are currently drilled. In these areas, power generation could be a possibility, and technologies to utilize lower temperature resources are likely to have the greatest economic impact and benefit for the majority of the state.

This study demonstrates a new approach to understanding the geothermal resource for the state, and compares this work to what work had been previously completed on geothermal potential in Colorado.

1. Introduction

Colorado has a rich history of geothermal resource utilization dating back to pre-Columbian times, primarily through the exploitation of thermal springs (CNAIS, 2020). However, the oil crisis of the early 1970s sparked a renewed interest in exploring and harnessing geothermal energy in the state. This period saw a surge in geothermal exploration efforts, culminating in numerous localized basin and thermal spring studies and a few comprehensive statewide assessments (Dick, 1976; Dick and Pearl, 1978; Galloway, 1980; Gwinn, 1981; Ringose, 1980, Zacharakis, 1981).

The Colorado Geological Survey (CGS) played a pivotal role in documenting and evaluating Colorado's geothermal potential. Prior to 2000, CGS published over 40 reports detailing various aspects of geothermal resources. These reports encompassed assessments of thermal springs, wells, geothermal gradients, and heat flow across the state. The most recent comprehensive study, led by Paul Morgan in 2016, provided detailed insights into Colorado's geothermal potential.

In recent years, Colorado has set goals to reduce statewide greenhouse gas emissions, underscoring the need for innovative energy solutions. Geothermal technology has emerged as a promising option, leveraging the Earth's heat for electricity generation, heating, cooling, and other energy applications. This has spurred significant interest and investment from both public and private sectors at state and federal levels.

Recognizing the potential of geothermal energy, recent legislative measures have given the Colorado Energy Conservation Management Commission (ECMC) the role of overseeing geothermal development among other technologies aligned with its expertise in oil and gas. To aid in this transition, legislation also mandated ECMC to complete a study to assess Colorado's geothermal resources comprehensively, identifying optimal technologies and opportunities for integrating existing infrastructure into the state's evolving energy landscape.

This paper examines the findings of this study, offering insights into the suitability of various geothermal technologies within Colorado's geological framework. It highlights emerging opportunities and strategies aimed at advancing geothermal energy as a cornerstone of the state's sustainable energy future. This new study represents a significant advancement in our understanding of Colorado's geothermal resources. Leveraging enhanced data collection and technological capabilities, the maps and assessments in this report offer a comprehensive update on the state's geothermal potential. Improved geological modeling and additional data have enabled a finer resolution analysis of geothermal gradients, heat flow, and resource potentials across different geological formations and regions of Colorado.

By comparing and contrasting past assessments with current data sets, this report identifies changes and trends in resource availability, offering valuable insights for future development and policy formulation. This iterative approach ensures that stakeholders and decision-makers have access to the most up-to-date information when evaluating the feasibility and economic viability of geothermal projects throughout the state.

2. Updated Thermal Resource Characterization

To complete a thermal resource characterization for the state of Colorado, well and thermal springs data was used to explore geothermal resource potential, model the geothermal gradient, and

calculate new thermal properties. The results of this work include a new understanding of the greater thermal regime and geothermal resource potential.

Subsurface temperature data were collected from well information. Bottomhole temperature (BHT) data for oil and gas wells in all the producing sedimentary basins in the state of Colorado were provided by CGS (Figure 1). This included only public well data. BHT data require a correction to estimate true formation temperature, as the raw data are impacted by circulating drilling fluids and are commonly cooler than the true formation temperature. Well data are limited to areas where wells exist, which is in sedimentary basins where the wells were drilled for oil and gas development. Maps created from the thermal calculations should be viewed with the knowledge that there are areas that are interpolated where well data do not exist.

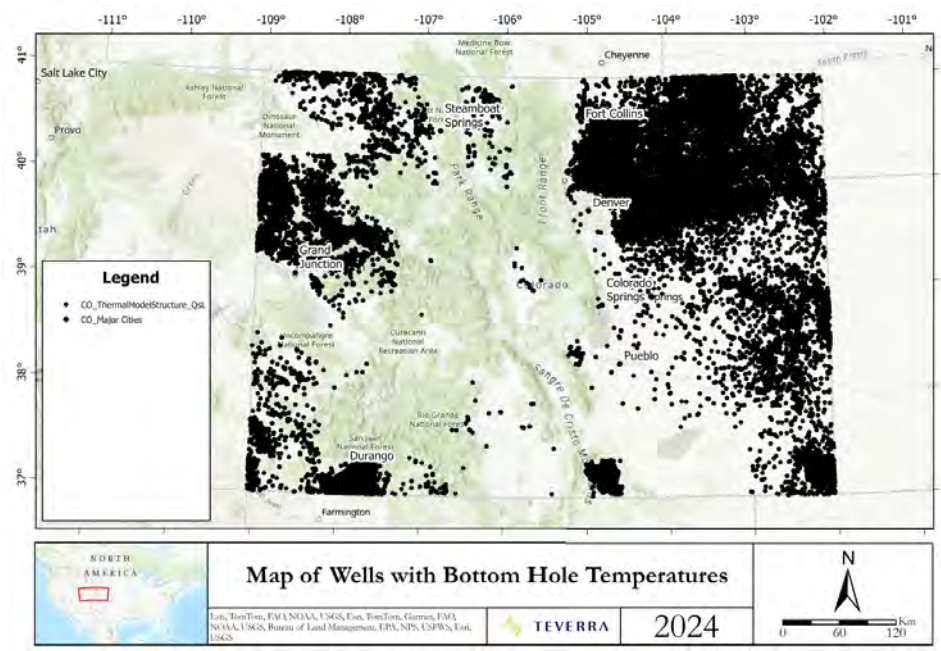

Figure 1: Map of oil and gas wells that contain BHT data provided by the Colorado Geological Survey.

To complete the thermal resource characterization, geothermal gradient, thermal conductivity models, heat flow and temperature at depth were calculated.

The geothermal gradients for all CGS-provided data points were computed and are depicted in Figure 2 in °C/km. The well data trends on the map indicate gradients ranging from 25°C-32°C/km (1.37°F-1.76°F/100 ft). This range exceeds the average continental geothermal gradient for the US, which is 25°C/km (1.37°F/100 ft), highlighting areas with a stronger thermal signature. These findings align well with previous CGS research, confirming higher gradients in specific regions. The updated geothermal gradient resource map offers enhanced data resolution across various areas. Resulting geothermal gradient values were utilized for heat flow and temperature at depth calculations.

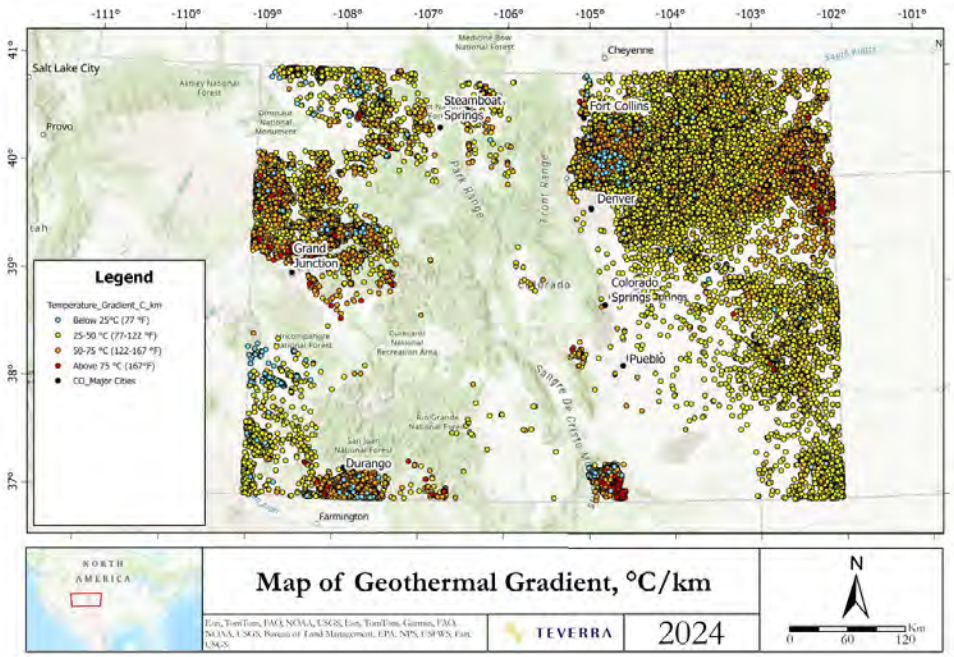

Figure 2: Map of geothermal gradient calculated for wells in Colorado.

In this study, the Bullard method (Bullard, 1940) was used to calculate heat flow, which requires a comprehensive stratigraphic column for the thermal conductivity model. The Bullard method utilizes thermal resistance (the reciprocal of thermal conductivity) to compute cumulative thermal resistance from the surface to the depth of temperature measurement. By plotting temperature against thermal resistance, the slope of the resultant line corresponds to the heat flow.

For our thermal conductivity model, formation lists and thicknesses were derived from supplied stratigraphic columns by CGS and the Correlation of Stratigraphic Units of North America (COSUNA) (AAPG, 1994). The COSUNA segments divide the state into approximately 13 sections based on distinct stratigraphy, each providing estimated thicknesses for their respective layers. These COSUNA segments were cross-referenced with CGS stratigraphic columns to ensure completeness and accuracy in thermal conductivity assignments. Estimated thermal conductivities were assigned based on lithology and formation using data from Gallardo and Blackwell (Gallardo, 1999) and Reiter et al. (1983, 1979, 2010). In cases where specific values were unavailable, generic values for the respective rock types were utilized.

All new heat flow values in this comprehensive study were derived from the Bottom Hole Temperature (BHT) data supplied by CGS. Additionally, equilibrium heat flow data collected statewide by CGS were incorporated into the analysis (Figure 3). The resulting heat flow map of Colorado (Figure 4) integrates the newly computed BHT-derived heat flow values along with approximately 140 measured equilibrium heat flow points provided by CGS. The 140 equilibrium heat flow points complement the BHT derived heat flow wells in that they have a greater spatial coverage in the regions lacking BHT coverage.

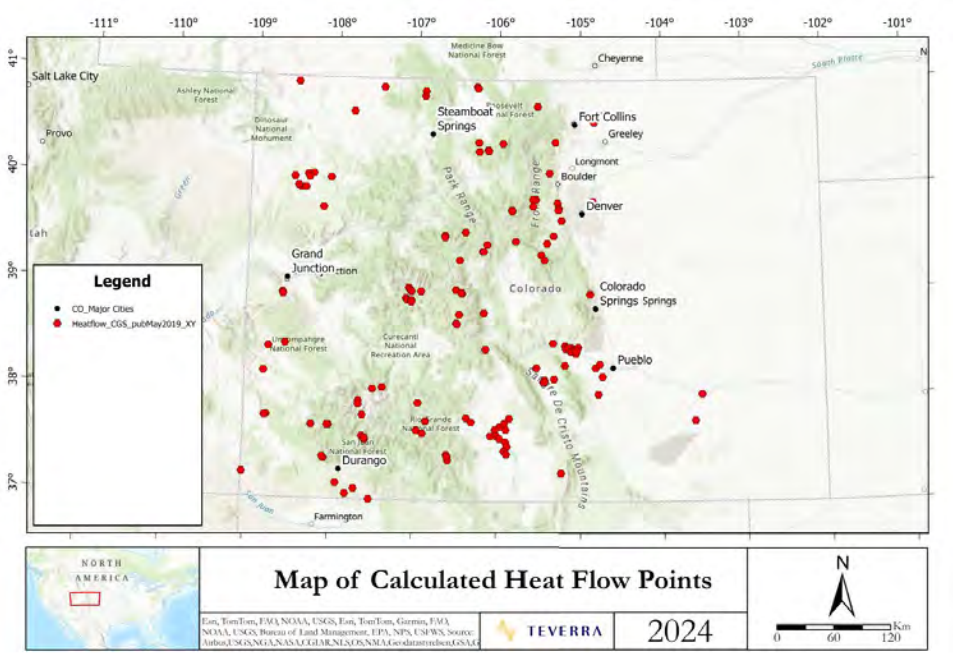

Figure 3: Map of heat flow point provided by CGS.

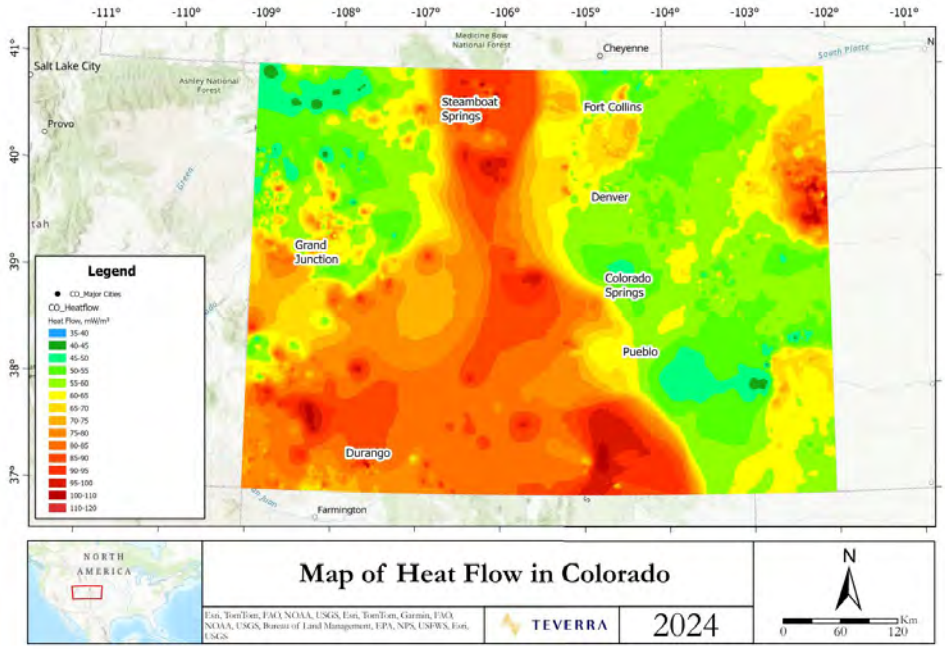

Figure 4: Map of estimated heat flow for the state of Colorado.

Across the state, heat flow varies, with some areas registering values at or below 50 mW/m² and others exceeding 80 mW/m². The global continental average heat flow stands at approximately 67 mW/m² (Lucazeau, 2019), highlighting certain areas in Colorado with above-average heat flow characteristics. Notably, southwestern Colorado, the Piceance Basin, and the central region exhibit the highest heat flows, ranging between 60 and 120 mW/m², albeit with considerable variability.

The statewide heat flow pattern shows a prominent central area of high heat flow, consistent with previous public maps (Blackwell et al., 2011). The inclusion of additional well data in this study enhances resolution and understanding, particularly in sedimentary basins across Colorado. Lower heat flow is observed in the High Plains region, with a poorly constrained low in the northwest corner of the state. Despite limited data, indications suggest a prevalence of high heat flow in the central region. The interpolation of high heat flow values is supported by the presence of numerous hot springs in this area, although the scarcity of data points challenges the accuracy of this interpolation. The abundance of hot springs in the central region suggests significant geothermal energy potential, although further assessment is needed to quantify these opportunities effectively.

Using the calculated heat flow, temperature versus depth was modeled and maps made of temperature at defined depths. These maps are provided to identify geothermal anomalies. Here, we utilized the Batir and Richards (2020) methodology to calculate the subsurface thermal regime. Note that this model assumes a crustal component with exponential decay of radiogenic heat production. This assumption, while used extensively for temperature—depth modeling in continental settings, may be an oversimplification of temperature distribution and heat flow throughout the crust, especially for areas with more recent tectonic activity and areas with variable crustal Petrology.

The most frequently drilled well depth in Colorado is less than 2.5 km (8,202 ft) (Figure 5). In this analysis, we present interpolated temperatures at the depth of 2.5 km (8,202 ft), incorporating temperature data points with maximum depths up to 2.5 km (8202 ft). Across the majority of the state at this depth, temperatures are generally below 100°C (212°F).

Areas extending from the San Juan Basin to the Raton Basin, and northward to the Piceance Basin, exhibit slightly higher temperatures ranging from approximately 100°C to 124°C (212°F to 255°F), with localized spots exceeding 150°C (302°F). Specifically, the Raton Basin shows temperatures between 100°C and 125°C (212°F to 255°F) at 2.5 km (8,202 ft) depth. Within the Denver Basin, the Wattenberg field demonstrates elevated temperatures ranging from 100°C to 110°C (212°F to 230°F) at depth. As previously noted, there is a localized area of elevated temperatures along the eastern border of the state. At a depth of 2.5 km (8202 ft), temperatures in this region are mapped up to 150°C (302°F).

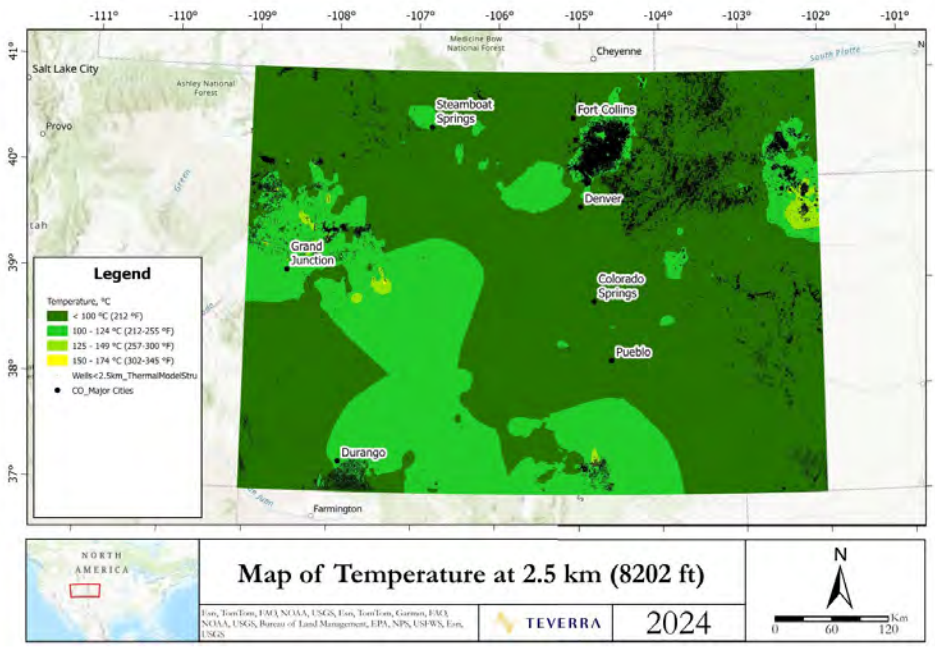

Figure 5: Map of calculated temperature at 2.5 km (8200 ft), used to represent the potential temperature at a common drilling depth for Colorado. The black dots are wells with temperature data that have a total depth of 2.5 km and shallower.

The temperature at 5 km (16,404 ft) represents the practical drilling limit for geothermal exploration in Colorado (Figure 6). While there are a few wells deeper than 5 km (16,404 ft) and plans for additional deep drilling, such wells are uncommon at present. Therefore, 5 km (16,404 ft) is currently considered the maximum feasible depth for geothermal exploration in the state.

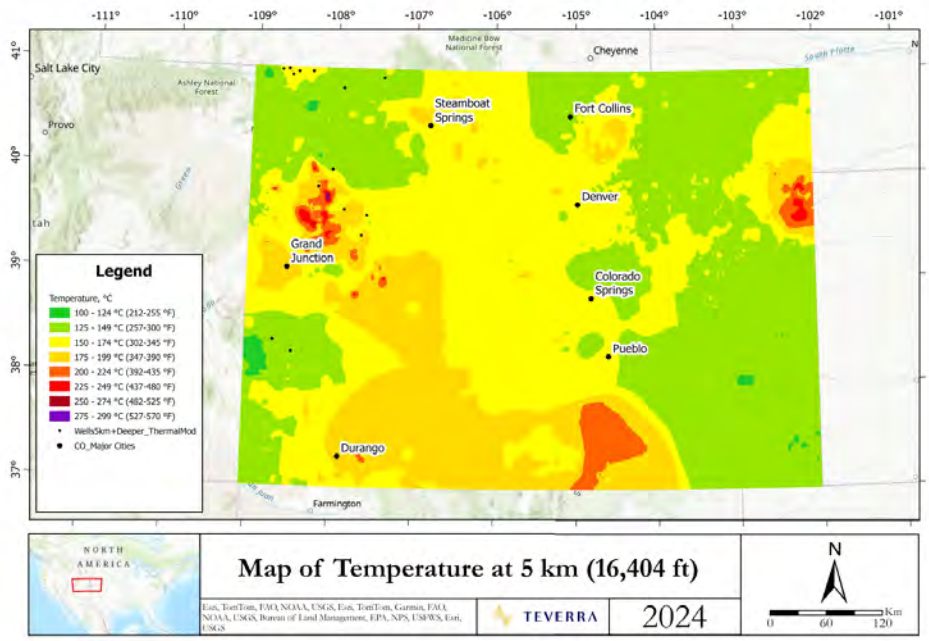

Figure 6: Map of calculated temperatures at 5 km (16,404 ft) depth, the estimated current technical limit for drilling.

Across most of the state, temperatures at 5 km (16,404 ft) are notably higher. The Piceance Basin, for instance, exhibits a thermal low in its northern area but generally maintains a high thermal regime with temperatures ranging from 180°C to 200°C (356°F to 392°F), and localized anomalies reaching 250°C to 300°C (482°F to 572°F). Due to abundant well data in this region, these elevated thermal readings are considered more reliable. In southwestern Colorado, temperatures typically range from 150°C to 200°C (302°F to 392°F), with the Paradox Basin along the western border displaying lower temperatures in the 100°C to 150°C (212°F to 302°F) range at depth. The central part of the state generally records temperatures at 5 km (16,404 ft) ranging from 150°C to 175°C (302°F to 347°F), except for the Raton Basin where temperatures slightly exceed 212°C (414°F). Eastern Colorado predominantly registers temperatures between 125°C and 150°C (257°F and 302°F) at this depth. The Wattenberg Field, situated in this area, reaches temperatures of 175°C to 182°C (347°F to 360°F). An extrapolated thermal high along the eastern border suggests temperatures up to 230°C (446°F), but this is based on shallow data and introduces greater uncertainty with depth.

Overall, drilling to 5 km (16,404 ft) offers greater potential for geothermal power production and higher temperature applications compared to depths of 2.5 km (8,202 ft). However, such deep drilling operations incur higher costs, aligning with current standard drilling depths for the region.

Lastly, temperature data at 7 km (22,966 ft) is presented to emphasize the potential for future deep drilling endeavors (Figure 7). Thermal trends observed at this depth parallel those at 5 km, albeit with markedly higher temperatures. The coolest temperatures, ranging from 150°C to 200°C (302°F to 392°F), are found in the Sand Wash Basin, Paradox Basin, and much of eastern Colorado.

Significantly elevated thermal regimes at 7 km (22,966 ft) are concentrated in the Piceance Basin, San Juan Basin, Raton Basin, the Wattenberg Field in the Denver Basin, eastern Denver Basin, and central Colorado, where temperatures range from 200°C to 300°C (392°F to 572°F). This depth holds substantial potential for electricity generation, but the advancement of deep drilling technologies is crucial for these resources to become economically viable for production. It is also important to note, few wells exist at these depths for ground truthing of the temperature-depth model. There is high potential, but also potential for high uncertainty.

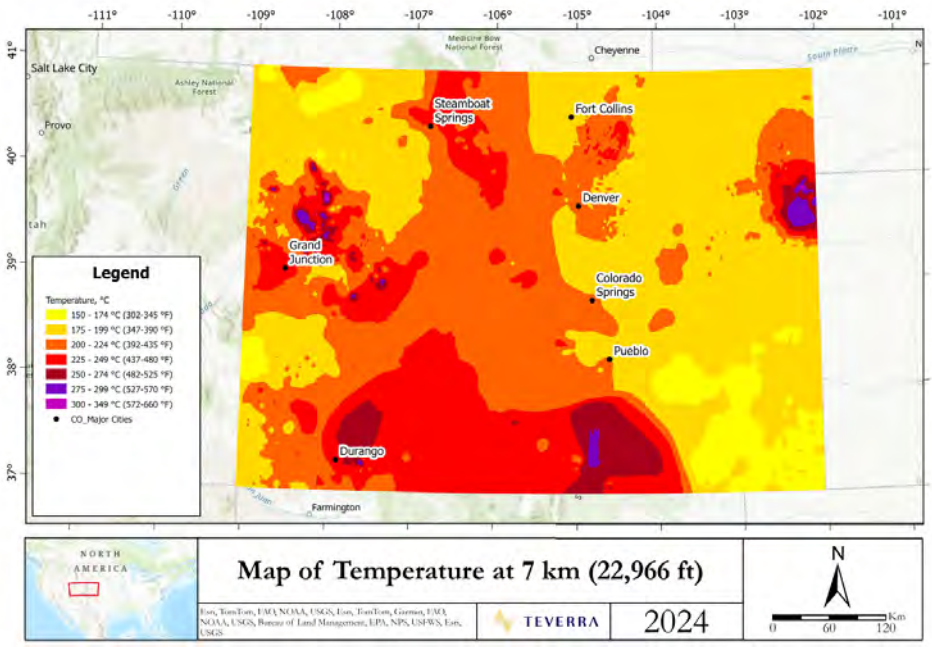

Figure 7: Map of temperatures at 7 km (22,966 ft) depth, presented as potential future deep drilling potential.

Overall, the temperature necessary for the desired utilization, whether direct use applications or geothermal power generation, can be reached. This becomes more of a parameter of how deep to drill to reach the desired resource. These maps are created from well data and are an interpolation from the well specific data. Therefore, these maps should not be considered adequate for site-specific exploration. Rather, these maps indicate where existing data can be used to suggest potential for thermal anomalies that may warrant exploration. Additionally, uncertainty analysis of the associated data points show where there are not enough data to make a discrete analysis, indicating where maps should be used with caution.

3. Discussion on Previous and Present Work Completed

For comparison of previous work to the new updated resource assessment in this study, regional state-wide maps and assessments will be discussed. While there are several focused studies completed on Colorado's sedimentary basins and localized thermal springs, these are much more detailed than what was assessed in this resource study.

An Interpretive Geothermal Gradient map (Figure 5) for the state was published in 2010 (Berkman and Watterson, 2010). In 2008, an Interpretive Geothermal Heat Flow map (Figure 6) was developed using the Southern Methodist University, University of North Dakota, and University

of Michigan databases and an additional 40 data points CGS calculated from borehole temperature-depth logs (Berkman and Carroll, 2008). In 2016, Paul Morgan presented at AAPG an updated Colorado Geothermal Map (Figure 7), which maps geothermal gradient by geologic formation and is refined through hand contouring (Morgan, 2016). Heat flow data points are mapped with the geothermal gradient. Mapping was focused where data was sufficiently spatially dense to avoid interpolation. Additionally, the isotherms of 50°C and 75°C were hand contoured where BHTs came close to the isotherm shown.

In this study, Teverra created a thermal conductivity model that was defined by geologic formations and formation thicknesses of thirteen areas throughout the state. The thermal conductivity values assigned were specific to the geologic formation assigned in that area and where no measurement was available, a general thermal conductivity value was used. The thermal conductivity model specific to lithology and local lithology thickness was then used to calculate the heat flow and temperature-at-depth. In other words, the heat flow and temperature at depth results were calculated for the appropriate geologic formation at depth. Furthermore, this method incorporated depth to basement as an estimation of sedimentary thickness and scaled all calculations to agree with total sediment package thickness.

The Interpretive Geothermal Gradient map of Colorado (Figure 8) has more interpolation and interpretation than the geothermal gradient map developed in this study (Berkman and Watterson, 2010). While this study mapped geothermal gradient as well data points, Berkman and Watterson (2010) extrapolated the data to cover the entire state in an interpretive map. Despite the mapping style differences, the overall data and mapped trends agree between the two maps. High and low geothermal gradients are agreeable between the 2010 and 2024 assessment maps.

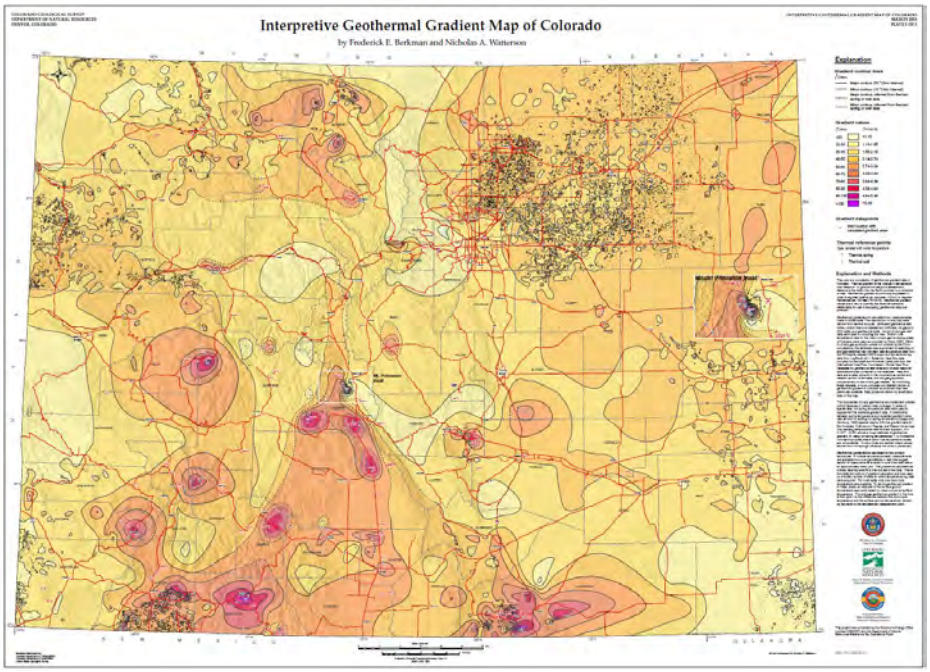

Figure 8: Interpretive Geothermal Gradient map published by CGS (Berkman and Watterson, 2010).

The Interpretive Geothermal Heat Flow map (Figure 9) published in 2008 shows heat flow trends that are mimicked by the heat flow assessment completed in this study. These two maps are in

agreement that there are three main heat flow provinces. The Great Plains province which has normal heat flow in majority eastern Colorado with an exceptional high for the Raton Basin. The Southern Rocky Mountains have an elevated heat flow in several localized areas, and the San Luis Valley where Mt. Princeton exists is the highest mapped heat flow. Slight differences occur in the heat flow values. The 2008 assessment contains some higher heat flow values and more detail on Mt. Princeton that was not available in the 2024 study. The location of the high heat flow areas align, but the exact values may slightly differ. The 2008 assessment has values over 200 mW/m^2 whereas the 2024 assessment specifically set a high value limit at 120 mW/m^2. The cause for this difference is likely due to differences in data and gridding procedures versus hand gridding.

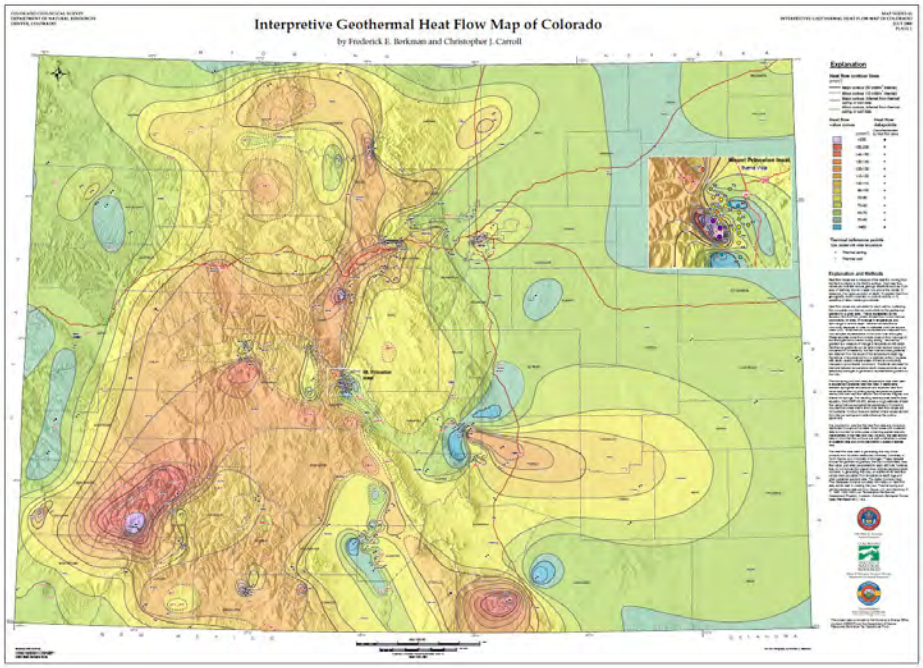

Figure 9: Interpretive Geothermal Heat Flow map published by CGS (Berkman and Carroll, 2008).

A visual comparison of the Colorado Geothermal Map (Figure 10) and the geothermal model in this study and resulting maps may show minor differences (Morgan, 2016). These differences are derived from the level of detail mapped and the slight differences in calculation methodology. The Colorado Geothermal Map provides more detail for each sedimentary basin as a formation evaluation only where adequate data points exist. The maps in this report are a large-scale exploration assessment and include interpolation at depth where the spatial database is limited. In these areas of interpolation, evaluation must be considered with the data density assessments. Visual differences between these maps do not necessarily suggest disagreement, but instead likely represent additional characterization of specific geologic formations in certain areas.

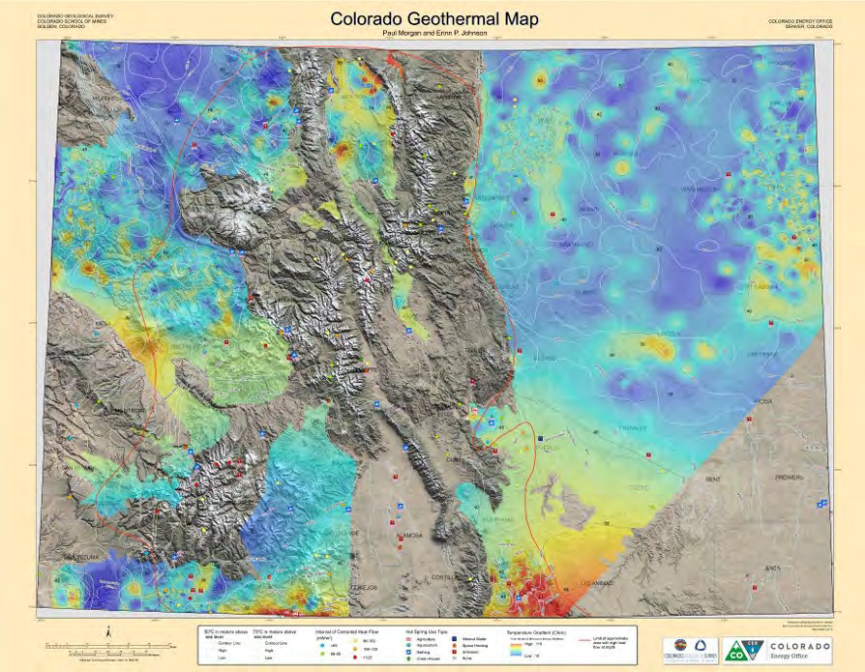

Figure 10: Colorado Geothermal map published by Paul Morgan, 2016.

4. Emerging Geothermal Utilization

Various types of geothermal utilization were examined based on available thermal resources to establish a hierarchy of opportunities, as depicted in Figure 11. High-temperature utilization technologies are constrained by minimum temperature thresholds, whereas low-temperature technologies can operate in the same areas if they are optimal for end-users. Therefore, locations utilizing high-temperature applications like Enhanced Geothermal Systems (EGS) for power production are suitable also support low-temperature uses such as direct heating.

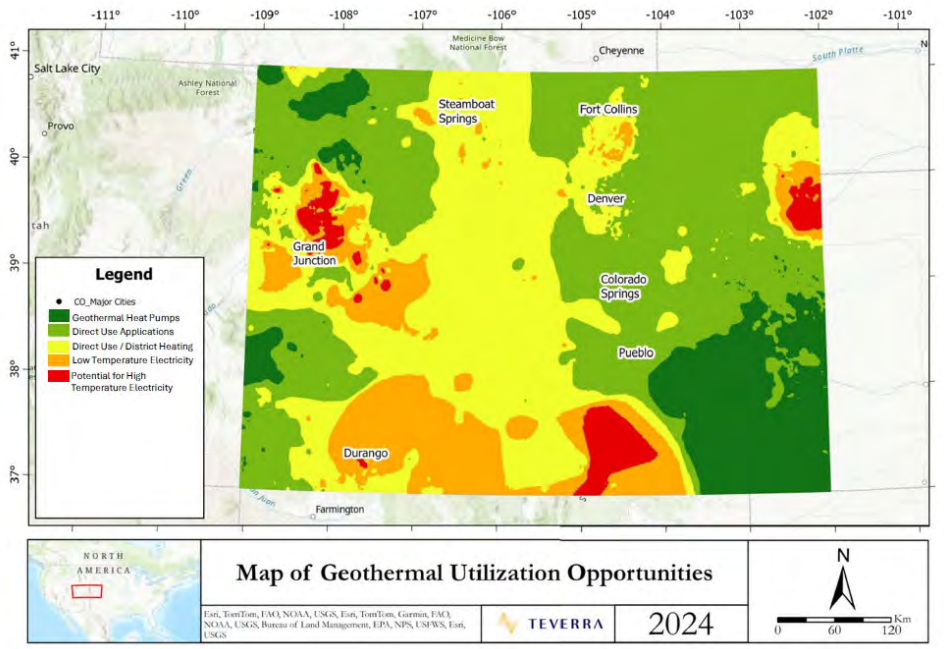

Figure 11: Map that indicates the geothermal utilization opportunities in Colorado. The uses here are cumulative.

In Figure 11, areas shaded dark green are most conducive to geothermal heat pumps due to their very low-temperature thermal resources. Light green and yellow areas are well-suited for direct use applications and thermal energy networks. Orange areas indicate potential for low-temperature electricity generation alongside direct use applications. Regions marked in red show potential for high-temperature power generation, depending on drilling depth, and also support low-temperature power generation, direct use, and thermal energy networks.

Energy storage solutions are particularly applicable in sedimentary basins where geological reservoirs are widespread and accessible. This framework helps prioritize geothermal utilization strategies tailored to the varying thermal characteristics and resource potentials across Colorado.

5. Conclusions

This statewide geothermal resource assessment was completed to comprehensively understand Colorado's geothermal potential, comparing current findings with historical knowledge. The assessment utilized oil and gas well data, equilibrium temperature logs and geothermal exploration data, and thermal spring geothermometry to analyze the thermal regime, revealing localized areas with high-temperature geothermal reservoir potential, though these are not widespread across the state. Instead, much of Colorado's geothermal resource at viable depths falls within the low-temperature range (< 180°C or < 356°F), with isolated pockets of higher temperatures exceeding 180°C (356°F).

Comparing this study to previous work completed by CGS reveals that the updated assessment and corresponding maps are largely consistent with previous research, yet benefit from enhanced data inputs that increase confidence and provide greater detail in certain regions. Although minor discrepancies may arise from differences in data sources or methodologies used for mapping and

assessment, the overall trends remain unchanged. The additional data significantly enriches our understanding and characterization of Colorado's geology and geothermal resources, offering deeper insights into potential energy opportunities across the state.

Given the geothermal resource of Colorado, there are many options for utilization. The geothermal industry typically targets temperatures above 180°C for power production, highlighting potential areas for high-temperature geothermal exploration in Colorado. However, present opportunities lie predominantly in utilizing low-temperature geothermal energy, supported by technologies such as direct use applications, thermal energy networks, and binary power production units. Direct use technologies, particularly suitable near population centers, offer prospects for heating buildings, homes, manufacturing facilities, and greenhouses. Furthermore, the repurposing of existing wells, especially those in the oil and gas sector, presents over 2,000 potential sites for generating geothermal electricity using binary systems.

Overall, the comprehensive study provides deeper insights into Colorado's geology and geothermal resources, offering a foundation for future exploration and utilization strategies in the state.

Acknowledgement

This project was funded by the Colorado Energy and Carbon Management Commission. A special acknowledgement to the project leaders Michael Rigby, John Morgan, and Marie Hoerner.

All data used in this project came from the Colorado Geological Society. Paul Morgan and Nathan Rogers were integral to organizing and providing data for this study.

Keywords

Sedimentary basins, reservoir characterization, Great Basin, exploration

ABSTRACT

Sedimentary geothermal resources are an emerging resource play in many basins in the United States. While many different exploration plays have been recognized as having sedimentary geothermal potential, detailed studies that refine drilling targets and characterize geothermal reservoirs are lacking. Because sedimentary basins have been the focus of decades of successful and unsuccessful petroleum exploration, many of these basins contain a wealth of legacy data that can be used for geothermal exploration. Here, we present a case study from the Great Salt Lake (GSL) basin where legacy data is integrated with outcrop analysis to characterize a deep sedimentary geothermal reservoir. Seismic structural cross sections, petrophysical data from legacy oil and gas wells, and outcrop analog studies are integrated to define potential drilling targets and inform techno-economic modeling and development concepts.

Oil and gas companies exploring the GSL basin in the 1970's and 1980's conducted extensive seismic surveys and exploration drilling. Structural mapping from regional gravity and seismic reflection data defines major extensional faults and three major sub-basins where sedimentary geothermal reservoirs are buried by 2–3 km (6,561–9,842 ft) of Miocene-recent sediment. These are the Gunnison Bay Basin, the Gilbert Bay Basin, and the Willard Bay Basin.

Exploration well data is used to build a stratigraphic framework and characterize potential geothermal reservoirs. The most prospective reservoirs are fractured Paleozoic carbonates, which reach temperatures greater than 150 °C (302 °F) at 3 km (9,842 ft) depth in the Gunnison Bay basin. Stratigraphic units of interest are the Ordovician Fish Haven Dolomite, Silurian Laketown Dolomite, and the Cambrian Nounan and St. Charles Dolomites. These formations which are massively bedded, commonly vuggy, and pervasively fractured. Fractures measured in Paleozoic carbonates in the Promontory Mountains show two consistent subvertical fracture sets oriented E-W and NNE-SSW.

Analysis of petrophysical logs indicate porous and permeable reservoirs in carbonate units below the 150 °C (302 °F) isotherm. Conservative estimates of log-derived porosity for these carbonates

varies between 5-15%, which is higher than many analogous fractured commercial petroleum reservoirs and comparable to other sedimentary geothermal developments.

The reservoir characterization is used to generate techno-economic models of conceptual sedimentary geothermal development and highlight fairways where sedimentary resources could be developed. While much of the GSL basin will be difficult to develop due to sensitive environmental issues or the challenges of drilling and developing under the lake, the northern extent of the Willard Bay Basin is onshore, above the GSL high stand and represents a favorable greenfield sedimentary geothermal exploration target area with no deep well penetrations. The approach detailed here is also beneficial as it can be applied to other sedimentary reservoirs and plays in basins containing legacy oil and gas exploration data.

1. Introduction

Geothermal exploration and development are currently expanding in the United States. New geothermal play concepts are being tested that were not previously considered economic (Norbeck and Latimer, 2023; Marcia, 2024). These exploration plays include sedimentary and enhanced geothermal systems (EGS), which typically have different geologic characteristics from conventional hydrothermal exploration plays. By most classifications, the vast majority of the operating geothermal power plants in the United States are conventional hydrothermal systems, except for sedimentary developments in the Salton Sea (Ramirez et al., 2023) and a single EGS production well near Blue Mountain, NV that began production in late 2023 (Fercho, 2023). A sedimentary geothermal play is currently under development by DEEP Earth Energy in the Williston Basin, in the province of Saskatchewan in Canada (Marcia, 2024). At that development the target reservoir is the Cambrian Deadwood formation that is between 120–125 °C (248–257 °F) at ~3.5 km (11,483 ft) depth and will be developed with horizontal wells that have 2 km (6,561 ft) long lateral sections.

These new EGS and sedimentary geothermal projects have opened many new basins to geothermal exploration. Of particular interest are basins where oil and gas exploration (both successful and not) has occurred, because those basins contain legacy data that can be re-used for geothermal exploration in a cost-effective way. In this study we present a workflow for how legacy petroleum exploration data can be used to detail play fairways, identify drilling targets, and characterize potential geothermal reservoirs. We use the Great Salt Lake (GSL) basin as a case study for this workflow.

The GSL basin has been identified as an area with the potential of hosting geothermal resources capable of power generation (Allis, et al., 2011; 2013; Blackett et al., 2018). The basin lies within a region of elevated heat flow in the Basin and Range province (Figure 1), which is the region containing most of the commercial power geothermal plants in the United States. In the GSL basin, the presence of elevated temperatures from oil and gas wells, in conjunction with deep, extensional Neogene sedimentary basins, has led several researchers to point out the potential for stratigraphic geothermal reservoirs there (Allis, et al., 2011; 2013; Edwards and Chapman, 2013; Blackett et al., 2018). While these previous studies have highlighted the high-level geothermal potential of the basin, none of them have detailed the various geothermal exploration concepts or characterized the potential geothermal reservoirs. Here, we re-examine and synthesize the available geothermal, geophysical, and geologic data in the GSL basin to create and describe potential exploration plays

and drilling targets in the basin, characterize the reservoir, and create a feasible economic model for development.

2. Geologic Setting

The geologic setting of the GSL basin has the potential to host conventional hydrothermal or sedimentary geothermal systems. The oldest rocks in the basin are Precambrian basement that unconformably underlie passive margin Paleozoic carbonates (Hintze, 1988). During the Sevier Orogeny, these rocks were folded and thrusted. The overthrusted structures can be observed in ranges like the Promontory Range (Crittenden, 1988) and in deep seismic sections (Velasco et al., 2010). Basin and Range extension began during the Neogene time and continues to the present day. This extension formed several deep sedimentary basins that are contained within the larger GSL basin. These basins are filled with alluvial and lacustrine sediments, with interbedded volcanics (Bortz, 1987).

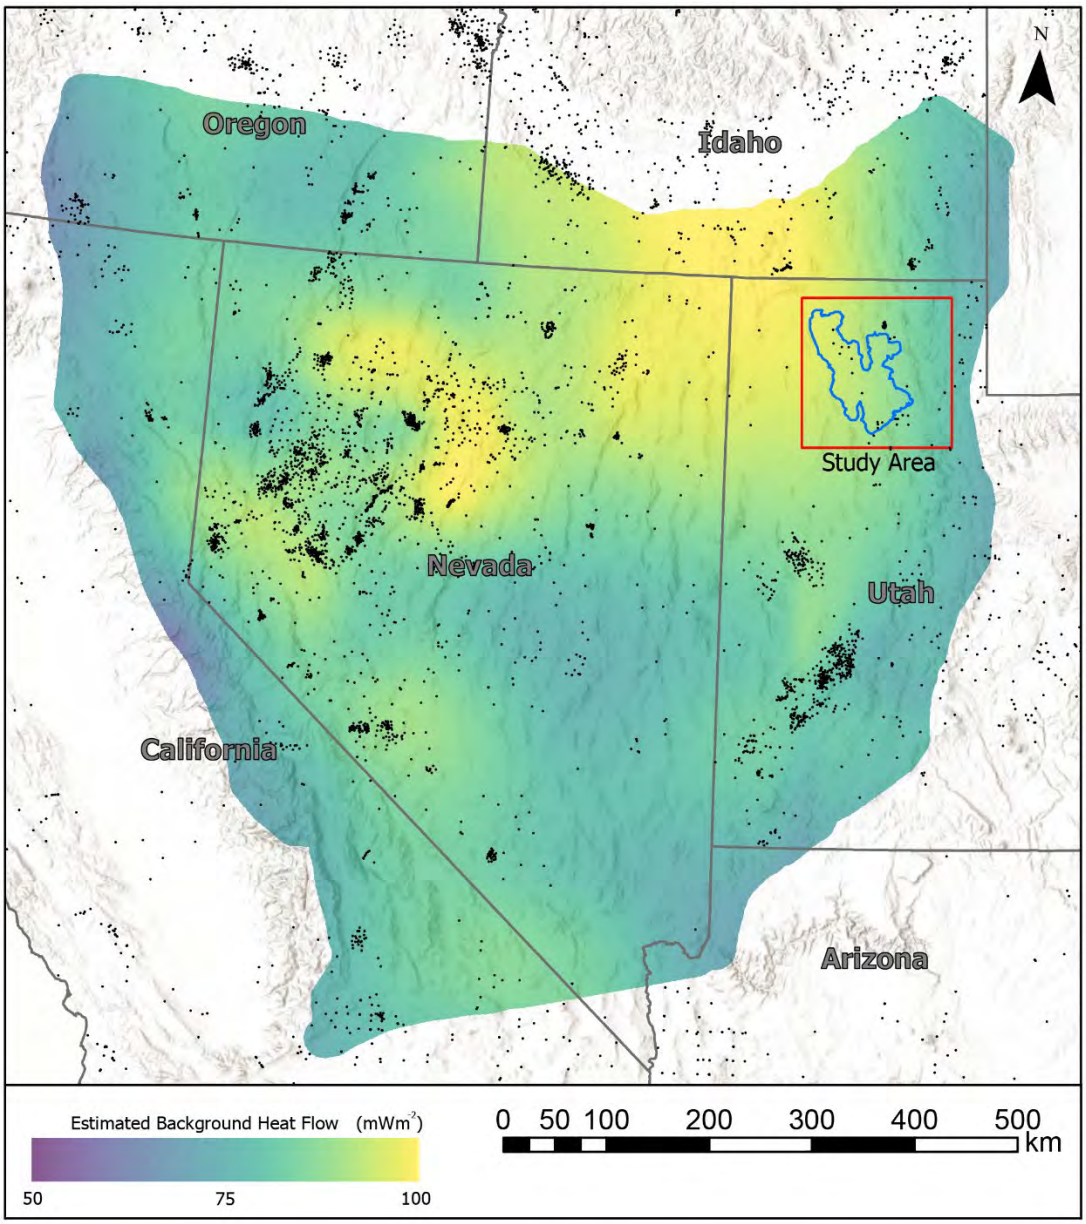

Figure 1: Great Basin estimated background heat flow map (mW/m^2) from DeAngelo et al. (2022) showing thermal data points (black dots) with the Great Salt Lake and study area outlined. The GSL Basin lies within an area of higher heat flow within Northern Utah.

3. Gravity

An isostatic gravity map for the GSL basin study area (Figure 2) was created from a public gravity dataset layer originally part of a larger Great Basin geothermal study (Glen et al, 2022). Gravity lows are generally interpreted to represent basins with sedimentary fill, due to the lower density of basin sediments compared with basement rocks (Hinze, et al., 2013; Paterson and Reeves, 1985). In the GSL area, several sub-basins can be delineated by the gravity data, which are named the

Gunnison Bay Basin (northeast), Gilbert Bay Basin (south), and Willard Bay Basin (northwest). These basins appear to be asymmetric, with interpreted N-S trending basin-bounding faults that correlate with many of the mapped quaternary faults across the basin (Bowman and Arabasz, 2017).

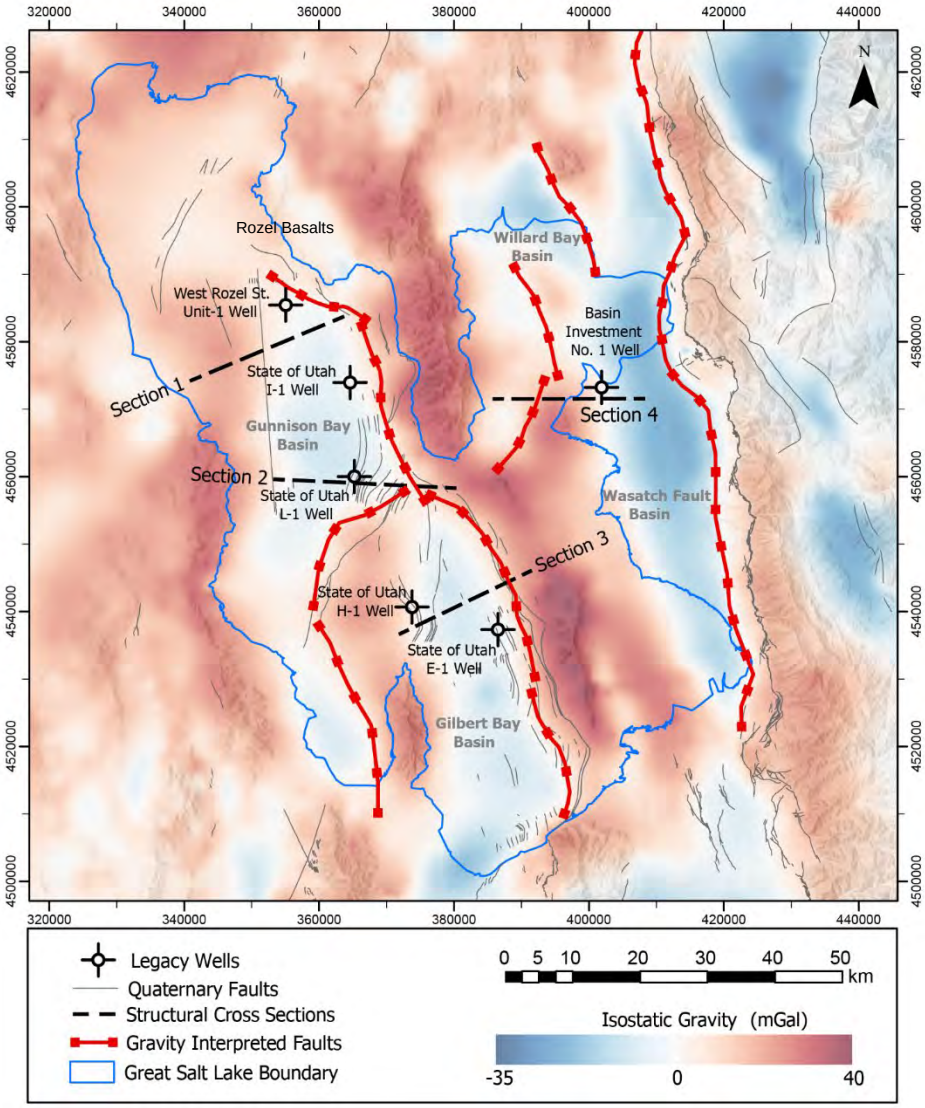

Figure 2: Isostatic gravity structure map encompassing the larger GSL basin showing the location of major sub-basins, structural elements, structural cross sections, and relevant deep oil and gas wells (source of gravity data from Glen et al., 2022). The Great Salt Lake shoreline is outlined by the solid blue line. The thick dashed black lines show the locations of legacy seismic lines and cross sections in this study. The thin grey lines represent quaternary faults from the Utah Geological Survey quaternary fault database (Bowman and Arabasz, 2017). Gravity lows are interpreted to represent major sub-basins. The red lines represent interpretations of major basin bounding faults from gravity data. There are three major sub-basins investigated in this study, the Gunnison Bay, Gilbert Bay, and Willard Bay basins. The depths and general structure of these sub-basins are also constrained by legacy deep oil and gas wells and seismic reflection data. These basins are useful analogs for other nearby sub-basins, like the Wasatch Fault Basin, that are less data constrained.

The gravity high in the northern part of the Gunnison Basin and extending onshore towards the Promontory mountains is due to the presence of the Rozel Basalts. These basalts were encountered in several oil and gas wells and are the reservoir rock for the only producing oil fields in the basin (Bortz, 1987).

4. Temperature

Several legacy deep oil and gas wells in the study area have temperature surveys that were used to understand variations in regional conductive geothermal gradients. These wells extend from 1,500 m (4,921 ft) to over 3,200 m (10,498 ft). The maximum temperature encountered is over 210 °C (410 °F) at the bottom of State of Utah I-1 well (Figure 3), which is in the center of the Gunnison Bay Basin (Figure 2). The State of Utah L-1 well, at the southern end of the Gunnison Basin reaches 150 °C (302 °F), which is commonly used as a threshold for economic power production in the Great Basin. The State of Utah E-1 well in the Gilbert Bay Basin reaches temperatures over 120 °C (248 °F) but is likely not in the hottest part of the basin. The well is located close to a basin-bounding fault (Figure 4) and is missing the Paleozoic carbonate section, which appears to be faulted out due to ~5 km (16,404 ft) of heave on the fault (Figures 4 & 5). There were no temperature surveys in the public database from the Willard Bay Basin.

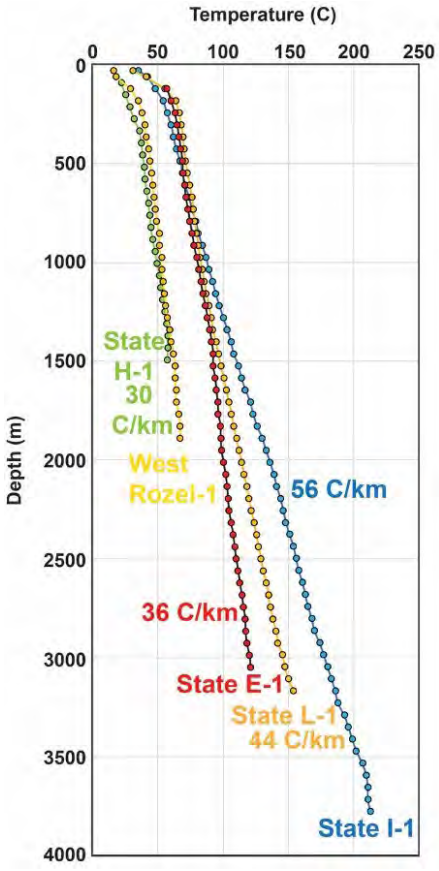

Figure 3: Temperature profiles from deep oil and gas wells in the Gunnison Bay and Gilbert Bay basins shown in Figure 2 (UDOGM, 2023). The wells in the Gunnison Bay basin have higher geothermal gradients and are the only wells that reach over 150 °C (302 °F) within the well's total depth. These profiles demonstrate a conductive geothermal gradient, and none of the examined wells encountered fault-hosted convection, even though the State of Utah E-1 well drilled through a large basin-bounding normal fault (Figure 4).

4. Seismic Reflection Profiles

Newly interpreted line drawings from published seismic sections across the major extensional basins in the Great Salt Lake area are shown in Figure 4. These seismic lines detail the major structural and stratigraphic features relevant to geothermal exploration. The deep petroleum exploration wells provide stratigraphic control on these structural interpretations. The seismic interpretations show dominantly asymmetric basins with west-dipping listric basin-bounding normal faults. Younger strata thicken significantly towards the fault in the hanging-wall, indicating these are growth strata deposited synchronously with fault activity and span a period of Miocene to recent time. The seismic line through the Willard Bay basin (Section 4) shows a buried horst block bounded by oppositely dipping extensional faults on both sides. The basin fill here is generally less thick due to small throw on the faults. This is consistent with the gravity map in Figure 2, which shows a gravity high across this seismic line. Figure 2 also shows a gravity low north of the Section 4 seismic profile, where the basin structure is likely more similar to the structure observed in the Gunnison Bay seismic profiles (Sections 1 & 2).

Synthetic and antithetic faults are common in hanging-wall anticlines; however, these faults primarily are contained within the growth strata units, and commonly do not reach the deeper Paleozoic carbonates or basin-bounding fault (Figure 4- Sections 2 & 3). Because of this, these faults are unlikely to host deep fluid heat convection. This could be significant since upflow along deep faults is thought to feed the sedimentary systems at the Brawley, Ormesa, and Salton Sea sedimentary geothermal fields, even though those fields produce from primary porosity and permeability in place (Ramirez et al., 2023).

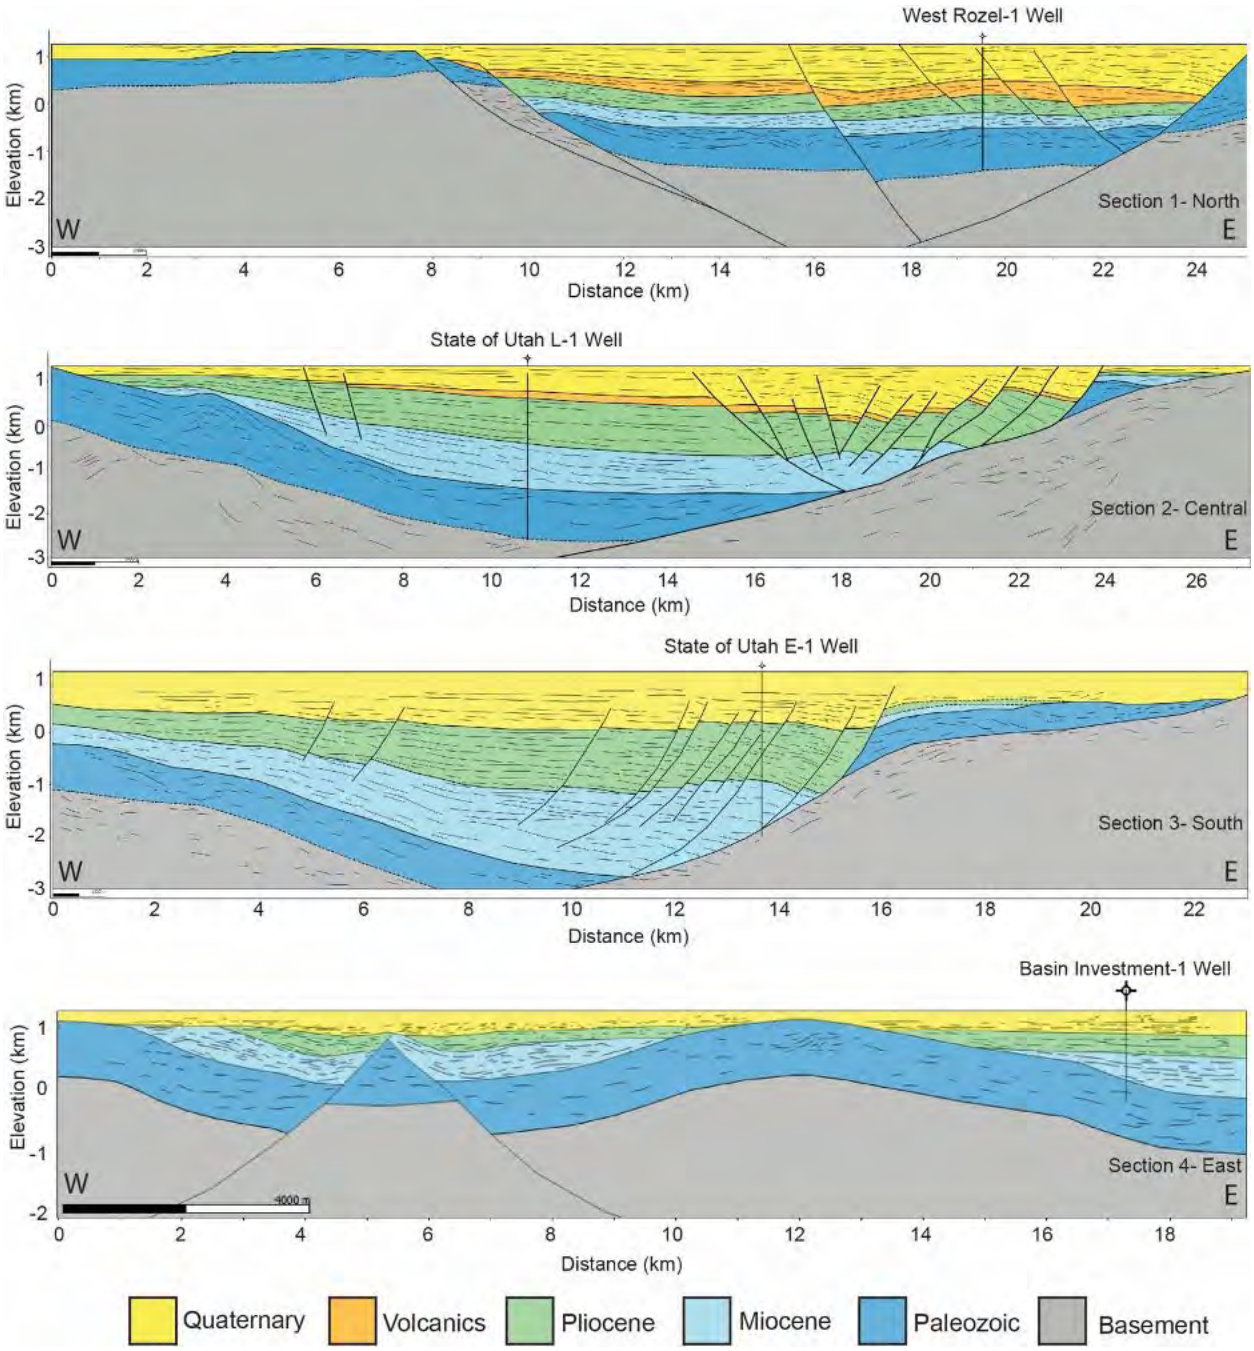

Figure 4: Line drawing interpretations of seismic reflection sections across the GSL basin. Locations of sections are shown in Figure 2. Nearby offset wells projected onto each section were used to define stratigraphic horizons. (A) Section across the northern Gunnison Bay basin, interpreted from Bortz (1987). (B) Section across the southern Gunnison Bay basin, interpreted from Velasco (2009). (C) Section across the Gilbert Bay basin, interpreted from Petropoulos (1994). (D) Section across the Willard Bay basin, interpreted from McNeil and Smith (1991).

5. Geothermal Reservoirs

5.1 Basin Stratigraphic Framework

Mud log reports from drilling were used to interpret major lithostratigraphic units in deep wells and correlate them across the basin (Figure 5). The uppermost unit is interpreted to be quaternary in age and consists almost entirely of fine-grained siltstones and shales. In the northern part of the basin, there are basalts underlying these fine-grained clastic rocks. These fractured basalts are part of the Rozel volcanic field and are the reservoir rocks for the legacy Rozel oil field (Bortz, 1987; Figure 2). Below the mudstones is a major lithostratigraphic unit that is ~500–700 m (1,640–2,296 ft) thick and is interpreted to be Pliocene in age. This unit consists mostly of shale with some thin sandstone beds. In the State of Utah E-1 well in the southern part of the study area, the top of this unit has a several hundred-meter-thick sandstone package. Underlying the Pliocene clastic rocks is a unit of interbedded shales and carbonates interpreted to be Miocene in age. Individual carbonate beds tend to be a few to tens of meters (10–100 ft) thick according to mud log reports. The basal stratigraphic unit consists of massively bedded limestones and dolomites. Mapping in the nearby Promontory Mountains (Crittenden, 1988) indicates these carbonates range from Cambrian-Pennsylvanian age.

These lithostratigraphic units also correlate to major stratigraphic packages observed in the regional seismic lines (Figure 4). The Miocene-Quaternary units exhibit growth geometries consistent with active extensional faulting during that period.

By integrating temperature data with this stratigraphic framework, potential geothermal reservoirs can be evaluated. The Miocene-Quaternary basin-fill sand and carbonate layers are likely too thin to be commercial reservoirs except for the 500 m (1,640 ft) thick sandstone unit encountered in the Gilbert Bay Basin. However, this sand is shallow and likely only ~60 °C (140 °F), far below the threshold needed for geothermal power production. The most prospective lithostratigraphic units in terms of temperature and lithology are the Paleozoic carbonates, which are especially prospective in the Gunnison Bay Basin, where these units are thick and reach temperatures over 200 °C (392 °F).

It is assumed that sedimentary geothermal reservoirs that are thick and not interbedded with shales are more desirable, because they will likely be more efficient at sweeping heat from a larger area when production wells are operating. The detailed geologic mapping by Crittenden (1988) in the Promontory Mountains identifies the Upper Cambrian Nounan and St. Charles Dolomites, the Ordovician Fish Haven Dolomite, and the Silurian Laketown Dolomite as carbonate units that are thick and massively bedded with few or no shaly interbeds. The Fish Haven and Laketown formations are described as commonly vuggy and all these units are described as having extensive fracture development, which can enhance reservoir quality in carbonate reservoirs.

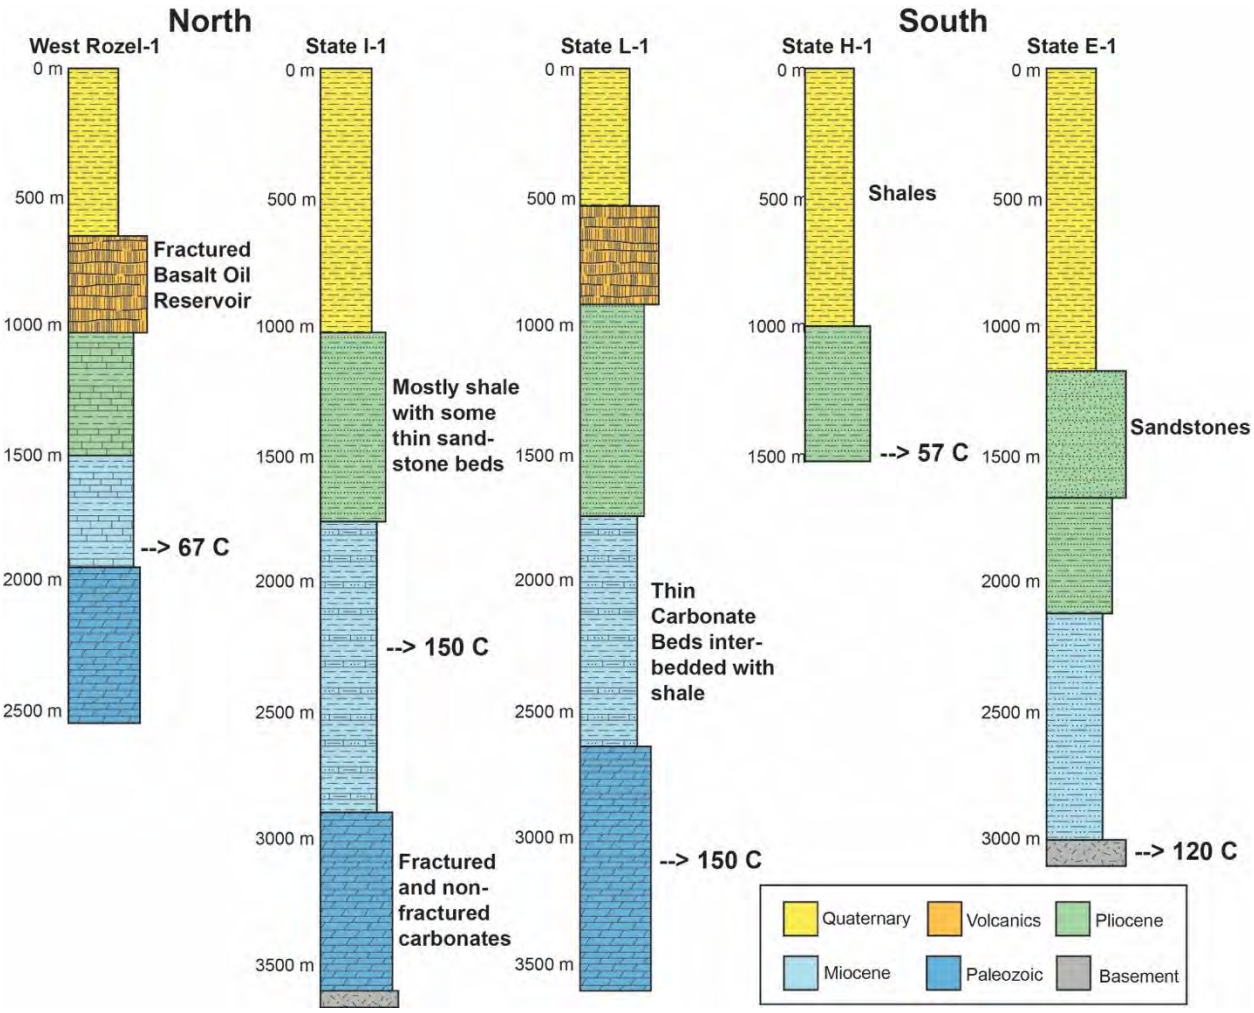

Figure 5: Stratigraphic cross section of deep oil and gas wells shown in Figure 2 showing the major lithostratigraphic framework of the GSL basin. Some temperature benchmarks from the temperature logs in Figure 3 are also shown.

5.2 Fracture Characterization

Naturally occurring fractures often play a critical role in contributing to porosity and permeability in carbonate reservoirs. Outcrop analysis of fractures in potential reservoir units was conducted to understand possible fracture density in the geothermal reservoir. The Paleozoic carbonate units that are encountered in the deep GSL basin wells are exposed in the Promontory Range, which is a major N-S trending horst block that separates the Gunnison and Willard Bay basins (Figure 2). Outcrops along the northern edge of the Promontory Range were visited and characterized for their potential as subsurface geothermal reservoirs (Figure 6).

Outcrops consisted of blue-gray, medium thickly bedded, heavily fractured limestones and dolostones interbedded with thin siltstones, mudstones, and cherts (Figure 6A). Fractures observed were closely spaced, with two primary fracture orientations measured: a generally E-W subvertical fracture set and a NNE-SSW trending subvertical fracture set (Figure 6B). These orientations were

consistent across the range and on oppositely dipping limbs of a small anticline, suggesting fracture development occurred after overthrusting of the Paleozoic units and could be regionally continuous. While some fractures were calcite filled, many were open with apertures ranging from <1–10mm (0.04–0.4 inches).

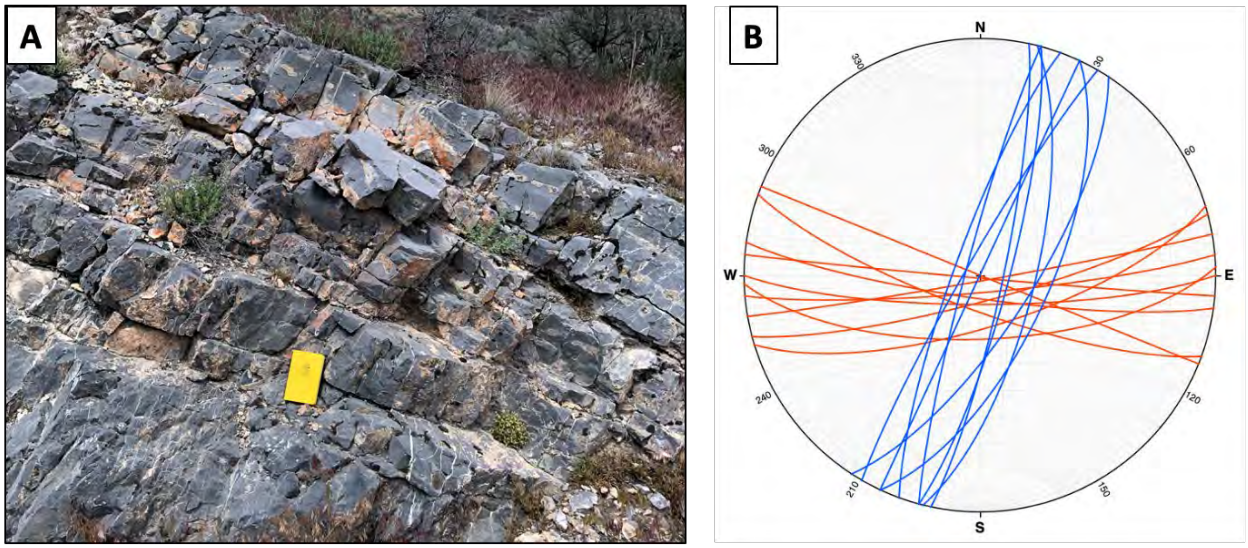

Figure 6: (A) Outcrop image of a fractured carbonate reservoir analog exposed along the northern edge of the Promontory Range. The image showed parallel, closely spaced fractures; some of which are calcite filled, while others are open. (B) Lower-hemisphere stereonet of measured fracture planes, consisting of an E-W trending subvertical set (red) and an NNE-SSW trending subvertical set (blue).

5.3 Well Log Interpretation and Reservoir Properties

Reservoir properties of Paleozoic carbonate units were investigated using well logs for the deep wells in the basin (UDOGM, 2023). Data availability for each well varies, but most of the wells in the GSL basin have mud logs and gamma-ray logs, and some have additional density, neutron porosity, resistivity, and/or sonic logs in raster log format. Figure 7 shows the typical log responses for a ~1,000 m (3,280 ft) of the State of Utah I-1 well (Indian Cove) well beginning near the top of the Paleozoic Carbonates. This well had the highest bottom-hole temperature of the wells in this study, with a temperature > 200 °C (392 °F).

Based on the well data, the Paleozoic Carbonates can be split into five stratigraphic units:

(1) 2,895–3,109 m (9,500–10,200 ft)- Characterized by medium and variable gamma ray, highly variable neutron porosity, medium and variable resistivity, and a caliper log with large spikes suggesting borehole cave-ins. Mud log reports interbedded dolomite/limestone and shales/anhydrites. Based on the mud log and well log signatures, it appears that the alternating carbonate/shale successions are thin to medium bedded, with the only thick carbonate unit being a massive 30 m (100 ft) dolomite interpreted at ~2,933 m (9,625 ft). The porous and conductive zones also correlate with caliper spikes and shale units on the mud log, suggesting the interbedded carbonates here are likely tight with low porosity.
(2) 3,109–3,127 m (10,200–10,260 ft)- Characterized by high gamma ray, high porosity, and low resistivity. Mud log reports a ~18 m (60 ft) section of shale.

(3) 3,127–3,352 m (10,260–11,000 ft)- Characterized by generally low gamma ray with short spikes, low porosity, and low resistivity. Mud log reports interbedded dolomite/limestones and shales, but with generally fewer and thinner shale units. Spikes in gamma, porosity, and resistivity are correlative and likely indicate the presence of shale units.
(4) 3,352–3,566 m (11,000–11,700 ft)- Characterized by low gamma ray with more infrequent but larger spikes, low and less variable neutron porosity, and low variable resistivity. Mud log reports primarily dolomite and limestones with few shales. Carbonates could be muddy, contributing to spikes in the log data.
(5) 3,566–3,672 m (11,7001–2,050 ft)- Characterized by low gamma ray, elevated neutron porosity, and low resistivity. Mud log reports dolomite with few to no interbedded shales. The top of the unit has a porosity spike that correlates with resistivity and caliper log lows. This suggests a major porous and permeable zone possibly capable of hosting a geothermal reservoir. Below this is another smaller porosity high that correlates with a conductive zone but is not accompanied by a significant change in the caliper log.

Unit 5 is interpreted to be the primary drilling target for geothermal reservoir exploration and the depths and temperatures associated with that unit are included in the economic models for this study. The measured temperature at the top of this unit is 210 °C (410 °F) and this prospective reservoir correlates with a small section of an isothermal temperature gradient in the temperature log (Figure 3).

The observed reservoir properties compare favorably with analogous systems for both petroleum and geothermal production. Log-derived porosity values for the carbonate reservoir in State of Utah I-1 well are shown in Figure 8 and compared with a potential analog reservoir from Railroad Valley, Nevada (Anna et al., 2007). The analog reservoir is an actively producing oil and gas reservoir and consists of Paleozoic carbonates. The Nevada reservoir has low matrix porosity and natural fractures are thought to be significant contributors to fluid flow.

Another analogous reservoir is the Cambro-Ordovician Deadwood Formation in the Williston Basin of Canada and North Dakota (USA) where DEEP Earth Energy is actively developing a sedimentary basin geothermal power project. The Deadwood Formation there has porosity ranging from 10-16% with 260 md permeability (Marcia, 2024) at 3,500 m (11,483 ft) depth. The DEEP Earth team has drilled several wells, performed long-term flow tests and plan to drill production wells with 2 km (6,561 ft) lateral sections that can sustain flow rates >1,000 gal/min with these reservoir properties (Marcia, 2024).

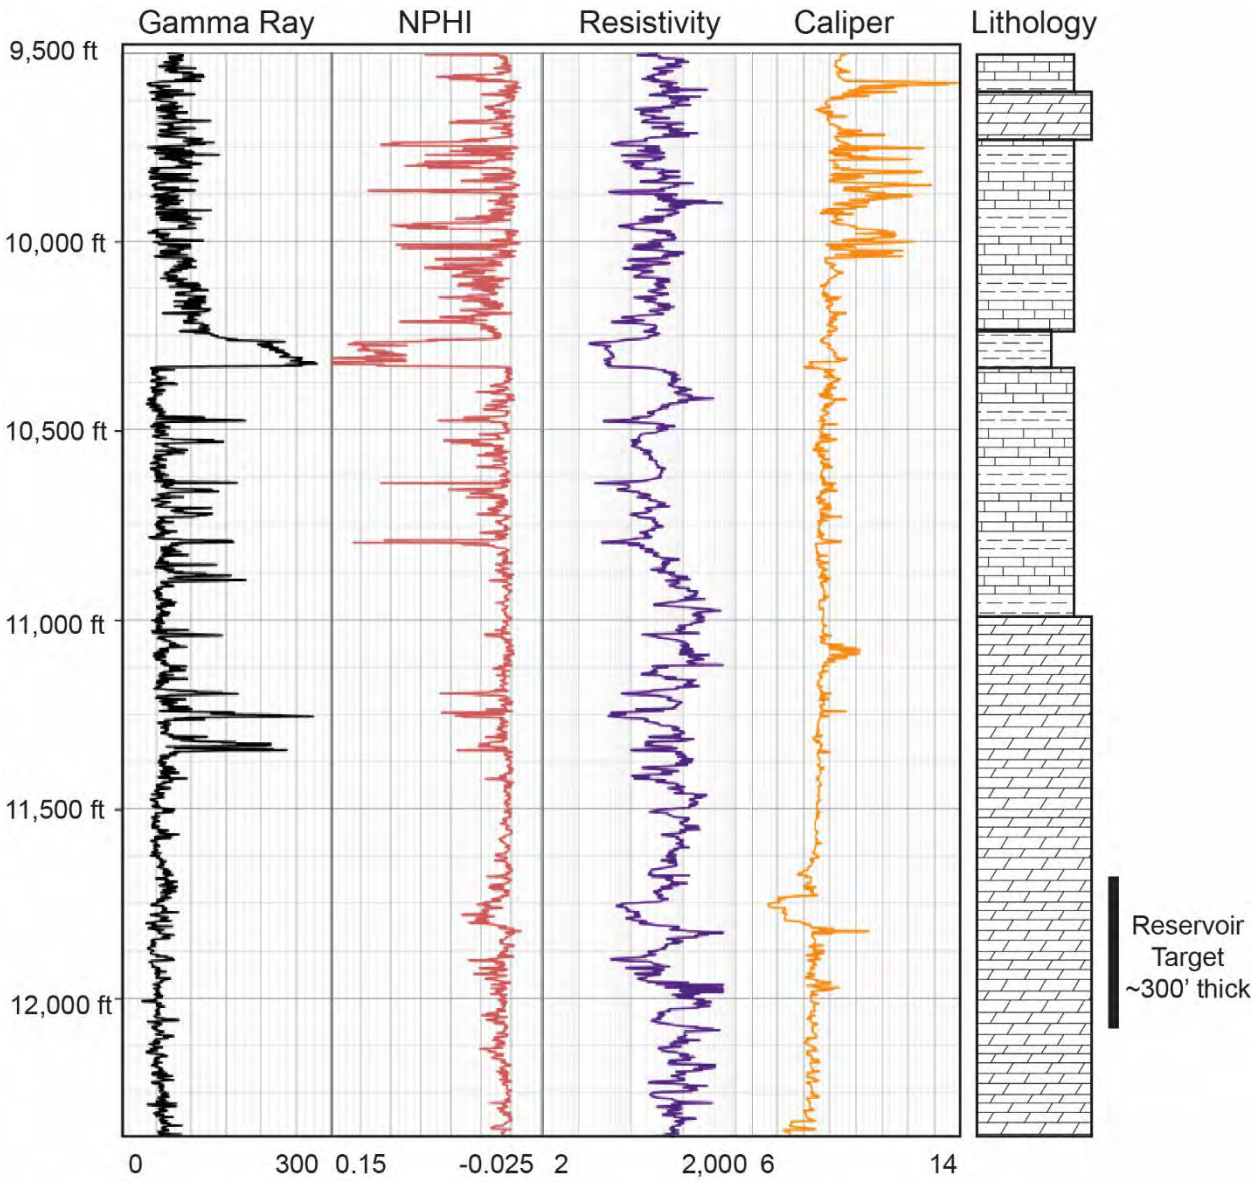

Figure 7: Example of standard well log responses and mud-log lithology from a selected interval in the State of Utah I-1 well. This 853 m (2,800 ft) section of well can be separated into 5 major lithologic units that have distinctive log responses.

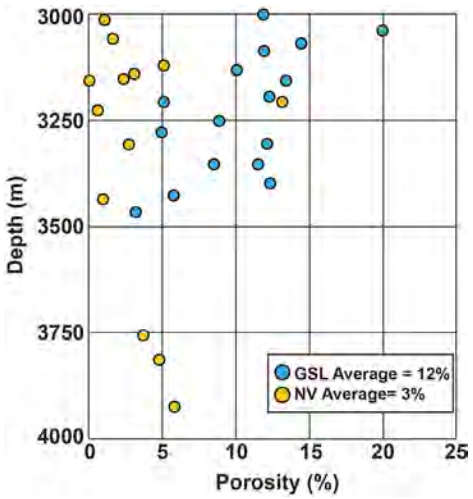

Figure 8: Log-derived porosity depth plot for Paleozoic carbonates in the State of Utah I-1 well (blue) and Railroad Valley, Nevada producing oil carbonate reservoirs (orange) (Anna et al., 2007) which serve a potential analog. Porosity values from Nevada are obtained from core, which might explain some of the measurement difference.

6. Discussion

6.1 Techno-economic Modeling

The geologic characterization described here can be used to model the economics of different development scenarios. NREL's Geophires techno-economic modeling tool (Beckers et al., 2019) was used to model the power production and levelized cost of electricity (LCOE) of a conceptual sedimentary geothermal development. For the scenario shown in Figure 9, a development consisting of 10 production wells and 8 injections wells at a depth of 3.5 km (11,483 ft) was modeled. For wells flowing with a pump at 1250 gal/min, the development would produce 56 megawatt electric (MWe) of net power with an LCOE of $63/MWh. While the modeled reservoir can handle an increased flow rate, the system becomes increasingly inefficient, relying on a large parasitic load to power downhole pumps. This is an example of one development scenario, but it demonstrates that reasonable reservoir inputs provide modeled outputs for power generation per well and LCOE that are economic in most modern offtake markets.

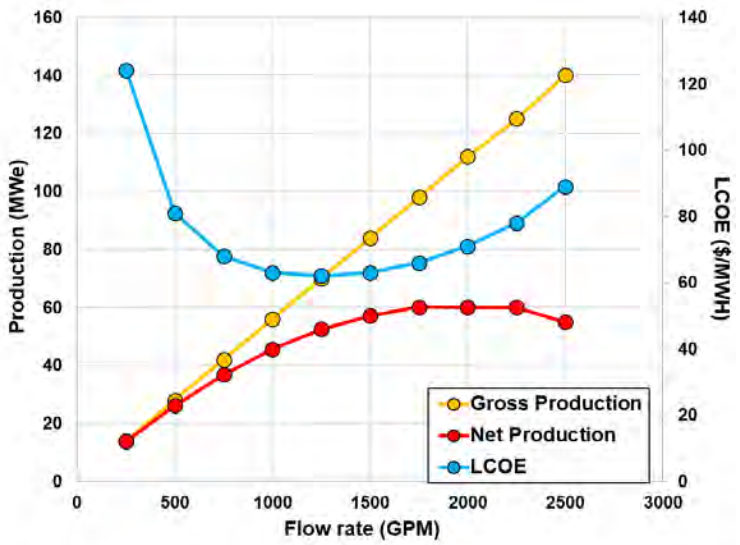

Figure 9: Output from a techno-economic model using the Geophires geothermal economic modeling tool (Beckers and McCabe., 2019) showing gross power (orange) net power (red) and levelized cost of electricity (LCOE; blue). This development concept is for a development consisting of 10 production wells and 8 injection wells at 3.5 km (11,483 ft) depth with a production temperature of 210 °C (410 °F).

6.2 Environmental Considerations & Development Concepts

The Great Salt Lake is a critical environmental resource to the state of Utah. Recently, the decreasing lake levels have brought increased attention to the role the lake plays in the local ecosystem and economy. Due to the environmental sensitivity of the lake, it is unlikely that geothermal development can be pursued in any part of the lake below the historical lake level high stand. While it might be intriguing to attempt to develop the sedimentary geothermal reservoirs under the lake from deviated wells drilled from onshore (i.e. drilling into the East Side of Gunnison Bay Basin from Western side of Promontory Mountains- Figure 2), the basin bounding faults have several miles of heave as observed in the seismic reflection lines (Figure 4). Reaching the carbonate drilling targets would likely require extended-reach drilling, which is a costly drilling technique that would likely make a geothermal development uneconomic.

Another approach would be to explore for and develop sedimentary geothermal reservoirs in areas of the basin that are above the Great Salt Lake shoreline high stand and are less environmentally sensitive. One such example is the northern end of the Willard Bay Basin, where a gravity low suggests a deep sub-basin (Figure 2). Unfortunately, there are no deep wells drilled in this sub-basin, but the insights gained from the offset wells in other parts of the basin, as detailed in this study, can be applied to exploration efforts in this area.

Our suggestion for successful exploration in an area like the onshore portion of the Willard Bay Basin would involve the following: collection of 2D seismic reflection profiles, magnetic, electromagnetic, and gravity data to constrain basin geometry; detailed studies on cuttings and core from nearby wells in adjacent basins that can be used as analogues; shallow and intermediate-depth temperature data; modeling heat flow and reservoir properties using data constrained from offset wells in the basin; and outcrop studies of potential reservoir hosting lithologies in the adjacent ranges to further help constrain fractures, and reservoir properties. These data would be

used to site a deep vertical exploration well that would be designed in a way so that it could be re-entered and side-tracked for a lateral leg in a proven reservoir.

One of the innovations of DEEP Earth Energy's Williston Basin sedimentary geothermal project is their well field layout, termed a "rib-cage" wellfield, which is a novel development concept for geothermal drilling and development. The concept drills a series of alternating production wells and injection wells, at regular intervals (e.g. 0.5 km or 1,640 ft), with the lateral legs parallel to each other. From each well pad, a twin well would be drilled in the opposite direction to minimize surface disturbance, permitting, and infrastructure. For the Northern Willard Bay development example in this study, a rib-cage geometry would work well, with the lateral legs oriented perpendicular to one of the two primary fracture sets in Figure 6 to maximize intersections with fracture systems that could connect between injection and production wells.

7. Conclusions

Sedimentary geothermal reservoirs are emerging geothermal resource plays in the United States and merit detailed geologic characterization to choose the right development location and concept. In many basins where oil and gas exploration has occurred, there is a wealth of legacy data that is in the public domain or can be obtained cheaply. We used an example from the Great Salt Lake Basin, Utah to show how this legacy data can be used to characterize a potential geothermal reservoir, determine drill targets, and model the economics of potential developments in a greenfield setting.

ABSTRACT

The INnovative Geothermal Exploration through Novel Investigations Of Undiscovered Systems (INGENIOUS) project aims to discover new, economically viable hidden geothermal systems in the Great Basin region by building on previous work in play fairway analysis and machine learning. A key objective of this project is to develop an exploration workflow to reduce geothermal exploration risks for hidden geothermal systems. A single preliminary play fairway workflow was developed from the assessment of the regional INGENIOUS geological, geophysical, and geochemical datasets. This workflow provided new preliminary predictive geothermal fairway maps for the INGENIOUS study area, which encompasses most of Nevada, western Utah, southern Idaho, southeastern Oregon, and easternmost California. However, a recent study (incorporating machine learning techniques) of a portion of Nevada identified four geologic domains and determined that the relative importance of individual datasets or features as indicators of geothermal potential may differ across these domains. The INGENIOUS study area includes a much larger and more geologically diverse region; therefore, additional geologic domains or sub-regions are expected. To assess the sub-regions in the INGENIOUS study area, principal component analysis and k-means clustering were applied. Preliminary results indicate that the INGENIOUS regional data cluster into groups that relate to different geologic domains in the Great Basin region. These include domains such as the Walker Lane, extensional western Great Basin region, broad lower strain region in the eastern Great Basin of western Utah and eastern Nevada, Quaternary volcanic fields, and the area adjacent to the Snake River Plain. These clusters are assessed to determine the key geologic drivers of the identified clusters. Understanding this variability can provide key insights for the exploration and characterization of hidden geothermal systems in the Great Basin region and could indicate the need to develop multiple geothermal conceptual models and play fairway workflows for the INGENIOUS study area.

1. Introduction

The Great Basin region in the western United States (Figure 1) is a world-class geothermal province. In Nevada alone, the installed geothermal capacity is reported to be 786 MWe (Muntean

et al., 2021), and researchers have proposed that geothermal potential could be much higher (e.g., Williams et al., 2009). Many of the historical discoveries of conventional hydrothermal systems in the Great Basin region have surface thermal features. However, future geothermal potential is thought to lie mostly in hidden or blind geothermal systems that lack surface thermal features such as hot springs (e.g., Coolbaugh et al., 2007; Faulds et al., 2019). In recent years, there has been an extensive effort to identify and develop more hidden geothermal systems (e.g., Faulds and Hinz, 2015; Faulds et al., 2021 a,b,c; Craig et al., 2021). The INnovative Geothermal Exploration through Novel Investigations Of Undiscovered Systems (INGENIOUS) project aims to discover new, economically viable hidden geothermal systems in the Great Basin region by integrating new and established techniques to develop a play fairway workflow that can reduce exploration risk. The study area for the project includes most of Nevada, western Utah, southern Idaho, southeastern Oregon, and easternmost California (Figure 1). A single preliminary play fairway workflow was developed from the assessment of the regional INGENIOUS geological, geophysical, and geochemical datasets, which provided new preliminary predictive geothermal fairway maps for the INGENIOUS study area (Hart-Wagoner et al., 2024). While the preliminary play fairway workflow is a crucial first step in producing updated predictive geothermal fairway maps, additional refinements are being evaluated to enhance that workflow.

One refinement being evaluated is the use of sub-regions in the regional play fairway workflow. This approach stems from the findings of Smith et al. (2023), who applied PCAk to the Nevada PFA study area in northern Nevada. They identified four geologic domains including the Walker Lane, western Great Basin, central Nevada seismic belt, and the carbonate aquifer. PCAk was applied to the Nevada PFA study area to determine the relative importance of individual features, as indicators of geothermal potential may differ across the region in the different geologic domains. The INGENIOUS study area includes a much larger and more geologically diverse region; therefore, additional geologic domains or sub-regions are expected. The existence of these geologically distinct sub-regions could indicate the need to develop multiple conceptual models and play fairway workflows for the INGENIOUS study area. Principal component analysis and k-means clustering were applied to the identified known geothermal systems within the INGENIOUS study area. Subsequently, the clusters were analyzed to determine how they might relate to geologically distinct sub-regions of the Great Basin region. We then weigh the key contributing features for known geothermal system clusters, providing insight into 1) the viability of the single preliminary play fairway workflow (Hart-Wagoner et al., 2024) and 2) the need for different geothermal conceptual models and exploration workflows for sub-regions of the INGENIOUS study area in the Great Basin region.

2. Data and Methods

2.1 Data

In Phase I of the INGENIOUS project, a regional-scale geoscience compilation of 14 datasets was completed for the 494,269 km² study area. These included: 1) location of Quaternary faults, 2) slip rates on Quaternary faults, 3) age or recency of faulting, 4) slip-dilation tendency (TSTD) on Quaternary faults, 5) active and paleo-geothermal features, 6) Quaternary volcanic distribution, 7)

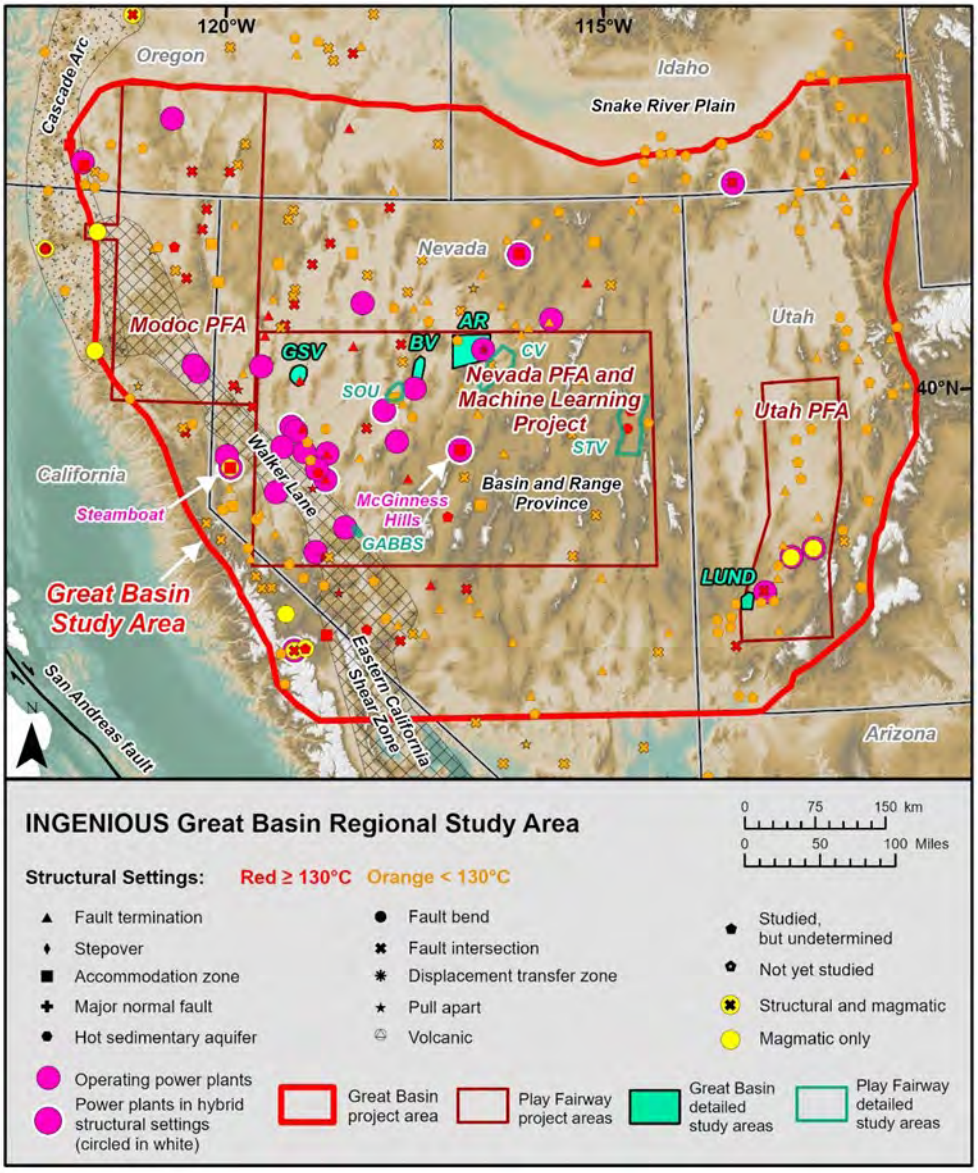

Figure 1: Regional setting of Great Basin study area for the INGENIOUS project, with locations of known geothermal systems, identified structural settings, previous PF projects (Modoc, Nevada, and Utah), and current detailed study areas (Granite Springs Valley-GSV; Argenta Rise-AR, Buffalo Valley-BV, and Lund). From Faulds and Richards (2023).

gravity data and models, 8) magnetic data and models, 9) magnetotelluric (MT) data and models, 10) geodetic strain rate, 11) earthquake distribution, 12) regional heat flow/temperatures, 13) temperature-geochemical data from wells and springs, and 14) two-meter temperature data. These datasets are a mixture of categorical and continuous numerical data. Many of the continuous numerical datasets were utilized in this study in their original form. However, categorical data needed to be transformed to continuous numerical datasets through feature engineering. An example was combining the fault and fault attribute data to generate Quaternary fault models for recency and slip rate (Hart-Wagoner et al., 2023). In this case, Euclidean distance and Euclidean allocation were utilized to transform these datasets into continuous grids. Then, weights-of-evidence (WofE) analysis was used to identify statistical relationships between known geothermal

systems and the data to build new Quaternary fault attribute models that were continuous gridded surfaces (Hart-Wagoner et al., 2023).

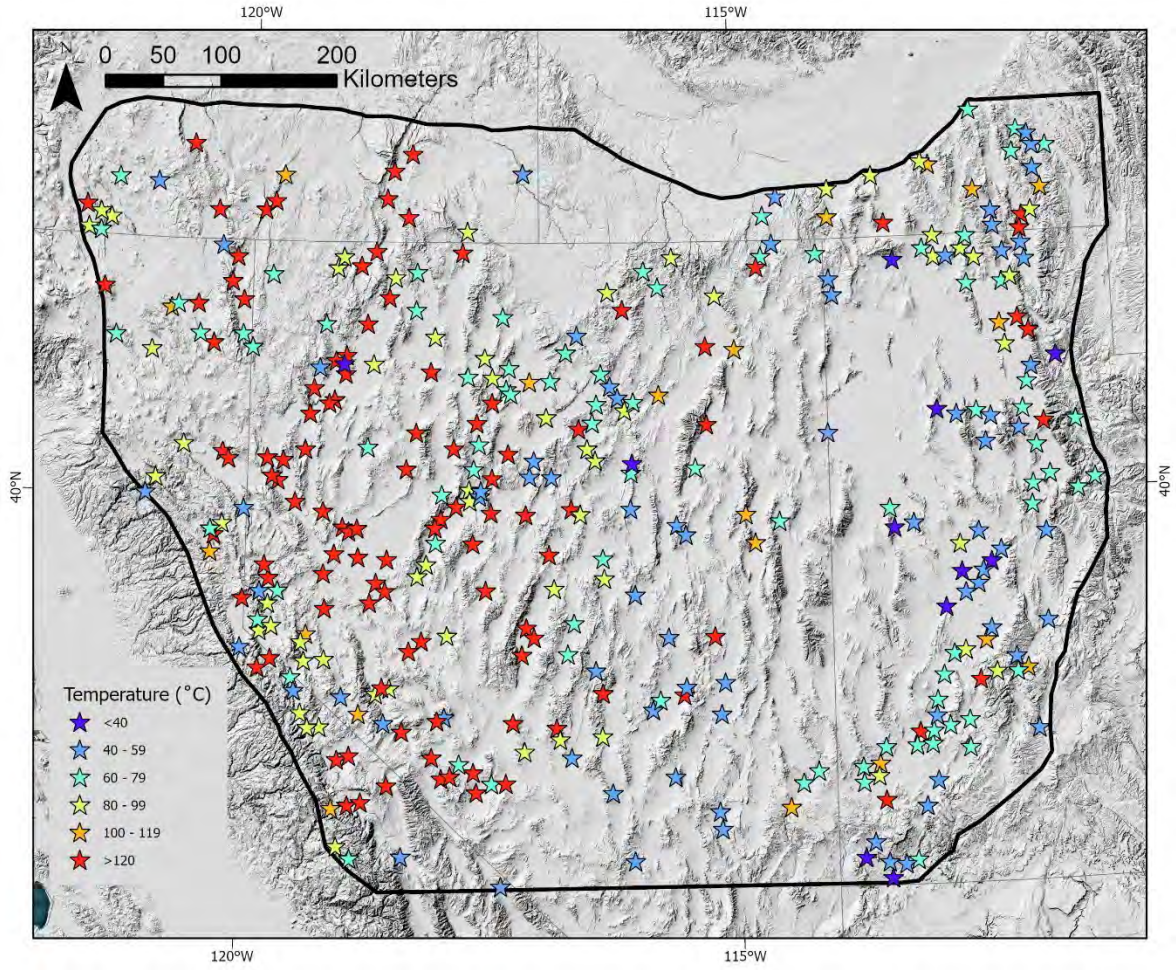

Figure 2: Compiled known geothermal systems in the INGENIOUS study area >37˚C. Data from the INGENIOUS datasets were extrapolated at each of these sites.

The data utilized in this study included features for earthquake rate density (Ayling et al., 2022), electrical conductance depth slices estimated from modeling of MT data (Peacock and Bedrosian, 2022), conductive heat flow (DeAngelo et al., 2022), depth to basement and potential field geophysical data (Glen et al., 2022), geodetic data (Ayling et al., 2022), Quaternary faults and fault attributes (Hart-Wagoner et al., 2023), and Quaternary volcanic vent composition. From these datasets, a total of 22 features were assessed in this analysis. The earthquake features included one independent (i.e., main shock) and one dependent earthquakes (i.e., aftershocks, foreshocks, and swarms) rate density model using N = 100 and an α value of 0.15 (N is the nearest number of earthquakes that were considered in generating the earthquake rate density map and α is a "declustering parameter" that distinguishes between independent and dependent earthquake events). The MT features included depth slices for: near-surface (2-12 km), middle crust (12-20 km), lower crust (20-50 km), upper mantle (50-90 km) and mantle (90-200 km). The potential field geophysical derived features included isostatic residual gravity anomalies, horizontal gravity gradient, magnetic intensity, horizontal magnetic gradient, and depth to basement. The geodetic

features included the second invariant, the dilatation rate, and the shear rate. The Quaternary fault features included recency, slip rate, and TSTD models. Lastly, the Quaternary volcanic features included distance to felsic, intermediate, and mafic volcanic vents.

A total of 354 known geothermal systems with known or estimated temperatures >37˚C in the INGENIOUS study area were identified as training sites for this analysis (Figure 2). These systems are either producing geothermal systems (i.e., contain operating geothermal power plants), identified geothermal systems that have not yet been developed, or geothermal systems that have been identified from measured well temperatures or temperatures estimated using geothermometry. A data value from each of the features listed above was extracted at each of the 354 known geothermal systems. These data were then utilized for PCAk modeling.

2.2 Unsupervised PCAk Modeling

Principal component analysis (PCA) (e.g., Pearson, 1901; Hotelling, 1933; Jolliffe, 2002) and k-means clustering (e.g., MacQueen, 1967; Lloyd, 1982; Jain, 2010) are unsupervised machine learning techniques that have been utilized for exploratory data analysis to support dimensionality reduction and to group and visualize multidimensional data. These methods have previously been used in tandem (PCAk) and shown utility in developing geothermal potential maps and guiding geothermal exploration studies at a finer regional scale (e.g., Smith et al., 2023). A similar approach is applied here to a different set of features to evaluate variability in the identified known geothermal systems of the much larger INGENIOUS study area.

PCA is a dimensionality reduction method that rotates and transforms the data to identify the principal components that account for the most variance in the input data. Since we are considering many potential features to characterize INGENIOUS known geothermal systems, PCA can be utilized to balance the consideration of these features, while maximizing the amount of explained variance considered in the analysis in fewer dimensions. The principal components are ordered by the proportion of the variance that they account for in the dataset, with lower principal component numbers accounting for more variance. A plot of the explained variance ratio can therefore be utilized to determine the number of principal components that should be considered in the analysis. These principal components also have loading values that indicate the contribution of each original feature to the principal components (e.g., Smith et al., 2023). These values can be used to identify which features are most influential in explaining the variance captured by each principal component.

K-means clustering is a method to group and visualize data for a user-defined number of clusters (k). The number of clusters can be defined by testing various number of clusters and calculating the within-cluster sum of squares for each tested k value. As the number of clusters increases, the within-cluster sum of squares generally decreases. The optimal number of clusters is usually determined where the within-cluster sum of squares difference becomes marginal. Once the optimal number of clusters is determined, K-means can build on the identified principal components by identifying data clusters and optimal centroid locations from the identified principal components. These clusters can then be mapped to illustrate the spatial extent of known geothermal system clusters. The loading values from the PCA analysis can be utilized to assess the importance of the features in each cluster (e.g., Smith et al., 2023). The ranking of features in each cluster can be used to evaluate the variability of known geothermal systems between different clusters.

3. Results

3.1 PCA Results

The PCA results indicate that none of the identified principal components explains more than 23.6% of the total variance of the dataset (Figure 3A). Four principal components are required in order to explain ~50% of the variance, while 10 components are required to explain 80% of the variance, and 14 components are required to explain ~90% of the variance (Figure 3B). To reduce dimensionality while still maximizing the amount of variance utilized in k-means, 14 principal components were retained and utilized in k-means clustering.

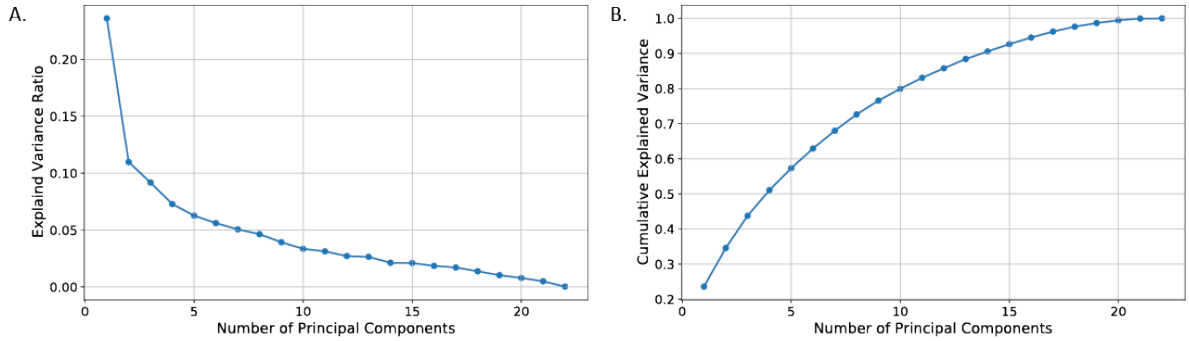

Figure 3: PCA scree plots. A. Explained variance ratio for each individual principal component. B. Cumulative explained variance ratio for combined principal components.

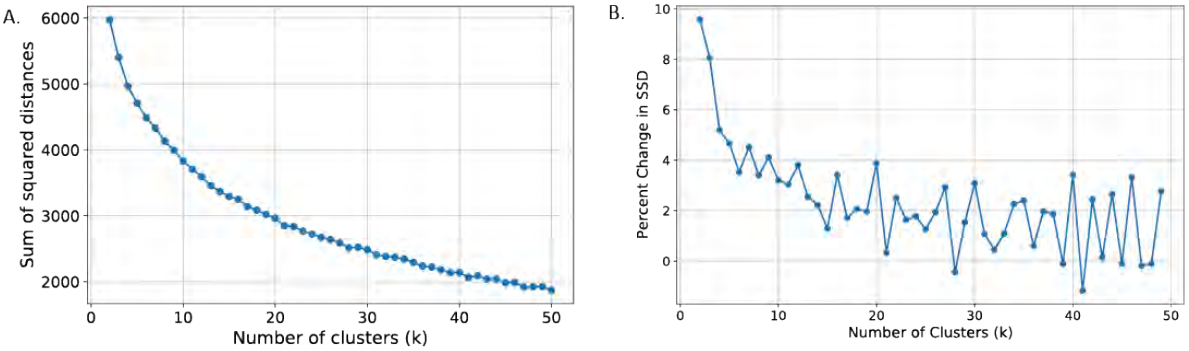

Figure 4: K-means scree plots. A. Within-cluster sum of squares for different k values. B. Percent change in the within-cluster sum of squares between different k values.

3.2 K-means Results

K-means clustering was completed using the PCA-transformed data (14 principal components). To identify the optimal number of clusters, k values from two to 50 were tested. The within-cluster sum of squares (Figure 4A) and the percent change of within-cluster sum of squares (Figure 4B) were utilized to identify six clusters for these data. If more than six clusters were utilized, there was only a marginal decrease in the within-cluster sum of squares.

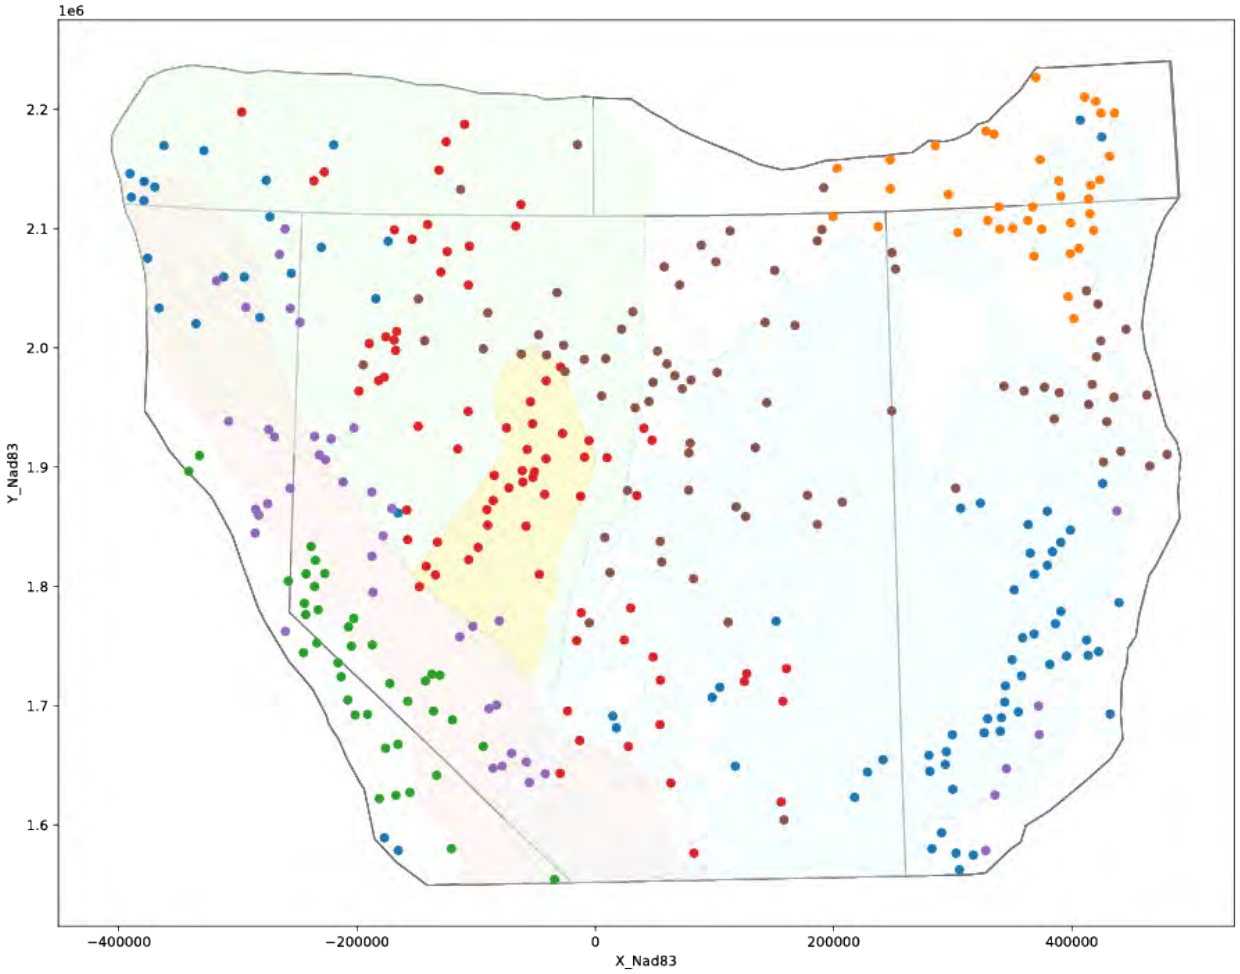

Figure 5: PCAk cluster map for the resulting six clusters. Different clusters of known geothermal systems are represented by different colored points. Polygons are based on the geologic domains utilized by Smith et al. (2023) and illustrate potential geologic sub-regions: green polygon – western Great Basin, red polygon – Walker Lane, yellow polygon – central Nevada seismic belt, blue polygon – carbonate aquifer.

The six clusters were then mapped to illustrate the geographic extent of the clusters (Figure 5). The sum of loading values from PCA were utilized to assess feature importance within each cluster (Figure 6). The features in each cluster were ordered based on the sum of loading scores to illustrate the relative contribution of features to the cluster (Figures 7-9). A high positive loading value indicates a strong contribution to the cluster and a positive relationship between the high feature values and high PC scores. A high negative loading value also indicates a strong contribution to the cluster and a negative relationship between high feature values and high PC scores.

The green cluster has 38 known geothermal systems, which are generally clustered in the southwest margin of the study area along the southwestern edge of the Walker Lane (Figure 5). Within the green cluster, the sum of loading values for this cluster has the strongest positive and negative relationships (Figure 6). The strongest contributing features with positive relationships are geodetic data, earthquake rate density, and Quaternary faults, and the strongest contributing features with negative relationships are isostatic gravity and distance to Quaternary volcanic vents (Figure 7A). These results indicate that the known geothermal systems in this cluster have an

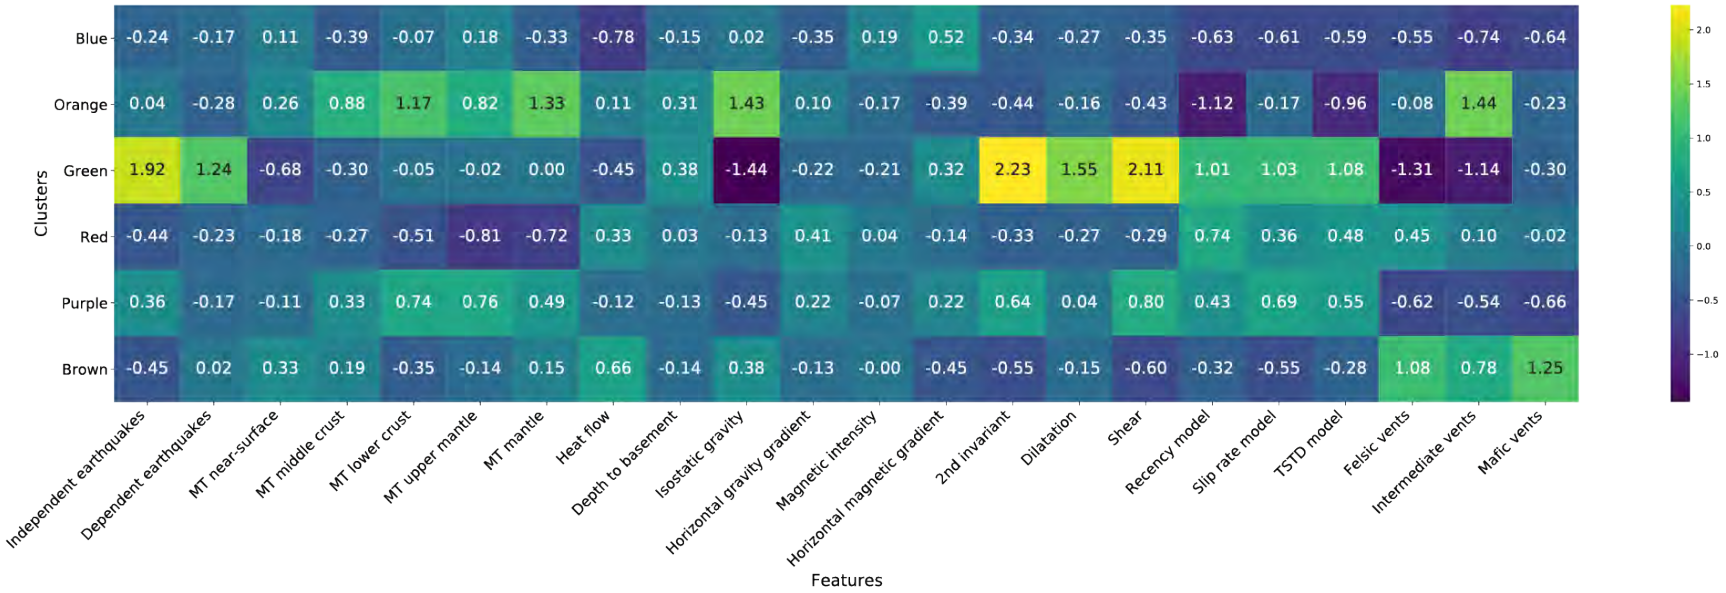

Figure 6: PCAk feature matrix for feature influence in each cluster. The value in the box is the sum of the loading values which is either negative or positive. Warmer colors indicate a positive relationship, and cooler colors indicate a negative relationship.

association with high second invariant and shear rates, high earthquake rate density, low isostatic gravity values, long distances to Quaternary volcanic vents, and high TSTD and slip rate.

The purple cluster has 43 known geothermal systems and is generally clustered along the southwest margin of the study area but more interior than the green cluster along the northeastern edge of the Walker Lane (Figure 5). Compared to some of the other clusters, the sum of loading values for this cluster are all relatively low (Figure 6). The strongest contributing features with positive relationships are geodetic data, MT, and Quaternary faults, and the strongest contributing factors with negative relationships are distance to volcanic vents (Figure 7B). These results indicate that the known geothermal systems in this cluster have an association with high shear rates, high conductance in the upper mantle and lower crust, high slip rates, and short distances to Quaternary volcanic vents.

The red cluster has 79 known geothermal systems and is generally more dispersed in the western part of the Great Basin study area (Figure 5). Compared to some of the other clusters, the sum of loading values for this cluster are all relatively low (Figure 6). The strongest contributing features with negative relationships are MT and earthquake rate density, and the strongest contributing features with positive relationships are Quaternary faults and distance to felsic volcanic vents (Figure 8A). These results indicate that the known geothermal systems in this cluster have an association with low conductance in the lower crust, upper mantle, and mantle, low earthquake rate density, long distances to Quaternary volcanic vents, and high TSTD.

The brown cluster has 80 known geothermal systems and is a bit more dispersed in the eastern part of the Great Basin study area (Figure 5). Compared to the other clusters, the sum of loading values for this cluster are higher with strong positive relationships (Figure 6). The strongest contributing features with positive relationships are distance to volcanic vents and heat flow, and the strongest contributing features with negative relationships are geodetic data and slip rate of Quaternary faults (Figure 8B). These results indicate that the known geothermal systems in this cluster have an association with long distances to Quaternary volcanic vents, high conductive heat flow, low second invariant and shear rates, and low slip rates.

The orange cluster has 37 known geothermal systems and is generally clustered in the northeast corner of the study area, adjacent to the Snake River Plain (Figure 5). Relative to some clusters, the sum of loading values for this cluster are higher with strong positive relationships (Figure 6). The strongest contributing features with positive relationships are distance to intermediate volcanic vents, isostatic gravity, MT, and a negative relationship with Quaternary fault recency and TSTD (Figure 9A). These results indicate that the known geothermal systems in this cluster have an association with long distances to Quaternary intermediate volcanic vents, high isostatic gravity values, high conductance in the mantle and lower crust, low TSTD, and older recency.

The blue cluster has 77 known geothermal systems and is generally clustered in the northwest corner of the study area near the Modoc Plateau and along the southern edge of the Wasatch Front (Figure 5). Compared to some of the other clusters, the sum of loading values for this cluster are all relatively low and exhibit stronger negative relationships (Figure 6). The strongest contributing features with negative relationships are heat flow, distance to volcanic vents, and Quaternary fault attributes (Figure 9B). These results indicate that the known geothermal systems in this cluster have an association with low conductive heat flow values, short distances to Quaternary volcanic vents, older recency, low slip rate, and low TSTD.

Bars are colored for like data types; pink: geodetic, red: heat flow, orange: Quaternary volcanic vents, green: MT, blue: Quaternary fault attributes, brown: earthquake rate density, gray: potential field.

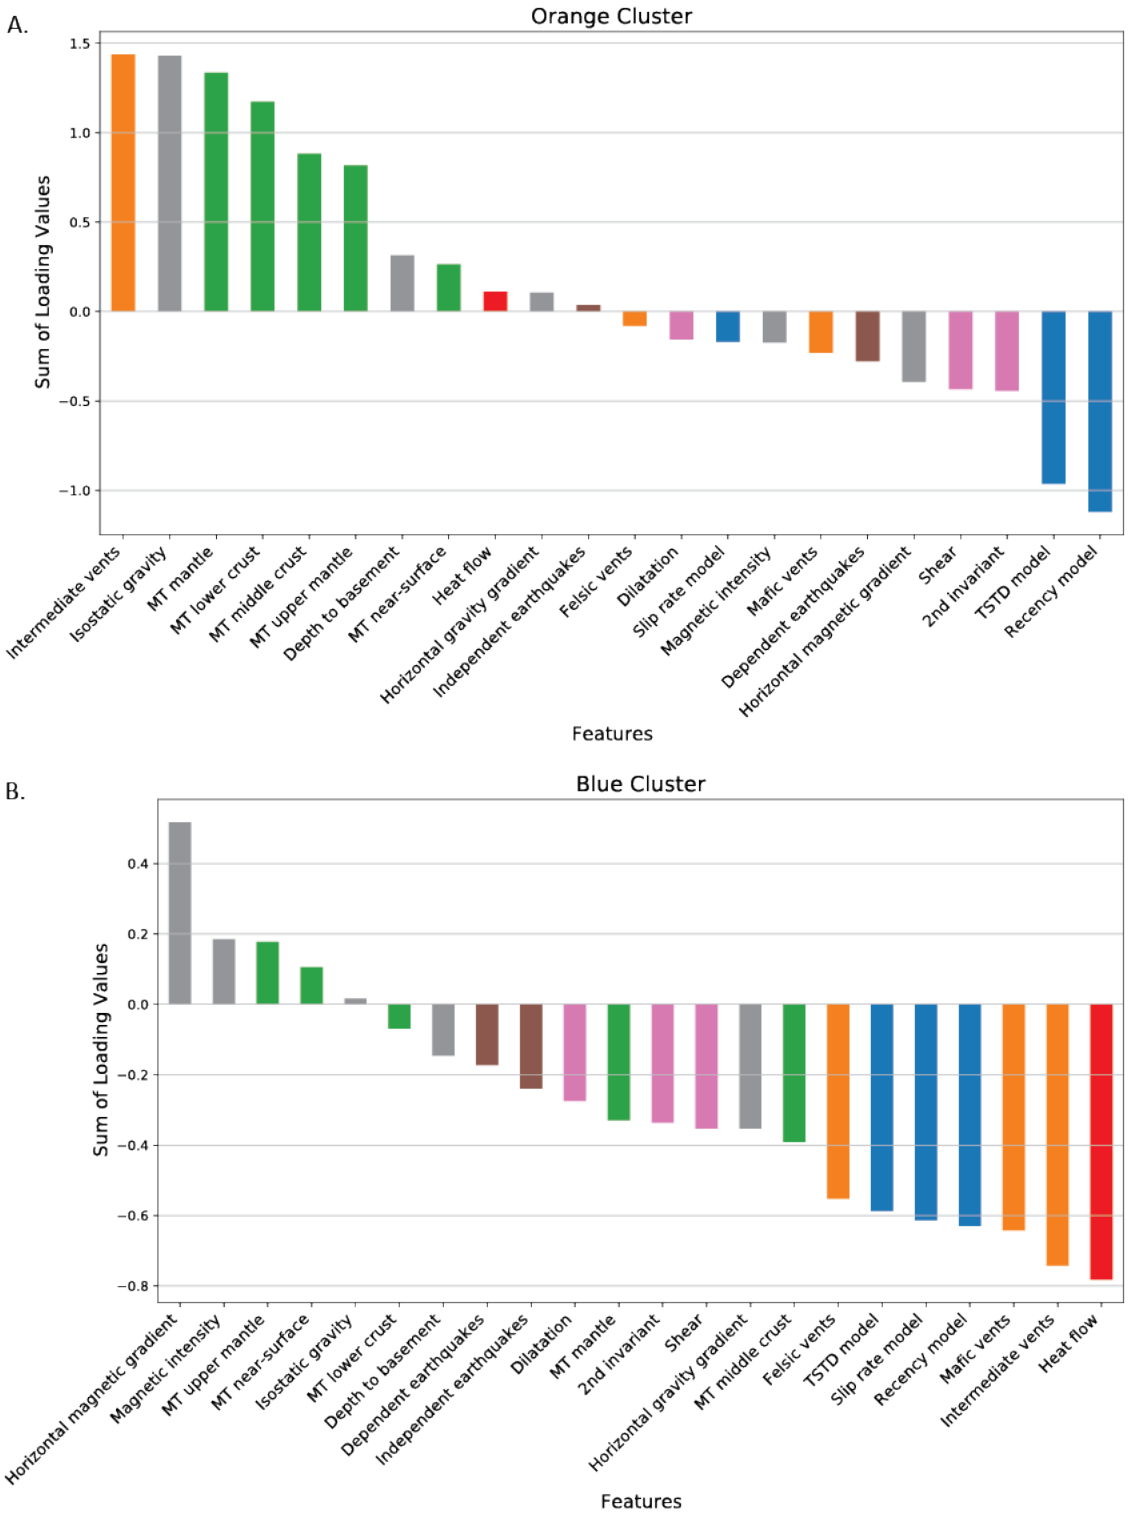

Figure 9: Relative sum of loading values ranking from high to low for the orange (adjacent to the Snake River Plain) cluster (A) and the blue (Quaternary volcanic field) cluster (B). Bars are colored for like data types; pink: geodetic, red: heat flow, orange: Quaternary volcanic vents, green: MT, blue: Quaternary fault attributes, brown: earthquake rate density, gray: potential field.

4. Discussion

4.1 PCA and K-means

These preliminary results indicate that while dimensionality reduction can be utilized, there are still many principal components required to explain the variance in the datasets. This was consistent in all the tests using different numbers of input features. The number of retained principal components utilized for k-means was also tested. If the number of principal components varied, the resulting clusters did not change significantly. The resulting clusters were still grouped in geographic areas that can be related to different geologic domains, independent of using geographic location data or assigning known geothermal systems to different geologic domains. As the number of principal components varied, the most variation in cluster designation occurred along the Wasatch Front. The geographic distribution of clusters in the western Great Basin remained largely consistent across the various tested numbers of principal components.

4.2 Clusters

Due to the western Great Basin clusters remaining largely consistent, this indicates high confidence in the differentiation of the clusters in the western Great Basin region. This includes the distinction of the green cluster on the southwestern side of the Walker Lane and the purple cluster on the northeastern side of the Walker Lane. The differentiation of these clusters seems to be mostly driven by geodetic data with higher strain rates in the green cluster and still high, but slightly lower strain rates in the purple cluster. Another difference noted in these clusters is that the green cluster is associated with slightly higher slip rates and slightly longer distances to some Quaternary faults than the purple cluster. This could be another line of evidence to support that geothermal systems in the green cluster may be associated with slightly longer distances to Quaternary faults potentially due to the high slip rates that commonly correspond to strike-slip faults or to very long and linear normal faults that are not as favorable for geothermal activity except in transtensional pull-apart basins or displacement transfer zones (Faulds et al., 2010, 2021b,c). These long linear normal faults may lack structural complexity and discontinuities, which could limit geothermal favorability, or these faults with high slip rates may generate more clay gouge that limits the permeability of the fault and lowers geothermal favorability (Faulds et al., 2010, 2021a,b,c; Hart-Wagoner et al., 2023). Either way, the variability between these clusters could be utilized to better characterize the geothermal systems along the Walker Lane.

These results also help to distinguish between the more dispersed clusters in the western and eastern Great Basin. The main distinguishing factor for these two clusters seems to be Quaternary fault attribute data. The brown cluster of the eastern Great Basin appears to have lower slip rates and older Quaternary faulting. This cluster also has longer distances to Quaternary faults and paleo-geothermal deposits, which could indicate that there is some difference in how the geothermal systems in the brown and red clusters interact with the near sub-surface to surface. It has previously been suggested that geothermal systems in the eastern Great Basin could be concealed within the carbonate aquifer domain (e.g., Smith et al., 2023). The longer distances to Quaternary faults and paleo-geothermal deposits identified in this study may support that hypothesis, as concealment could cause geothermal fluids to travel greater distances through the subsurface before reaching the surface. From the analysis of the features utilized in this study, it is not clear what feature could be causing potential concealment of geothermal systems in the

eastern Great Basin. Additional features, such as lithological data (Smith et al., 2023) may provide more insight into the factors that could be causing concealment in this sub-region.

The orange cluster that is adjacent to the Snake River Plain has strong positive contributing features of MT depth slices (middle crust to mantle) and isostatic gravity. This indicates that in this sub-region, there may be a conductive and dense body in the sub-surface. More work is needed to identify how this is impacting geothermal systems in this sub-region. This cluster also has strong negative contributing factors indicating that these systems have a relationship with low TSTD and older recency. This may indicate that these older Quaternary faults may not be oriented optimally to slip or dilate. This may suggest that Quaternary faulting is not as significant of a positive factor for geothermal systems in this sub-region.

The blue cluster is the only cluster that includes two geographic areas of the study area. While this cluster has weaker contributing factors than most of the other clusters, the key contributing feature for this cluster is distance to Quaternary volcanic vents, and this cluster aligns with the major Quaternary volcanic fields of the Great Basin. While Quaternary volcanic fields and this cluster do not compose a large portion of the Great Basin, they are still an important distinction because they offer insight into how the relationships between features and geothermal systems in these volcanic regions vary from other sub-regions of the Great Basin. Generally, these results show inverse relationships with many of the features that are key contributing features in much of the rest of the Great Basin, such as geodetic data, earthquake rate density, and Quaternary fault attributes. The distinctions that this cluster provides are key to more accurately model geothermal favorability in the volcanic fields of the INGENIOUS study area.

4.3 Distribution of Known Geothermal Systems between Clusters

The number of known geothermal systems in each cluster ranges from 37-80, with the highest number of geothermal systems occurring in the brown (n=80), red (n=79), and blue (n=77) clusters and nearly half as many geothermal systems in the orange, green, and purple clusters. This indicates that there are more identified geothermal systems in the eastern Great Basin, western Great Basin, and Quaternary volcanic field domains. However, this count considers both lower and higher temperature geothermal systems. If only the higher temperature systems are considered, the distribution of geothermal systems from highest to lowest is: red (n=42), purple (n=23), brown (n=15), green (n=13), blue (n=13), and orange (n=3). This could imply that the potential for higher temperature geothermal systems is greater in the western Great Basin and along the Walker Lane. Alternately, this could also suggest that current geothermal exploration has not found the key to identifying higher temperature geothermal systems in the other sub-regions.

The estimated temperatures of the higher temperature systems in each cluster were also assessed (Figure 10). This shows that the blue cluster (Quaternary volcanic fields) contains the highest temperature systems but also has the largest range in temperature. The mean temperature for this cluster is 175 ˚C. While the orange cluster (adjacent to the Snake River Plain) only has a few higher-temperature known geothermal systems, these have the smallest temperature range and a mean temperature of 172˚C. This could suggest that while there are few identified systems in this sub-region, there may be high potential for additional higher temperature systems, if we can isolate the best exploration approach for identifying hidden systems in this sub-region. Similarly, the brown cluster (eastern Great Basin) has a mean temperature of 170˚C, indicating there may be high potential to identify additional higher temperature systems in the eastern Great Basin as well.

The mean temperatures for geothermal systems in the green, red, and purple clusters (Walker Lane and the western Great Basin) were 160˚C, 158˚C, and 153˚C, respectively.

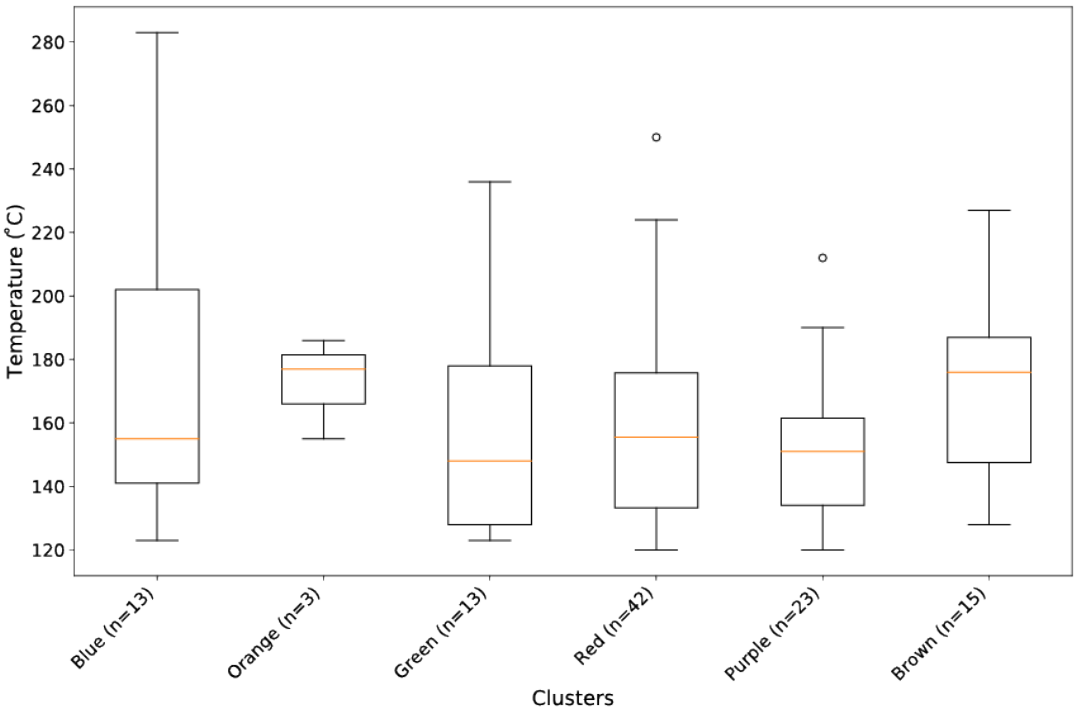

Figure 10: Box and whisker plot of the estimated temperatures for the known geothermal systems in each cluster.

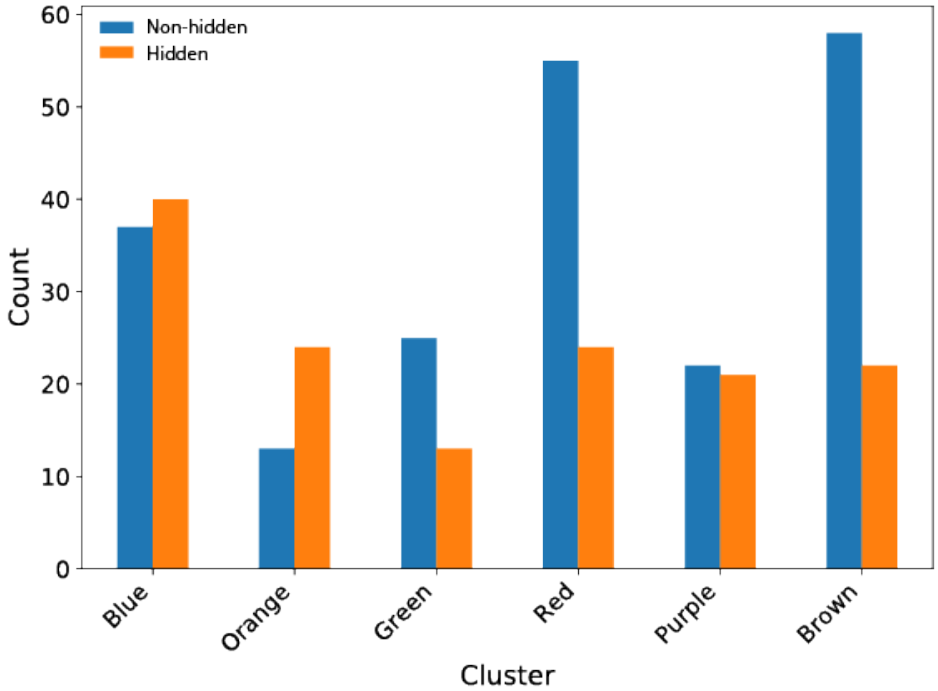

Figure 11: Number of hidden and non-hidden geothermal systems in each cluster.

It has been estimated that nearly three quarters of the geothermal resources in the Great Basin region lack surface expressions (e.g., Faulds et al., 2015). To understand the distribution of hidden and non-hidden geothermal systems in the clusters, the known geothermal systems were classified as hidden (no active surface thermal features) or non-hidden (has active surface thermal features such as a hot spring). Figure 11 shows the distribution of hidden and non-hidden geothermal systems in each cluster. The brown (eastern Great Basin), red (western Great Basin), and green (southwestern Walker Lane) clusters have significantly more non-hidden geothermal systems. This could suggest that these sub-regions have a higher potential for geothermal fluids to interact with the surface and form surface thermal features. In contrast, the orange (adjacent to the Snake River Plain) cluster has a higher proportion of hidden geothermal systems, which could suggest a higher likelihood for geothermal systems in this sub-region to be hidden. The blue (Quaternary volcanic fields) and purple (northeastern Walker Lane) have similar proportions of hidden and non-hidden systems.

There are not many known geothermal systems that are categorized as magmatic systems in the Great Basin region. Some of the magmatic systems that have been identified reside in the blue cluster, which is associated with Quaternary volcanic fields. However, there are also several that are in the green cluster, which is associated with the southwestern side of the Walker Lane. This suggests that while it might be limited, there may be a magmatic component in this Walker Lane sub-region.

Lastly, we identified the clusters where the current Great Basin geothermal power plants reside. The clusters with the highest concentration of actively producing geothermal power plants are the red cluster (western Great Basin) and the purple cluster (northeastern Walker Lane), each containing 27% of the power plants. The blue cluster (Quaternary volcanic fields) contains 19% and the brown (eastern Great Basin) cluster has 15% of the power plants. The green (southwestern Walker Lane) cluster and the orange cluster (adjacent to the Snake River Plain) have the lowest concentration, with 8% and 4% of the active power plants, respectively.

4.4 Implications for Modeling Geothermal Favorability

A cut-off of 120˚C is commonly used for assessing higher temperature geothermal systems (e.g., Hart-Wagoner et al., 2023), but here we utilized a lower temperature threshold to increase the number of systems utilized in the analysis. Even though some of these systems are lower temperature, having additional training sites in some of the areas with few identified higher temperature systems may help better characterize the geologic variability of geothermal systems in these regions. However, an analysis of just the higher temperature systems may provide more insight on the potential of the most productive geothermal systems in the study area.

Many of the higher temperature known geothermal systems are located in the western Great Basin. These higher temperature systems are commonly utilized in statistical techniques to develop relationships between geothermal favorability and these known geothermal systems. If these relationships are utilized to model geothermal favorability across the entire Great Basin, it is likely that the high contribution features, identified through this study, in the western Great Basin region are disproportionately favored in these models. Therefore, if these models are applied to areas such as the eastern Great Basin, geothermal favorability may not be modeled appropriately for that sub-region. This study is aligned with results from the Nevada PFA study area (e.g., Smith et al., 2021; Trainor-Guitton and Rosado, 2023) and suggests that the identified features may need to be

weighted differently for sub-regions to more accurately model geothermal favorability across the sub-regions of the INGENIOUS Great Basin region study area. More work is needed to assess the high contributing features in each of these clusters or sub-regions and how they relate fundamentally to the conceptual model for Great Basin geothermal systems. Additionally, these results need to be assessed for how they can be integrated into the INGENIOUS regional play fairway workflow to model geothermal favorability across the Great Basin sub-regions.

5. Preliminary Conclusions

This preliminary PCA analysis has shown that while dimensionality reduction can be applied, there are still many principal components required to explain the variance of the dataset. Additionally, the k-means clustering analysis utilized six clusters, and independent of assigning geologic domains to the known geothermal systems, the known geothermal systems cluster geographically and align with various geologic sub-regions of the Great Basin region. These include sub-regions such as the Walker Lane, extensional western Great Basin region, broad lower strain region in the eastern Great Basin, the area adjacent to the Snake River Plain, and Quaternary volcanic fields. The identified clusters were also assessed to discern the key contributing features and their positive and negative relationships to better assess geothermal variability between the clusters and sub-regions. The identified clusters also provide insight into the temperature distributions, proportion of hidden and non-hidden geothermal systems, and geothermal potential in each sub-region. Finally, the results of this study suggest that features may need to be weighted differently for individual sub-regions to more accurately model geothermal favorability across the sub-regions of the Great Basin.

Acknowledgements

This project is funded by U.S. Department of Energy - Geothermal Technologies Office under award DE-EE0009254 to the University of Nevada, Reno. Thank you to the entire INGENIOUS team (Great Basin Center for Geothermal Energy, Nevada Bureau of Mines and Geology, University of Nevada Reno, Aprovechar Lab L3C, Cyrq Energy, Inc., Geothermal Resource Group, Hi-Q Geophysical, Inc., Idaho Geological Survey, Innovate Geothermal Ltd, Lawrence Berkeley National Laboratory, National Renewable Energy Laboratory, Petrolern Ltd., U.S. Geological Survey, and the Utah Geological Survey) for their contributions to the INGENIOUS project, which supported this work. Geologic Mapping, Conceptual Modeling, Best Practices, Risk, Well Targeting, Resource Assessment

ABSTRACT

Geological mapping is a vital component of geothermal exploration programs because faults penetrating formations with rock properties favorable to forming open space fracture permeability are an important conceptual element of almost all geothermal reservoirs developed for power generation. Depending on exposures and site access, geologic maps typically have several relevant components including stratigraphy, faults, structural data, active and inactive geothermal surface manifestations, type, and extent of alteration and, for volcano-associated systems, eruption vents and age. Each of these components contributes to the interpretation of geophysics and geochemistry and the integration of these with thermodynamics in a geothermal resource conceptual model.

Geological mapping projects begin with reviews of earlier maps, but most geological maps are produced for purposes other than the assessment of a specific geothermal prospect, such as characterizing regional tectonics, assessing hazards, or exploring for minerals. Although the fundamentals of geological mapping are the same for these applications, their differing scales and objectives can limit their relevance to geothermal exploration. For example, a regional study might provide important overall context regarding a major strike-slip fault that extends through a geothermal prospect, but it might omit the local step-over in the fault that accounts for the geothermal upflow. Where structures are obscured by recent volcanic ash eruptions or alluvial deposits within a prospect, regional structures are typically interpolated, implying greater local uncertainty. When a team is integrating a wide range of data sets into geothermal resource conceptual models used to assess well target risk and resource capacity, geoscientists who are not geologists must understand how to appropriately weight the evidence from a range of geological maps. To address these needs, we have reviewed best-practice standards for the specialists who produce geological maps for the geothermal industry, and we have proposed a checklist that we recommend prospect assessment teams and managers use to weight evidence from geologic maps.

1. Introduction

Geological maps provide the overall context for the interpretation of geochemistry, geophysics, hydrology and well data for geothermal resource characterization and reservoir management. They also provide surface evidence for interpreting the structures and formation properties that constrain the permeable pathways hosting hot geothermal upflows and buoyant outflows and, commonly just as importantly, cold meteoric downflows and crossflows.

Geological mapping provides 2D constraints that, when integrated with other geoscience data, can be projected into a 3D subsurface model of the lithology and structural elements of geothermal resource conceptual models. These maps integrate the line and point observations obtained from geological fieldwork with remote sensing image analysis, well data, geophysics and, increasingly, Light Detection and Ranging (LiDAR) data. The fundamentals of geologic mapping for geothermal purposes are the same as those for exploration of other natural resources, for hazard assessment and for geoscience research but there are major differences in emphasis that are commonly not appreciated within the industry. After airborne and satellite remote sensing imaging became widely available through the mid-1900s and especially after computer analysis of lineaments, structures, and general geomorphology became ubiquitous in the late-1900s, they have become essential for planning field mapping and interpolating between surface measurement points. In recent years, the technology used in field mapping has advanced significantly with the advent of high-resolution LiDAR imaging, integrated into electronic displays with GPS and cameras supporting the insertion of photographs of mapped features directly into a geolocated field map database. However, the fundamental concepts of field geology have not changed (e.g., Compton, 1985, 2017; Freeman 1999; Walker and Cohen, 2009; Spencer, 2017).

High quality geologic mapping provides the principal constraint on several important elements of geothermal resource conceptual models used in geothermal exploration and development. For example, faults are associated with the fracture permeability of upflows in both deep circulation systems (Faulds and Hinz, 2015) and most magmatically heated systems (Hinz et al., 2016). Reservoir boundaries are also commonly associated with mapped faults and lithologic contacts. Geologic mapping supports the interpretation of permeability patterns associated with structural settings, stress orientations, Quaternary fault activity and stratigraphy. The extent, type and activity of exposed alteration is correlated with the existence and size of geothermal reservoirs (Stelling et al., 2016). Geologic mapping also helps identify potential holes in the smectite cap that protects geothermal reservoirs from cold meteoric downflows commonly associated with recent volcanic domes and vents and exposed fractured crystalline rocks. In addition to its support for building the conceptual model, geological mapping sometimes identifies new areas for geochemistry sampling and usually supports the design of geophysical surveys. Ideally, geological mapping should be treated as an iterative collaboration among geoscientists; for example, local field geology might follow up a gap in a smectite cap detected by MT or an offset in shallow formations wells consistent with faulting not shown in existing maps. The crucial step for effectively using geologic mapping is its consistent integration with geochemistry, geophysics and supporting data in the geothermal resource conceptual model.

Although making a lineament map from remote sensing images is an essential step in the process of producing effective geologic maps, the mistaken assumption that lineament maps alone can reliably constrain subsurface structural geology is a common pitfall in the geothermal industry. Because of the higher cost and much more demanding level of expertise and physical fitness

required to effectively conduct field mapping, geologic maps used for geothermal exploration and development have been mainly based on lineaments derived from remote sensing data, with little or no ground verification. Given the larger number of features typically included in lineament maps relative to ground-verified geologic maps, the lineament maps are often given more emphasis in well targeting decisions, resulting in a confirmation bias in favor of using such maps, even if the predictive value of the lineament maps is much poorer than ground-truthed geologic maps. Although LiDAR lineament analyses are an important aid to field mapping, the use of lineament maps rather than geological maps consistent with best practice mapping standards tends to increase risk in resource evaluation and well targeting (Stark et al., 2022).

This paper summarizes the best practices of geologic mapping programs for geothermal applications. In Section 2 we propose a brief checklist that geologists, other geoscientists, and decision-makers can apply when assessing what weight to give to geologic map elements in an integrated conceptual model and what priority to give to acquiring new geology data. In Section 3, we supply a quality assurance checklist that geologists can use to assess the adequacy of existing maps and determine suitable objectives for new or infill geologic mapping. Section 4 recommends steps for planning geologic mapping fieldwork and recording field observations, including desktop analysis of LiDAR and integration of supporting data prior to completing fieldwork. Section 5 reviews established best practice standards for completing a geologic map, supporting cross-sections and an accompanying geologic report. To illustrate these points, we review three published case studies that include older and revised geological maps and highlight pitfalls and successes related to the maps, along with comparisons to other geoscience data and conceptual models of the resources. These case studies include Sorik Marapi (Indonesia), Kibiro (Uganda) and Blue Mountain (United States). Other geothermal areas are discussed in brief with citations to highlight key applications, pitfalls, and remedies.

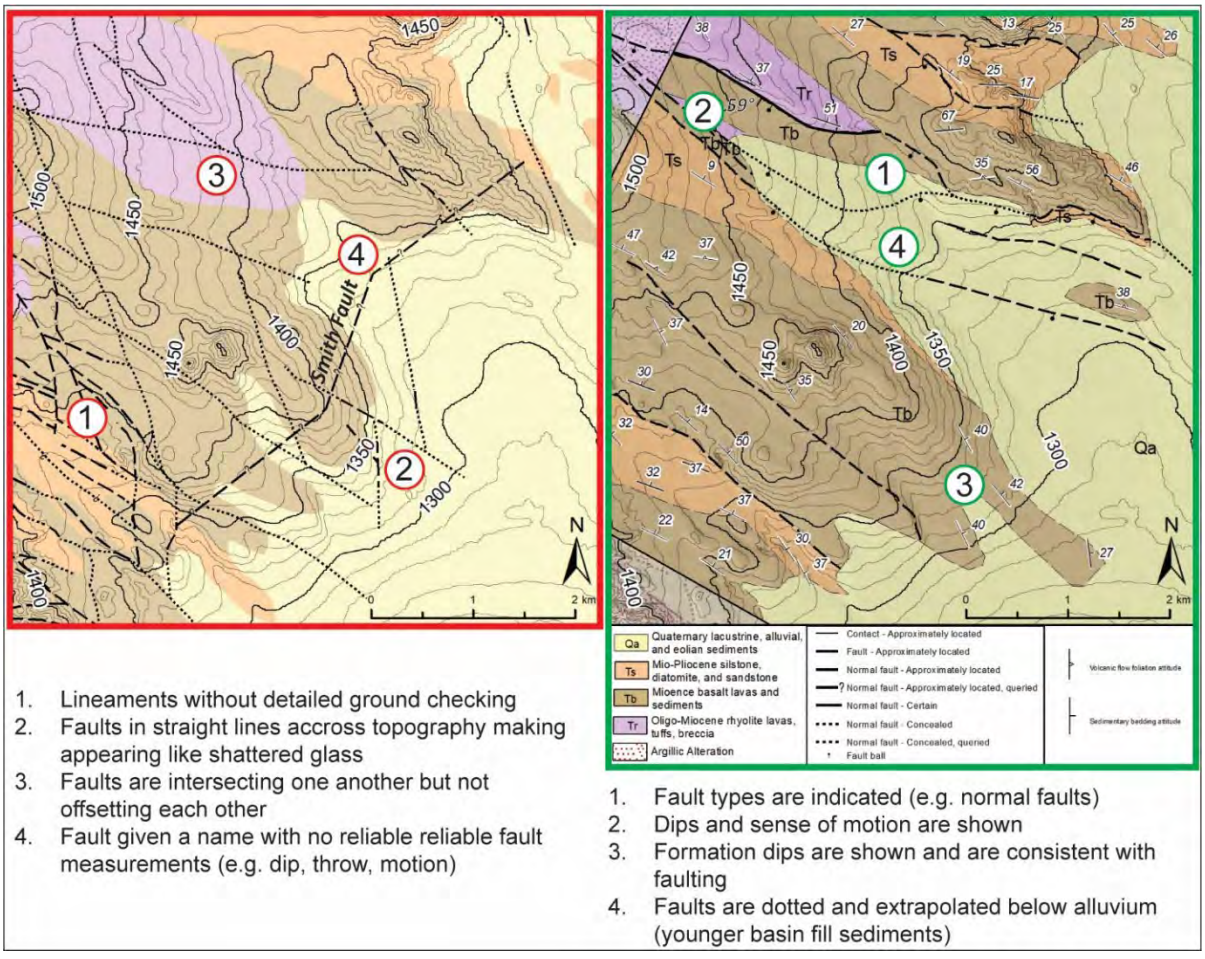
2. Assessing Confidence in Geologic Map Elements and the Need for New Mapping

Some types of geologic mapping are almost always available for any geothermal prospect, but these geologic maps are usually not been developed with a focus on characterizing a specific geothermal prospect. These maps can have a broad range in scales, quality, and detail. Therefore, the first step in geologic mapping is an assessment of the suitability of the existing geologic map data for the geothermal application. This initial assessment is typically completed by a geologist but the same information is relevant to non-specialists assessing whether to acquire more geology data or considering what weight to give to particular map features when integrating the evidence from the map with other geoscience data in conceptual models used to target wells and assess resource geometry.

To facilitate the review of existing mapping by geologists, other geoscientists and resource managers, a simplified checklist is provided in Table 1 below. To illustrate the application of this checklist, two side by side geologic maps of the same geothermal area have been provided in Figure 1 to show examples of each checklist item.

Table 1: Checklist for evaluating the quality of existing geologic mapping and gaps that may pose a risk to guiding an exploration program. Examples of this checklist are provided in Figure 1.

A check in this list indicates high risk	Missing a check in this list indicates high risk
☐ Does the map mainly show lineaments without detailed ground checking of "faults" important to the interpretation?	☐ Are types of faults indicated (normal, srike-slip, etc.)?
☐ Are "faults" straight lines in every direction creating the appearance of shattered glass?	☐ Are dip and sense motion shown?
☐ Are many of the faults intersecting, but not offset each other?	☐ Are formation dips shown and are they consistent with fault dips in the section?
☐ Are faults given names that are not previously documented and lack reliable measurements at several exposures or data types showing dip, throw and motion?	☐ Are faults dotted or narrowed to indicate extrapolation across alluvium?



1. Lineaments without detailed ground checking
2. Faults in straight lines accross topography making appearing like shattered glass
3. Faults are intersecting one another but not offsetting each other
4. Fault given a name with no reliable reliable fault measurements (e.g. dip, throw, motion)

1. Fault types are indicated (e.g. normal faults)
2. Dips and sense of motion are shown
3. Formation dips are shown and are consistent with faulting
4. Faults are dotted and extrapolated below alluvium (younger basin fill sediments)

Figure 1: Two geologic maps of the same area with checklist elements from Table 1 listed by number to locate examples on each map. The map on the left outlined in red is an example of a high-risk geologic map (checking all four boxes on left column of Table 1). The map on the right outlined in green is an example of the high-quality mapping required for successful geothermal exploration and development (checking all four of the boxes on the right column in Table 1).

If the checklist in Table 1 indicates relatively high risk in using the existing geological maps, then the next step may be to review whether circumstances are favorable for significantly improving the map quality. In some cases, improving the map might be problematic, say because alluvium obscures structure. In these cases, alternative data sets like MT and/or temperature gradient wells might more suitably constrain resource decisions. Some circumstances warrant a more detailed data gaps analysis that considers the impacts of gaps relative to each other and the project goals. If additional mapping is warranted for a given project, best practices for implementing a geologic mapping program are provided in the following sections.

3. Determining Map Area and Mapping Objectives

The first step in geologic mapping is to determine the area that needs to be covered. Start by reviewing the quality of existing geologic maps (Section 2) and well data (if available) to design and plan details of the geologic mapping program. Planning the area for mapping should consider access restrictions and geology questions related to both resource assessment and to the design of supporting surveys.

In geothermal exploration there is typically a specific lead that attracts initial interest, such as hot springs, fumaroles, alteration, hot wells, silica sinter or a pattern of resistivity (Stelling et al., 2016; Sewell et al., 2024). The area of the likely range of geothermal conceptual models associated with the lead is the focus of exploration. A geologic map should be focused on key conceptual model elements that can be controlled by geology (e.g., permeability, hot upflow, hot/warm outflow, cold influx, acid influence, and cap rock). The proposed map area should cover the likely stratigraphy and structure associated with the geothermal resource. The map area does not need to be rectangular or even linear on any edge. Typically, the lateral extent is several times larger than the lateral extent of the anticipated resource area as indicated by potentially analogous reservoirs, including both upflows and outflows. All likely geometries should be covered, and sufficient area should be reviewed to capture the broader structural and stratigraphic frameworks.

The map area can be extended in greater distance parallel to the structural trend and a lesser distance perpendicular to it. This will ensure that a greater understanding of the local and broader regional structural framework is captured in the geologic mapping. Since even high-quality geological mapping is relatively low cost, it is usually better to capture a larger area surrounding the lead than would be considered for geophysical surveys. Different elements of the map might cover different areas. A larger area might be the focus of field checks for key stratigraphic and structural controls of the geothermal resource that may not be located at the surface in the immediate vicinity of the initial geothermal lead. To help focus the geologic map area, mapping objectives and ensure that they are accounted for when designing the map area and implementing the field work, a general checklist for review of geologic mapping objectives is provided in Table 2.

4. Implementing a Geologic Mapping Survey

This section focuses on implementation of the objectives identified in the previous section.

3.1 LiDAR and Aerial or Satellite Photo Analysis

A beginning step for many geothermal mapping projects is to complete a desktop analysis of LiDAR data to assess Quaternary fault traces. These data help geological mapping efforts and give insights into local and regional structural complexities that could control permeable pathways for hot fluids (Faulds et al., 2015), reservoir boundaries (Hinz et al., 2021). When planning LiDAR acquisition or analysis, it includes an area 25-50% larger than the expected geologic map area to help integrate local and regional fault patterns. Although LiDAR data significantly improves the efficiency and reliability of the geologic mapping process, they are not essential to complete a geologic map suitable for geothermal exploration and development in most settings.

Table 2: Geologic map review check list. A check mark in the table below indicates that the related data is more likely to be reliable and in turn have valuable utility to geothermal resource conceptual modeling.

Geologic Map Objectives		
Is it present? ("√" if yes)	***Map element***	***Description***
	Stratigraphy	Unit extent shown in map and age sequence in legend, with accompanying text describing of each unit, even if only one or two units in an entire map area.
	Structural data	Include bedding attitudes, and fault dips if surface outcrops are available.
	Fault symbology	Faults and contacts drawn to indicate confidence based on exposed/not exposed, uncertainty of location or existence. Examples may include **Solid** = certain; **Dashed** = approximate; **Dotted** = concealed; Queried = fault or contact uncertain (symbolized with **dashed lines** and "**?**"). Faults should also be clearly distinguished from lineaments with different symbology.
	Fault kinematics	If kinematic evidence is available, kinematic labels should be included (e.g., up/down, strike-slip arrows)
	Fault trace geometry	Map traces of faults should include kinematic labels. Examples include: -Strike-slip faults typically very straight along strike -Normal or reverse faults typically sinuous along strike -Low angle normal or thrust faults are very sinuous along strike
	Realistic fault network pattern	Most geothermal prospects include only a few well-defined active major faults with kinematically consistent subsidiary faults and older faults that may be less consistent. Realistic fault patterns rarely look like randomly broken glass.
	Geothermal features	If present, location, and alteration details should be included with geothermal surface manifestations.
	Cross section	Geologic maps should include at least one cross section each.
	Regional correlation	The geology of the map area fits the regional geology.
	Well data	If well data is available, well lithology observations fit with available geologic map data in a supporting cross-section.

Figure 2 illustrates a typical LiDAR and structural analysis workflow. This typically includes evaluating geomorphic features associated with faults visible in low sun-angle hillshades and/or from slope shades in LiDAR images (Figure 2a). These geomorphic features can include fault scarps which are ramps in the ground surface that connect offset depositional or erosional surfaces (e.g., Bennett et al., 2018). A high-resolution elevation profile like Figure 2b can detect subtle fault motion related to scarps and a series of profiles can help sort out the continuity of faults, often iterating with field observations. Other features include scissoring of fault scarps, closed depressions, contractional ridges along strike-slip faults (e.g., Hunter et al., 2011; Gold et al., 2014) or pop-up wedges or ground folds associated with reverse or thrust faults (e.g., Koehler and Woods, 2013). Although LiDAR resolution of the ground surface below dense tropical forest is typically lower than would be expected for the arid desert environment shown in Figure 2, the value of LiDAR is comparable because it significantly offsets the greater difficulty of field mapping in tropical forest. Therefore, structure relevant to geothermal exploration can be mapped with LiDAR globally across all fault types and through most vegetation cover.

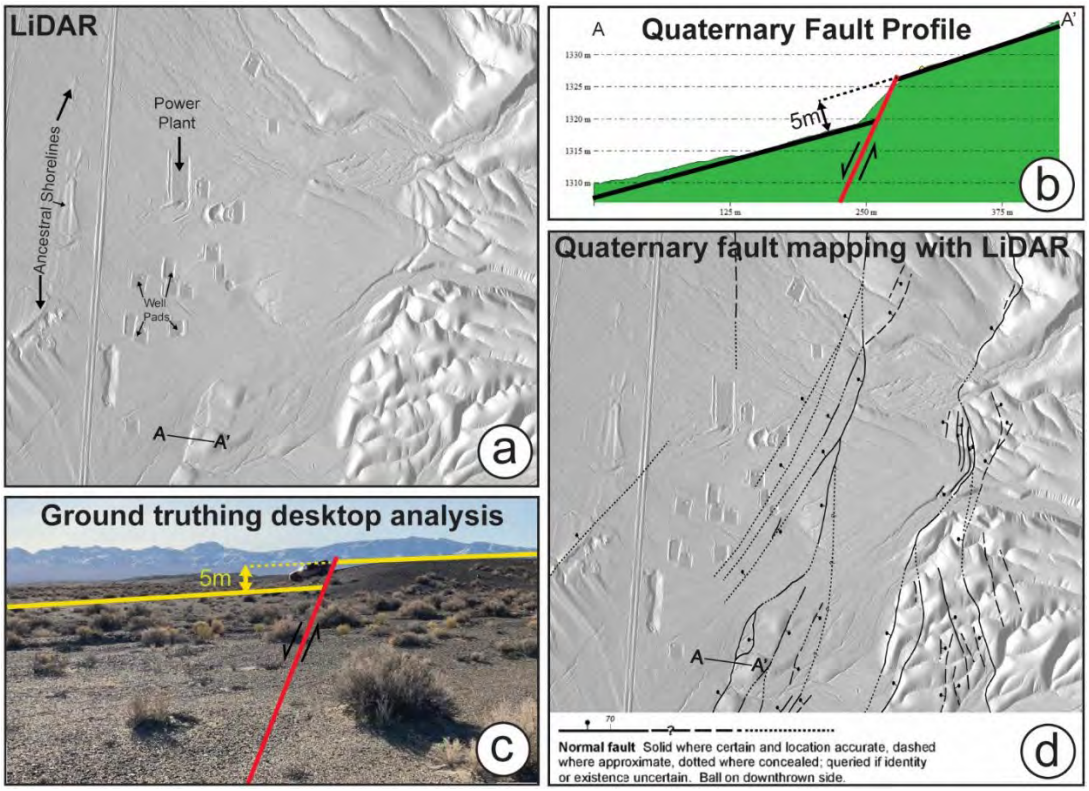


Figure 2: Example dataset and workflow for Quaternary fault focused LiDAR analysis. a: raw hill shade exported from LiDAR data of the Star Peak geothermal area (Fercho et al., 2020) with examples of non-fault lineaments, anthropogenic features, and cross section A-A' across a Quaternary active fault scarp in the younger basin fill sediments. b: elevation profile of A-A' showing the planer and near parallel surfaces of the basin fill sediments offset by a ~5 m normal fault. c: an example of in field ground truthing of the features identified in LiDAR with a pickup truck parked on the steep slope of a fault scarp. d: The resulting map after the desktop analysis and ground truthing of the LiDAR (Fercho et al., 2020).

Geomorphic features visible in LiDAR data that can be confused with fault scarps include fluvial scarps, the break-in-slope features associated with differential erosion between separate stratigraphic horizons, and paleo-shorelines of lakes (Figure 2). Other natural features that are

commonly identified as LiDAR lineaments but typically do not directly correspond to faults include river or stream channels, edges of lava flows, edges of mud flows and tops of ridges (Figure 2). Non-geologic features that may be confused with fault scarps include anthropogonic ground disturbances like roads and vegetation alignments that have not been eliminated in the processing of the raw LiDAR data to generate the Bare Earth DEM. The ambiguity of the interpretation of such features can be reduced by interpreting the LiDAR images together with aerial or satellite photo imagery and supporting geophysical data but, in most cases, additional field mapping will be required to fully characterize faults initially identified using LiDAR (Milton et al., 2023).

At the exploration stage of a project, it has seldom been feasible to conduct a drone-based thermal infrared + visible (RGB) photo survey over a sufficient area to be decisive but this option should be considered if practical at a suitable cost.

The desktop analysis of LiDAR and satellite photo imaging supports the preparation of an overall field strategy and a list of specific field objectives and priorities. These include confirming Quaternary fault traces, collecting field data on suspected fault traces, assessing any questionable features in the LiDAR that may be faults (Figure 2) and checking any evidence of potential alteration detected in the satellite photo images (or any drone-based surveys).

3.2 Geologic Field Mapping

Field notes should be recorded whenever observations can be found that are key to part of the overall mapping objectives of any given study. The spacing of locations in which field observations are recorded is based on geological complexity and availability of features that can be investigated. The geologic map should be updated with acquisition of each significant field point and at the end of each day the geologic map should be reviewed to make sure all updates have been incorporated. The next day's list of field objectives should also be revised to address new or remaining questions.

All field observations should include GPS (or similar) location data (including coordinate system used), a general description of the site location and photographs, with scale, if relevant to the type of feature described. A digital tablet/smartphone using appropriate software can significantly automate this task and promote the integration of LiDAR and other supporting data. Further details of the notes necessary for each site depend on the available geologic features, the geologic reason for selecting the site for recording observations and/or obtaining quantitative measurements. Each observation point may include focus on one or more of the following categories with requisite information required for each category based on field data available.

Stratigraphic Framework: Clearly delineate the stratigraphic framework, including bedrock and unconsolidated surficial deposits, contact relations and relative ages, distribution, thickness, overall composition, and compositional variation in 3D space. Where possible, attitudes in the bedrock units should be collected. When field analysis of outcrops and hand samples is not sufficient to clearly delineate lithologic units, collecting samples and completing thin section analysis can help define lithology. Key stratigraphic observations and map elements include:

- Unit descriptions include color, texture, mineralogy, and variability of these qualities. Provide interpretation of lithology and formation as applicable.
- Contacts

    - Record which unit is exposed on either side of the contact and if the contact is depositional, intrusive, faulted, or a combination thereof
    - Record the dip of the contact
    - Observe and record the degree and type of alteration if present
- Attitudes of stratigraphic units (e.g., bedding, foliation)

Structural Framework: Determine the structural framework, including geometry, kinematics, magnitude of offset, recency, and slip rates as data is available. Emphasis should be placed on determination of Quaternary active faults, including ones that may be immediately adjacent to geothermal prospects and acting as one of the primary faults in a major fault step-over, pull-apart, or other key structural setting. Key structural observations and map elements include:

- Faults
    - Attitudes of faults
    - Damage zone characterization (if applicable)
        - Width
        - Fabric and composition (breccia, clay gouge)
        - Alteration mineralogy, type, and intensity
    - Kinematic data from fault surfaces with photos to document features
        - Trend and plunge or rake of striae in fault plane
        - Riedel shears or steps along a fault surface (e.g., van der Pluijm and Marshak, 2004; Fodor, 2007)
        - Offset planar or linear features along the fault
    - Quaternary fault scarp characterization such as trend or strike, vertical offset of surfaces (apparent offset), slope, single or multi-event, observations relative to determining if normal, reverse, oblique, or strike-slip. Photos as applicable.
- Folding
    - General description
    - Measure and record geometry as data is available
- Metamorphic fabrics
    - Describe type(s) of fabric (e.g., planar, linear)
    - Record orientations of strike and dip or trend and plunge as necessary depending on the fabrics present.

Alteration: Determine if alteration is present at the surface. If so, map the extent, type, intensity (e.g., Gifkins et al., 2005). If areas of alteration are present, determine relative age(s) such as recent/active or relict. Relict could be 10s or 100s of thousands of years old or millions of years old. If a suitable analog provides a potential guide to alteration association and age, note which analog is used and why. Alteration assemblages can be difficult to identify in hand sample. Collecting rock samples in the field for lab analysis (e.g., x-ray diffraction and/or thin section analysis) can help define the alteration associated with modern and relict geothermal systems. Ideally, a shallow soil temperature probe should be inserted to refusal into soft clay alteration to assess its current state and, if the temperature is significantly higher than ambient, the feature should be identified as a thermal manifestation and labeled hot altered ground. Key alteration observations and map elements include:

- Alteration descriptions (e.g., Thompson et al., 1996)
    - Describe the alteration relative to the protolith (e.g., primary, or secondary)

- Describe color, texture, minerology, and alteration intensity

Surface Manifestations: Map active and inactive geothermal surface manifestations. These may include thermal springs, steaming ground, fumaroles, gas seeps, hot altered ground, or spring deposits such as travertine or sinter. Key geothermal surface manifestation observations that should be noted by field geologists and included as map elements include:

- Geothermal surface manifestation description, temperature, any odor of sulfur, photos, and notes on whether the location is associated with stratigraphic and/or structural elements.
- Hot spring observations should include temperature, pH and chloride content using test strips. More complete geochemistry sampling might be warranted if access is limited.
- Mineral spring deposits (e.g., sinter, travertine) characterization, description, photos

Table 2 is a summary of these key geologic map elements and serves as a checklist of key observations and structural elements for a geologist when planning and implementing geologic mapping focused on a geothermal resource. The absence of one or more of these key observations is not necessarily a reflection of the quality of the geological map. In fact, the common practice of setting quotas on the numbers of fault observations that field geologists must find tends to greatly degrade the quality of the resulting maps since most lineaments are not correlated with faults and so expertly confirming that the fault does not exist is an important goal of the field geologist. Therefore, it is important to detail in the geologic map and report those key structural elements that are observable in the field and those lineaments and previously interpreted faults that could not be confirmed in the field.

Additional details of potential observations and approaches to collecting observations on each type of geologic feature can be found in many geologic mapping reference books (e.g., Compton, 1985, 2017; Freeman 1999; Walker and Cohen, 2009; Spencer, 2017).

4. Final Geologic Map Production and Reporting

After fieldwork is complete, a final map needs to be generated with colors, symbols, and labels of polygon, line, and point data clearly presented. Faults need to be attributed as concealed where they extended under young surficial deposits or bedrock units and where the fault does not extend to the surface. Faults also need to have kinematic indicators on the map (where this is known) such as which side is up or down or if strike-slip if left-lateral or right-lateral. A unit list, unit descriptions, and unit/age correlation diagram or chart should accompany the map. To illustrate the interpreted geologic framework in the subsurface, one or more geologic cross sections should accompany each part of the map area that is of exploration interest and differs significantly from other sections. Typically, cross sections are generated perpendicular to the overall structural strike across a given map area to communicate framework geology most effectively. Information from nearby wells and geophysical cross-sections should be considered in the making the geology cross-section and, in many cases, it will be advantageous to align a geological cross-section with such data. Finally, a checklist of map components and cartographic details can be helpful as part of the final internal review of a map product. Examples are available through multiple state and federal geologic surveys globally (e.g., Nevada Bureau of Mines and Geology: NBMG).

A geologic report should accompany all mapping projects and should include summaries of the field mapping accomplished, including integration of multiple datasets as available, and comments on map data accuracy and remaining data gaps based on limitations of field access or exposures.

The core of the report should provide a summary of the stratigraphic and structural framework, alteration, and distribution of surface geothermal features, as relevant. Annotated field photos, inset map figures, and plots of structural data typically strengthen the report and summary interpretations relevant to supporting geothermal exploration and development projects. The final map and accompanying report, along with assessments of remaining data gaps can then be used as an effective tool at identifying structural target areas (e.g., Fauld and Hinz, 2015; Faulds et al., 2021; and Hinz et al., 2023) along with integrating with geophysics, geochemistry, and well data, as available, for conceptual modelling purposes.

5. Case Studies

Three representative case studies compare old mapping that illustrates pitfalls and new mapping completed according to geologic mapping best practices. These examples illustrate several key components of geologic maps in a range of geological settings, including volcanic and non-volcanic geothermal prospects in dense forests and deserts. Sorik Marapi, located in Indonesia, is an operating field in a volcanic arc setting with a field area mostly covered by dense tropical forest and locally covered by agricultural fields. Kibiro, located in Uganda, is an undeveloped deep-circulation system with moderate vegetation coverage in the western branch of the East African Rift System. Blue Mountain, located in the United States, is deep circulation system associated with an operating field in an arid desert region.

Although these three case studies are representative of geological mapping efforts in a variety of settings, geological mapping best practices have been applied successfully in many other areas. This includes geothermal fields in the Great Basin region of the western USA, fields in the eastern and western branches of the East African Rift System (EARS), and in subduction arc settings. Many publications describe geological maps that are consistent with the standards outlined in this paper and, together with subsequent papers on resource development, illustrate how important such maps can be to the conceptual models of the related geothermal fields, including:

- in the US Basin & Range region, at Desert Peak (Faulds et al., 2010, 2012), Bradys (Faulds et al., 2010, 2017), Desert Queen (Dellerman, 2021; Faulds et al., 2010, 2022), Patua (Faulds et al., 2011), Emerson Pass (Anderson, 2013; Anderson et al., 2013), Black Warrior area (Sadowski, 2016; Sadowski and Faulds, 2016), San Emidio/North Valleys (Rhodes, 2011; Rhodes et al., 2011), Lee-Allen (Hinz et al., 2010), Salt Wells (Hinz et al., 2011), Wabuska (Hinz et al., 2013), southeastern Gabbs Valley (Craig, 2018; Craig et al., 2021); Reese River Narrows (Hinz et al, 2013); Crescent Valley (McConville, 2018); Tuscarora (Dering, 2013; Dering and Faulds, 2013); Steptoe Valley (Hinz et al., 2020b); and Neal Hot Springs (Edwards, 2013).
- in the East African Rift, at Suswa, Kenya (Haizlip et al., 2020); Menengai, Kenya (Riedl et al, 2019); Songwe, Tanzania (Hinz et al., 2018); Panyimur, Uganda (Hinz et al., 2018); Buranga, Uganda (Natukunda et al., 2024); Faile, Djibouti (Guellah et al., 2023), Bweengwa, Zambia (Hinz et al., 2020c).
- in arc settings, at Akutan, USA (Stelling et al., 2015), Sokoria, Indonesia (Hinz et al., 2020a). Many other geology maps of geothermal prospects may meet the standards advocated here but either are not published or are published only after so much subsurface data is available that the initial surface mapping standards are not emphasized (e.g., Muara Laboh, Indonesia, Stimac et al., 2019; Salak, Indonesia, Stimac et al., 2010; Rantau Dedap, Indonesia, Ramadhan, et al., 2021).

In addition, where geophysical imaging and/or well data has been available, 3D geological models have increasingly enhanced conceptual models of geothermal systems in many areas worldwide (Siler et al., 2021, 2023).

Sorik Marapi, Sumatra, Indonesia

The Sorik Marapi geothermal project is located on the northeast flank of the Sorik Marapi volcano, and along a major active strand of the Sumatra fault system, on Sumatra, Indonesia (Figure 3). Drilling began in 2016 with the first 45MW installed by 2019. As of 2023, the field has been operating for four years with a current installed capacity of 180 MW. Multiple geologic maps have been published for this field and four of these are reviewed relative to geologic best practices and to how effectively they inform the conceptual model of Hinz et al. (2021).

The geologic aspects of the 2024 conceptual model for the Sorik Marapi reservoir (Figures 4 and 5) remain mostly unchanged from that published in Hinz et al. (2021). In this model, the vapor core of Sorik Marapi is isolated to a chimney underlying the volcano's summit area and the geothermal reservoir is a hydrologically separate, neutral >320°C upflow about 1 km west of the main strand of the active SFS, with associated elongate <260°C outflows to the north and south. The inferred upflow area is based on well temperature data, fluid geochemistry, locally elevated non-condensable gases, and permeability patterns. Overall, the upflow appears to be elongated NE-SW, possibly associated with a concealed NE-striking fault zone. A NE-striking fault that connects the major western and eastern strands of the dextral NNW-striking Sumatra fault system in this area could function as a pull-apart, a common structural setting of operating geothermal systems in Sumatra.

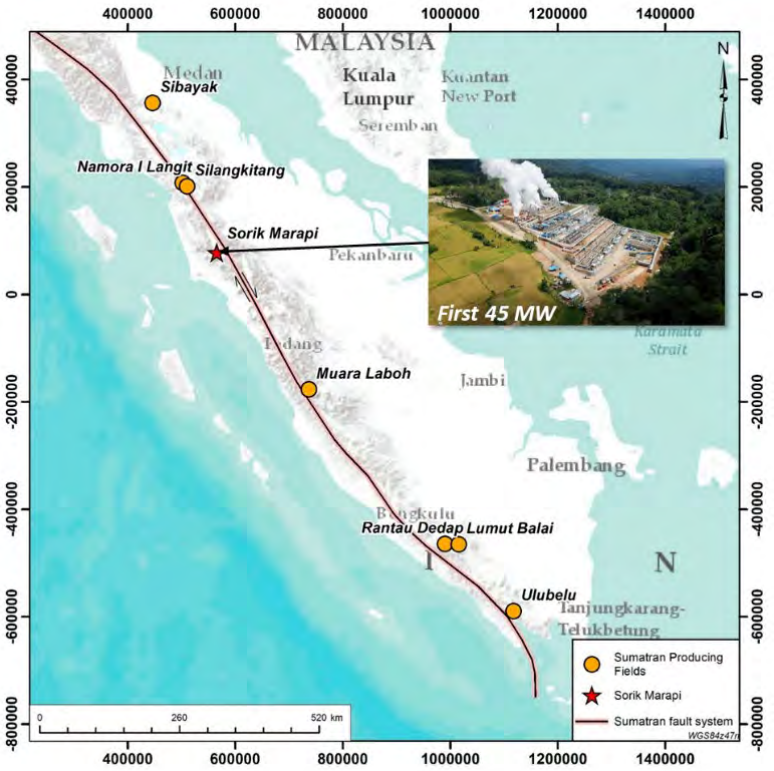

Figure 3: Location map of Sorik Marapi geothermal project (from Hinz et al, 2021).

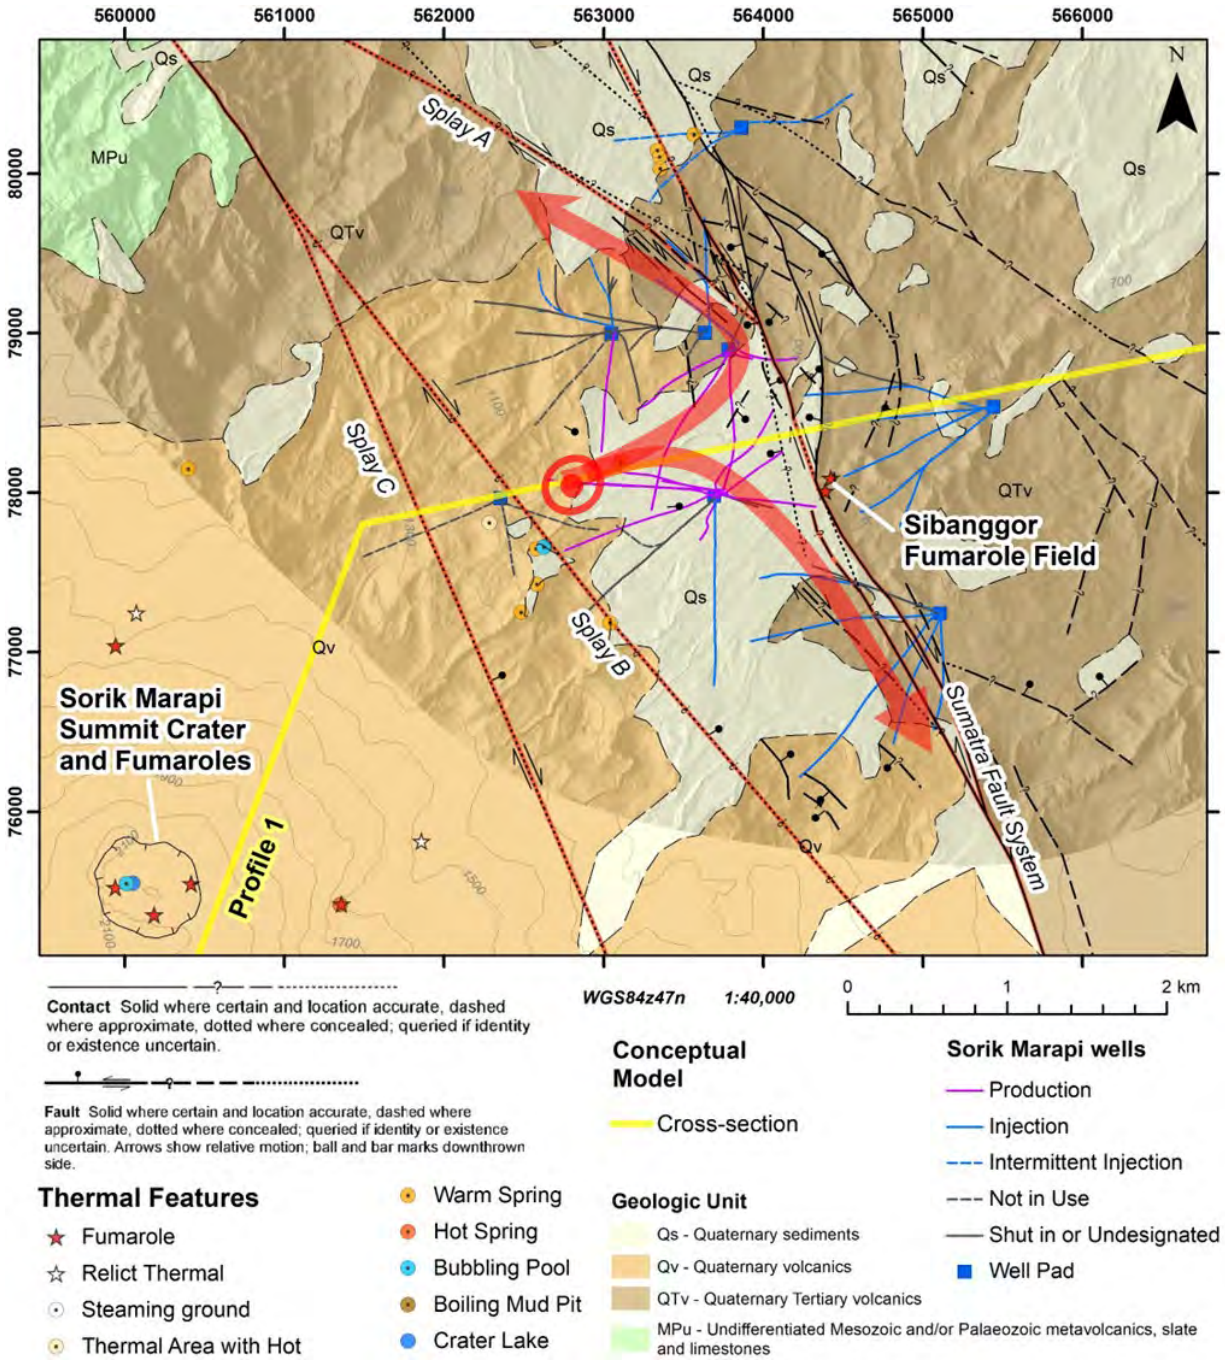

Figure 4: Geologic map of the Sorik Marapi field, modified from Hinz et al. (2021). Wells drilled within the currently developed Sorik Marapi Geothermal Reservoir. Red lines highlighting some faults correspond to major strands of the Sumatra fault system and are discussed in the text. Key conceptual model elements are also shown; upflow (arrowed circle) and outflow pathways (red arrows).

The reservoir is largely hosted in pre-Cenozoic metamorphic rocks and late Cenozoic intrusive rocks. Image data indicate that fractures are predominantly oriented with an approximate NNE-strike and moderate to steep dips both east and west; however, permeable fractures have been encountered with a large range of strikes and dips (Hinz et al., 2021). Of note, most of the major faults identified in the reservoir from drilling data do not reach the surface or are covered by young

volcanics and can only be identified by subsurface data. The northern and eastern margins of the reservoir are bound by major strike-slip faults and the western margin has also been hypothesized to be bound by a major strike-slip fault (Kim et al., 2020, 2024; Hinz et al. 2021; Turk et al., 2024).

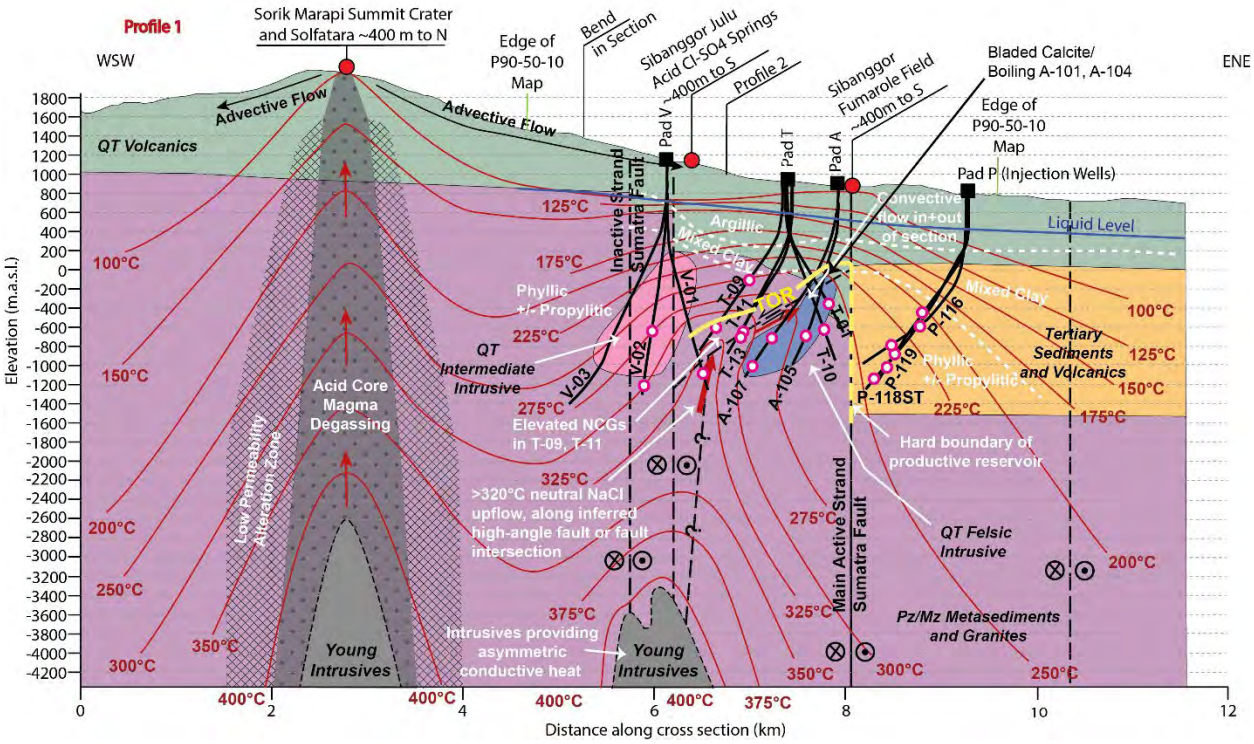

Figure 5: Geologic cross section of the Sorik Marapi field, modified from Hinz et al. (2021) and borrowed from Turk et al. (2024). Cross-section crosses through Figure 4 and full extent is shown on the map in Hinz et al. (2021).

Multiple geologic mapping efforts have been completed at different scales by government and private companies. Of these, four maps have been published, two pre-drilling (Rock et al., 1983; Rezkey and Hermawan, 2015), and two during exploration and development drilling (Sarmiento et al., 2017; Hinz et al, 2021). The surface manifestations (fumaroles and hot springs) were first mapped in detail by SKM (2011), and all subsequent maps have confirmed this distribution. There is acid-sulfate and argillic alteration exposed at and near the locations of the active surface manifestations. None of the maps have identified any major areas of relict high rank alteration that could indicate cap erosion and areas that could host cool down-flow. Although the map investigations of surface manifestations and alteration are similar, there are key differences in the stratigraphic and structural framework between these maps. Thus, the stratigraphic and structural framework elements of these maps are reviewed relative to geologic mapping best practices and to the current conceptual model to highlight predictive value and data gaps.

Rock et al. (1983): This map provided broad regional coverage with major strands of the Sumatra fault system, and major stratigraphic units from Cenozoic volcanics and sediments to older pre-Cenozoic metamorphic and granitic rocks (Figure 6: upper left). Some of the value for early exploration of this field is that it shows discontinuous coverage of Quaternary and Tertiary volcanics across the region, supporting that at least in part of the reservoir is likely hosted in pre-Cenozoic metamorphic and/or plutonic rocks. There are no kinematic indicators associated with

the fault traces and no structural data plotted on this map. One could assume that the NNW-striking faults probably have dextral strike-slip or oblique strike-slip motion based on the geologic setting. However, even if some of these data were included, the resolution at 1:250,000 scale is typically insufficient for identifying key kinematic structural models to guide exploration.

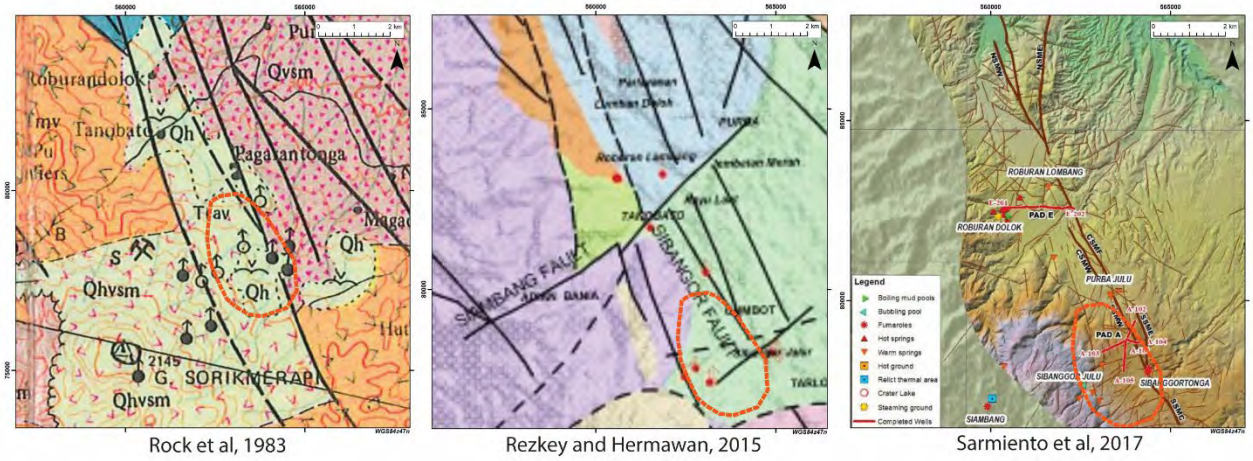

Figure 6: Three maps of the Sorik Marapi geothermal prospect at the same scale (1:60,000) showing the variability in geologic map detail and the same reservoir area (dashed red polygon) modified from Hinz et al, 2021).

Rezkey and Hermawan (2015): This map shows slight differences to lithologic contacts relative to Rock et al., (1983) and a different fault pattern. A key implication for conceptual modeling is that the Cenozoic volcanic rocks are likely relatively thin, and the reservoir is likely hosted in pre-Cenozoic strata. However, like the previous map, there are no kinematic indicators associated with the fault traces and no structural data plotted on this map indicates the likely geometry of the pre-Cenozoic rocks. No cross section was available to illustrate subsurface expectations based on the map data.

Sarmiento et al. (2017): This map is the first publication of this field to include lineament analysis of LiDAR data which could support a detailed geomorphic evaluation of this part of the Sumatra fault zone (Figure 6). The main strands of the Sumatra fault are symbolized with a bold red line while all other lineaments are thin red lines; however, the publication does not report how the individual primary or secondary lineaments were selected (e.g., general topographic feature, fault scarp, fault surface, and/or offset stratigraphy). Missing descriptive elements for the lineaments include kinematic indicators (e.g., strike-slip, normal slip), designation of recency, and concealed versus exposed fault segments. There is also no update of the stratigraphy based on surface mapping. The reported stratigraphic framework was updated in the subsurface based on well data, indicating that the cap and reservoir were entirely comprised of volcanic stratigraphy. Having the reservoir hosted in volcanic stratigraphy is a departure from earlier models such as SKM (2011) that hypothesized that the reservoir was likely hosted largely, or in part, in metamorphic and/or crystalline rock based on the initial mapping of the area by Rock et al. (1983).

Hinz et al., (2021): The geological map in Figure 4 and the cross-section in Figure 5 were based on the stratigraphy from Rock et al. (1983), reanalysis of LiDAR data in 2018 and 2019, field mapping in 2019 and 2021, and new detailed well lithologic logs compiled in 2019 and 2020. Below is a summary of the stratigraphy and structure.

- The stratigraphic framework for the developed geothermal area based on surface exposures and drilling data includes the following: Quaternary volcanics and sediments (Qv and Qs, respectively), Quaternary-Tertiary volcanics (QTv). Metasedimentary rocks (MPu).
- The structural framework is dominated by strands of the Sumatra fault zone. The main active trace, labeled Sumatra Fault System on Figure 4, is associated with fault scarps along much of the length, with some segments covered by recent sediments (Qs). In cross-section, this main strand is associated with a major offset in stratigraphy with a thick section of Tertiary sediments (Ts) to the east of the fault and Cenozoic volcanics (Qs and QTv) overlying metamorphic and intrusive rocks to the west (Figure 5). There is also evidence for dextral offset of stream and river channels along this primary segment (Hinz et al., 2021).
- In addition to the main active trace of the Sumatra fault there are three other segments based on drilling data and geophysics, each with variable surface exposures. These fault segments are labeled Splay A, B, and C on Figure 4. Splay A is associated with a discontinuous series of fault scarps along the trace and an abrupt change in the base of the low resistivity smectite clay alteration detected by MT, shallow over the reservoir and much deeper to the northeast of the Splay A. Splay B is exposed where volcanics are juxtaposed against metamorphic rocks northwest of the reservoir, which is locally supported by drilling data. Slay B likely extends to the northwest based on possible fault scarps north of the map in Figure 4 (Hinz et al., 2021). In cross section there is an abrupt thickening of the Cenozoic volcanics across Splay B from west to east (Figure 5). Splay C is a branch of Splay B and is supported by drilling data and map data to the south of Figure 4 (Hinz et al., 2021).

A key lesson from geologic mapping in this field is that the major strike slip faults bounding the reservoir have typically acted as permeability barriers, whereas the relatively minor faults within the reservoir that are directly contributing to permeability and are not well-exposed on the surface. This is a key pattern in other fields in Sumatra and around the world (e.g., Geysers, California) where major strike-slip faults act as boundaries to reservoirs. Permeability is often associated with the damage zone on one side of the fault, but permeability across the main fault strand is very low, likely due to gouge in the fault core. At Sorik Marapi, the permeability of the reservoir outflow is likely controlled by geomechanics associated with an extensional step-over between two major strands of the Sumatra Fault System, whereas the structural control on the upflow is still not confirmed. The current theory is that upflow is hosted along a ~NNE- to NE-striking high angle fault segment in the west central part of the well field (Hinz et al., 2021).

Kibiro, Uganda

Figure 7: Kibiro location indicated by red star.

The Kibiro geothermal prospect is in Uganda along the east side of Lake Albert (Figure 7). Geothermal investigations at Kibiro were initiated by Ugandan government in 1993 with multiple studies continued intermittently through 2016. As reported in Hinz et a., (2018), new detailed geologic mapping was completed at Kibiro in 2018.

Previous mapping is shown in Figure 8A, where the Northern Toro Bunyoro (NTB) fault is shown as perfectly straight. The new mapping shows that the Kibiro geothermal area is located along a complex system of fault step-overs with a combined length over 1.5 km and width of up to 150 m (EAGER, 2018a; Figure 8B). Each step is also associated with one or more fault intersections in the footwall and/or hanging-wall side.

Fault dip measurements on the upper splay of the NTB fault and the Kachuru fault are 65° NW and 46° to 50° NW, respectively. The 65° dip measurement of the upper splay of the NTB fault matches with the drill-hole data-derived 65° dip estimate on the main strand of the NTB fault north of Kibiro (Alexander et al., 2016a) and the 2D MT inversion model (Figure 9B). Quaternary scarps are associated with both strands of the NTB fault and the first 2-3 km of the Kachuru fault as it extends south from the NTB fault. Based on the distribution of fault scarps it is probable that Quaternary slip on the north end of the Kachuru fault is synchronous with slip along the NTB fault zone.

Surficial geothermal features include four clusters of hot springs, inactive oil seeps, bedrock alteration, and an area of steaming ground (Figure 8B). The hottest cluster of springs ranges from 77 to 87°C and emanates from the NE end of the upper NTB fault adjacent to where it merges with the outer main NTB fault. Three other clusters of hot springs are present outboard of the main NTB fault and are aligned along a possible concealed NE-SW striking step-faults. An area of steaming ground (labeled fumarole) with 45°C temperature was discovered at the SW end of the step-over in an area of intense argillic bedrock alteration, native sulfur, and bitumen (Hinz et al., 2018). The fumarole extends the distance of surface thermal features about 750 m SW of the previously identified hot springs. Results of the previous soil CO_2 and soil temperature studies (Alexander et al., 2016) are consistent with the distribution of active thermal manifestations at either end of the double-ended step-over along the NTB fault.

To revise the conceptual model, the updated structural mapping and the TEM conductance were overlaid as in Figure 9A to support the subsurface structural and MT resistivity cross-section in Figure 9B. The previous UNEP structural model (Alexander et al., 2016) involved a single fault intersection between the NTB fault and the Kachuru fault, suggesting that the upflow was likely focused along a narrow, steeply plunging fault intersection. However, the width of the step-over region along the NTB fault and the extent of the anomalous soil temperatures closely correlated with the NE-SW extent of the high TEM conductance (low average resistivity in orange to red areas) interpreted as smectite alteration in the basin-fill sediments. The consistency between the thermodynamic implications of geology, surficial thermal data, and TEM conductance provides increased confidence in a larger extent of the conceptual model along strike.

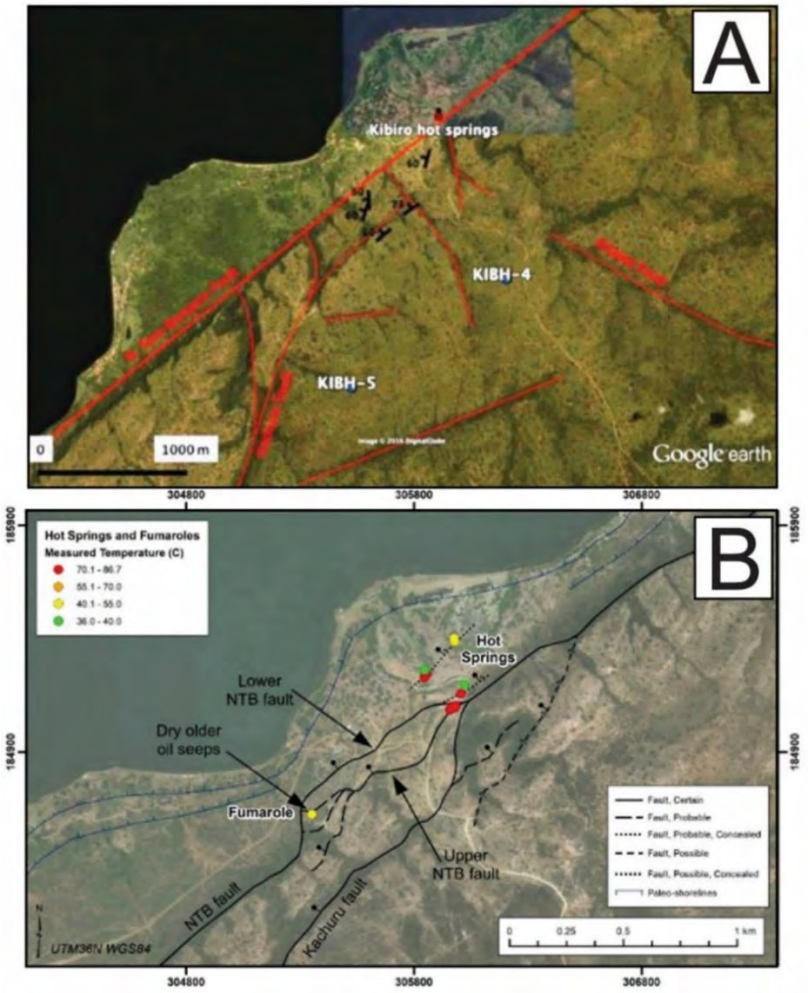

Figure 8: Figure modified from Hinz et al., (2018): (A) Previous geologic map of Kibiro on left (Alexander et al., 2016). (B) New structural geologic map of Kibiro (EAGER, 2018a).

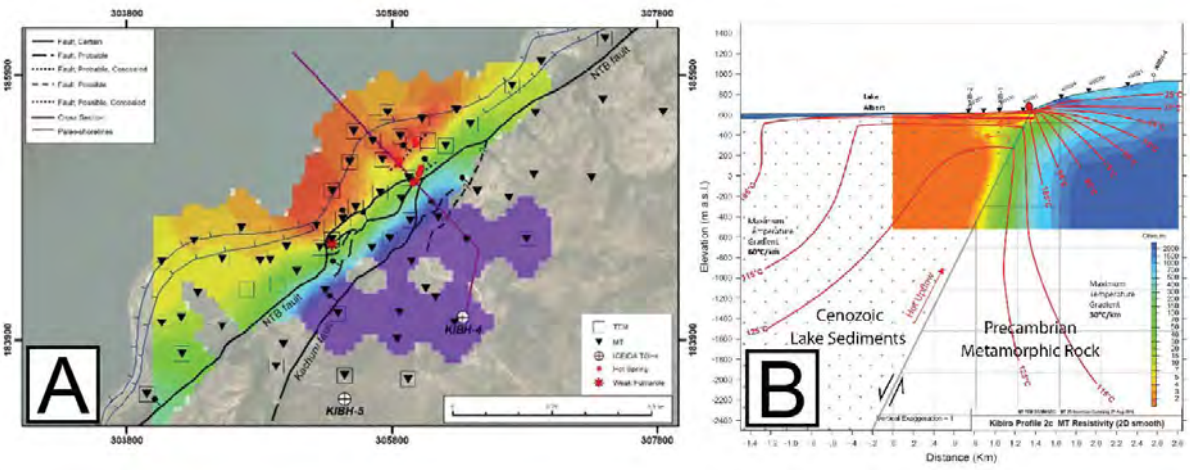

Figure 9: Figures modified from Hinz et al, 2018: (A) Map of TEM conductance to 200 m depth from Alexander et al. (2016) plotted on the new generated structural map (Hinz et al., 2018). (B) MT 2D cross-section with conceptual model isotherms associated with upflow in a fault with 65° dip and outflow into shallow gravels.

The additional data collected in 2018 support the previous model (Alexander et al., 2016) with these additions: 1) higher confidence in achieving commercial production from within the NTB fault zone, and 2) equal or greater confidence in achieving commercial production from within stratigraphic-hosted outflow given higher confidence in fault-hosted up-flow, which suggests a broader area of combined fault and formation-hosted reservoir compared with the previous model. The main uncertainty with respect to targeting the potential outflow is the unknown permeability of the coarser basin-fill deposits and this remains unchanged by this study (a secondary risk issue is its likely lower temperature). The main risk with respect to targeting the upflow in the fault zone is the variable permeability within such fault zones.

An updated median conceptual model cross-section is presented in Figure 9B with isotherms illustrating a 125°C upflow in the NTB fault dipping 65°. Given the higher confidence that the step-over along the NTB fault provides the conduit for deep circulation, the updated conceptual model is constructed to >2000 m a.s.l. to illustrate the control that convection along this structure has on the isotherms.

Blue Mountain, Nevada, United States

Figure 10. Location of the Blue Mountain geothermal area, Nevada, USA.

The Blue Mountain geothermal area in Nevada and has been operating since 2009, with 25 MWe net power capacity as of 2021 (Figure 10). The upflow is >225°C and most production is from a 175-200°C hot outflow. Twenty-six wells have been drilled and of these, seven have been successful as producers. A comparison of recent mapping by Fercho et al. (2023) to previous generations of maps and associated models illustrates what improvements in geological mapping might have contributed to well targeting success.

Six geologic maps (Figure 11) were published for the Blue Mountain geothermal area from 1999 to 2016. All of these maps show a variety of structural complexity at the nose of the mountain range that juts into the basin. Four of these (Fairbank and Ross, 1999; Melosh et al., 2008; Casteel et al., 2010, Swyer et al., 2016) were compiled from a combination of surface observations, geophysics, and well data. However, all four maps lack fault recency and kinematic data needed to develop a kinematic-structural model that could be used to predict subsurface permeability patterns. The map by Wyld (2002) provides kinematic data, but focuses on the Mesozoic basement rocks exposed in the mountain range and does not provide detail on faults that extend into the basin where the reservoir is located. The map by Faulds and Melosh (2008) provide a map with kinematic data, characterization of fault recency, photos and descriptions of Quaternary active fault segments, and they used these data to identify three possible structural setting models for how the geothermal reservoir could be hosted where the mountain range points into the basin. The mapping by Faulds and Melosh (2008) was regional in scale, and they recommended that more detail would be needed to refine the structural model options used to predict subsurface permeability and characterize uncertainty in targeting.

Fercho et al., (2023) picked up from where the mapping by Faulds and Melosh (2008) left off with the new mapping defining that the structural setting is a displacement transfer zone whereby NE-striking, NW-dipping normal faults splay off the north side of a WNW-striking dextral-normal fault (Figure 12). The mapping of the WNW-striking fault is based on multiple fault surface

exposures where dip and kinematic data were measured. Furthermore, the mapping N- and NNE-striking fault segments were based on bedrock exposures of fault surface and fault scarps in Quaternary alluvium. In the updated conceptual model, upflow is along a major normal fault close to where it splays north form the dextral-normal fault. Outflow is between normal faults to the NE. This updated structural model is consistent with one of the previous models identified by Faulds and Melosh (2008).

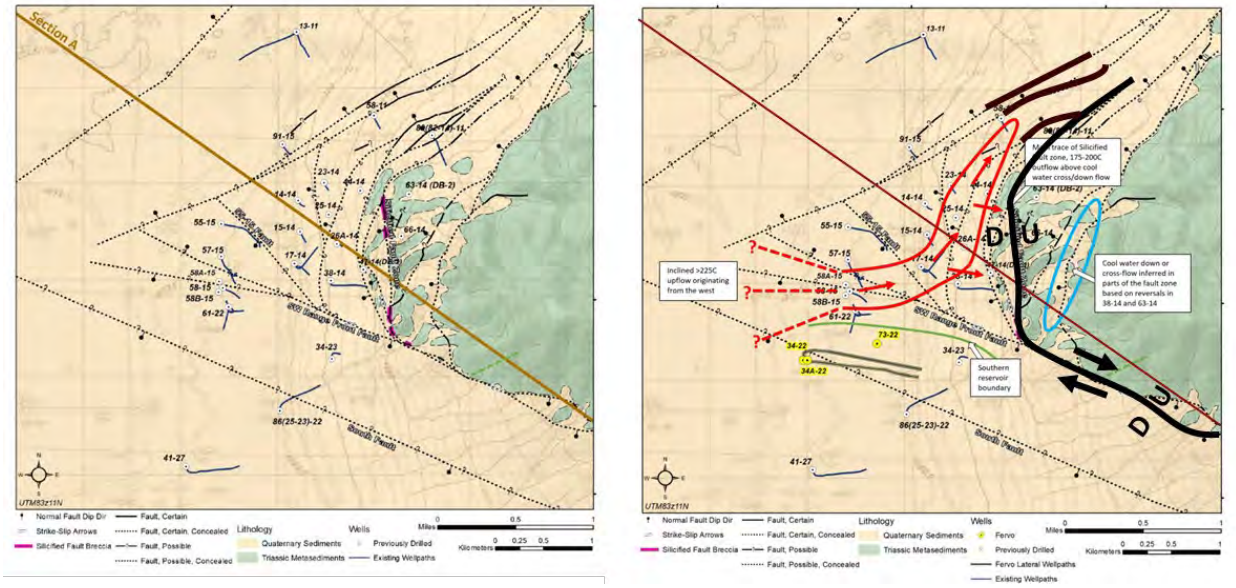

Figure 12:Updated geologic map (left) and conceptual model (right) from the Blue Mountain geothermal area (Fercho et al., 2023).

6. Conclusions

Geologic mapping is an important dataset used to support the development of geothermal resource conceptual models for both high and low temperature geothermal systems in all geological settings worldwide. When initially exploring a prospective resource, previous geologic mapping is typically available. Evaluating the quality and utility of existing geologic mapping is critical to planning exploration and developing resource conceptual models. The consistent use of a checklist like Table 1 can help identify the need for new geologic maps and can help assess the weight given to elements of a geologic map when constructing a conceptual model or targeting a well. When an update is required, geologic mapping based on best practices outlined in this paper can provide geologic maps suitable for integration with conceptual models. Checklists like those presented in Table 2 can help improve the acquisition and interpretation of geologic surface maps so that they will be more predictive of the subsurface.

Geologic mapping is an iterative process that should be periodically revisited as exploration and development progresses and other data sets are acquired. For example, at the Rantau Dedap geothermal field in Sumatra, MT resistivity detected several gaps in the low resistivity smectite cap, one near the proposed upflow target area. Surface geological mapping detected relict higher temperature clay alteration at the surface that well data subsequently showed was related to advanced argillic surrounding an intrusion that is correlated with the current upflow (Ramadhan et al., 2021). The same case history illustrates how a shallow landslide block can obscure the deep structure that is most closely correlated with reservoir permeability. Although geological mapping is initially conducted to predict subsurface conditions in geothermal fields, as development proceeds, surface mapping can be refined to diagnose geothermal resource development issues.

Issues not addressed in this discussion include quantifying the uncertainty of projections of structure into the subsurface based on surface geologic maps. This is becoming particularly important in 3D visualizations that are commonly misinterpreted as having much less uncertainty

than is implied by the supporting data. Further comparisons of surface maps of structure to well data, production zones and wellbore image logs (e.g., Wallis et al., 2012, 2023) would help characterize how predictive surface mapping can be, extending results like that of Guevarra-Segura et al. (2015).

Evaluation of the Geothermal Potential of the Southern San Luis Basin, Taos County, New Mexico

Keywords
temperature logs; discharge temperatures; San Luis Basin, Taos County, Rio Grande rift

ABSTRACT
Temperature-depth measurements from shallow water wells and deep monitoring wells are used to investigate the affects of fluid flow in faults and fluid flow in aquifers on the thermal structure of the southern San Luis Basin (SLB) in north-central New Mexico. Two areas with the highest geothermal gradients are located in the Miranda graben on southern margin and in the No Agua-Cerro de los Taoses area on the western margin of the basin. The ENE-striking, north-down, left-lateral Embudo fault system is an accommodation structure connecting two Rio-Grande-rift half-graben basins, the west-dipping Española Basin to the south and the east-dipping SLB to the north. The Embudo fault cuts the older, north-striking, 8-km-wide Picuris-Pecos fault zone, a Laramide structure that generally is an east-down, strike-slip fault. Toward the east, the Embudo fault transitions to the north-striking, west-dipping, 2-km-wide, Sangre de Cristo fault zone by progressively changing to a dip-slip fault. The intense fracturing of basement rocks caused by the complex interactions among these faults provides pathways to connect deep aquifers with shallow aquifers. Within the Picuris-Pecos fault zone, a series of horsts and grabens, referred to collectively as the Miranda graben, controls the location of Ponce de Leon warm springs. Three water wells (128 to 273 m deep) were logged in Miranda Canyon. Geothermal gradients (32–58°C/km) in all three wells are modified by flowing water. The highest elevation well records downflow and the two lower elevation wells record upflow. Discharge temperatures at the low-elevation end of this system are as high as 35°C.

A second area with elevated geothermal gradients and discharge temperatures extends from the No Agua rhyolite dome along the western margin of the basin eastward to Cerro de los Taoses near the center of the basin. Three thermal profiles collected near No Agua record lateral fluid flow in a thin zone (1–5 m) in a basalt interval. The well at No Agua displays upflow of 33°C water from the screened interval (276–330 m) within a sandstone just above granite basement. In contrast, the three wells at Cerro de los Taoses, which were measured in air, have linear gradients of 50 to 70°C/km in wells 120 to 170 m deep. The temperature data, in combination with published water chemistry data, indicates that the recharge area for this system lies to the west in the Tusas

Mountains. The meteoric water has circulated deeply, picking up heat and chemical constituents and is discharging along buried faults.

Temperature profiles collected from 24 shallow wells scattered throughout the basin are disturbed by fluid flow through vesicular and flow-breccia intervals in the basalt flows of the Taos Plateau volcanic field, masking the deeper thermal structure of the basin. Three deep monitoring wells (410–900 m deep) penetrate below the basalt into the underlying rift-fill sediments. These wells have geothermal gradients of 26.4–28.3 °C/km.

1. Introduction

This investigation focuses on evaluating the geothermal potential of the southern San Luis Basin (SLB) in Taos County, NM (Fig. 1). This basin is part of the Rio Grande rift, a north-striking zone of extension that started forming at 30 to 25 Ma. The heat flow in this particular section of the rift is 71 to 130 mW/m^2 (Edwards et al., 1978). Previous resource evaluations were primarily based on collecting and modeling aqueous and gas geochemistry data from the three known hot springs in the area: Manby (sometimes called Stagecoach spring, 32.8–38°C); Black Rock spring(sometimes called Hondo; 36.9–41°C), and Ponce de Leon spring (34.0–34.6°C). Early water and gas chemistry collection studies include Summers (1976), Swanberg (1980, 1984), and Norman and Bernhardt (1982). Trainer and Lyford (1979) used mixing models of existing data to conclude that the thermal waters are much diluted, hot spring discharge is low, and based on the low temperatures recorded in the chalcedony geothermometers (<100°C) , that the fluids have traveled far from the source of heat.

A systematic analysis of all thermal data available in the southern SLB from a geothermal perspective has yet to be completed. In this study, temperature-depth measurements from shallow water wells and deep monitoring wells are used to investigate the affects of fluid flow in faults and in aquifers within basalt flows and in rift-fill sediments on the thermal structure of the southern SLB. Both local and regional-scale, topographically driven, deep circulation and heating of fluid in an elevated heat flow thermal regime variably controls the elevated gradients observed in the SLB.

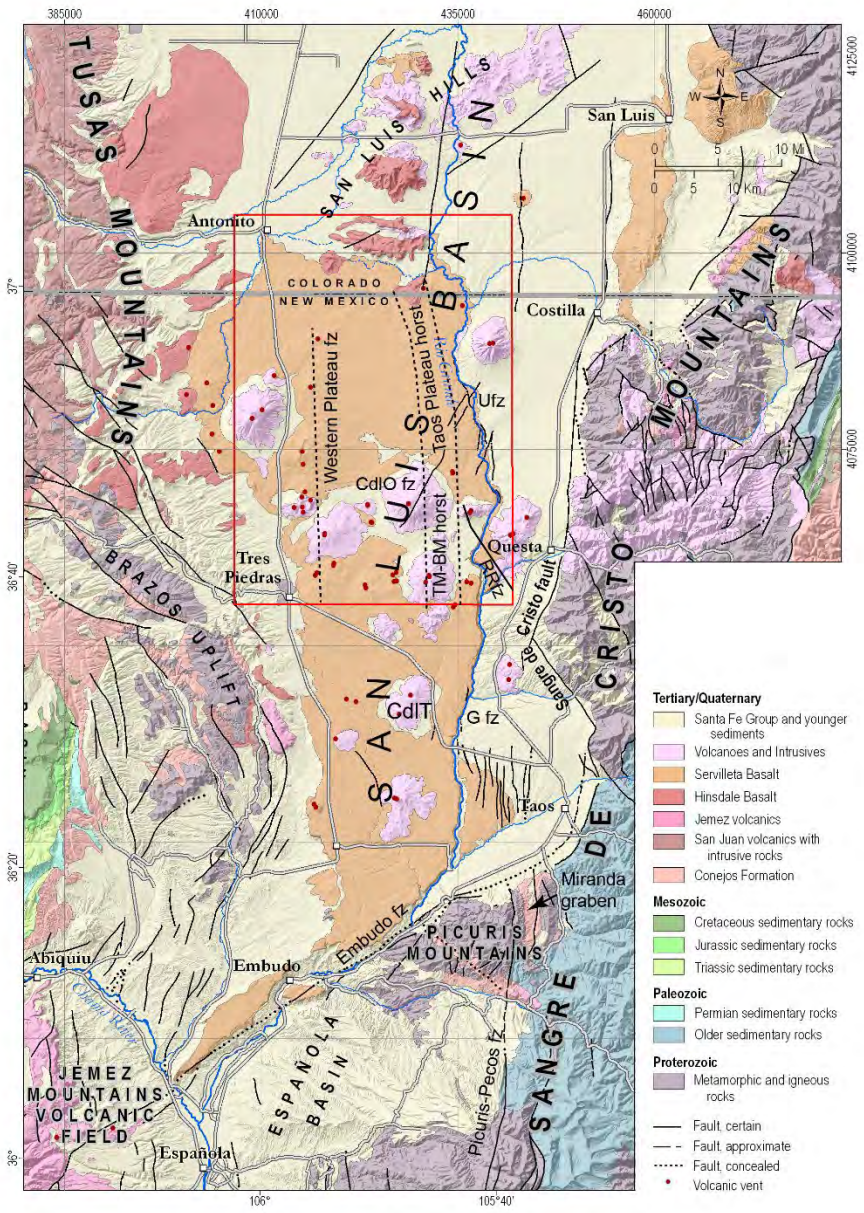

Figure 1. Simplified geologic map of the southern San Luis Basin and the surrounding mountains modified from Johnson and Bauer (2012) The red box shows the extent of the Johnson and Bauer (2012) hydrogeologic study. fz=fault zone; Ufz=Ute Mountain fault zone, CdlO fz=Cerro de la Olla fault zone; G fz=Gorge fault zone; CdlT=Cerro de los Taoses.

2. Geologic Setting

The southern SLB is in the northern part of the Rio Grande rift, a zone of extension that bisects the state of New Mexico. The Sangre de Cristo Mountains are located to the east of the basin and the basement-cored Tusas Mountains lie to the west (Fig. 1). The Picuris Mountains, bounded on the northwest by a left-lateral strike slip fault, the Embudo fault, form the southern boundary of the basin; this fault has a minor north-side-down normal component. The Picuris Mountains are separated from the Sangre de Cristo Mountains by the north-striking Picuris-Pecos fault zone that was active during Proterozoic, Laramide, and Rio Grande rift episodes of deformation (Miller et al., 1963, Bauer and Kelson, 2004; Cather et al., 2011). Gravity and aeromagnetic surveys reveal that the SLB is deepest along a narrow zone next to the west-dipping, western bounding faults of Sangre de Cristo Mountains (Cordell, 1978; Keller et al., 1984). This narrow feature, the Taos graben, is bordered on the west by the buried east-dipping Gorge fault (Grauch and Keller, 2004). Manby and Black Rock hot springs emerge from one of the few strands of the Gorge fault that reaches the surface. An intrarift horst on the west side of the Taos graben is marked at the surface by exposures of Oligocene volcanic rocks on Timber Mountain and Brushy Mountain (Lipman and Mehnert, 1979; Thompson et al., 1991; Grauch et al., 2017)). Johnson and Bauer (2012) extend this feature to the north into Colorado as the buried Taos Plateau horst (Fig. 1). The Jemez lineament, a zone of NE-striking low-velocity mantle that is associated with < 10 Ma volcanism, including the 6 to 1 Ma Taos Plateau volcanic field (Lipman and Mehnert, 1979; Appelt, 1998), crosses the area of interest. Basalt flows of the Taos Plateau field cover the central and western parts of the basin.

Several tectonic events, including Proterozoic continental assembly, Pennsylvanian Ancestral Rocky Mountain, Late Mesozoic to Early Cenozoic Laramide, and Middle to Late Cenozoic Rio Grande Rift deformation, have shaped the structural and depositional elements of the basin. Volcanic and volcaniclastic rocks derived from the Late Eocene to Miocene San Juan volcanic field to the northwest and the Oligocene to Miocene Latir volcanic field on the eastern margin of the basin near Questa are preserved throughout the region. As extension in northern New Mexico began at 30–25 Ma, the developing rift basin filled with debris shed from the surrounding highlands. As extension continued, prominent, rounded andesitic to dacitic to rhyolitic domes erupted between 5 and 3 Ma at the same time that Servilleta basaltic shield volcanoes were active 5.2 to 3.6 Ma, thus creating the Taos Plateau volcanic field. Extension has continued; both the Sangre de Cristo fault and the Embudo fault zones have been active during Quaternary time (Menges, 1990).

3. Aquifers

The principal aquifers in the southern SLB in proximity to the town of Taos are sedimentary units in the Late Oligocene to Miocene Santa Fe Group. This unit includes (from oldest to youngest): alluvial/fluvial basin-fill deposits (Chama-El Rito Member of the Tesuque Formation), well-sorted eolian sands (Ojo Caliente Sandstone Member of the Tesuque Formation), and a younger set of alluvial and fluvial basin-fill deposits assigned to the Chamita Formation. The basalt lava flows of the Taos Plateau volcanic field assigned to the Servilleta Formation (Drakos et al., 2004; Johnson and Bauer, 2012; Johnson et al., 2016). The middle Pleistocene Lama Formation is intercalated with and overlies the basalt flows. The Lama Formation is comprised of distal-alluvial-fan sand and gravel derived from the Sangre de Cristo Mountains. This unit was deposited before the development of the Rio Grande gorge. All basin-fill units and the basalts generally thin towards

the south and east, eventually pinching out against the mountain fronts (Johnson et al., 2016). Fractures in the fault damage zones in the basement rocks are generally open (Johnson et al., 2016). In contrast, fault damage zones in the Santa Fe Group are generally filled with clay (Johnson et al., 2016); thus, aquifers within the Santa Fe Group tend to be compartmentalized. The basalts are also important aquifers. Columnar jointing is common and basal flow breccias and vesicular flow tops facilitate groundwater flow.

The Servilleta Formation is the principal aquifer in the western portion of the SLB in northern New Mexico (Johnson and Bauer, 2012). The basalt flows are thick, continuous and are interbedded with clay and silt. Permeability in the basalt is high due to the presence of columnar joints, vesicular flow tops, basal breccias, and lava tubes. The Santa Fe Group underlies the basalt flows of the Servilleta Formation. In the western part of the basin, the Oligocene Hinsdale basalt that was derived from volcanic centers in Colorado is an important deep aquifer that delivers groundwater from the Tusas Mountains to the SLB (Johnson and Bauer, 2012).

4. Important Structures

4.1 Southern basin

Johnson et al. (2016), building on the earlier work of Bauer et al. (2004), document that the complex interaction between the older, north-striking, 8-km-wide Picuris-Pecos fault zone and the younger, ENE-striking, north-down, left-lateral Embudo fault system. This interaction intensely fractured the basement rocks on the southern margin of the SLB, thus providing pathways to connect deep aquifers with shallow aquifers. Overall, the Picuris-Pecos fault zone is an E-down, strike-slip fault, but in detail in the Miranda graben near Talpa, the zone actually consists of a series of horsts and grabens. The Miranda graben developed during Laramide offset along the Pecos-Picuris fault. The graben was filled by the 28.35±0.11 Ma Picuris Formation derived from the San Juan Mountains; these sediments were subsequently cut by the fault (Johnson et al., 2016). The Picuris-Pecos system continues northward and is buried beneath the rift-fill deposits of the SLB. The buried fault appears to have been reactivated as the Los Cordovas system that offsets alluvial fans as young as Quaternary (early to middle Pleistocene). Latest motion on the Embudo fault system is constrained to be late Pleistocene to Holocene. Toward the east, the Embudo fault transitions to the N-striking, W-dipping, 2-km-wide, Sangre de Cristo fault zone by progressively changing to a dip-slip fault.

4.2 Western basin

Johnson and Bauer (2012) identified four surface faults that cut the volcanic rocks of the Taos Plateau volcanic field and two possible buried structures that control groundwater flow in the SLB west of the Rio Grande (Fig. 1). The four surface faults are the northwest-striking, east-down Red River fault zone, the northeast-striking, east-down Ute Mountain and Cerro de la Olla faults, and complex Gorge fault zone largely identified using aeromagnetic data (Machette et al., 2007). The Red River fault zone cuts Pleistocene gravels (Kelson et al., 2008). Older Oligocene volcanic rocks are exposed on the Timber Mountain-Brushy Mountain horst. Johnson and Bauer (2012) extend this horst, named the Taos Plateau horst, northward into Colorado based on the presence of elevated discharge temperatures, water chemistry, and aeromagnetic data. The presence of the Western Plateau faults is based on the alignment of volcanic vents and on a decrease in hydraulic gradient across the proposed structure.

5. Temperature Measurement Methods

Johnson and Bauer (2012) and Johnson et al. (2016) identified several open wells with no pumps (either monitoring wells or undeveloped wells) for data logger installation. These types of wells are perfect for equilibrium temperature log analysis. Eighteen thermal logs measured in open wells were collected as part of this study. In addition, we compiled thermal profile data from published thermal gradient/heat flow studies (Swanberg, 1984; Edwards et al., 1978; Reiter et al., 1975, Reiter and Sandoval, 2004). Published thermal profiles from deep monitoring and production wells have not been previously analyzed in the context of rock types encountered in the wells. We gathered data from driller's logs and available geophysical logs and compared these data to variations in geothermal gradient in each well to determine the influence of rock type on geothermal gradient and to evaluate conductive versus convective affects.

The New Mexico Bureau of Geology and Mineral Resources temperature-logging equipment uses a thermistor attached to a wireline cable to measure resistance as a function of depth. Resistance is translated to temperature using a laboratory calibration. Resistance is recorded at 1-m depth intervals using a digital multimeter and a computer. Profiles in the southern basin were measured with a sensor designed to measure resistance in water; consequently, the air readings for these logs are not in thermal equilibrium. In contrast, many of the open holes west of the Rio Grande are dry, so a different, fast-response thermistor was used to measure temperature in the vadose zone. The logging rate varied from one to 4 m/minute.

The distribution of temperature measurements discussed in this paper is illustrated in Figure 2. Many of the shallow wells are disturbed by shallow fluid flow, masking the geothermal potential of the deeper system (e.g., Fig. 3G). Consequently, this investigation will primarily focus on the deeper monitoring and water wells highlighted by yellow dots on Figure 2, although a few warm, shallow wells are included in the analysis.

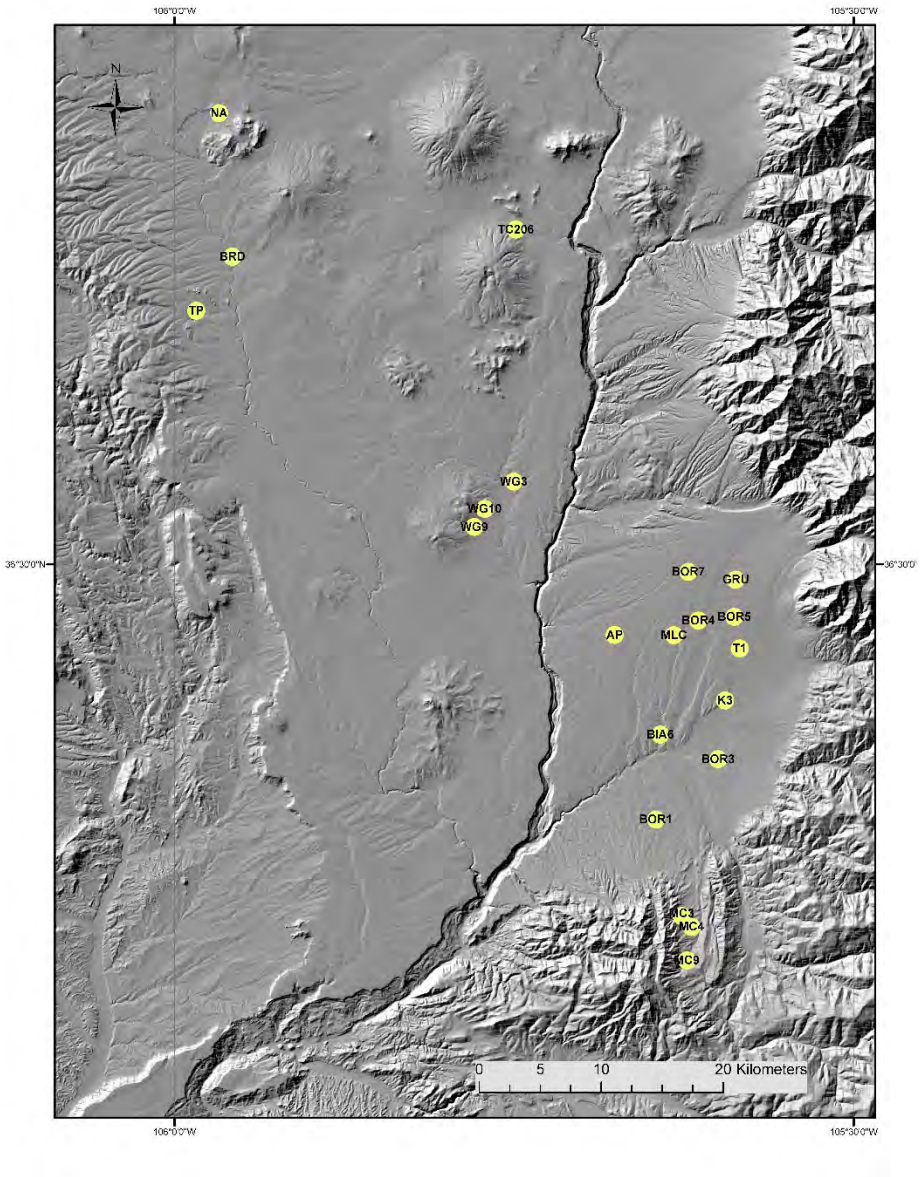

Figure 2. Location of the water and monitoring well included in this analysis.

6. Temperature Log Results

The discussion of the results is organized by location within the southern SLB. Fluid movement in aquifers influences thermal profiles from deep monitoring wells and intermediate-depth water wells east of the Rio Grande. Measured temperatures in the Miranda graben are potentially affected by fluids moving through highly fractured rocks in the Embudo and Picuris-Pecos fault zones and contain information about both recharge and discharge. Anomalously high geothermal gradients characterize the data from the west side of the basin between Cerro de los Taoses and Tres Piedras.

6.1 East of the Rio Grande (Eastern Basin)

Eight deep (305 to 944 m) monitoring and production wells and two shallow water were logged in an area that is within a few kilometers north, west, and southwest of the town of Taos. Reiter and Sandoval (2004) published temperature logs from five monitoring and production wells drilled by the Bureau of Reclamation in cooperation with the town of Taos, and one well was re-logged as part of this study. BOR1 is a deep monitoring well (610 m) drilled south of the basalt pinch out. A shallow well (140 m) is part of the piezometer nest. BOR1 was completed on 11/22/99 and Reiter and Sandoval (2004) logged the well August 2002. As part of this study, we logged both the co-located shallow and deep monitoring wells on 7/17/12. The temperatures in both the shallow and the deep piezometers measured in 2012 at depths less than 140 m are nearly identical; however, the temperature in the deep BOR1 borehole has changed significantly between 2002 and 2012 (Fig. 3A). At depths shallower than 500 m, the well has cooled about 1.6°C, and the well has warmed about 0.7 °C below 500 m between 2001 and 2012. Wells do equilibrate through time as the surrounding rocks recover from thermal changes caused by drilling. The usual trend is warming through time, but cooling has been observed. Furthermore, purging of monitoring wells during water sampling may modify the temperature distribution in a well. The most recent thermal profile is disturbed by cool water flowing through gravel and sand intervals at 403–433 m (flowing around the well casing) and 439–488 m (coincides with the upper-screened interval). Linear gradients in the shallow part of the deep BOR1 and in shallow well are 24–26 °C/km; analysis of the Reiter and Sandoval (2004) log over this same depth range yields a similar result. Gradients in the deeper part of BOR1 are 30–33°C/km.

Well BOR3 (Fig. 3B) penetrates the Servilleta and Chamita formations, and the Chama-El Rito Member of the Tesuque Formation. The gradient shows a small inflection at the contact between the Servilleta Formation and the Chamita Formation that is likely related to thermal conductivity contrast between rock types; the gradient is slightly higher in the basalt. The gradient is linear (20.1°C/km) through the upper part of the Chamita Formation, and then the gradient becomes nearly isothermal below 420 m. Cold water enters the well at the top of the screen and appears to move down the well (Reiter, 2004).

Deep monitoring well BOR4 (Fig. 3C) penetrates Servilleta Formation, Chamita Formation, and the Chama-El Rito Member of the Tesuque Formation. The gradients in BOR4 are moderately disturbed by upflow, with water coming into the borehole near the top of the screen in the Chamita Formation. The geothermal gradient below the disturbed interval is 28.7°C/km.

Chamita Formation, and the Ojo Caliente and Chama-El Rito members of the Tesuque Formation are encountered in BOR5 (Fig. 3D); the well bottoms in one of the older basalts. Two zones of cold water, one a ~205 m and one at ~460 m locally modify the gradient. The upper cold zone is in the Chamita Formation and the cool water is flowing around the casing. The lower cold zone is in the Chama-El Rito Member. Water enters the borehole within the screened interval. The gradient in the relatively undisturbed middle section of the well is 35°C/km.

BOR7 (Fig. 3E), the deepest well logged (900 m), goes through thick Lama Formation, Servilleta Formation, Chamita Formation and both members of the Tesuque Formation. The top of the log is greatly affected by cold water flowing through Servilleta Formation basalt. Below the basalt, the geothermal gradient is linear (28°C/km) and the slight changes in gradient line up with changes in rock type. The maximum measured temperature in this deep drillhole is 38°C.

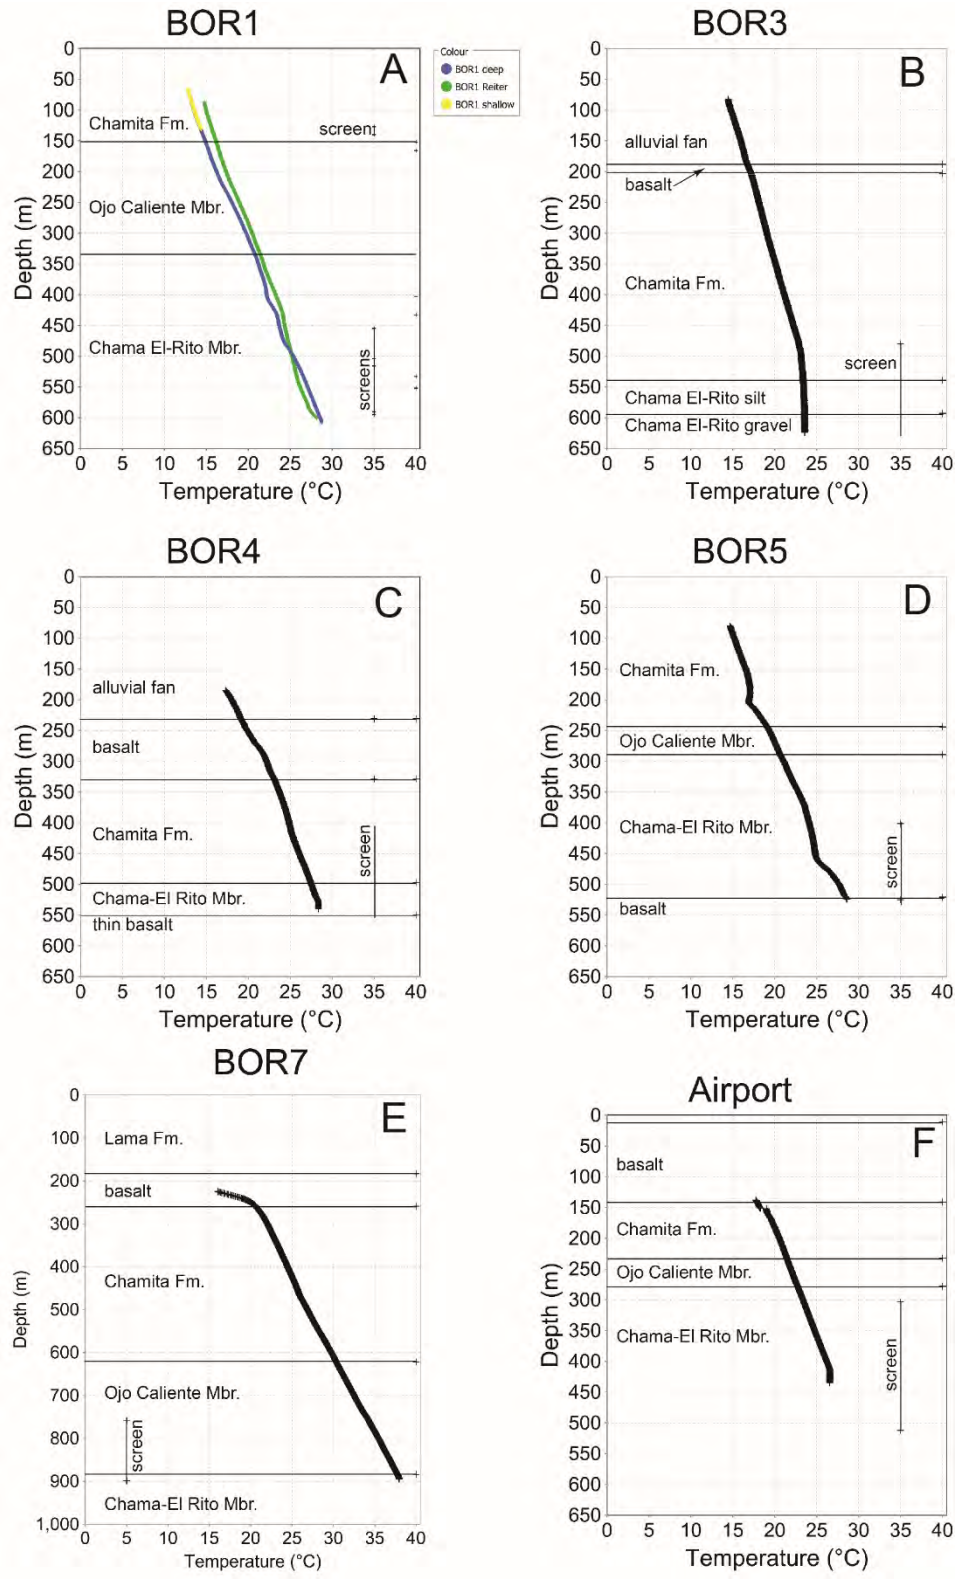

Figure 3A-F: Thermal profiles in deep boreholes near Taos from Reiter and Sandoval (2004). The rocks units in each well were added as part of this investigation. The Ojo Caliente and the Chama-El Rito are members of the Tesuque Formation.

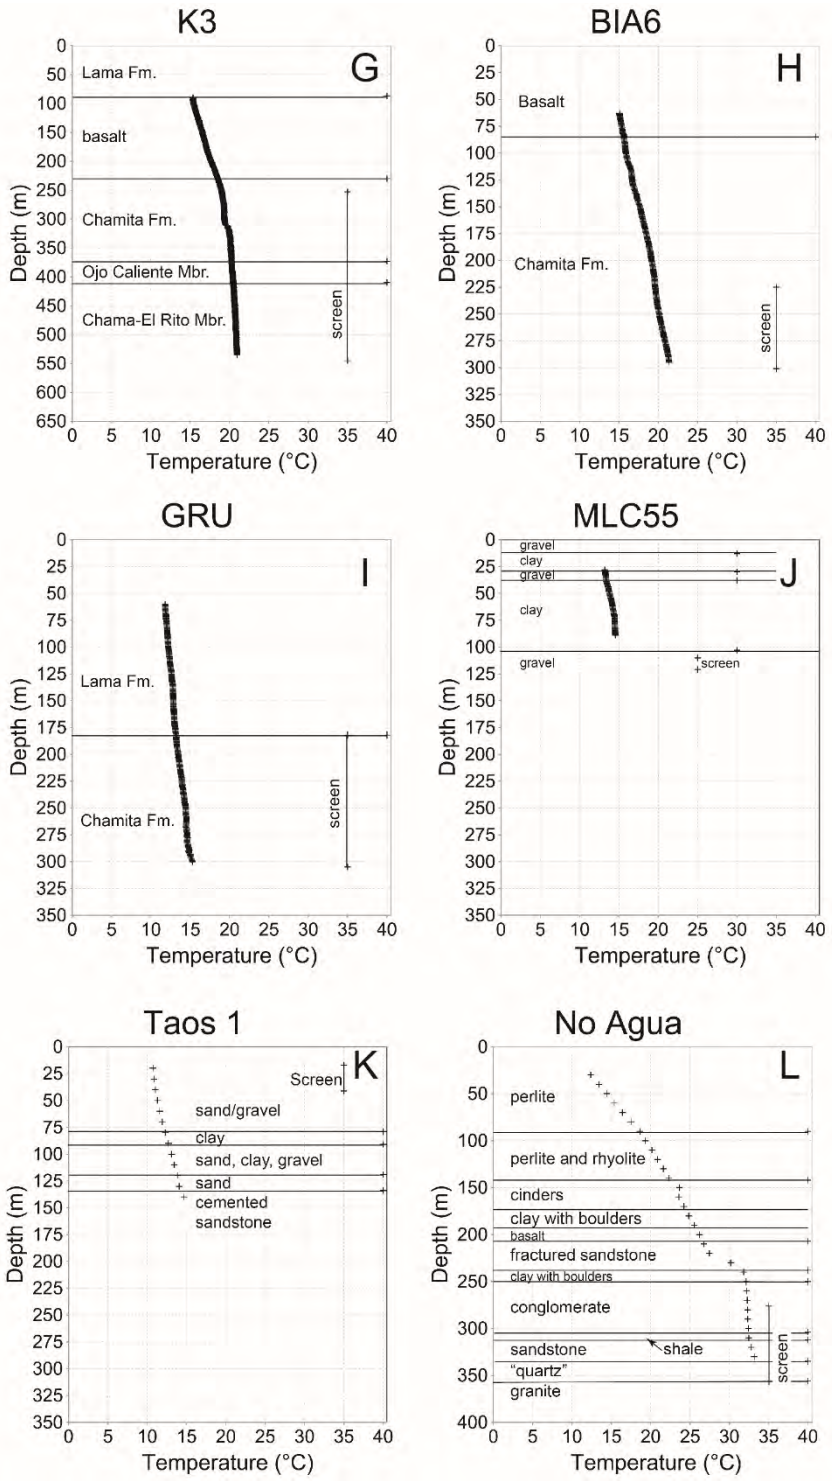

Figure 3G-L: Temperature-depth logs from Reiter (2004; G, H, I), this study (J); Edwards et al. (1978; K) and Reiter et al. (1975; L). The rocks units in each well were added as part of this investigation.

The deep well at the Taos Airport (Fig. 3F), which is located closer to the center of the Taos Plateau, has a conductive gradient of 28°C/km through the Chamita Formation and both members of the Tesuque Formation. Minor cooling near the top of the log may be related to cool water flowing through the overlying Servilleta Formation.

K3 (Fig. 3G) encounters Lama, Servilleta, and Chamita formations and the Ojo Caliente and Chama-El Rito members of the Tesuque Formation. The geothermal gradient through the Servilleta Formation is 23°C/km. Cool water enters the drill hole through the screen at 230 m, indicating a downward hydraulic gradient (Reiter and Sandoval, 2004).

BIA6 (Fig. 3H), which is located near the Rio Pueblo de Taos (Fig. 2), is in Servilleta Formation basalt above 85 m and the well is completed in Chamita Formation. Water coming into the well near the top of the screen is flowing up the borehole. The gradient above the disturbed interval is 25°C/km.

The Lama and Chamita formations were encountered in GRU (Fig. 3I); the Servilleta Formation is not present. This well generally has a low geothermal gradient (19°C/km), likely due to its proximity to the Sangre de Cristo mountain front. Two minor influxes of cool water are within the screened interval, one near the Lama/Chamita contact, and the second in the Chamita Formation near the bottom of the well.

One shallow well, MLC-55 (Fig. 3J), was logged as part of this study. The drillers log indicates that the well encountered alternating layers of gravel and clay. Cool water enters the well through the screen and flows up, indicating an upward hydraulic gradient. The geothermal gradient between 40 to 70 m is 31°C/km. A second shallow well, Taos 1 (Fig. 3K), was measured by Edwards et al. (1978) and is drilled into sand, gravel, and clay of the Santa Fe Group. Small variations in gradient correlate to rock type changes, indicating conductive heat flow in this well. Measured gradients are 37 to 42°C/km.

6.2 Miranda graben

Three wells that are 128 to 273 m deep were logged in Miranda Canyon (Fig. 4C). Geothermal gradients in all three wells are modified by flowing water. The calculated gradients for two of the wells are estimated from short linear segments that may not coincide with changes in rock type. The shape of the thermal profile in Miranda Canyon 3 is typical of slow upflow in the wellbore. The gradients measured in the middle part of the Miranda Canyon 4 hole coincide with fine-grained (57.8°C/km) and coarse-grained interval (51.2°C/km) interpreted from the driller's logs. Water from a cool aquifer enters the Miranda Canyon 4 well at the screened interval. Miranda Canyon 9 penetrates alternating beds of sand and gravel and one clay layer. Cold water appears to flow around the top of the wellbore. A background gradient of 32.4°C/km was calculated for depths greater than 103 m.

6.3 Western margin

Previous measurements of heat flow by Reiter et al. (1975) identified two wells with elevated geothermal gradients on the western margin of the Taos Plateau. The well at Tres Piedras (Fig. 4 B, TP) is about 170 m deep; no driller's logs are available. The average linear geothermal gradient is 51°C/km through the middle of the well, and warm water enters the well at ~140 m. The second well with published heat flow data is the water well that supplies the No Agua perlite mine (Figs.

3L, NA on Fig.4B). The upper part of the well, which is in perlite and rhyolite, is conductive. The drillers log mentions lost circulation in the sandstone interval. Warm water flows around the well near the top of a basalt flow at a depth of 150 m. Sandstone, conglomerate, and clay that likely belongs to the Santa Fe Group underlies the basalt. Warm water enters the well through the screen near the bottom of the hole and flows up the well bore. The well bottoms in Proterozoic rocks**.** Interval gradient in the No Agua well are 64.3 to 100.9°C/km.

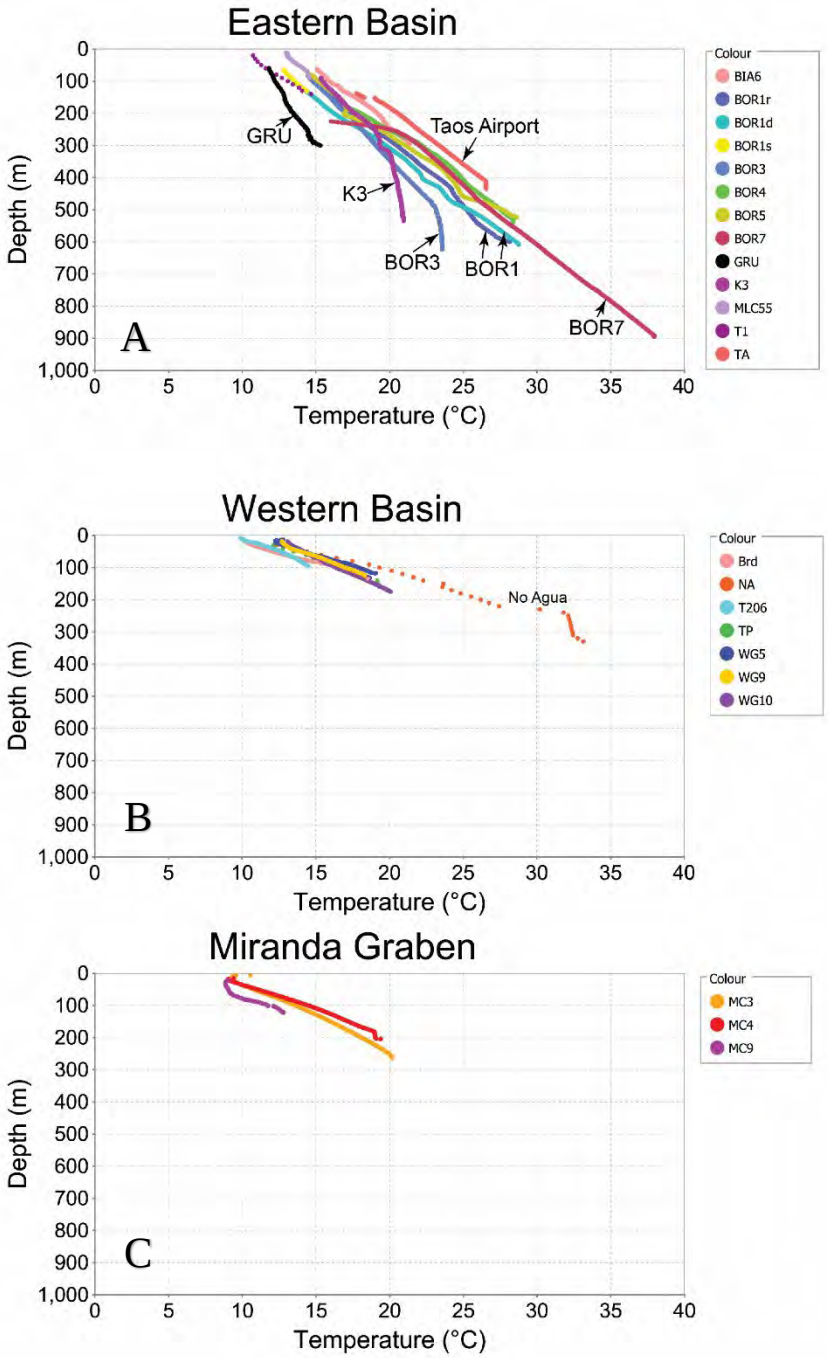

Figure 4: Comparison of temperature logs from the southern San Luis Basin.

Five wells west of the Rio Grande were logged as part of this study. T206 (Fig. 4B) is located in the middle of the basin north of Highway 64. Well T206 has conductive gradients ranging from 51 (shallow) to 36 (deep) °C/km; no driller's log is available for this well. Three wells were logged near Highway 64 west of the Rio Grande in the Cerros de los Taoses. WG5 (Fig 4B) is a dry hole that penetrates Lama Formation, Servilleta Formation basalt flows and intercalated clay or sand and gravel beds, and bottoms in the Chamita Formation. The thermal profile is noisy because the casing has been removed and vadose zone moisture appears to be moving along flow breaks and within the basalt flows. A rainstorm at the surface during the time of logging might also have contributed to the noise. The linear gradient through a thick clay layer at the bottom of the well is 55.7 °C/km. WG9 (Fig. 4B) is a dry hole that penetrates 153 m of "andesite" and interbedded sandstone. Linear gradients range from 56 (shallow) to 44 (deep)°C/km. WG10 (Fig. 4B) is a dry well with no driller log, but the hole is likely in the Servilleta Formation. The linear gradient near the bottom of the hole is 50 °C/km. The final well logged in this region was the Bradley (Fig. 4B, Brd) well, a dry hole about 106 m deep that bottoms in Proterozoic granite on the west side of the basin adjacent to the Tusas Mountains. This warm well has gradients that vary from 74 (shallow) to 112 (deep) °C/km.

7. Discussion

7.1 Margins of the basin

Two areas of geothermal interest along the southern and western margins of the SLB that appear to be structurally controlled are characterized by elevated geothermal gradients compared to the gradients in the eastern part of the basin (east of the Rio Grande; Fig. 4). One area is associated with the well-known Ponce de Leon warm spring located at the north end of the Miranda graben (Fig. 1). This hydrologic system is controlled by flow pathways along strands of the N-striking Picuris-Pecos fault zone interacting with the northeast-striking Embudo fault zone. The new temperature logs from the Miranda graben provide information about the recharge area and the flow paths that lead to discharge of the spring. Johnson et al. (2016) describe the hydrogeologic framework of the southern margin of the SLB using a combination of major and trace element geochemistry and isotopic analysis. These authors document elevated groundwater discharge temperatures associated with the Ponce de Leon thermal spring along the south edge of the SLB. The temperatures are 21.9 to 34.9 °C in a zone about two km north of the spring. Elevated temperatures in the outflow plume extend 7.5 km northeast into a shallow aquifer along extrapolated projections of the buried Picuris-Pecos fault zone. The chemistry of the groundwater at the Ponce de Leon spring (Na-Cl-SO_4) is unique compared to groundwater in the headwaters in the Miranda graben (Ca-Mn-Mg-HCO_3). Johnson et al. (2016) suggest that the chemistry of the Ponce de Leon system is related to deep circulation of groundwater through Pennsylvanian carbonates and evaporites and volcaniclastic Picuris Formation within and beneath the graben.

The second prospect is located along the western margin of the Taos Plateau north of the village of Tres Piedras. The presence of elevated geothermal gradients in this area has long been known (Reiter et al., 1975), but new data collected during this investigation expand the zone of high geothermal gradients eastward into the Cerros de los Taoses. Johnson and Bauer (2012) identified elevated discharge temperatures in several wells on and just west of the No Agua rhyolite dome that range from 25 to 31 °C. These authors propose a model of deep underflow from the Tusas Mountains into the western SLB through the Hindsdale basalt and fractured Proterozoic basement

based on the chemistry of the Ca-Mg-rich HO_3 groundwater that characterize this area. Oxygen and deuterium data from this region support the concept of deep circulation within the Tusas Mountains. Deuterium depletion suggests that the groundwater originated at high elevation and a positive ^{18}O shift (0.5 to 1.0%, fig. 32, Johnson and Bauer, 2012) indicates water-rock interactions at high temperatures. Groundwater residence times are 8000–5500 radiocarbon-years before present.

7.2 East of the Rio Grande

In contrast to the basin margins, the thermal architecture of the SLB east of the Rio Grande near the town of Taos reflects the interaction between the regional geothermal gradient and groundwater flow in aquifers. Cool water flowing through basalt flows and though discrete beds in Santa Fe Group sedimentary units is documented in several wells. The aquifers at depth are confined. Differences in hydraulic gradient cause upflow and downflow within wellbores, which is observed in the thermal profiles of several wells in this region. Johnson et al. (2016) also note differences in hydraulic gradient in piezometer nests in this area. The gradients is slightly down near Rio Grande del Rancho, but near Rio Pueblo de Taos, the gradient is up (Johnson et al., 2016). The background geothermal gradient is 28°C/km east of the river.

7.3 Other prospective areas

7.3.1 Red River fault zone

Johnson and Bauer (2016) measured relatively warm discharge temperatures of 16.5–18.1°C from wells near the northwest-striking Red River fault zone (Fig. 1) and its projection northward into the buried Taos Plateau horst. Three warm springs (16.5–17.5°C) discharge from the fault zone. The groundwater near projections of the Red River fault zone and its intersection with the Cerro de la Olla-Ute Mountain faults zone is Na-rich with relatively high concentrations of Cl and SO_4. A relatively elevated Cl/Br ratio of 190 was measured in this area.

7.3.2 Sunshine Valley

Temperature logs for the three wells were measured by Rawling and Kelley (2020); all three were isothermal due to groundwater flow in the basalt in that area, with warmer temperatures measured near the village of Costilla just south of the Colorado border. Warm discharge temperatures of 16.4 to 23.8 °C were measured in two wells near Costilla. An important finding from that study was that, based on chloride mass balance calculations, more than half of the recharge occurs as groundwater underflow into the aquifer directly from the Sangre de Cristo mountain block. The steep topography and geologic features of the Questa caldera probably influence the large amount of recharge by underflow in this part of the SLB.

7. Conclusion

In general, groundwater flow in aquifers in the Servilleta Formation basalt flows and in permeable layers within the Santa Fe Group mask the true geothermal potential of the southern SLB. Despite this challenge, local, structurally controlled, deep-circulation systems in the Miranda graben and north of Tres Piedras have been identified using a combination tof temperature logs, spring and

well discharge temperatures, and groundwater geochemistry. Other areas that warrant further investigation are located along the Red River fault zone and near the village of Costilla.

Acknowledgement

Jeff Pepin helped with the fieldwork. Paul Bauer provided important information about the rock units in the BOR wells.

Remote Sensing Case Studies for Detection and Interpretation of Geothermal Surface Materials for Geothermal Exploration in the Basin and Range, Nevada, USA

Kurt O. Kraal and Paul C. Schwering

Sandia National Laboratories

BRIDGE, SWIR, Hyperspectral, Remote Sensing, Exploration, Sinter, Great Basin

ABSTRACT

"Blind" geothermal systems, lacking active geothermal surface manifestations such as hot springs or fumaroles, are difficult to discover. However, there are often surface or near-surface materials indicative of subsurface geothermal activity above a blind system. These are typically products from springs/fumaroles related to the system that are no longer active or exposure of hydrothermal alteration minerals due to faulting and/or erosion. Examples of shallow or surface materials indicative of possible geothermal activity include silica polymorphs (e.g., opal/chalcedony, found in silica sinter, silicification or veining), carbonates (e.g., tufa, travertine, calcite veining), advanced argillic alteration (e.g., kaolinite, alunite), intermediate argillic alteration (smectite, illite) and borates. We utilize publicly available airborne hyperspectral data in the visible and short-wave infrared (SWIR) wavelength range over western Nevada to create thematic maps of geothermal indicator minerals over known geothermal systems and prospects for use in exploration. We map several benchmark areas with known geothermal surface materials: Salt Wells, and Lee Allen. We then apply these techniques to produce mineral maps of prospective resource areas in Gabbs Valley, Hawthorne, and Bell Flat, Nevada. We synthesize these maps with existing data to explore how they may inform exploration activities and potential conceptual models.

1. Introduction

The goal of this paper is to demonstrate the use of publicly available hyperspectral data in the Great Basin region of the western USA for geothermal exploration by identifying geothermal surface materials and paleo-geothermal deposits. This work, funded by the U.S. Department of Energy's Geothermal Technologies Office, is part of the Basin & Range Investigations for Developing Geothermal Energy (BRIDGE) Project to advance the exploration practices of discovering and characterizing hidden (or "blind") geothermal resources in the region (Schwering

et al., 2022). First, we will describe a conceptual framework for the shallow environment of geothermal systems and the formation of various hydrothermal minerals. We will then review previous examples of using remote sensing techniques to map geothermal surface materials. We will then look at two benchmark locations where previous mapping has identified sinter and silicified sediments (i.e., Lee Allen Hot Springs and Salt Wells Geothermal Field, Nevada) and evaluate techniques and data quality for geothermal exploration activities. We will then apply those techniques and data sources for geothermal exploration in several greenfield locations with high geothermal resource potential.

1.1 Conceptual Framework

Geothermal systems produce distinctive mineral products and landforms on the surface or in the near subsurface through the discharge of various fluid types (Sillitoe, 2015; e.g., Figure 1). These landforms and mineral products can be the product of surface hot springs and/or fumaroles or be formed in the subsurface and exposed by faulting and/or erosion. Even when there are no active hot springs or fumaroles, such as at a blind geothermal system, there may be relict paleo-geothermal deposits that were active in the past. These surface features and shallow hydrothermal alteration zones can be identified by distinct minerals or mineral mixtures. Several of these materials can be detected with remote sensing techniques, including silica (opal/chalcedony), carbonates (calcite, aragonite), and phyllosilicates (smectite, kaolinite, illite; e.g., Figures 2 & 3).

Silica polymorphs (e.g., opal and chalcedony) can be found in several shallow and surficial geothermal environments with neutral-pH chloride thermal waters. The classic example is silica sinter discharged at the surface in hot springs, and the presence of sinter is considered a good indicator for a high temperature geothermal reservoir (greater than ~175 °C per Fournier, 1983). Hot springs can only occur where the water table intersects the surface, which may occur proximal or distal to the inferred upwelling location, or not at all. Hot fluids (~100 °C) supersaturated in silica precipitate opal-A (amorphous silica) in cones, aprons, terraces, pools or marshes producing several distinct sinter facies (e.g., Cady & Farmer, 1996). As it ages over ~50,000 years, the opal-A will transition through several intermediary steps to microcrystalline quartz (chalcedony) (Sillitoe, 2015). Historically active sinter terraces are present at Steamboat Springs (White et al., 1964) and Beowawe geothermal fields in Nevada (Rimstidt & Cole, 1983). Common features observed at high temperature geothermal fields in the Great Basin are silicified sediments, such as at Salt Wells and Desert Peak, often found alongside sinter and is sometimes exposed at the surface through erosion (Garside & Schilling, 1979; Coolbaugh et al., 2004, Yap et al., 2018; Ayling et al., 2022). In a lacustrine environment, as were many basins in the Great Basin during the Pleistocene epoch (Russel, 1885, Adams & Wesnousky, 1999; Benson et al., 2011), silica can be precipitated as amorphous silica sediments, hydrothermal chert or silicified lacustrine sediments (Sillitoe, 2015). Additional near-surface formation environments for silica polymorphs are as water table silicification (opal) beneath steam-heated zones, and in veins (see below).

Carbonates can be found as surficial deposits of travertine, tufa, or calcite veins. Travertine and tufa are distinguished by their textures and inferred formation environment. Travertine is formed when CO_2 rich fluids degas in springs, causing supersaturation with and precipitation of

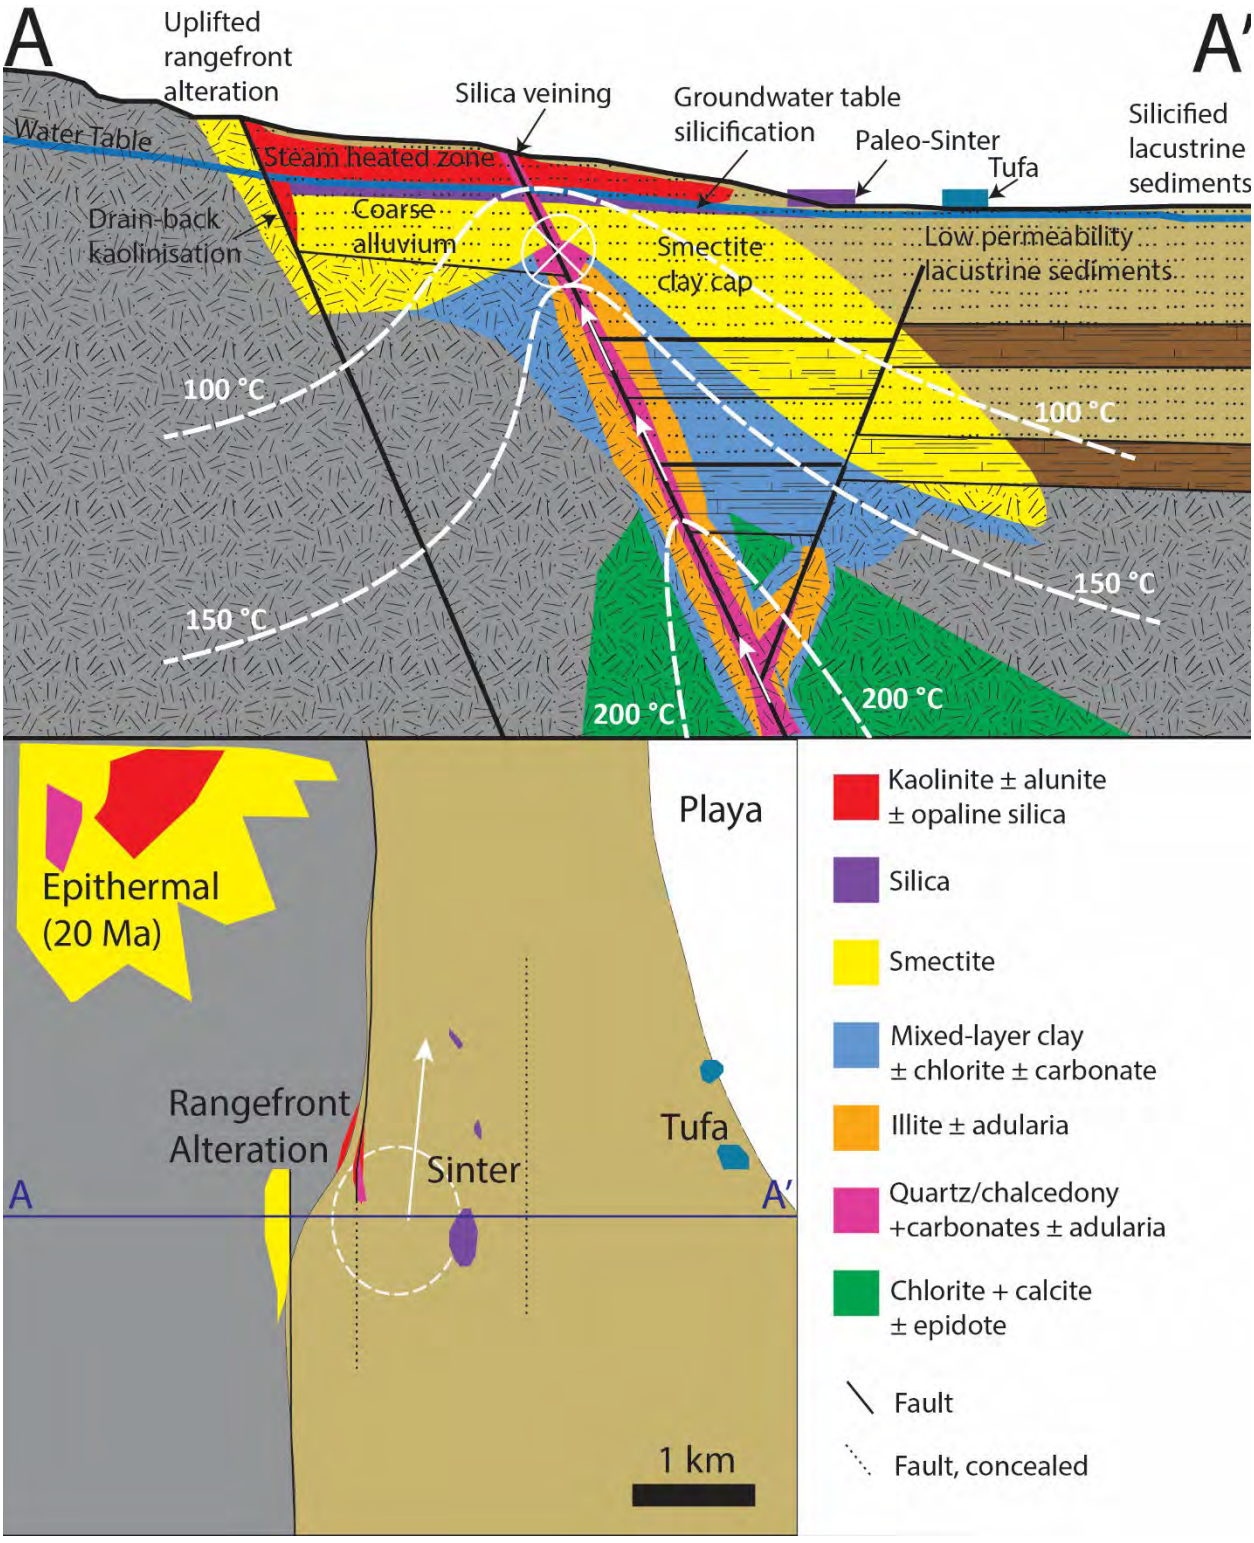

Figure 1: Conceptual model for hydrothermal alteration mineral zonation and paleo-geothermal deposits for deep-circulation-type geothermal systems in the Great Basin region. Adapted from and/or inspired by observations of the authors, Cole and Ravinsky, (1984), Reyes, (1990); Hedenquist et al., (2000), Richards and Blackwell, (2002), Simmons et al., (2005), Cumming (2009), Hinz et al., (2014), Sillitoe (2015), Delwiche et al., (2018), Siler et al., (2019), Jolie et al., (2021), Hedenquist & Arribas (2022), Kraal, (2023).

$CaCO_3$. Travertines form terraced-mounds, fissure-ridges or eroded sheets (Hancock et al., 1999). Tufa is formed in lakes where calcium enriched subaqueous spring fluids mix with CO_2 saturated lake waters (Bensen, 1994; Coolbaugh et al., 2009), and is characterized by a crumbly texture and deposits shaped like cones, towers, and pinnacles (Hancock et al., 1999). It is uncertain if travertine and tufa are directly related to high-temperature geothermal reservoirs or epithermal mineral systems, since many springs forming travertine are cold, and distal to the geothermal reservoir or mineral deposit (Sillitoe, 2015). However, in the Great Basin region, it has been found that many large tufa deposits are associated with thermal springs, some with high geothermometry (e.g., 150-170 °C at Needle Rocks and Pyramid Rock, NV per Coolbaugh et al., 2009), and therefore they are a resource exploration target.

The shallowest hydrothermal alteration zone typically encountered in geothermal systems is the steam-heated zone (Figure 1). The steam-heated zone is formed in the vadose zone above the water table where H_2S bearing steam condensates, producing oxidized low (2-3) pH fluids that form a the so-called "advanced argillic" alteration assemblage (opaline silica, alunite, anhydrite, kaolinite, diaspore; Sillitoe 2015, Hedenquist & Arribas, 2022). Commonly also present is native sulfur, and hematite that originally formed as pyrite but quickly oxidized (Sillitoe, 2015). Beneath the steam-heated zone, laterally extensive silicification (opal->chalcedony) can form where acidic fluids dissolve silica and deposit it at the groundwater table (Sillitoe 1993; Hedenquist et al., 2000; Sillitoe, 2015). Kaolinite (± smectite ± siderite ± pyrite) can also be formed by weakly acidic fluids (pH 4-5) where CO_2-rich condensates in the shallow hydrothermal environment below the groundwater table, commonly referred to as intermediate argillic alteration (Hedenquist & Arribas, 2022). Acidic fluids formed in the shallow environment can sometimes downwell along permeable pathways and produce drain-back kaolinization (Sillitoe, 2015). Active steam-heated zones in the Great Basin region are found at Steamboat Hills, Nevada, San Emidio, Nevada, and Cove Fort/Sulfurdale, Utah.

Studies of hydrothermal alteration minerals in active geothermal field around the world have found characteristic temperature-dependent mineral zonation with depth (Browne, 1978; Henley and Ellis, 1983; Cole and Ravinsky, 1984; Reyes, 1990; Figure 1). The specifics of this zonation are a product of the fluid chemistry, temperature, water/rock ratio, time, wall rock characteristics, and geologic structure (e.g., Reed, 1997). To generalize for near-neutral pH fluids: at shallowest depths/temperatures (<150 °C) smectite clay is predominant, along with carbonates, opal, and zeolites. This smectite zone is typically termed the "clay cap" and is a target for exploration geophysics as smectite has a low electrical/electromagnetic resistivity (Usher et al., 2000; Cumming, 2009; Folsom et al., 2020; Sewell et al., 2023). At intermediate temperatures (~150-200 °C), mixed-layered clays (illite/smectite or chlorite/smectite), are predominant. More proximal to fluid flow pathways, illite and adularia are common hydrothermal phases. In the center of the hydrothermal upflow, typically quartz or chalcedony, carbonates ± adularia is precipitated. At higher depths/temperatures (>180 °C), but with lower water/rock ratio, chlorite + calcite is formed, ± epidote where temperature is >250 °C. When exploring for active geothermal fields, deeper (hotter) alteration mineral assemblages observed at the surface, such as chlorite + calcite ± epidote are not a good indicator of active geothermal activity, because significant uplift and/or erosion must occur to expose them. Similarly, large (>0.5 km^2) zones of clay alteration within the range are most likely related to older paleo-geothermal fields (such as those that produce epithermal mineral deposits) that are no longer active. However, Quaternary-Pliocene aged epithermal deposits are often found proximal to high (>150 °C) geothermal systems in the region

(Coolbaugh et al., 2005). Smaller (1-500 m^2) zones containing smectite, kaolinite, or silicification exposed in the footwall of Quaternary faults may be a good target for geothermal exploration because their exposure can be relatively recent and they indicate the presence of these minerals just beneath the surface (as observed at Tungsten Mountain, Delwiche et al., 2018; Kraal, 2023).

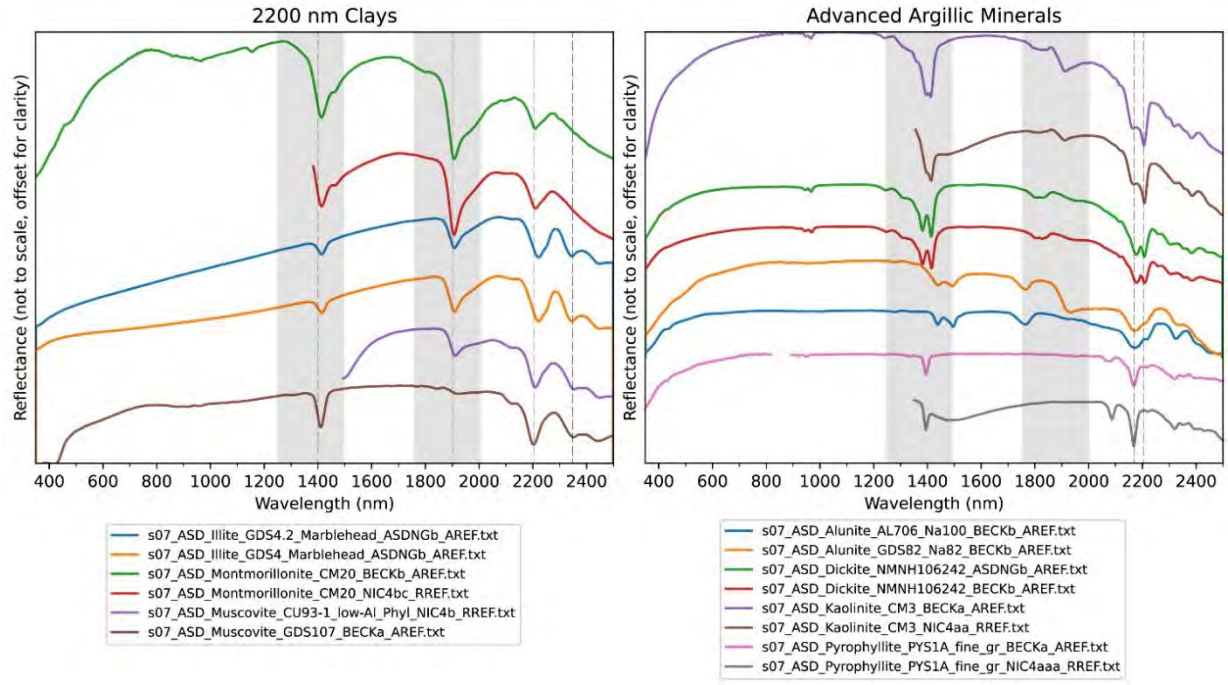

Figure 2: Example library mineral spectra from Kokaly et al., (2017), showing "2200 nm clays", or minerals with distinct 2200 nm absorption features associated with argillic/illitic/phyllic alteration (montmorillonite, illite, muscovite), and minerals associated with advanced argillic alteration (kaolinite, dickite, alunite, pyrophyllite). Grey areas are obscured by atmospheric effects.

Therefore, the most reliable paleo-geothermal deposits or hydrothermal alteration mineral targets for exploration using remote sensing are as follows: Silica (found in sinter, silicified sediments, groundwater table silicification, and silica veining); Carbonate (found in tufa, or in veins), kaolinite (found in steam-heated zones and shallow geothermal environments), and smectite (found in the clay cap). Outcrops of these in basins, or along a range front, are prioritized. The location of these minerals relative to Quaternary faults, complex structural settings, shallow low-resistivity anomalies, and shallow temperature anomalies can provide the foundation for multi-disciplinary greenfield geothermal exploration for blind systems.

1.2 Previous applications of SWIR remote sensing to geothermal exploration

Infrared reflectance spectroscopy in the Short-Wave Infrared Range (SWIR) is commonly used for identification and mapping of many hydrothermal alteration minerals, in particular phyllosilicates and other O-H bearing silicates, carbonates, and phosphates, because these minerals have diagnostic "absorption features" in the SWIR (1000-2500 nm) and are associated with distinct hydrothermal alteration mineral assemblages (Thompson et al., 1999). The shape and location of absorption features in a measured mineral's spectra are compared with standard mineral reference libraries for mineral or mineral mixture identification (e.g., Kokaly et al., 2017; Figures 2 & 3). Use of SWIR spectroscopy for remote sensing, field, and laboratory applications is common in the

mineral exploration industry to map zonation of hydrothermal alteration minerals (e.g., Thompson et al., 1999; Agar & Coulter, 2007). It has also been applied for geothermal exploration activities (e.g., Kratt et al., 2010a; van de Meer et al., 2014; Calvin et al., 2015; Calvin and Pace, 2016; Hart-Wagoner et al., 2022; Kraal, 2023). As additional high-quality, publicly available hyperspectral data is acquired in the coming years (e.g., through the USGS Earth MRI program, and new satellites), there is potential for the discovery of new blind geothermal systems in the western USA.

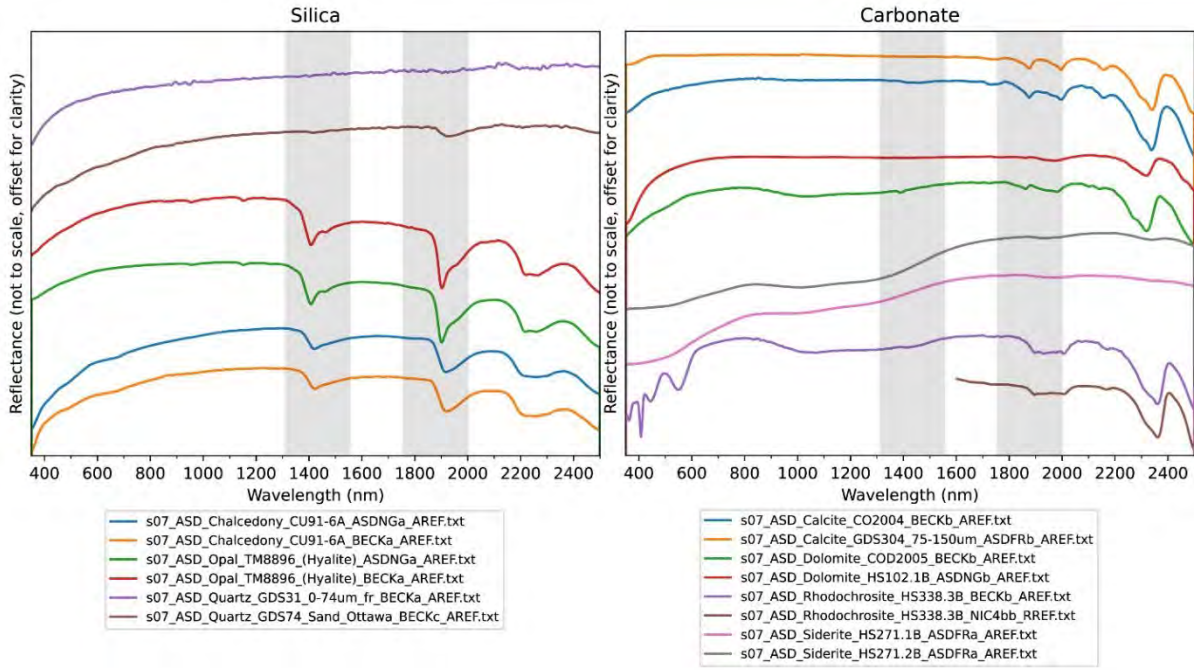

Figure 3: Example library mineral spectra from Kokaly et al., (2017) showing silica phases (quartz, chalcedony, opal) and carbonate phases (calcite, dolomite, rhodochrosite, siderite). Note that quartz does not have absorption features in this wavelength range.

2. Methods

2.1 Data Source

Remote sensing data for this study was collected by the Airborne Visible/Infrared Imaging Spectrometer classic (AVIRIS-c) instrument operated by the Jet Propulsion Laboratory (JPL). The AVIRIS-c instrument collects data over 225 spectral channels from 400 to 2500 nm with a pixel size of 14 m. The data was converted from radiance to reflectance and available to download from the AVIRIS Classic Data Portal website. Bands between 1312-1492 and 1800-2066 nm are not analyzed due to atmospheric interference. Additional residual atmospheric contamination artefacts obscure the region between 2350-2500 nm, as observed by Kokaly et al., (2021). Portions of the following AVIRIS lines were interpreted: f180828t01p00r07, f180605t01p00r07, f180604t01p00r12, f180828t01p00r06.

2.2 Data Processing Techniques

Remote sensing data was processed and interpreted using ENVI software. Several statistical and expert driven approaches are performed to classify spectra in the image and identify endmember

spectra to use in supervised classification. The general procedure is to utilize false color images emphasizing specific absorption features (such as at 2200 nm for clay and opal/chalcedony, or 2165 for kaolinite) to identify areas with minerals of interest. Endmember pixels identified using either statistical or expert driven techniques are collected using ENVI's Region of Interest (ROI) tool. Class statistics of each ROI are used to determine if they represented scene endmembers well. Comparison with the USGS spectral reference library (Kokaly et al., 2017) are used to classify scene endmembers by mineral or mineral mixture, (or other material, such as vegetation).

The ROIs then served as inputs for the Matched Filtering (MF) supervised classification algorithms. In addition to using ROIs for Matched Filtering, we also utilize library mineral spectra from the USGS library (Kokaly et al., 2017). This is performed where specific minerals of interest (such as opal or chalcedony) were not easily identifiable in the scene. MF is an algorithm for finding user-defined endmembers within a scene by performing partial unmixing. This technique is useful because it does not require knowledge of every endmember within a particular scene. Threshold based ROIs are then used to create a thematic map. Threshold minimum of 0.5 was found to work best for many endmember classes based on analysis of class statistics, and spatial coherence in map view. The matched filtering algorithm was applied in most scenes to the wavelengths between 2140 and 2300 nm, where data quality was the highest and the most diagnostic spectral features are located for the minerals of interest in this study (opal, chalcedony, smectite, kaolinite). Due to the atmospheric residual artefacts in the 2350-2500 nm wavelength region, it is difficult to distinguish smectite from illite or muscovite, which can usually be distinguished by an absorption feature at 2350, and therefore these minerals are grouped in our analysis. Carbonate minerals were also difficult to identify/distinguish when the mineral abundances are low due to these data artefacts.

The results produced in this study are thematic maps showing the location of minerals of interest utilizing the MF algorithm. We grouped the results into 2-4 endmembers per map: "2200 nm clays", representing smectite, illite, and/or muscovite; kaolinite (possibly kaolinite + smectite); carbonate (calcite); and silica (opal and/or chalcedony). There is a balance between using conservative thresholding to produce more accurate thematic maps (i.e., every pixel in map the map contains the intended spectra), with the risk of missing some pixels, and utilizing wider thresholds that may produce "false positives". Here, we utilize the more conservative approach, which we find to be the most useful for exploration applications. A conservative thresholding approach combined with manual classification of missed pixels based on visual inspection of spectra could improve the spatial coherence of mapped zones, however this approach was not undertaken in this study because our goal is to utilize these techniques for exploration and identify previously unknown paleo-geothermal deposits rather than to make the most accurate map.

We compared the newly interpreted hyperspectral data in this study to pre-existing hydrothermal alteration maps of the Basin and Range province compiled from interpretation of multi-spectral Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) Data (Mars, 2013). Mars utilized Interactive Data Language logical operator algorithms to map hydrothermally altered rocks, grouping them into (1) hydrothermal silica-rich rock, (2) propylitic rocks, (3) argillic rocks, and (4) phyllic rocks, and available to download as ArcGIS shape files. Argillic and phyllic rocks are mapped by Mars with 30-m spatial resolution and identified based on the 2165 nm and 2200 nm absorption features. The hydrothermal silica-rich rock is mapped with 90-m resolution, based

on the O-H absorption feature between 2260-2400 nm, and the thermal infrared band associated with the 9090 nm quartz absorption feature.

3.0 Results

3.1 Benchmark Sites

To validate that the publicly available remote sensing data has sufficient spectral and spatial resolution, as well as sufficient data quality to detect paleo-geothermal deposits, we investigated two areas with known paleo-geothermal deposits. Salt Wells and Lee Allen Springs have been previously mapped by Coolbaugh et al., (2004, 2006), and/or Hinz et al., (2011, 2014), both located in the vicinity of Fallon, NV.

3.1.1 Lee Allen

Lee Allen is the location of the Lee "Hot Spring", formed from a blown-out well from the 1930s, and the Allen Springs (adjacent to Allen Ridge). Hinz (2010) mapped silica-cemented sands of Pleistocene age, and Tufa of Miocene age adjacent to the Lee and Allen springs (Figure 4, Left). Currently, geyserite is forming in the Lee "Hot Spring". Quartz geothermometry indicate equilibration at ~165 °C (Mariner, 1974).

Four scene endmembers are mapped in the thematic map: silicified zones (opal, or chalcedony), kaolinite, 2200 nm clay (likely smectite or illite), and carbonate (likely calcite) (Figures 4 & 5). The silicified zones are distinguished in the scene by a sharp dip in reflectance at ~2190 nm, and a relatively broad/rounded absorption or flat zone between 2200-2300 nm (Figure 5). The largest silicified sediments zone mapped by Hinz et al., (2010) was easily identifiable in the AVIRIS dataset (mapped in Figure 4A, to the northwest of "Allen Springs" label). The smallest, northern area of silicification mapped by Hinz et al, (2010) was not discernable using this dataset (Figure 4C). Individual pixels in the southern silicified area (northwest of "Lee" label, Figure 4B) had characteristic spectra associated with opal/chalcedony but were difficult to map using the matched-filtering technique without also classifying too many non-silica pixels in the map area.

Kaolinite and 2200 nm clay signatures are observed near the small northern silicified zone, possibly related to hydrothermal alteration (Figure 4C). The large kaolinite zone in the north of the map (Figure 4G) is associated with a rhyolite dome and the Tuff of Campbell Creek units, and sediments derived from these units (Hinz et al., 2010), and may be the product of weathering. Carbonate spectra were also observed throughout the map area and are co-located with mapped tufa deposits and mounds (Figure 4D), and beach deposits of late Miocene age (Figure 4E, Hinz et al., 2010). The multispectral map from Mars (2013) did not identify the silica sinter in the area immediately around the Lee and Allen springs (Figure 6).

Figure 6 shows hyperspectral and multispectral thematic maps in the wider Lee Allen area. In the northern portion of the map, silica is identified but appears to be associated with Tertiary Rhyolitic breccias, sands, and gravels of middle Miocene age mapped by Hinz et al., (2010), and unlikely to be related hydrothermal activity. Several small outcrops of Tertiary volcanics - Tcc (Tuff of Campbell Creek) and unknown Tuff (Ttu) are associated with 2200 nm clay and kaolinite in both maps (Figure 6, Hinz et al., 2010). In the west, small kaolinite and silica zones are co-located with faulting of Miocene basalt lavas and interbedded diatomite (Figure 6, Hinz et al., 2010).

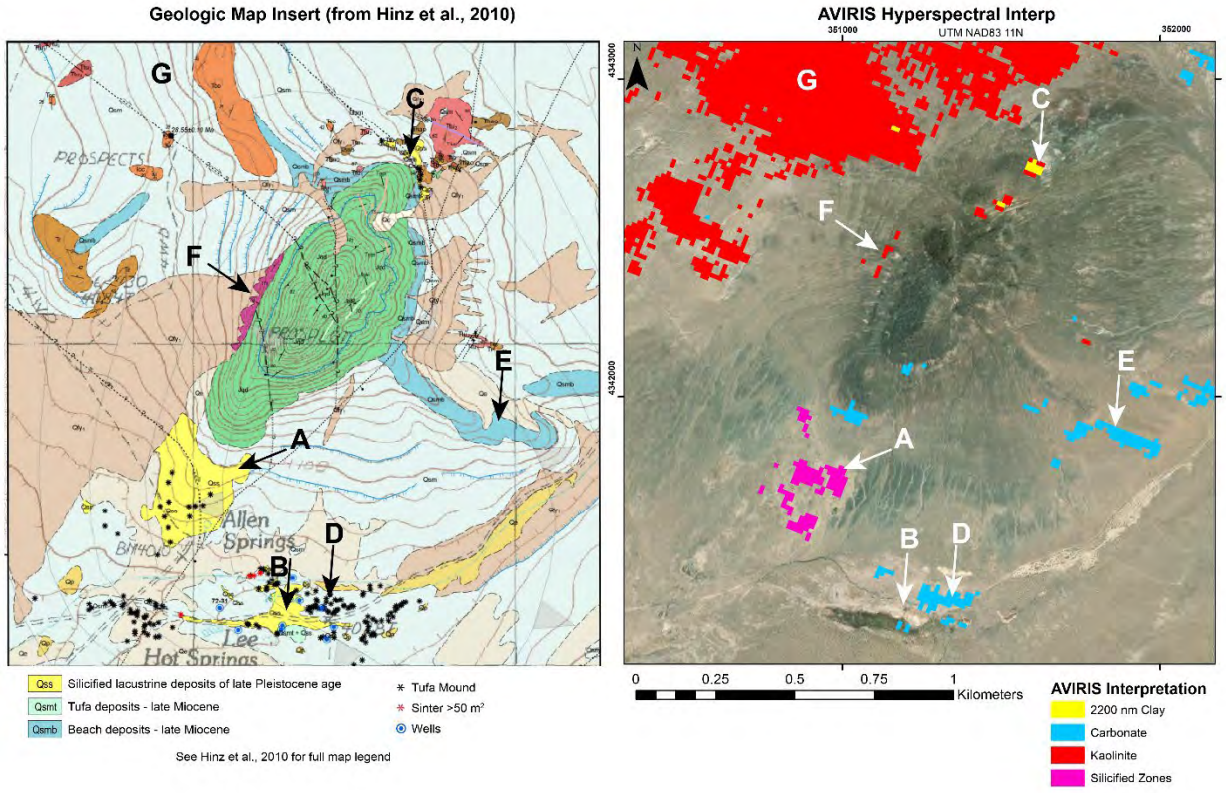

Figure 4: Arrows indicate locations discussed in the text. Left: Map from Hinz et al., 2010 showing geology, faults, and paleo-geothermal deposits at the Lee and Allen springs area. Right: Thematic map showing the interpretation of the AVIRIS Hyperspectral data, showing silicified zones, carbonate rich zones, kaolinite rich zones, and 2200 nm clay zones.

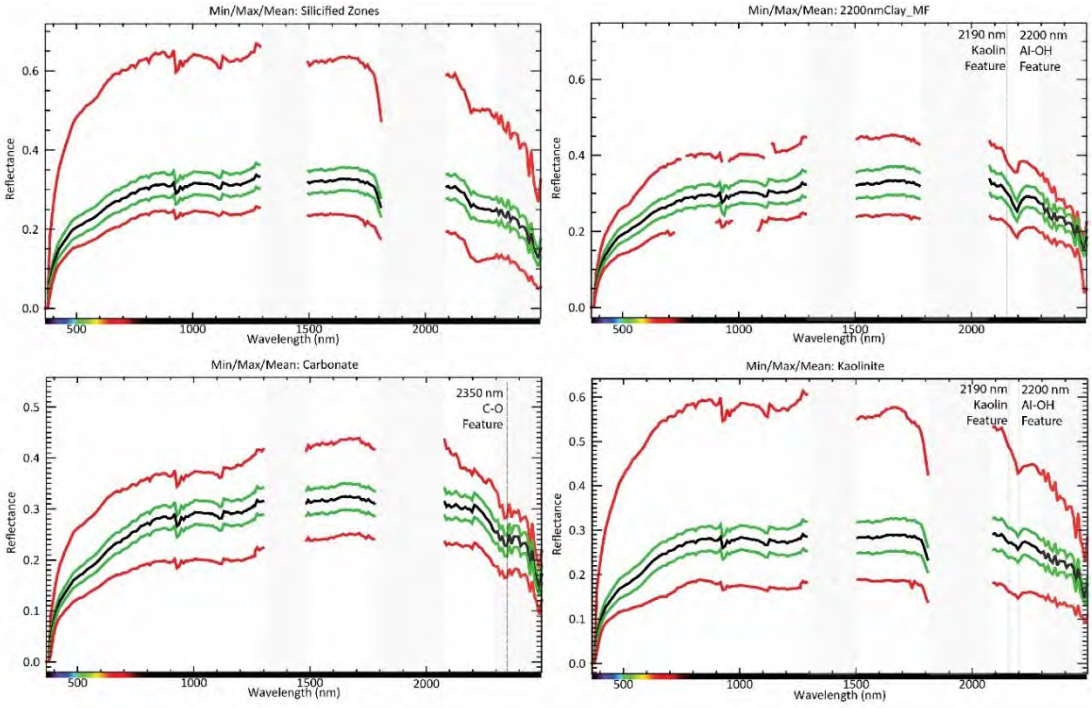

Figure 5: Class statistics for thematic mineral maps of Lee Allen (Figure 4, Figure 6).

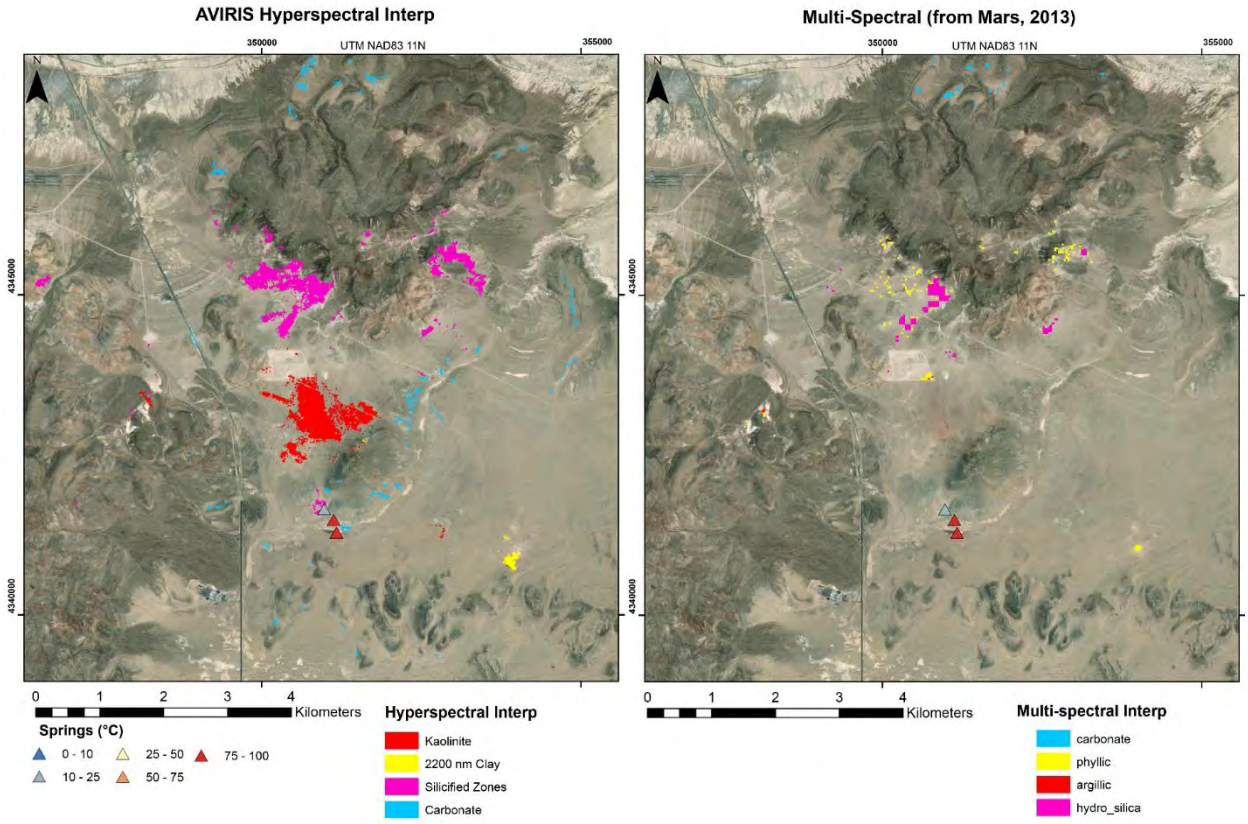

Figure 6: Thematic maps from AVIRIS hyperspectral mineral interpretation, and Mars, (2013) multi-spectral interpretation of the wider Lee Allen area.

3.1.2 Salt Wells, Nevada

The Salt Wells geothermal field producing 9.6 net MWe as of 2022 (Jowitt et al., 2023), and currently operated by Ormat Technologies, Inc. Thermal features currently active at Salt Wells are a few areas of warm ground, however hot springs were active into the early 20th century (Coolbaugh et al., 2004 citing Garside and Schilling, 1979). There are 3 types of sinter present at Salt Wells: massive opaline material, siliceous oolites, and silicified roots, mud and algal matter (Coolbaugh et al., 2004). Often the silicified sands are overlain by 5 cm – 2m thick lenses of sinter, and sometimes tufa (Coolbaugh et al., 2004). In addition, Hinz et al. (2014) mapped several argillic-altered bedrock outcrops near the silica deposits.

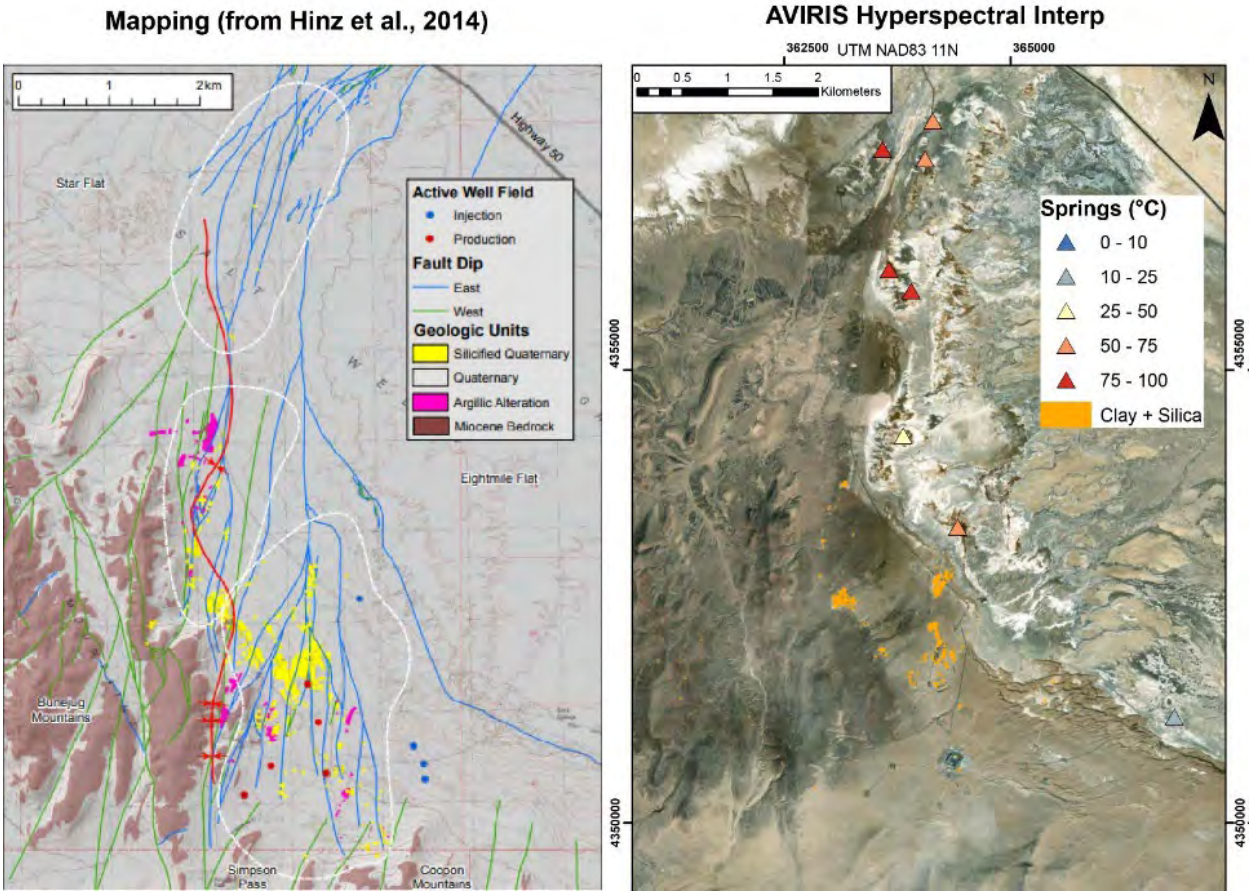

Figure 7: Paleogeothermal deposits of Salt Wells, Nevada. Both maps are the same scale/location. Left: Map from Hinz et al., 2014, showing the location of mapped paleogeothermal deposits, faults, and the active well field at Salt Wells. Right: Results of AVIRIS hyperspectral interpretation showing zones of clay + silica (orange) that roughly corresponds to mapped silicified quaternary sediments. Also shown is the location of hot springs.

Silicified zones mapped by Coolbaugh et al., (2004; 2006), and Hinz et al., (2014) were co-located with a distinct 2200 nm clay signature in the AVIRIS data (Figure 7), rather than a pure opal/chalcedony spectrum, likely a product of mixed 2200 nm clay + kaolinite + silica composition (Figure 8). This spectral signature was distinct enough to be mapped using matched filtering technique, and the macro-level geometry of these deposits are consistent with previous mapping. These clay/silica areas were not mapped in the Mars (2013) multi-spectral compilation. The

argillic-altered bedrock mapped by Hinz et al., (2014) was not discernable in the hyperspectral data, perhaps because the exposures were too small for the spatial resolution of the data.

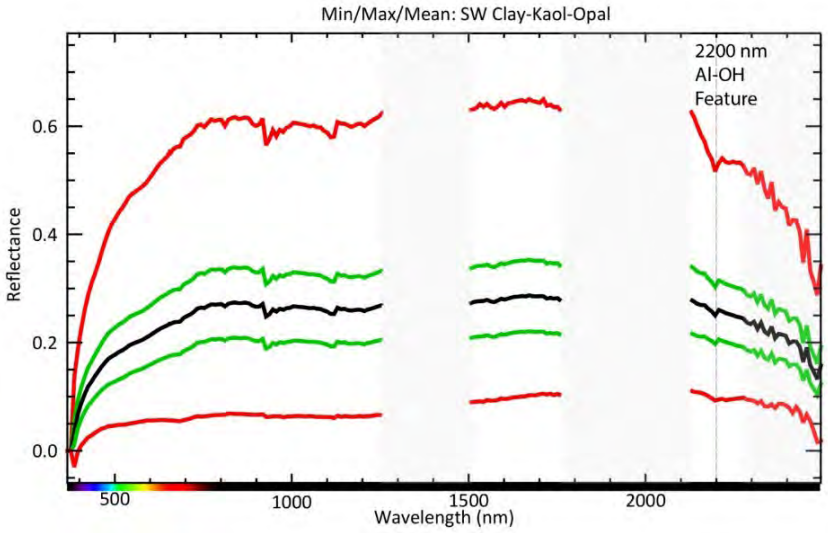

Figure 8: Class statistics for Clay + Silica zone, consistent with mapped silicified sediments from Salt Wells. Note that the 2200 nm Al-OH absorption feature is the most prominent.

3.2 Exploration Case Studies

3.2.1 Gabbs Valley

Gabbs Valley is the location of several known geothermal systems and prospects, including the Don. A Campbell geothermal power plant operated by Ormat Technologies Inc. with 26.1 MWe net production in 2022 (Jowitt et al., 2023). Known thermal anomalies are also present, including Petrified Springs, North Gabbs, Rawhide Hot Spring, near the town of Gabbs, and near the warm "Gene Sawyer" well. Additional prospects without temperature data identified during the BRIDGE project include Kaiser and Dead Cow Splay (Downs et al., 2023; Figure 9, Figure 10).

Figure 9 shows the results of the AVIRIS hyperspectral interpretation from this study (Left), and the multi-spectral interpretation by Mars (2013; Right) in northern/central Gabbs Valley. The largest kaolinite and 2200 nm clay zones occur in the northern Montecristo Mountains, adjacent to the Kaiser Fluorspar mining area (labeled "F"). Several opal/silica signatures are observed near the Starfire Opal Mine (labeled "O"). Near the 2-m temperature anomaly at North Gabbs (NG), there is some kaolinite and 2200 nm clay detected, co-located with the northern termination of the Montecristo western range-bounding fault and fault step-overs within (Figure 9A), however it is uncertain if this argillic zone is associated with the larger (likely older) alteration around the Kaiser Mine area. On the other side of the range, there are small patches of clay alteration along the range-front adjacent to the Kaiser geothermal prospect (co-located with the northern termination of the faults bounding the east side of the Montecristo mountains; Figure 9B). Near the Rawhide Hot Springs (RHS), there is small patches of kaolinite and 2200 nm clay alteration ~1.5 km east along Fissure Ridge, within a Miocene or Oligocene tuff unit (Figure 9C; Ekren & Byers, 1986) that is relatively anomalous, given that the other tuffs of this unit are not altered adjacent to this location. Lastly, there is possible silicification along strike two fault segments that stepover mapped by Ekren and Byers (1986) near Cobble Cuesta (CC; Figure 9D).

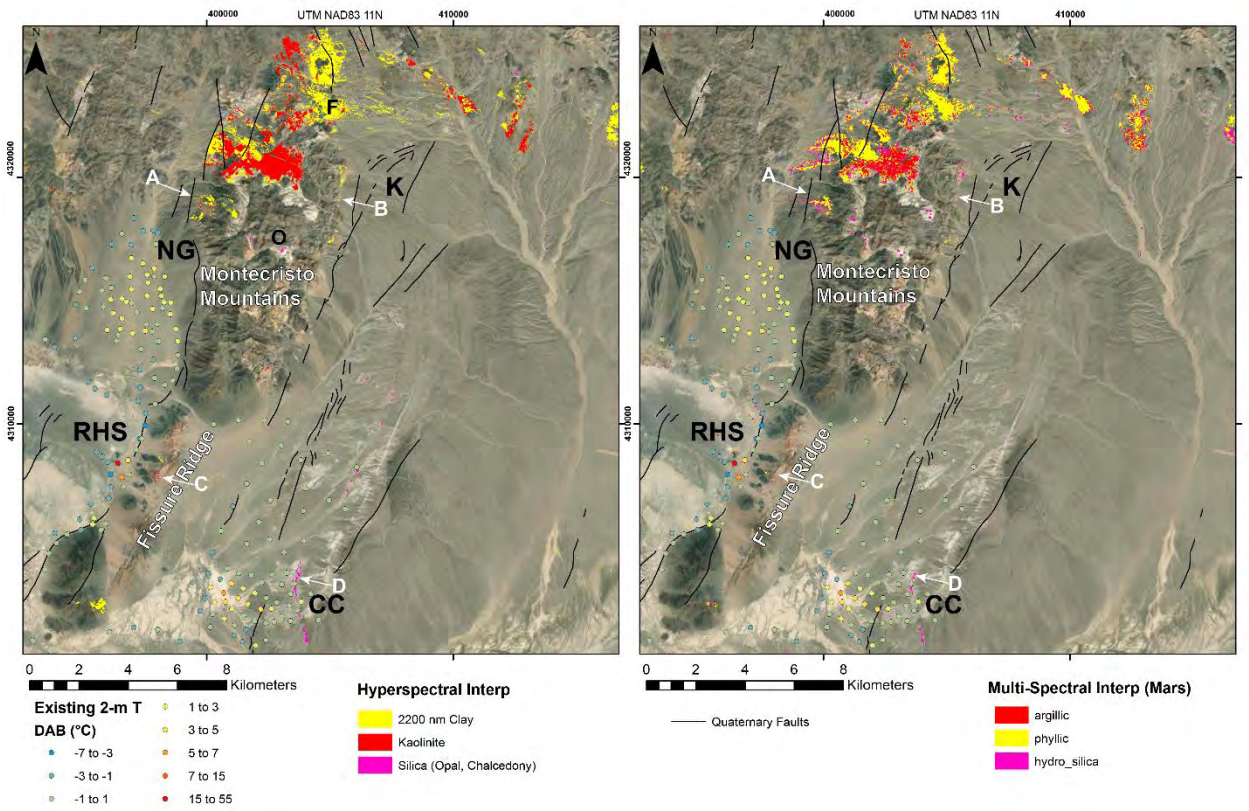

Figure 9: North Central Gabbs Valley, centered on Fissure Ridge. Several geothermal prospects are in this map, including North Gabbs (NG), Rawhide Hot Springs (RHS), Cobble Cuesta (CC) and Kaiser (K). White arrows refer to areas discussed in the text.

Figure 10 shows the hyperspectral interpretation thematic mineral map for southern Gabbs Valley, the location of the Don A. Campbell geothermal plant, and the Petrified Springs and Dead Cow Splay geothermal prospects. Large kaolinite and 2200 nm clay rich zones occur associated with known mineral resources, such as to the southwest (Au, Ag, Blue Sphinx Property, Gold Pen Mine, Lone Star Group, Randall property etc.), and the to the southwest (Hg, Au, Paradise Peak Mine, Finger Rock Mercury prospect). Several smaller kaolinite or 2200 nm clay rich zones occur along or near Quaternary faults such as at location 10A, 10B, 10C, 10D and 10F, some of which are associated with Au or Hg mineral resources (Figure 10). Location 10E has several small 2200 nm clay patches and is associated with a “Fire Clay” silica mine, adjacent to Dead Cow Splay. There does not seem to be any surface hydrothermal alteration associated with Don A. Campbell or Petrified Springs.

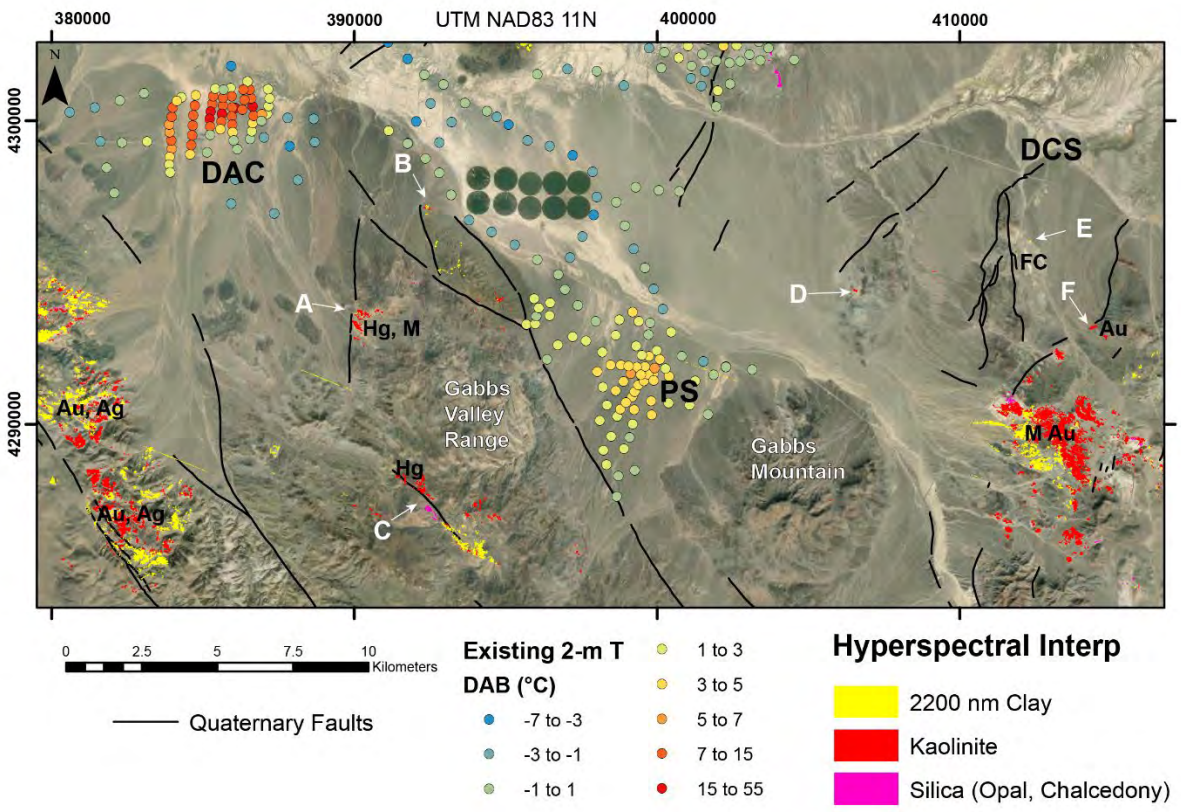

Figure 10: Southern Gabbs Valley hyperspectral interpretation thematic map, along with two-meter temperature data. DAC refers to Don A Campbell geothermal plant, PS refers to petrified springs geothermal prospect, and DCS refers to Dead Cow Splay geothermal prospect. Also shown are the location of known mineral occurrences from the Mineral Resources Data System (Mason and Arndt, 1996).

3.2.2 East Hawthorne

East Hawthorne is a geothermal prospect within the Hawthorne Army Depot identified from shallow temperature surveys (Kratt et al., 2010b; Figure 11) and temperature gradient drilling. Resent geophysical analysis by the BRIDGE team found a shallow dipping conductor co-located with the 2-m temperature anomaly (Sewell et al., 2023). Preliminary analysis of geophysical data suggest that this anomaly is associated with a displacement transfer zone where a northwest striking strike-slip fault connects with one or more northeast striking normal faults. Several clay anomalies are observed in Mesozoic highly silicified meta-volcanic units mapped by Hinz et al., (2010). A small outcrop of kaolinite mapped in both hyperspectral and multi-spectral data ~2 km east of 2-m T anomaly (Figure 11B). Another kaolinite-altered outcrop mapped in the hyperspectral data is ~4 km south of the 2-m T anomaly, ~ 1 km east of the inferred intersection of the strike-slip and normal fault inferred from geophysics (Figure 11C). There is a large 2200 nm clay anomaly near the 2-m T anomaly, possibly related to low-resistivity zone seen in geophysics datasets (Figure 11A). Additional widespread 2200 nm clay to the south within the range, likely unrelated to recent geothermal activity, and co-located with known gold mines and prospects. The remote sensing did not detect carbonate near a known tufa deposit, perhaps because it is too small (Figure 11D), and it is uncertain if this tufa is related to the thermal anomaly zone outlined by the temperature surveys.

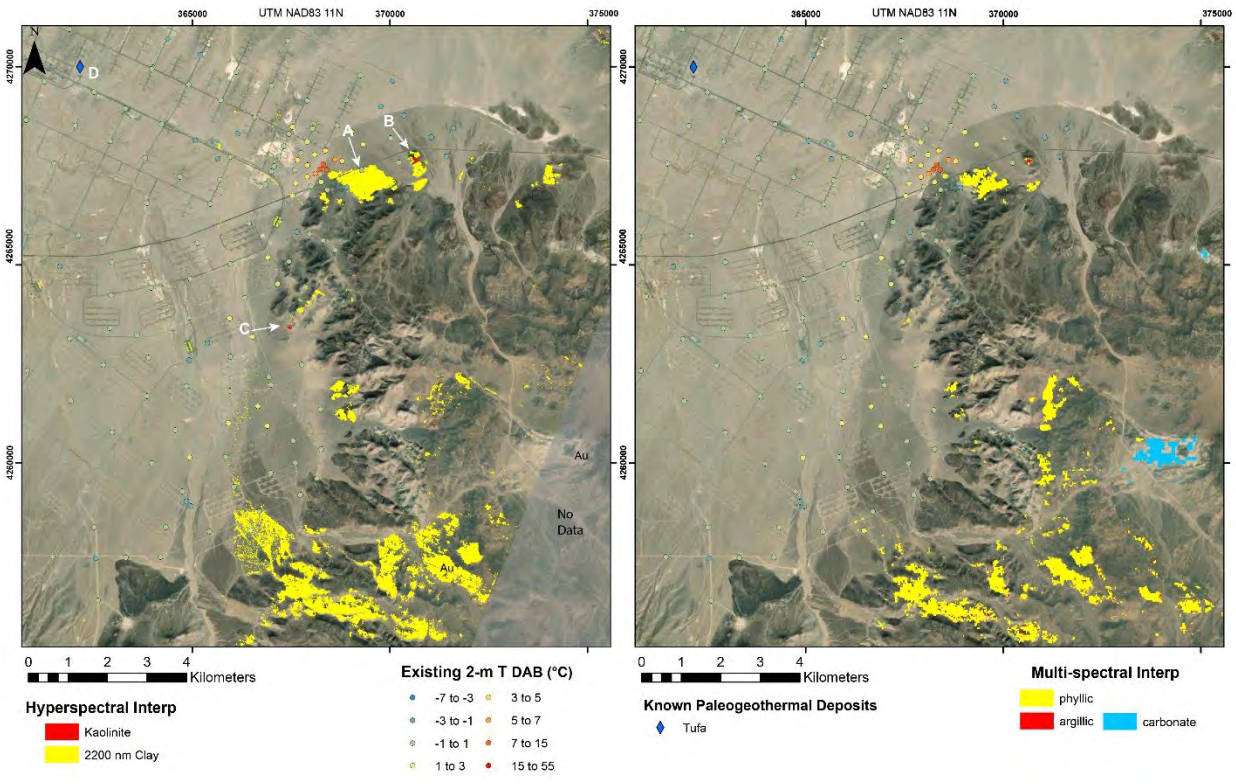

Figure 11: Thematic mineral maps of the East Hawthorne geothermal prospect.

3.2.3 Bell Flat

Bell Flat is a basin just north of Gabbs Valley in NV with no known thermal anomalies. However, active faulting (including historical ruptures, Caskey et al., 1996) and multiple favorable structural settings (step-overs, fault terminations, and fault intersections) contribute to its high favorability for hosting undiscovered blind geothermal resources. Several locations along the Fairview Fault Zone on the western margin of the basin have 2200 nm clay and kaolinite anomalies as indicated by the remote sensing hyperspectral data (Figure 12). Zone 12A is the location of kaolinite and 2200 nm clay alteration, associated with a minor step-over in the range bounding fault. Zone 12B contains kaolinite and clay anomalies within a larger normal fault step-over. Therefore, these locations would be good targets for shallow temperature surveying based on the presence of favorable structural features and possible argillic alteration.

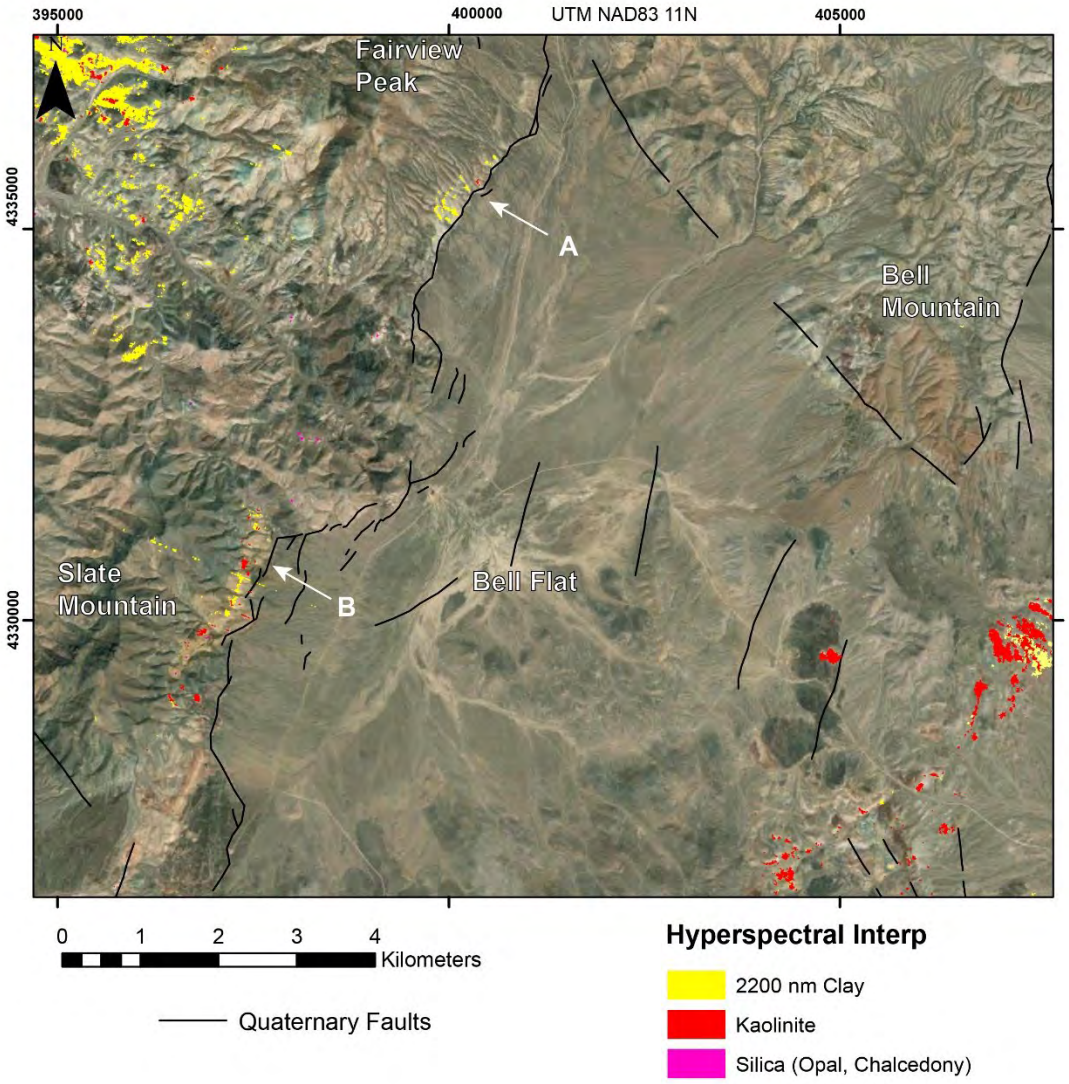

Figure 12: Thematic remote sensing mineral map of Bell Flat, Nevada.

4. Conclusion

Remote sensing using publicly available hyperspectral data can be successfully and efficiently used for geothermal exploration by mapping minerals and mineral mixtures commonly found on the surface or in shallow portions of active geothermal systems. Generally there is agreement between the hyperspectral and multispectral interpretations reviewed here. Higher spatial and spectral resolution allowed for (a) more detail in the maps produced from the hyperspectral data and (b) identification of additional hydrothermally altered outcrops. When a conceptual model framework is applied, these mineral maps can help inform further exploration activities and decisions about resource potential. Caution must be used to discern potentially recent hydrothermal alteration minerals, commonly found in basins or along active fault traces, versus relict Cenozoic or older hydrothermal alteration minerals associated with past hydrothermal activity or the results of weathering. Future work includes field verification of mapped hydrothermally altered zones and laboratory analysis of field samples to validate the SWIR interpretations.

ABSTRACT

The Hawai‘i Play Fairway project produced the State of Hawai‘i’s first statewide geothermal resource assessment since the 1980s and Hawai‘i’s first quantitative geothermal resource probability model. Funded $2.3 million by the U.S. Department of Energy, the project operated over three phases from 2014 to 2021. During the first two phases, the project developed a statewide geothermal resource probability map and a Play Fairway methodology and identified 10 locations for geothermal prospecting. During the third phase, the project tested the methodology, drilled a temperature observation well on Lāna‘i Island to a depth of ~1km, and developed final statewide probability maps. At 1-km depth, the temperature within Lāna‘i Well 10 exceeds those of two wells in Kīlauea’s East Rift Zone and a third well in the Saddle region of Hawai‘i Island that exhibited an elevated temperature gradient from 1-2km depth. The Phase 3 work reconsidered some of our earlier evaluations in the production of final statewide probability of heat maps. In our final assessment, we now take fluid probability of Fluid and exclude probability of Permeability due to a dearth of data at anticipated resource depths. This differs from our Phase 1 presentation of a combined resource probability achieved by multiplying the three together.

1. Introduction

Despite a 100% renewable policy objective and a significant continuing reliance on fossils fuels, surprisingly little is known about Hawai‘i’s geothermal resource potential. Geothermal exploration in the 1970’s and 80’s was concentrated within Kīlauea’s East Rift Zone (KERZ) on Hawai‘i Island, where several exploratory wells were drilled. Outside of Kīlauea’s summit and ERZ, Hawai‘i’s geothermal resources are blind, and prior to the Hawai‘i Play Fairway project, little work had gone into the exploration of blind resources over the rest of the state.

Areas of high heat in Hawai‘i reflect recent intrusions, including unerupted magma, so prospecting for heat naturally targets the main pathways of magma movement through Hawaiian shield volcanoes: calderas, rift zones, and volcanic vents. In most locations in the state, rock in the upper 1-2 km of the volcanoes has high permeability, which results in a relatively deep water table. We, therefore, expect geothermal resources statewide to be 2 km or more below the ground surface.

The Hawai‘i Play Fairway project took place over 3 phases. The results of the first two project phases are summarized across four publications in the journal Geothermics (Lautze et al., 2017a, 2017b, 2020; Ito et al., 2017). The main task in Phase 3 was to execute a drilling project on Lāna‘i Island, the detailed results of which are expected to be published soon (Lautze et al., in review, Geothermics). In Phase 3, we incorporated the Lāna‘i drilling data in our probability model and also updated our rationale on the probabilities of fluid and permeability at resource depths, such that the Probability of Fluid across the state is equal to 1 (due to the expectation that resources will be below sea level), and the Probability of Permeability is excluded from analysis at this time as we lack data to constrain it. Therefore, given current state of knowledge, we advocate for using our final probability of heat, and our confidence in this probability, to guide the next phase of exploration. We regard further development of geothermal energy in Hawai‘i as essential to enable the state to achieve its 100% renewable policy objective and look forward to enabling Hawai‘i’s transition from fossil fuels through geothermal discovery and development.

2. Final Probability and Confidence Calculations

Our published maps for each island in the State of Hawai‘i from project Phase 1 show a) calculated probabilities of three attributes: Heat (Pr_H), Fluid (Pr_F), and Permeability (Pr_P); b) the combined probability of a Resource (Pr_R), calculated as the product of the individual three probabilities:

$$PrR(x)=PrH(x)PrF(x)PrP(x) \quad (1)$$

and c) our computed Confidence in Pr_R (Ito et al.; 2017). In this discussion, an “x” denotes a location on the map. We refer to equation (1) as the “Veto Equation” because the probabilities Pr_H, Pr_F, and Pr_P are independent and range between 0 and 1 and if any one of them is low, so too will be the resource probability $Pr_R(x)$. The approximation in this product of probabilities is the same as that of the naive Bayesian classifier in which conditional probabilities are estimated by marginal probabilities (e.g., Domingos and Pazzani, 1997). As seen in Figure 1 and as is generally true statewide (Ito et al., 2017; Lautze et al., 2017b), the calculated Phase 1 resource probabilities (Pr_R) are low. In fact, our calculated Pr_R was less than 10% across most of the state, only above 30% off of Hawai‘i Island, and only 45% at the state’s only proven site, Puna Geothermal Venture (PGV).

We now consider that our Phase 1 results were too conservative. Upon further interpretation, we consider that everywhere in Hawai‘i, Pr_F will be approximately equal to 1 at resource depths below sea level (so across all of the state except its highest volcanic peaks). Further, due to the paucity of deep drilling data in Hawai‘i outside the one known geothermal resource region along KERZ, we have little data to constrain Pr_P at expected resource. We therefore suggest that the statewide maps of Pr_H and Confidence in Pr_H guide future exploration activities, however we are also aimed at better constraining subsurface permeability, for example through core drilling.

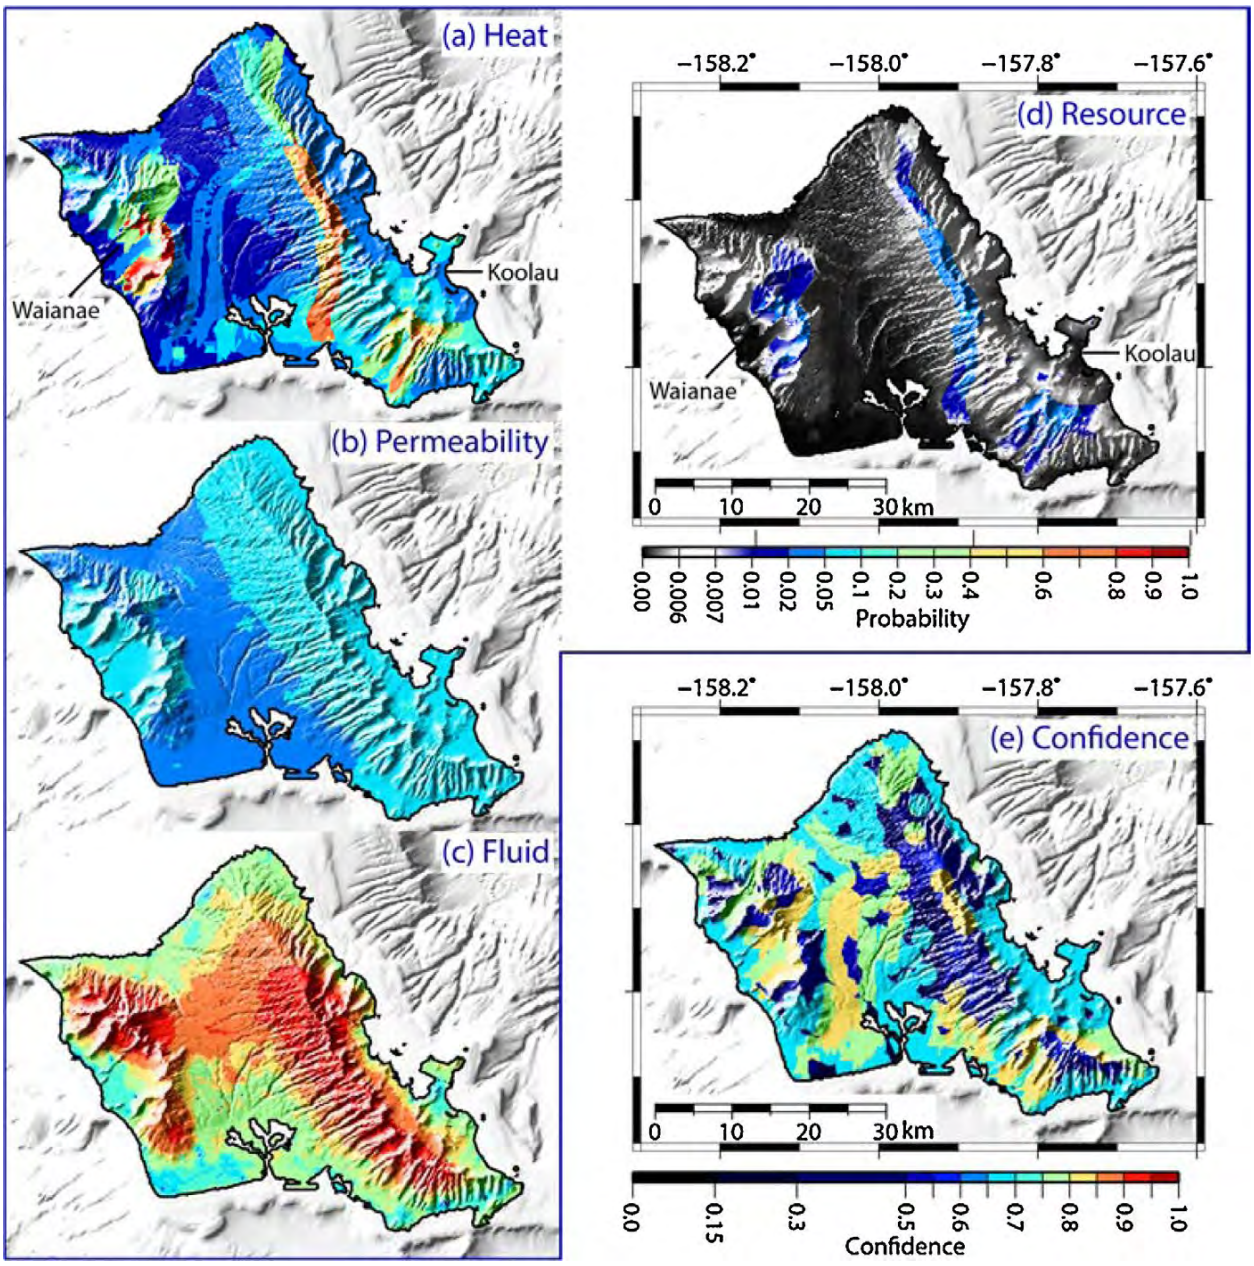

Figure 1. Phase 1 Probability and Confidence results for the Island of Oʻahu. This is Fig. 6 in Ito et al. (2017).

2.1 Phase 3 probability of heat (PR_H) calculation: updated heat loss with time function based on Lānaʻi drilling results

Figures 2 and 3 show the probability of heat in the subsurface across the State of Hawaiʻi, calculated following the method outlined by Ito et al. (2017), but excluding all evidence used during Phase 1 from groundwater data due lack of confidence in groundwater flow directions. Figure 3 shows the same probability results as Figure 2 but with water well temperatures overlaid for qualitative analyses. These final probability values incorporate all of the Phase 2 geophysical data, as well as an updated function for "heat decay with time since last eruption" based on the

new Lāna‘i Well 10 (Phase 3 drilling) temperature measurements (Lautze et al., in review, Geothermics).

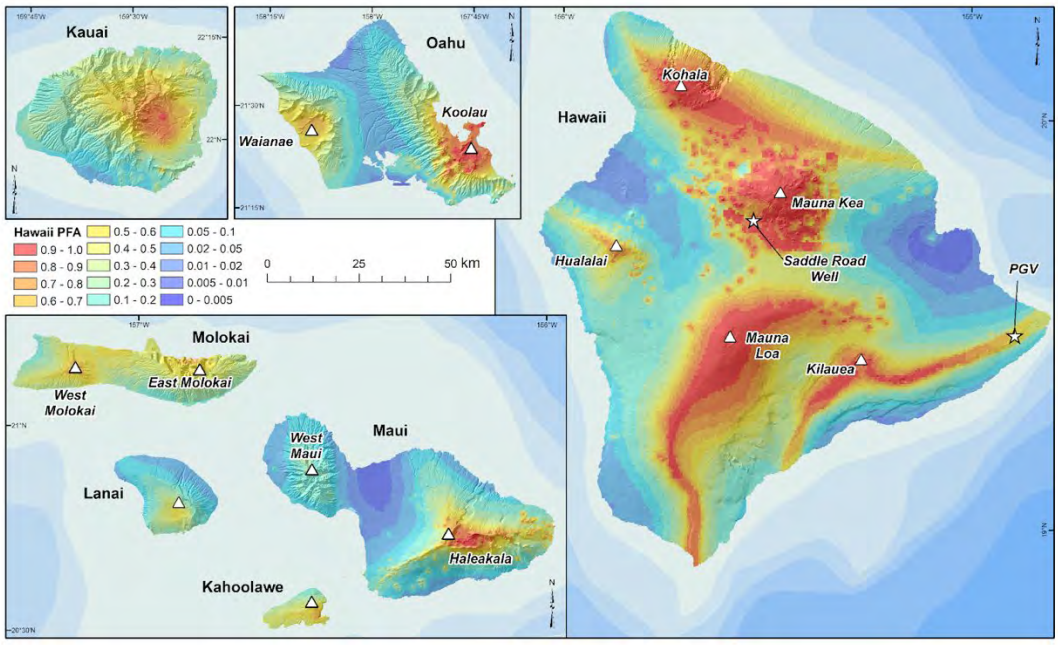

Figure 2. Probability of subsurface Heat across the State of Hawai‘i.

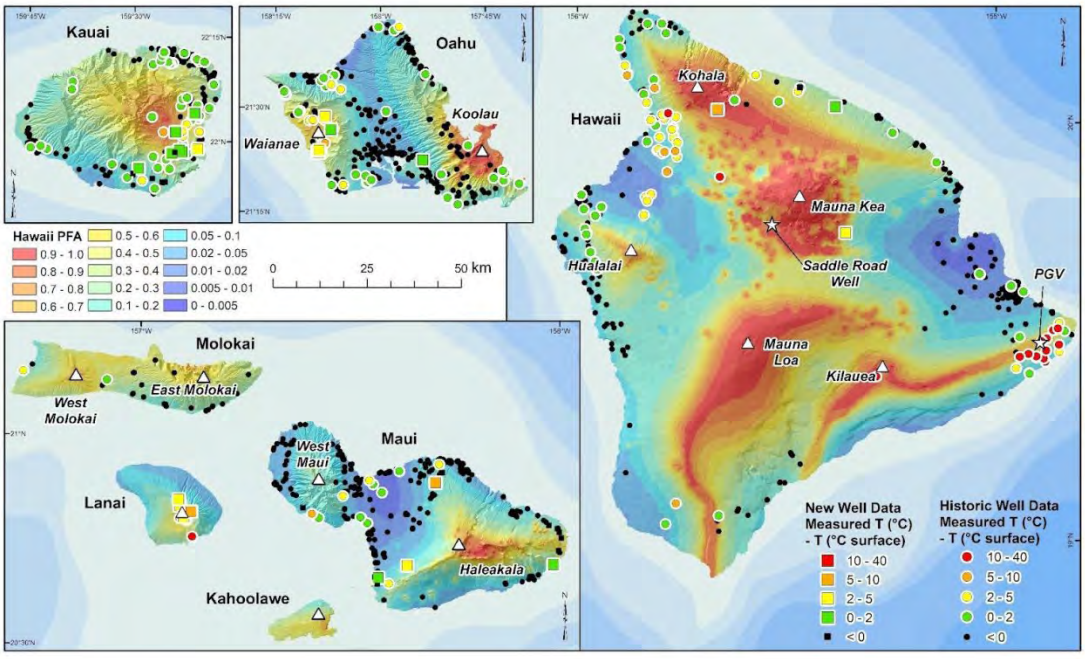

Figure 3. Probability of subsurface Heat across the State of Hawai‘i, overlaid with the location and temperature of groundwater wells. “New Well Data” (squares) were collected in Phase 2 of this Play Fairway project. Wells without any known temperature anomalies are shown as small black circles.

3. Discussion of PR_H Results

Figure 2 indicates a probability of heat above 50% at each shield volcano in the state except West Maui, with the largest and highest probabilities near the summit regions of the active Kīlauea and Mauna Loa volcanoes. Each shield volcano on Hawai‘i Island has a probability of heat >90% except Hualālai at ~70%. Haleakalā has a Pr_H of 70-80% at the summit, decreasing to 60% or below along its rift zones; Lāna‘i, West and East Moloka‘i, and Wai‘anae have a Pr_H ~60 -70 %, and Kaua‘i and Ko‘olau have a slightly higher Pr_H at ~80%. These probabilities in general accord with the size and lifespan of the volcanoes, and are further supported by groundwater data. Figure 3 shows a presence of notably warm groundwaters in the vicinity of PGV along KERZ, along Mauna Loa's South rift, on and South of Kohala volcano (waters to the south have a mixed source from Kohala and Mauna Kea; Tachera 2018), on Lāna‘i, in Wai‘anae caldera, and on Kaua‘i. Broadly, and not surprisingly, the statewide Pr_H shown in Figure 2 closely aligns with our current state-of-knowledge regarding Hawai‘i's volcanic geology.

4. CONCLUSIONS

This paper presents final Hawai‘i statewide maps of the probability of a geothermal resource (Pr_R). In contrast to our prior maps of Pr_R, which were based on the products of the computed probabilities of substantial Heat, Fluid, and Permeability, PrR(x)=PrH(x)PrF(x)PrP(x), our updated maps presume PrR(x)=PrH(x). The probability of fluid is now approximated as being equal to one because extensive evidence indicates that fluid is pervasive in the Hawaiian crust below sea level, which coincides with the expected subsurface depths of Hawai‘i's geothermal resources where production would be viable. Calculations of the probability of permeability Pr_P are presented to motivate future measurements of this property, but large uncertainties in these calculations render them useless for the calculation of Pr_R. We also present an updated map of confidence in our Probability of Heat based on the number and quality of data at a given location which shows highest confidence near eruptive centers and where geophysical data have been collected.

Overall, the Hawai‘i Play Fairway project represents a major advancement in the exploration of geothermal resources in Hawai‘i. We have now compiled all relevant data into maps of Pr_H, which provide a roadmap for future exploration activities. With $20M to $200M invested in geothermal exploration over the next 5-10 years, Hawai‘i would be able to better define the nature and extent of its geothermal resource and have an informed conversation on where and how further development could begin.

Acknowledgements

We thank the U.S. Department of Energy's Geothermal Technologies Office for funding and management of this project, under award number DE-EE0006729, and a generous donation from Pūlama Lāna‘i in their support of this project. We are deeply grateful to the too-numerous-to-mention students, field assistants, drilling and core-archiving crews, water well-owners and landowners who enabled this project's success.

CO_2-entrapment, injectate, tonalite, fluid-rock interaction

ABSTRACT

The University of Auckland's "Reversing Carbon Emissions in the Geothermal Industry" five-year project, aims to mitigate Green House Gas (GHG) emissions by employing innovative techniques in carbon capture and storage. A key focus of the project involves developing processes that will enable trapping of gases, especially CO_2, in solid form at optimal distances from the injection point, thereby promoting negative-emissions energy generation. A high-temperature-pressure reactor is currently under construction to carry out laboratory experiments involving saturating cored samples with CO_2-rich fluid. Prior to these experiments, it is critical to fully characterise the physical properties of the cored samples. Our experiments are designed to identify the favourable fluid-rock interactions and trapping mechanisms that govern CO_2 entrapment. Following our experiments, we will model fluid-rock interactions and the storage capabilities of the rock. We present the mineralogical, textural, and elemental characterisation of cored samples immediately adjacent to an injection depth, prior to it being used for reinjection, from one New Zealand geothermal field. Methods for rock characterisation include; (1) scanning electron microscopy to assess microscopic void dimensions, distribution, and connectivity and to examine reactive surfaces, (2) petrography to determine mineral relationships, mineral percentages and textural components, (3) X-ray fluorescence and energy dispersive spectroscopy to identify elemental compositions, (4) computerised tomography to establish rock density, and connected flow pathways. We are working with our industry partners to undertake field trials following completion of our experiments. New Zealand is taking significant steps in addressing climate change and minimising its environmental footprint. This MBIE-funded project is a notable advancement towards achieving this goal.

1. Introduction: Reversing carbon emissions (RCE) project overview

Geothermal fluids carry a variety of gases, primarily CO_2 along with traces of H_2S, NH_3, CH_4, and H_2. Currently these gases are captured directly without dilution (without mixing with the air) in

steam condensers. However, geothermal wastewater presents an opportunity to dissolve and permanently capture the GHG before reinjection, a focus of numerous international trials. For example, projects in Iceland (Gislason et al. 2018), the USA (Richard, 1990), Japan (Yanagisawa, 2010; Kaieda et al. 2009), Türkiye (Yücetaş et al. 2018), and the Philippines (Joselito et al. 2005) have explored this concept. Some of these trials utilise mineral entrapment of gases in specific deep geological formations, such as basalt (Gislason et al. 2018). The potential for CO_2 sequestration in basalts has also been investigated extensively by McGrail et al. (2006), Matter et al. (2007), and Snæbjornsdottir et al. (2014), in the United States and Iceland, on land and offshore. Keeping CO_2 underground in mineral form is important for long-term storage because mineralisation provides a stable and predictable means of storing CO_2, significantly reducing the volume of stored CO_2, and mitigating risks regarding potential CO_2 leakage, migration, and associated operational and environmental impacts.

New Zealand has committed to a 50% reduction in net greenhouse gas emissions by 2030, as announced during the UN's COP26 climate summit. To facilitate this transition, the Renewable Energy Strategy has been established, aimed at expanding the energy supply and achieving net-zero carbon emissions status by 2050. This research initiative seeks to contribute to these goals by developing processes that will enable trapping gases, especially CO_2, in solid form while boosting fluid production from geothermal resources. This will require characterising the unique geochemical, geological, petrophysical, and fluid dynamic properties to investigate potential mechanisms for trapping GHGs, to allow negative-emission energy generation.

Throughout this five-year project, we will assess the suitability of various host rocks in the Taupō Volcanic Zone (TVZ) for GHG entrapment. The programme involves an innovative stepwise approach:

- Step one consists of analysing and characterising rocks from injection depths. These analyses will include X-Ray Diffraction (XRD), Scanning Electron Microscopy (SEM), Energy Dispersive Spectroscopy (EDS), Computerised Tomography (CT), petrographic microscopy, rock strength compressibility tests, and density and porosity measurements.
- Step two involves constructing a pressure-temperature chamber. Experiments will be conducted on characterised TVZ geothermal host rocks placed inside the chamber, exposing them to varying amounts of CO_2-rich fluid. Changes within host rocks before and after exposure to the experimental conditions of the pressure chamber will be documented. The novel aspect of this programme involves injecting chemical agents into the pressure chamber to increase the quantity of available cations, which will promote permanent entrapment of GHG.
- In step three, we will determine the optimal chemical agents required for injection that will favour permanent GHG entrapment, and identify the most suitable TVZ formations to be targeted for our field trials.
- Step four will involve modelling the predictive behaviour of chemical reactions based on our laboratory results and field trials.

We are collaborating with our industry partners on laboratory and field-scale tests. The utilisation of large-scale field data will validate and enhance our research on the influence of GHG-rock-geothermal wastewater interactions, assess the short- and long-term impacts of GHG reinjection, and identify potential risks to the environment and geothermal development operations.

Concurrently, we will quantify the benefits of reservoir pressure support resulting from the injected GHG, ultimately leading to higher generation efficiency.

2. Ngā Tamariki Geothermal Field, New Zealand and NM9 injection well

Ngā Tamariki Geothermal Field is located within the Taupo Volcanic Zone (TVZ), North Island of New Zealand (Fig. 1). This geothermal field is a high enthalpy geothermal system comprised of three different aquifers; a shallow meteoric groundwater zone, chloride-bicarbonate waters at depth, and a chloride geothermal reservoir of 290 °C below 1000 m depth (Bignall, 2009). There are very few natural surface thermal manifestations at Ngā Tamariki. Only minor hot springs and steam-heated features are present (Mongillo and Clelland, 1984). Situated at the northern extent of the field is Pavlova Spring which discharges dilute alkali chloride-bicarbonate water (Campbell et al. 2002). Brotheridge (1995) has documented hydrothermal eruptions in the area.

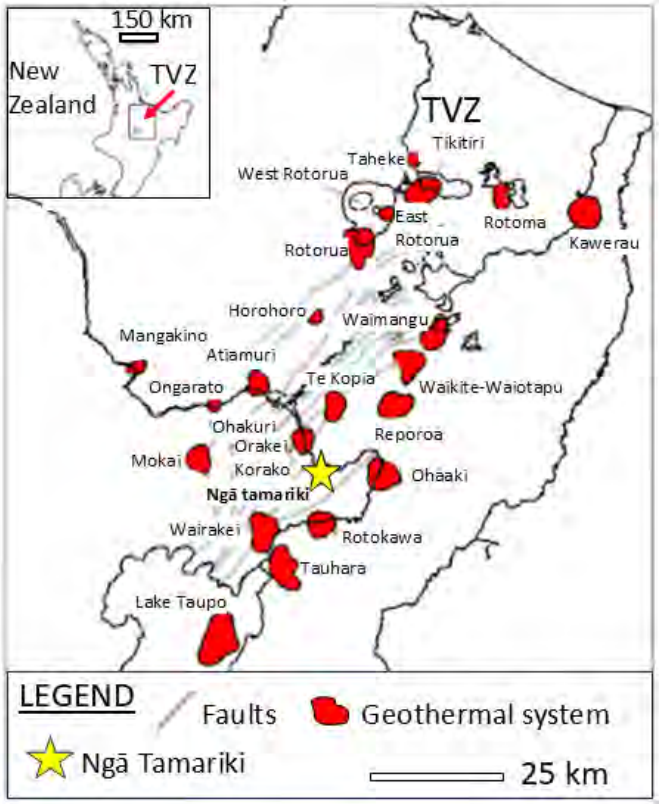

Figure 1: Location of Ngā Tamariki geothermal field and other geothermal fields within the Taupo Volcanic Zone (Kissling and Weir, 2005).

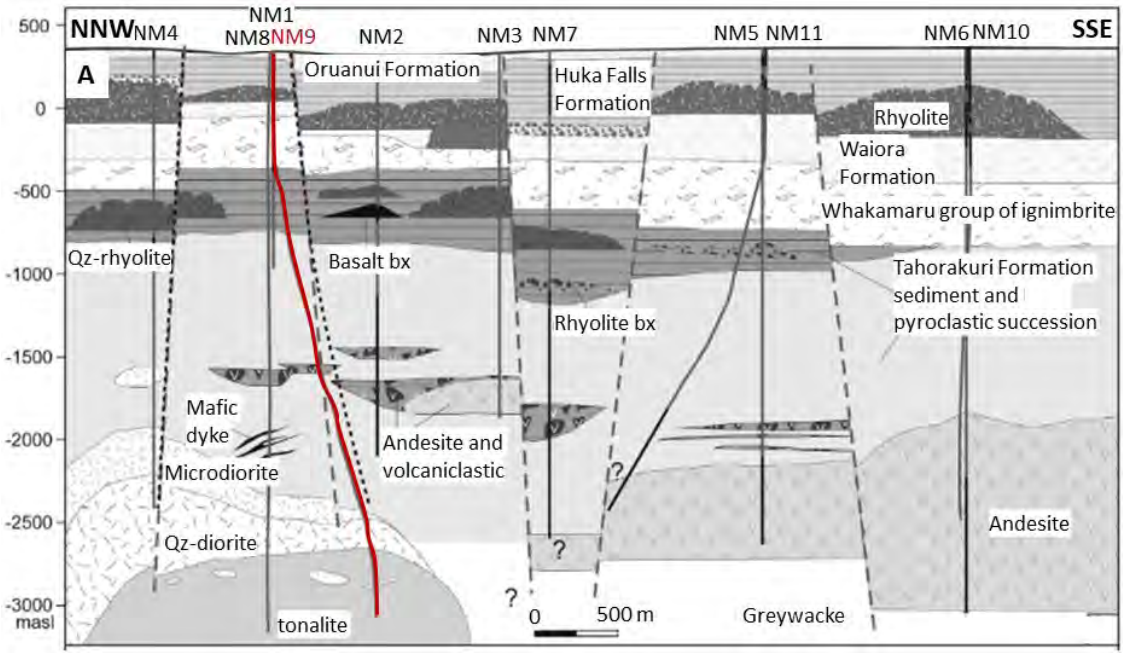
We selected the Ngā Tamariki Geothermal Field as a primary focus for this paper due to its implementation of CO_2 reinjection practices aimed at minimising carbon emissions. As part of this initiative, non-condensable gases (NCGs) from one of its units are injected back into the reservoir through a designated reinjection well (NM9). This ongoing CO_2 reinjection trial at Ngā Tamariki has been operational at one of its four units since October 2021, injecting 25% of the total station's emissions per year, amounting to over 8,000 tons of CO_2 equivalent annually.

The general geology of the field is fairly typical of a TVZ geothermal system (Fig. 2A). Hydrothermal alteration at depth predominantly results from fluid-rock interaction with high

temperature, neutral-pH fluids, leading to the formation of minerals such as illite, chlorite, epidote and pyrite (Chambefort et al., 2014).

However, Ngā Tamariki exhibits unique geological features. Drillholes NM4, NM8 and NM9, located in the north of the field (Fig. 2A), have intersected an intrusive complex consisting of diorite and tonalite between 2300 m and 3500 m depth. This intrusive complex has an associated magmatic-hydrothermal alteration halo representative of a high-intermediate-sulfidation state, epithermal mineralization (Chambefort et al., 2014). This relict high temperature advanced argillic to potassic hydrothermal alteration halo consists of biotite and magnetite with rare K-feldspar, quartz, pyrophyllite/muscovite, and rare andalusite and topaz (Arehart et al., 2002; Christenson et al., 2002; Lewis et al., 2013; Chambefort et al., 2014; Fig. 2B).

Injection wells NM8 and NM9 were drilled in 2012. Clearwater et al., (2015) documented two key observations; (i) initially these wells increased in injectivity for differing lengths of time which was attributed to thermal contraction of the rock expanding fractures, and (ii) both wells experienced a decline in injectivity which was attributed to silica scaling in the formation. Clearwater et al., (2015) also report fluctuations in injectivity that do not appear to be explained by temperature variation of the injectate. Their investigation highlighted the need for further analyses on compositional changes of the injectate, including variability in the gas content of the reinjection fluid.



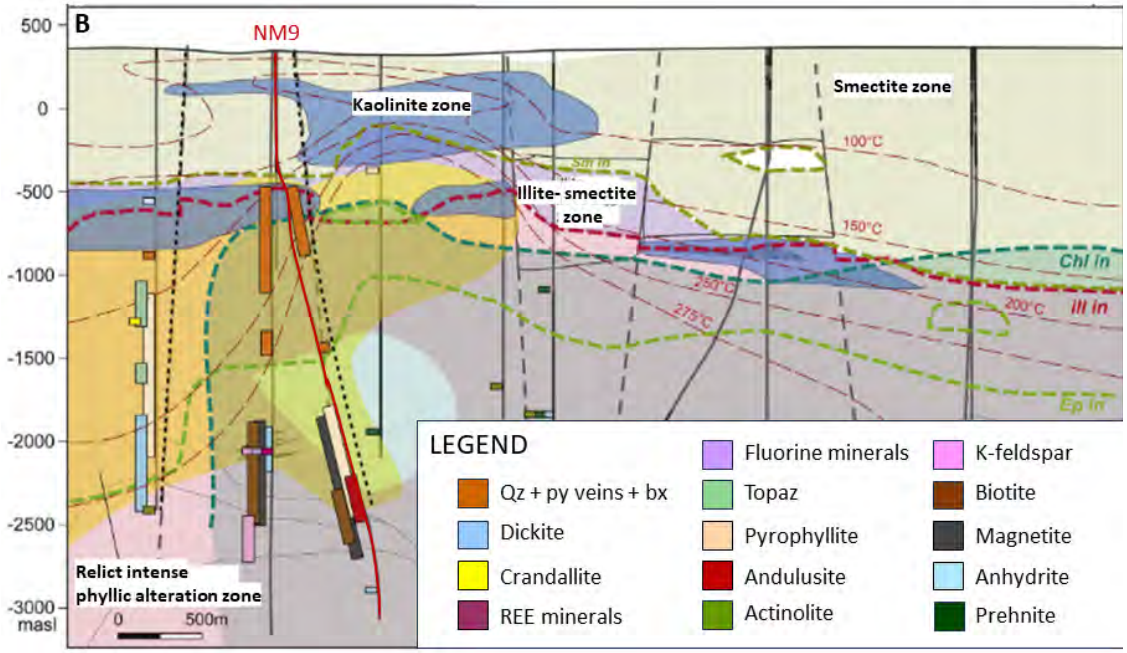


Figure 2: Cross-sections through Ngā Tamariki Geothermal Field with the location of injection well NM9 highlighted in red (Chambefort et al., 2016). (A) Geological cross-section with rock types shown. (B) Cross-section showing isotherms and mineralogy (Chambefort et al., 2016).

Step one of our 5-year RCE project is reported herein. Step one involves characterising the textural, elemental and mineralogical characteristics of the tonalite from NM9, located immediately below the current injection depth. The samples analysed in step one, have not been exposed to reinjection fluid as they were recovered prior to well NM9 being used for reinjection. Step two involves fluid-rock experiments in a specifically-designed test chamber. The purpose-built chamber is designed to sample and analyse the tonalite core at various time intervals, after exposure to different CO_2-rich fluid concentrations. Core characterisation pre- and post-experiments will be conducted using identical analytical techniques so a direct comparison of fluid-rock interaction can be assessed, with the aim of documenting how the tonalite intrusive complex is reacting to CO_2-rich injectate fluid. Step three involves modelling the predicted behaviour of the rocks using real fluid-rock input data. Step four includes modelling the predictive behaviour of chemical reactions based on our laboratory results and field trials.

3. NM9 core samples

For our RCE project, Mercury Energy donated a 0.45 m core of tonalite from injection well NM9, from 3201.1 to 3201.55 m depth (Fig. 3A), located immediately below the current injection depth. This core is referred to as the RCE core.

In 2013, prior to the RCE project, Mercury Energy provided four pieces of tonalite core from injection well NM9, for characterisation of void distribution, connectivity and dimensions, specifically using Scanning Electron Microscopy (SEM) and Energy Dispersive Spectroscopy (EDS). The four samples were from depths between 3204 m and 3206.9 m (Fig. 3B-3E). The results presented by Lynne (2013) provide valuable information on the void characteristics of the

NM9 tonalite core between 3204 m and 3206.9 m depth. As fluid is contained in and travels through voids in rocks such as pore spaces, fractures and mineral defects, the results from Lynne (2013) on void connectivity, dimensions, distribution and quantity is relevant to the RCE project and have been included in this study. Inclusion of these samples extends the tonalite characterisation from NM9 injection well from 0.45 m to 6.8 m.

All the core samples analysed in this study were collected before well NM9 was used as an injection well. Therefore, they have not yet reacted with injectate fluid.

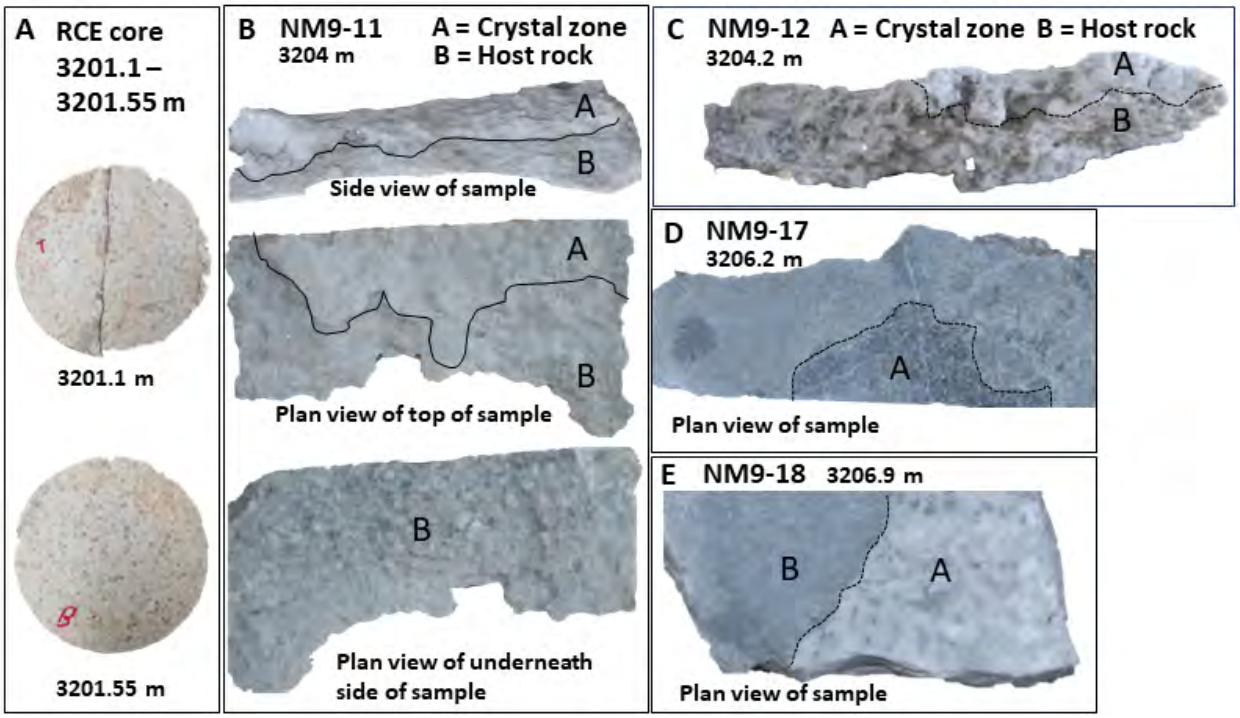

Figure 3: Samples of tonalite core from the Ngā Tamariki geothermal field. (A) Mildly-altered white tonalite from 3201.1 to 3201.55 m depth. (B-C) Highly-altered tonalite core from 3204 m depth with crystal zones (A) and host rock areas (B). (D) Grey tonalite core from 3206.2 m depth with dark grey alteration halo and white infilled fractures. (E) Boundary between grey and white tonalite core from 3206.9 m depth. Least altered core. (B-E) Samples from Lynne, (2013).

4. Methods

A multi-analytical-technique approach was chosen for Step One of the RCE project and is aimed at characterising the core prior to Step Two. Analytical methods have been chosen that will enable void characterisation, reveal potential reactive surface areas, determine the textural, elemental and mineralogical composition and establish the rock strength, before interacting with CO_2-rich fluids in our experimental chamber.

The 0.45 m long tonalite RCE core from NM-9 was examined using petrography, micro-CT scanning, X-Ray Fluorescence (XRF), and Scanning Electron Microscopy (SEM). Void, reactive surfaces and elemental composition of the tonalite core from 3204 m to 3206.9 m depth have been characterised using SEM and EDS (Lynne, 2013). Planned for later this year, but not available at

the time of writing this paper is X-Ray Diffraction (XRD) and compressibility testing on the samples. Prior to placing the samples in the experimental chamber, a full set of analyses will be completed on all samples.

4.1 Petrography

Petrographic thin sections of the upper and lower sections of the RCE core were made at the University of Christchurch. They were analysed on a Nikon Eclipse LV100 PDL petrographic microscope and photographed on a Nikon DS-Ri1 camera.

4.2 Elemental composition (XRF and EDS)

Bulk composition of the RCE core was determined via X-Ray Fluorescence (XRF). Samples were taken from both the upper (3201.1 m depth) and lower sections of the tonalite core (3201.55 m). Samples were crushed in a rock crusher before being sieved through a 710 µm sieve. Once sieved, the samples were cleaned in distilled water in a Bandelin Sonorex Digitec ultrasonic bath. The samples were then dried for 24 hours at 60°C prior to being placed in a rock mill for 2 minutes each, to produce a powder. All samples were heated to 200°C for 48 hours to find the ignition loss. The major oxide concentration (%) was evaluated by the glass bead method which was prepared by the 1:3 dilution method. This means that 3g of a sample was combined with 9g of flux. The flux that was used contained 67% $Li_2B_4O_7$ and 33% $LiBO_2$. For trace element analysis, samples were prepared by the pressed pellet technique in which 7.5g of sample was mixed with 2.5g of binder. XRF analysis was conducted using an S8 TIGER (Series 2) wavelength dispersive X-ray fluorescence spectrometer (WDXRF).

Energy Dispersive Spectroscopy (EDS) was used to analyse mineral-specific compositions in samples NM9-11, NM9-12, NM9-17 and NM9-18. EDS analyses were performed to obtain semi-quantitative compositional data on the mineral phases. EDS operating conditions were 20 keV accelerating voltage, with a spot size of 5 µm, and a working distance of 5 mm. No EDS scans were collected on the RCE core as the EDS was out of action.

4.3 Density measurements

Micro-Computerised Tomography was used to determine the bulk density of the sample and to examine void networks and fracture infill. Two 40 mm wide slabs were cut from the top of the tonalite core at 3201.1 m depth. No sample could be prepared from 3201.55 m depth due to a problematic fracture. Samples were cut using the Metkon Geocut Geological Cutter. Once slabbed, the samples were cored using a 10 mm diameter core drill bit to gain 6.5mm diameter sub cores. One sample was taken from each 40 mm slab. For analysis, the samples were placed in a plastic straw and mounted in a Bruker Skyscan 1272 micro-CT scanner. The acquisition parameters were: 85 kV, 110 µA beam current, 3750 mS exposure time, 2x Al filters, 2 µm pixel resolution, camera pixels 2452 x 1640. Scan parameters were: 0.25° rotation step, 2x frame averaging, 3 random movement and 360° rotation. The imaging time was 5.5 hours per sample. The images were reconstructed using InstaRecon CBR Server Premium 15K in conjunction with Nrecon 2.2.2 and subsequently visualised in 3D using CTVox V 3.3. Analysis was completed using CTAn V1.18.4.0.

4.4 Scanning Electron Microscopy (SEM) and Energy Dispersive Spectroscopy (EDS)

SEM was used to document the microscopic void size, abundance, distribution and connectivity. For the RCE core SEM imaging, analysis was conducted on fresh surface specimens produced from the sub-core drilling process as outlined in the micro-CT methods. A TESCAN CLARA instrument, working at a voltage of 10 keV, was used to conduct the SEM analysis. These images were used to assess the pore spaces within the samples and the degree to which they are interconnected. EDS would normally be conducted alongside SEM; however, the University of Auckland Science Department's EDS machine was out of order at the time of SEM analysis.

For samples NM9-11, NM9-12, NM9-17 and NM9-18, each sample was mounted on an aluminium stub and powder coated with platinum (10 nm coating thickness) for ~7 minutes at 10 mA using a high resolution Polaron SC7640 sputter coater. Samples were examined using a Phillips (FEI) XL30S field emission gun SEM. SEM operating conditions were 10 keV accelerating voltage, spot size of 3 μm, and a working distance of at least 5 mm. Energy Dispersive Spectroscopy (EDS) was performed on selected areas within the samples to obtain semi-qualitative compositional data. EDS operating conditions were 20 keV accelerating voltage, with a spot size of 5 μm and a minimum working distance of 5 mm. SEM and EDS equipment was located at RCSMS, University of Auckland.

5. Results

5.1 Characterisation of tonalite core from 3201.1 to 3201.55 m depth (RCE core)

5.1.1 Mineralogy and textures

At 3201.1 m depth, petrographic images reveal primary plagioclase feldspars are partially altered to calcite, anhydrite, muscovite, K-feldspar and epidote. Opaque minerals are also present. Primary quartz phenocrysts are fractured and infilled with clay. Some remnant primary minerals have completely altered to anhydrite and/or calcite (Fig. 4A-B). At 3201.55 m depth petrographic observations indicate primary plagioclase with secondary minerals of calcite, biotite, muscovite, adularia, epidote, pyrophyllite, K-feldspar and chlorite. Chlorite occurs as veins and alteration rims around primary plagioclase phenocrysts. The matrix consists of microcrystalline quartz with disseminated opaques and minor pyrophyllite alteration (Fig. 4C-D).

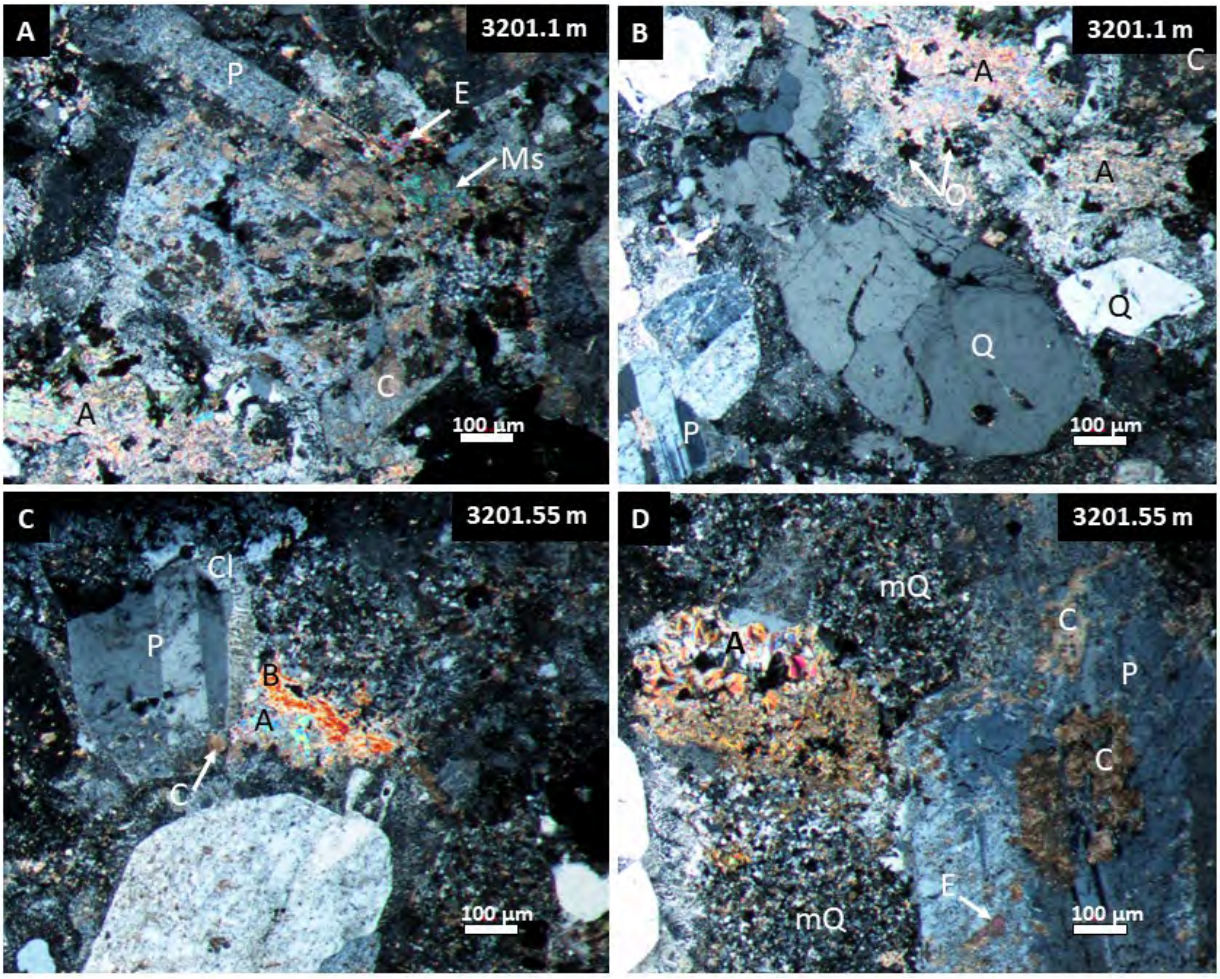

Figure 4: Petrographic thin section images of RCE core. (A-B) 3201.1 m depth. (A) Patchy alteration of primary plagioclase feldspar phenocryst to secondary calcite, anhydrite, muscovite, and epidote. (B) Large, fractured, quartz phenocryst with fractures infilled with clay. Remnant primary phenocrysts completely altered to anhydrite with disseminated opaques and calcite. (C-D) 3201.55 m depth. (C) Hydrothermal alteration of primary plagioclase to biotite and muscovite. Calcite and chlorite veins within microcrystalline quartz matrix are present. (D) Remnant phenocryst displays intense pyrophyllite alteration. Patchy calcite alteration, as well as minor epidote, is visible. Matrix consists of microcrystalline quartz with minor pyrophyllite alteration (Q = quartz, A = anhydrite, B = biotite, C = calcite, Cl = chlorite, E = epidote, mQ = microcrystalline quartz, O = opaques, Ms = muscovite, P = plagioclase feldspar).

5.1.2 Elemental composition (XRF)

Eleven major oxides (Table 1) and 28 trace elements were analysed using XRF. SiO_2 and Al_2O_3 dominate the major oxides with lesser amounts of Na_2O, K_2O and CaO.

Table 1: XRF results for the RCE core showing concentrations of major oxides, prior to experiments.

Major Oxides (%)		
Formula	**Tonalite (3201.1m)**	**Tonalite (3201.55m)**
Na_2O	3.83	3.88
MgO	0.40	0.53
Al_2O_3	13.46	13.84
SiO_2	72.92	71.72
P_2O_5	0.037	0.053
MnO	0.010	0.013
SO_4	1.78	2.32
K_2O	3.29	2.39
CaO	2.19	2.79
TiO_2	0.27	0.26
Fe_2O_3	1.41	1.92
LOI (Loss of Ignition)	0.040	0.040
Sum	99.62	99.76

5.1.3 Mapping RCE core density

Micro-Computerised Tomography (CT) performed on the sample revealed this sample is a fairly uniform low-density sample but with isolated patched of higher density mineralisation. With the rare exception, fractures remain unfilled (Fig. 5).

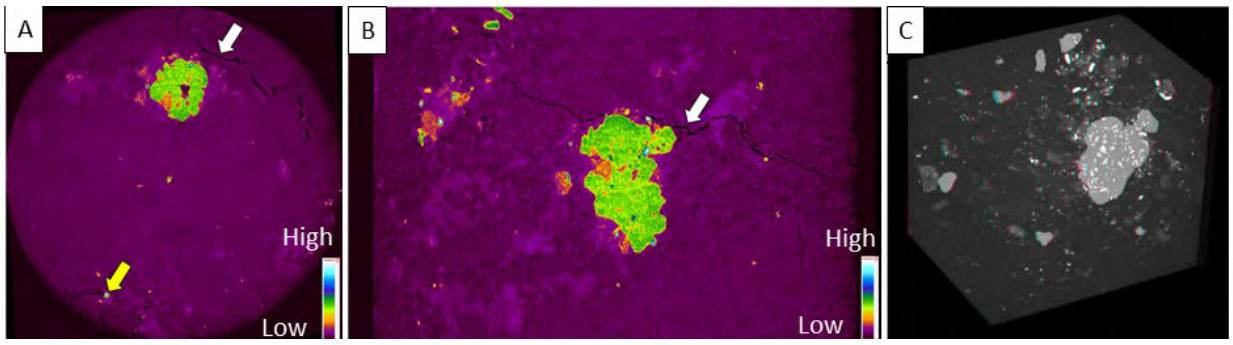

Figure 5: Micro-CT scans of the RCE sample. (A) Transaxial view. (B) Lateral view. (A-B) High-density phenocryst with some alteration within a relatively homogeneous low-density matrix. Fractures are dominantly unfilled (white arrows) but there is rare mineralisation in fractures (yellow arrows). (C) 3D model demonstrates density variations related to spatially patchy mineralisation within the core.

5.1.4 Morphology (SEM) and elemental composition (EDS)

SEM images of the RCE cored sample demonstrate a lack of void connectivity at depths of 3201.1 to 3201.55 m (Fig. 6). At 3201.1 m depth isolated voids range in size up to 15 µm x 5 µm (Fig. 6A-C), while at 3201.55 m depth, isolated voids are smaller with maximum dimensions of 6 µm x 3 µm (Fig. 6D-F). Rare fractures are observed at 3201.55 m depth that are 4 µm wide and continuous over >100 µm (Fig. 6D-E).

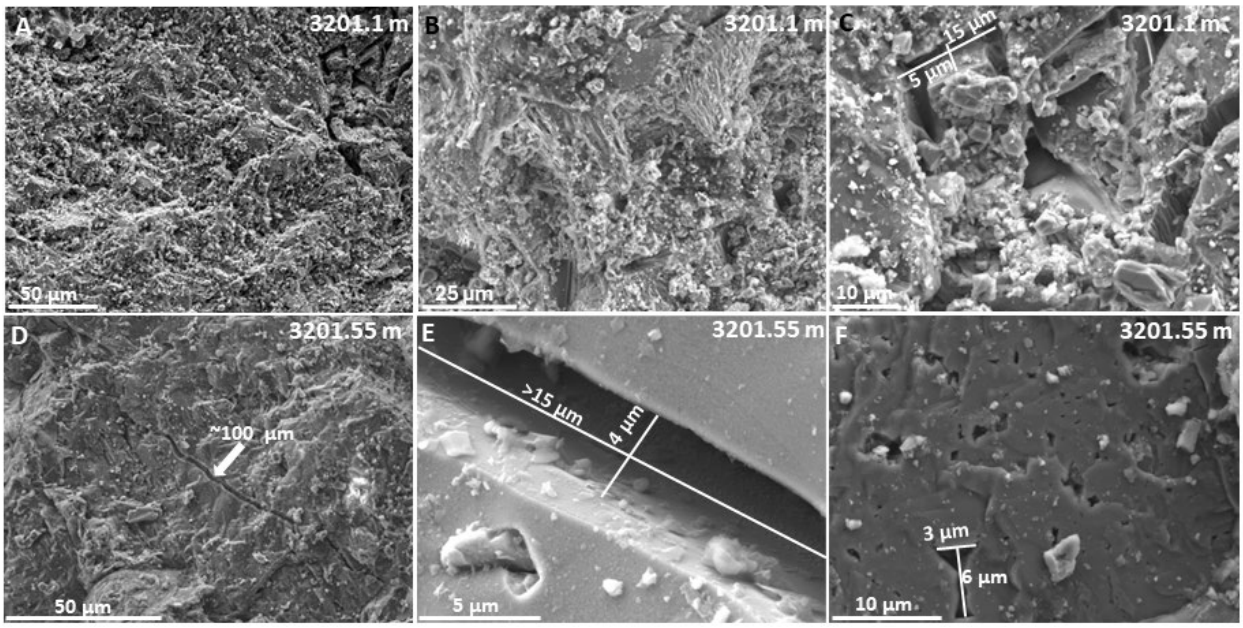

Figure 6: SEM images of the RCE core. (A-C) Depth 3201.1 m. (D-F) Depth 3201.55 m. (A) Overview of sample. (B) Minimal to no voids present. (C) Isolated voids up to 15 µm x 5 µm. (D) Rare fracture >100 µm in length. (E) Fracture >15 µm x 4 µm with minor clay platelets on inner fractured surface. (F) Isolated voids 3 µm x 6 µm.

5.2 Mineralogical and morphological characterisation of NM9 core from 3204 m, 3206.2 and 3206.9 m depth

5.2.1 NM9-11 Depth 3204 m

Sample NM9-11 consists of a crystal-rich fracture zone that overlies the host rock (Fig. 3B). SEM and EDS examination of the crystal-rich zone (Area A on Fig. 7A) revealed intergrowths of high temperature hydrothermal alteration minerals of epidote (>250 °C) and illite (>220 °C) on large quartz and Ca-rich silicate crystals (Fig. 7A-D). The underlying host rock (Area B on Fig. 3) does not reveal high temperature hydrothermal minerals, suggesting the flow of high temperature fluids was confined to the fracture zone, at this depth. Abundant connected voids around crystals in Area A vary in size up to 500 µm x 300 µm (Fig. 7C). Voids within Area B host rock are common, vary in size and many are isolated (Fig. 7E-F). Abundant reactive surfaces are present within this sample that would facilitate ongoing fluid-rock reactions.

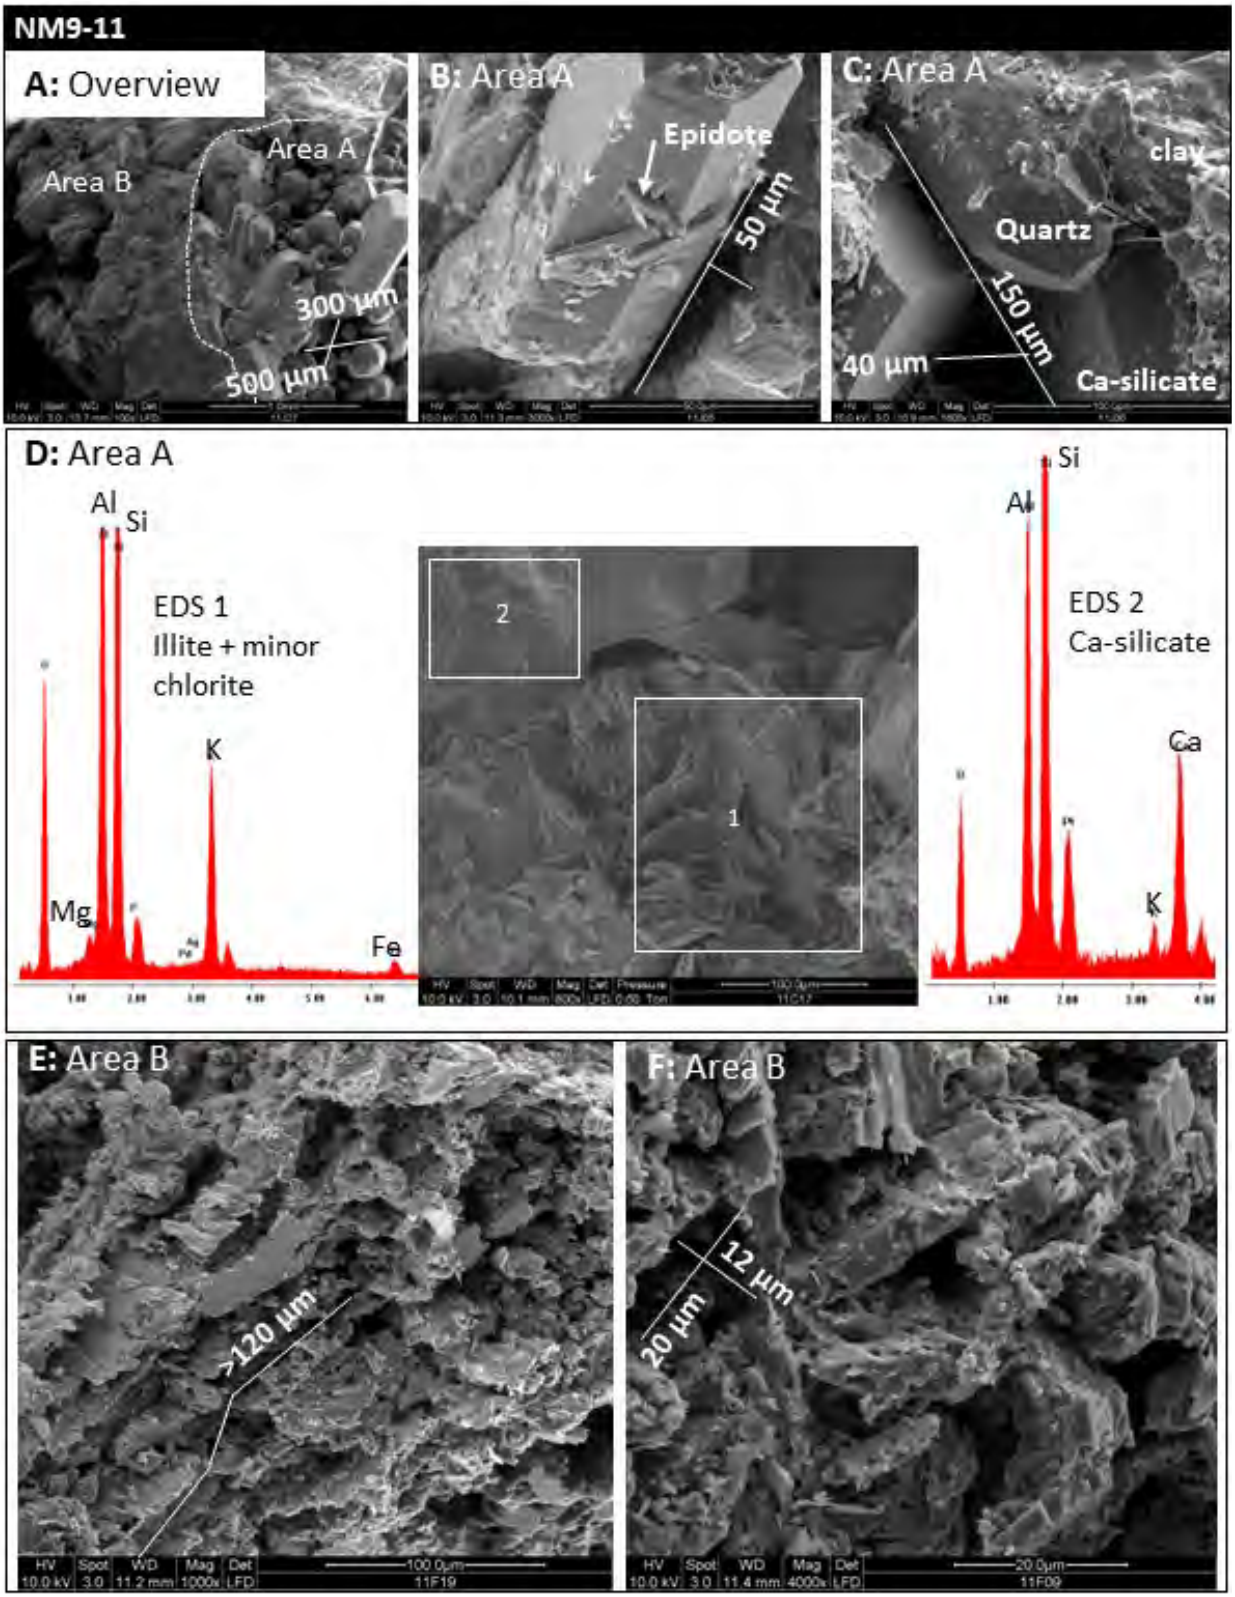

Figure 7: SEM images sample NM9-11. (A) Overview of sample shows a crystal-rich fracture zone (Area A) and the underlying host rock (Area B). (B-D) Quartz, Ca-silicate, epidote and illite in Area A. (E-F) Variation in void size and connectivity within Area B.

5.2.2 NM9-12 depth 3204 m but below NM9-11

Sample NM9-12 (Fig. 3C) revealed hydrothermal alteration minerals of quartz, epidote (>250 °C) and calcite growing into open space within a fracture (Fig. 8A-C, 8E-F). Illite (>220 °C) is also observed in the host rock (Fig. 8D, 8F). Connected voids in the fracture zone are >200 µm in length. Isolated voids of ~50 µm in length occur in the host rock. Abundant reactive surfaces occur within the fracture zone but are limited in the host rock.

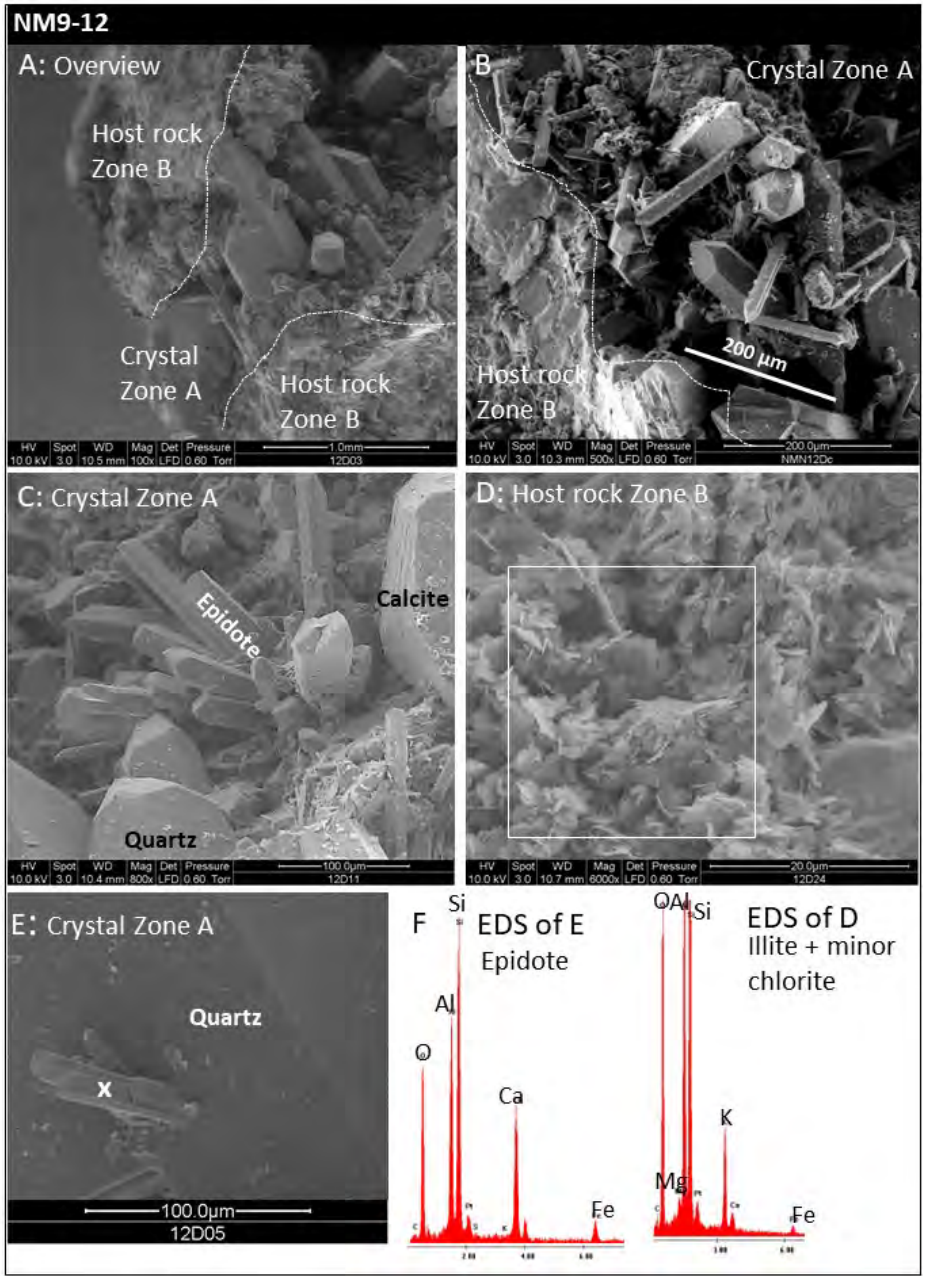

Figure 8: SEM images sample NM9-12. (A) Overview of sample. (B-C and E-F) Crystal-rich fracture zone partially infilled with hydrothermal alteration minerals of epidote, calcite and quartz. (D) Alteration to illite within host rock. White box is site of EDS shown in F. (E) Epidote and quartz in crystal rich fracture zone A. X marks site of EDS shown in (F). (F) EDS scans of x in (E) and white box in (D).

5.2.3 NM9-17

Sample NM9-17 (Fig. 3D) revealed the presence of hydrothermal alteration minerals of anhydrite, illite and chlorite (Fig. 9). Voids are limited to between individual clay platelets and fractures within anhydrite crystals.

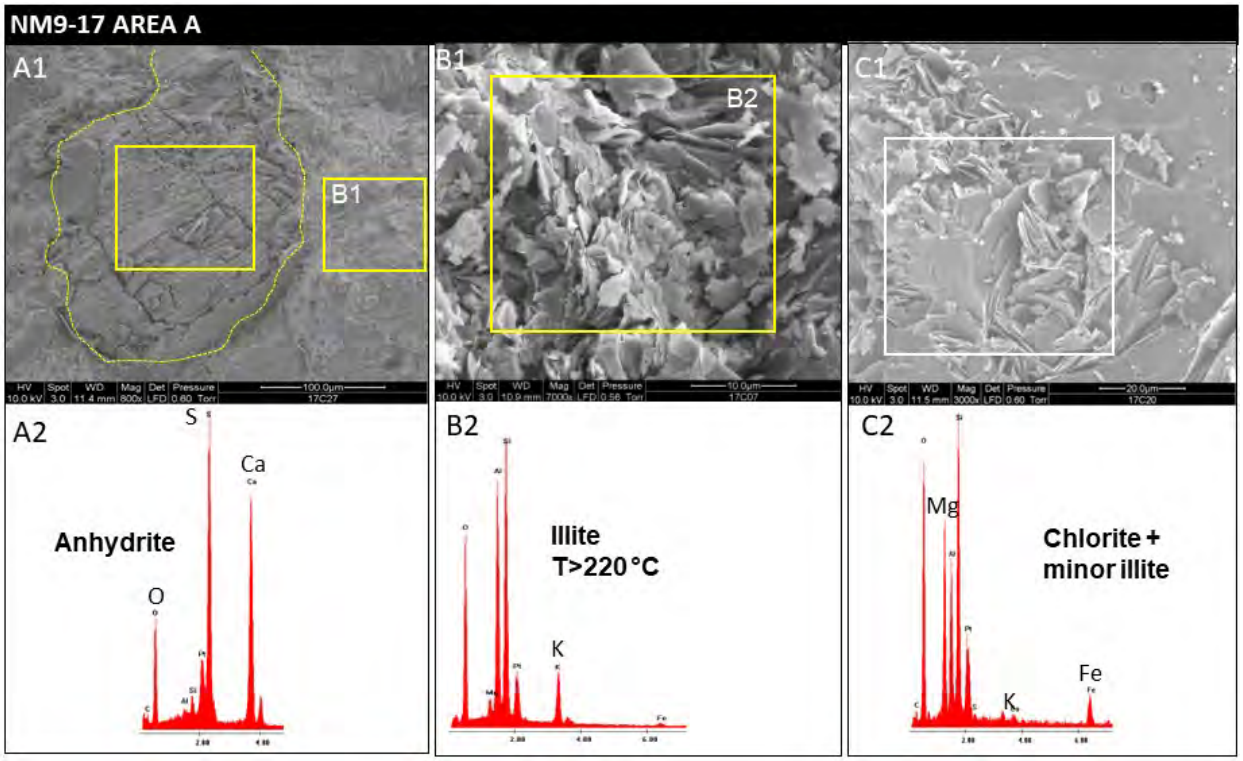

Figure 9: SEM and EDS images of sample NM9-17. (A1-A2, B1-B2) Large, fractured, anhydrite crystals surrounded by illite. Boxed areas indicate sites of EDS scans. (C1-C2) Chlorite and minor illite shown by EDS scan of boxed area.

5.2.4 NM9-18

Core sample NM9-18 (Fig. 3E) shows a boundary between grey (NM9-18B) and white (NM9-18A) tonalite. Both NM9-18A and NM9-18B revealed varying quantities of illite and chlorite. Chlorite dominates the grey tonalite, while illite dominates the white tonalite. Hydrothermal alteration minerals of anhydrite were observed in the grey tonalite but not in the white tonalite. Voids are dominantly limited to open spaces between clay platelets in both samples and are minimal (Fig. 10).

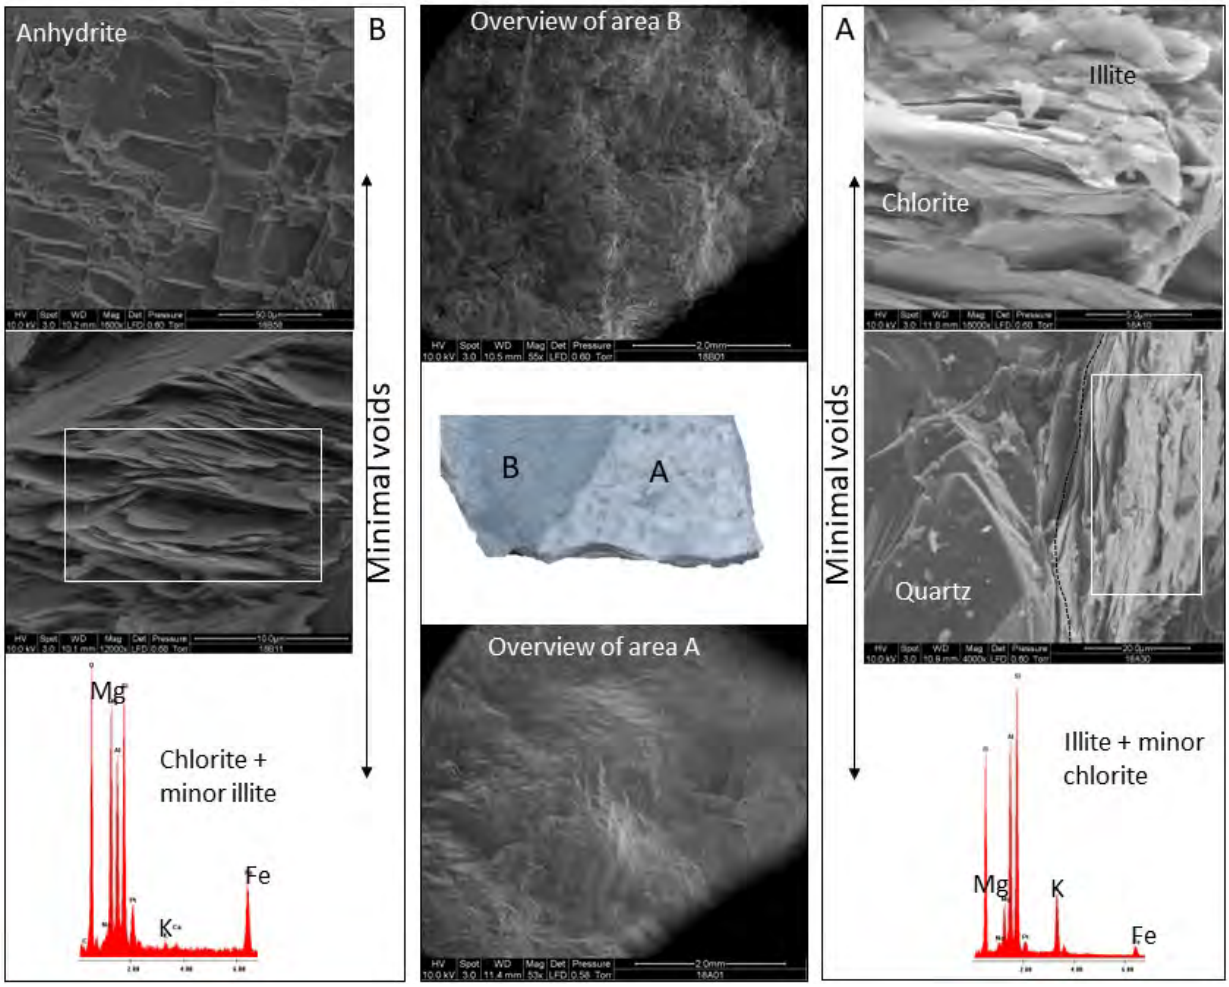

Figure 10: SEM images of sample NM9-18. Overview of sample (centre). (Left) Grey tonalite (area B) with hydrothermal alteration minerals of chlorite, minor illite and anhydrite. (Right) White tonalite (area A) shows areas of illite and chlorite, and large quartz crystals.

5.3 Elemental composition characterisation of core from 3204 m, 3206.2 and 3206.9 m depth

Crystals and clays within each of the four samples were examined by EDS to determine their elemental composition (Fig. 11). As CO_2-rich injectate will readily react with Ca-bearing minerals, it is important to document the occurrence of Ca, trapped in Ca-bearing minerals, their specific elemental composition and their depths. Our results indicate that the concentration of Ca in Ca-bearing minerals and clays varies within the tonalite host rock, within the fracture versus non-fracture zones and with depth.

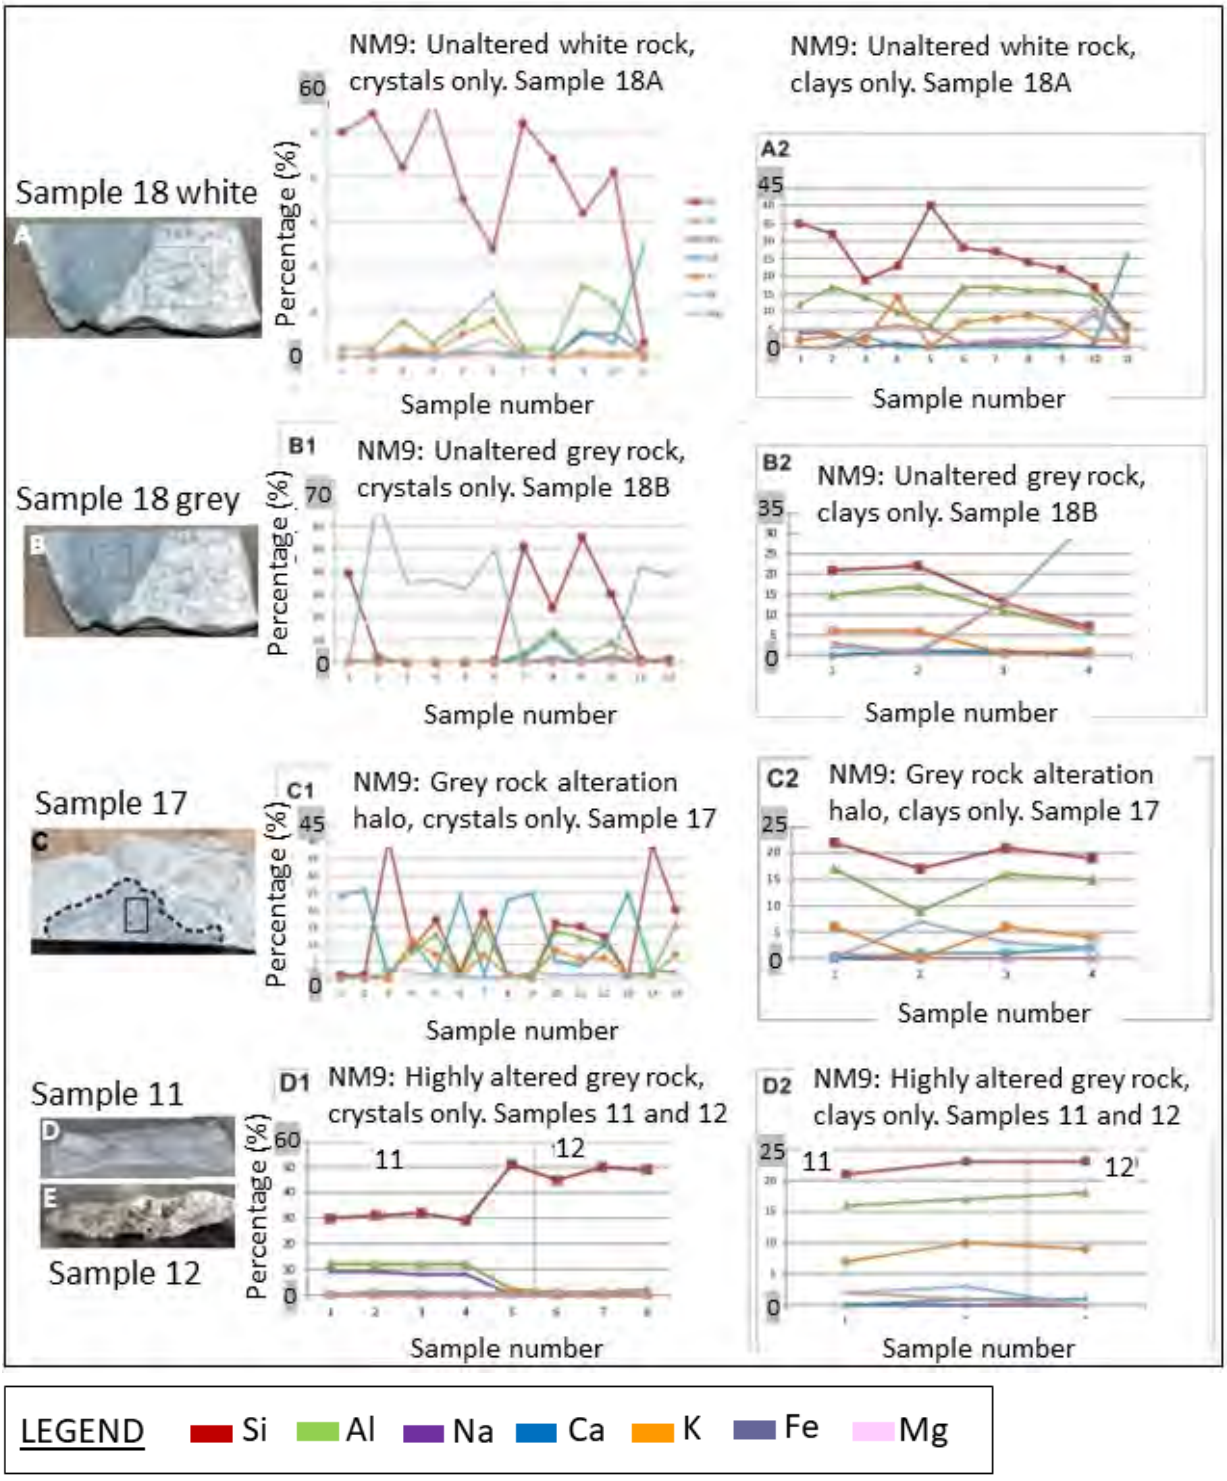

Figure 11: Summary of EDS results for the four tonalite samples between 3204 m and 3206.9 m depth.

6. Discussion

The presence of tonalite, an igneous, intrusive rock, within a TVZ hosted geothermal system such as Ngā Tamariki, is quite unique. Tonalite is of felsic composition, rich in feldspars and silica. The

feldspars are usually oligocase (Na-rich) or andesine (Na-Ca-rich) with <10% alkali feldspars (K-feldspar) and >20% quartz. However, the tonalite in Ngā Tamariki NM9 injection well is associated with magmatic-hydrothermal alteration representative of high-intermediate-sulfidation state epithermal mineralisation (Chambefort et al., 2017). Over the 6.8 m of core analysed we document the presence of quartz, alkali feldspar, and plagioclase feldspar primary minerals and hydrothermal alteration minerals of chlorite, illite, calcite, anhydrite, epidote, quartz, and adularia.

CO_2 mineral entrapment can be enhanced or inhibited by the availability of cations, reactive surfaces, host rock mineralogy, rock textures, voids, fractures, crystal size and crystal shape. Our multi-analytical approach has characterised host rock from injection well NM9 at Ngā Tamariki geothermal field. We documented;

- The presence of Ca-bearing minerals such as anhydrite, calcite and epidote, thus favouring chemical reactions and potentially facilitating CO_2 entrapment when in contact with CO_2-rich injectate fluid,
- Our EDS results document elemental composition variability over 6.8 m of core.
- Voids decrease with depth over the 6.8 m length of core,
- Connected voids are dominantly limited to isolated fractures in the RCE core and the crystal-rich fracture zones of samples NM9-11 and NM9-12,
- The dominance of crystals within the fracture zones of NM9-11 and NM9-12 provide abundant reactive surfaces for continued reactions to occur, when exposed to CO_2-rich fluid experiments,
- The open fractures provide space for future mineral growth and CO_2-mineral entrapment processes,
- Large isolated voids, such as those in the host rock of NM9-11, would increase the fluid storage capacity of the rock but fluid-rock interaction and/or CO_2-entrapment could only occur if fluid was able to reach the voids,

The pre-experimental characterisation of the tonalite core from NM9 injection well (step one) highlights the complex interplay of multiple parameters that will control permanent CO_2 entrapment. It also demonstrates the heterogeneity of the tonalite core over 6.8 m. These results emphasize why it is important to fully characterise the rocks in order to understand and predict how rocks of the same type, but at different depths, may react upon contact with CO_2-rich injectate. Rock variability within the same formation as shown in this study, will influence the rocks suitability for CO_2 uptake. By understanding the variable characteristics of formations in injection wells, the most ideal injection depth for CO_2 uptake can be better targeted.

Step two of the study involves the experimental laboratory work on the NM9 tonalite core characterised in this study. Step two will provide real-time data showcasing mineral reactions under known; (i) fluid-rock conditions, (ii) mineralogy, elemental composition and textures, (iii) density, void and fracture characteristics.

Following on from the post-experiment characterisation of the tonalite core, will be field geochemical and geophysical monitoring, and reactive transport and numerical modelling, using real rock data. These are all essential tools necessary to assess and predict the behaviour of CO_2 within the reservoir rocks. In collaboration with our industry partners, we are actively working on creating numerical models which can serve as a tool for investigating fluid-rock interaction parameters within reservoir-scale investigations. This comprehensive approach aims to unlock

insights into potential precipitation mechanisms, specifically those linked to NCG reinjection. This also allows us to identify primary and secondary minerals that have been identified in the various host rocks common in the diverse reservoir rocks prevalent within the TVZ geothermal systems.

Acknowledgements

This work was supported by the NZ Ministry of Business, Innovation and Employment for funding the work through MBIE Research Programme: UOAX2211 “Reversing Carbon Emissions in the Geothermal Energy Industry: Template for Emission-Intensive Industries”. We would also like to thank Mercury Energy for access to the core samples. The work by Lynne (2013) was supported by the Foundation of Research Science and Technology, project number 3608884. We also thank Mercury Energy (formerly Mighty River Power) for supplying the cored rock samples for the 2013 study.

Geothermal Play Fairway Analysis (GPFA) - Part II: Texas/Gulf Coast Mechanisms of Heat Generation

Kevin McCarthy[1]*, Will Pettitt[1], Rich Priem[2]

[1] Baker Hughes [2] Priemere GeoTechnology

Keywords

Geothermal, Play Fairway Analysis (PFA), Exploration

ABSTRACT

Geothermal Play Fairway Analysis (GPFA) is an exploration process adopted to geothermal, that integrates data of critical risk elements inherent to that specific geothermal play type. The key function of GPFA is to reduce risk and increase focus for improving exploration success rates. GPFA begins at the regional/basin scale, and progressively focuses in on the play scale. It then examines the critical risk element data to highlight which play areas have the highest likelihood of success (prospects).

The outputs from the GPFA process are Common Risk Segment (CRS) & Composite Common Risk Segment (CCRS) Maps. CRS maps define areas that contain the same general Probability of Success (PoS) for each individual risk element based on the input data. Operator analyzed/ determined cutoff values or classes are then applied to each map with color assignments indicating high (red), medium (yellow) and low (green) risk areas for each element under consideration. Each individual CRS map is then composited into a single CCRS map.

Publicly available data on hundreds of thousands of boreholes in Texas and the Gulf Coast demonstrate excellent potential for geothermal electricity generation from either current or abandoned oil and gas wells. Near-surface geothermal resources, at depths of 3 km (9,842 ft) or less, are generally less than 150°C (302°F) in Texas. Economically feasible electricity generation is possible with available subsurface temperature conditions within reasonable depths—generally greater than 120°C (248°F) within 4 km (13,123 ft) – given the prolific oil and gas well drilling. Extensive data exists to depths as much as 8 km (26,246 ft), indicating temperatures in excess of 300°C (572°F).

When initiating an investigation into a new geothermal exploration area, a "high-level first pass" should be conducted for the heat resource before initiating the full GPFA process or detailed feasibility assessment. This is an important first step prior to conducting a detailed study so that you can determine if there is a heat resource to be exploited prior to investing significant time and effort on an extensive study. The initial step is to investigate for any temperature data to determine

geothermal gradients within the exploration area. This will usually be in the form of borehole temperature/completion logs from previously drilled oil and gas wells and any available publications. It is critically important in the GPFA process not to only identify areas of adequate geothermal (heat) resource but to also understand the mechanisms driving the existence of these geothermal gradients. Understanding the subsurface geology and mechanics of heat generation will allow the investigator to identify the most critical risk parameters particular to that prospect.

1. Introduction - Geothermal Systems

Geothermal fields are found throughout the world in a range of geological settings and are increasingly being developed as a significant long-term energy resource. Geothermal systems have distinct characteristics which are reflected in the chemistry of the geothermal fluids and their potential applications. However, they all have in common a heat source which drives water present in the upper sections of the Earth's crust into convection. Many geothermal resources can be used for space heating applications (e.g., urban district heating schemes, greenhouse heating, etc...) while higher temperature systems (>150°C) are used to generate electricity through the production of steam. Before moving into the application of GPFA, it is important to understand the defining characteristics of a “geothermal system”.

If you are involved with the geothermal world, you have likely heard the terms "hydrothermal" and "Geothermal Heat Pump", which are correlated with conventional geothermal systems. Additionally, terms like "Enhanced Geothermal Systems (EGS)" and "Advanced Geothermal Systems" which are linked to unconventional geothermal systems. While these are one way to "define" a geothermal system, we are not discussing that here. In this context, we are looking at the general characteristics that are associated with geothermal systems; liquid vs. vapor dominated, low or high temperature, sedimentary or volcanic, etc.

Geothermal systems are commonly classified by a series of descriptive terms:

Reservoir equilibrium state: This is the fundamental division between geothermal systems and is based on the circulation of the reservoir fluid and the mechanism of heat transfer. Systems in dynamic equilibrium are continually recharged by water entering the reservoir. The water is heated and then discharged out of the reservoir, either to the surface or to underground permeable horizons. Heat is transferred through the system by convection and circulation of the fluid. Systems in static equilibrium have minor to no recharge in the reservoir and heat is transferred only by conduction.

Fluid type: The reservoir fluid can be composed mainly of liquid water (liquid-dominated) or steam (vapor-dominated). In the majority of reservoirs, both steam and liquid water exist in varying proportions as two-phase. Liquid-dominated systems are most common, some which contain a steam cap which can expand or develop on exploitation as happened at Wairakei, New Zealand. Systems which discharge only steam are rare - the best known are Larderello, Italy and The Geysers, USA. Note that liquid-dominated systems are sometimes called water-dominated; this is not a good term since all hydrothermal fields are composed of water in either the liquid or vapor phase. Vapor-dominated systems are also referred to as steam fields.

Reservoir temperature: The temperature (or enthalpy) of geothermal reservoirs is an important parameter in terms of fluid chemistry and potential resource usage. Systems are commonly

described as low-temperature (<150°C) or high-temperature (>150°C). Low-temperature systems are used for "direct-use" applications (e.g., heating), while high-temperature systems can be used for electricity generation as well as direct-use applications.

Host rock: The rocks which contain the geothermal reservoir (the "host rocks") react with the geothermal fluid. As fluid-rock interactions determine the final composition of the geothermal waters and gases, a knowledge of the host rocks is important for application of geothermometers and understanding potential scaling problems if the field is developed. Volcanic, clastic-sedimentary, and carbonate-sedimentary rocks (and the metamorphic equivalents of these lithologies) all yield geothermal fluids with contrasting and distinct chemistries. If the subsurface geology is poorly understood, it may be possible to predict the lithologies from the water chemistry.

Heat source: The heat source for the system is a function of the geological or tectonic setting. If the heat flow is provided by a magma, then such systems are termed volcanogenic and are invariably high-temperature systems. Heat is not always supplied by magma, and a geothermal system can be generated in areas of tectonic activity. For example, heat may be supplied by the tectonic uplift of hot basement rocks, or water can be heated by unusually deep circulation created by movement of a permeable horizon or faulting. These are termed non-volcanogenic systems and include examples of both high and low-temperature reservoirs.

2. Geothermal Play Fairway Analysis (GPFA)

GPFA, an exploration process developed by the oil and gas industry and now adopted to Geothermal, integrates data of critical risk elements inherent to that specific geothermal play type (Nielson et al., 2015). The key function of GPFA is to reduce risk and increase focus for improving exploration success rates.

GPFA was first applied to petroleum systems and is now being developed for understanding geothermal systems. The elements required for a conventional petroleum play or “petroleum system” are a source rock, reservoir rock, migration pathway, and seal (Figure 1). To be considered a prospect (high PoS), the play must also contain structural or stratigraphic traps, and have a source rock sufficiently heated to generate hydrocarbons at a time – the critical moment – when all the other required elements (e.g., reservoirs, pathways, seals, traps) were in place.

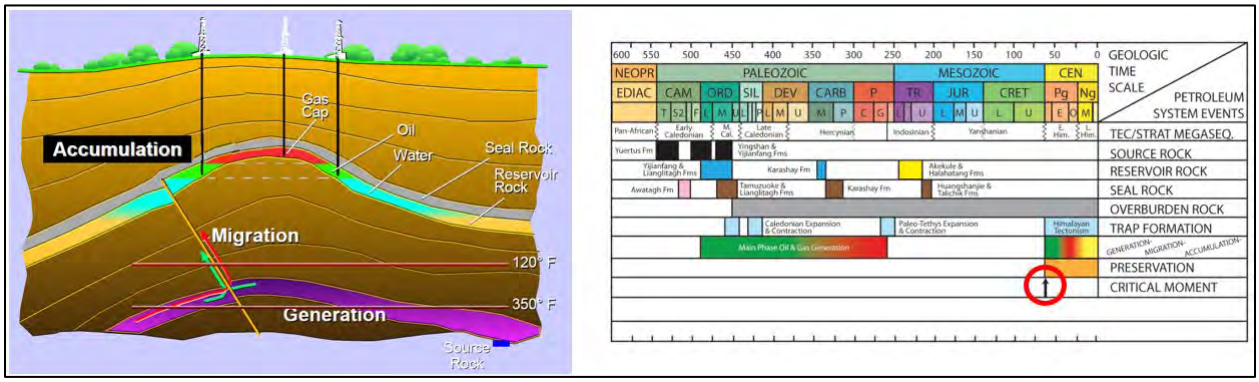

Figure 1: Elements required for a conventional petroleum play or “petroleum system”; source rock, reservoir rock, migration pathway, and seal.

The elements required for an unconventional petroleum play or "petroleum system" are inherently different from a conventional system as the source rock is also the reservoir (Figure 2). The low permeability organic rich shale reaches required thermal maturity to produce hydrocarbons which are then produced through hydraulic fracturing (artificial permeability network).

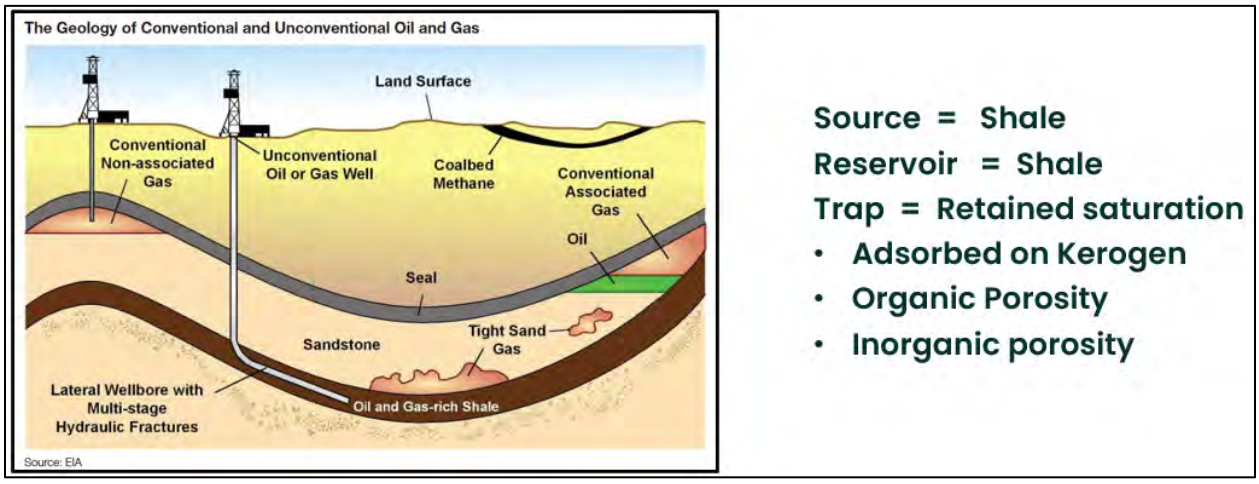

Figure 2: Elements required for an unconventional petroleum play or "petroleum system" are inherently different from a conventional system as the source rock is also the reservoir.

GPFA begins at the regional/basin scale, and progressively focuses in on the play scale (Figure 3). It then examines the critical risk element data to highlight which play areas have the highest likelihood of success (prospects).

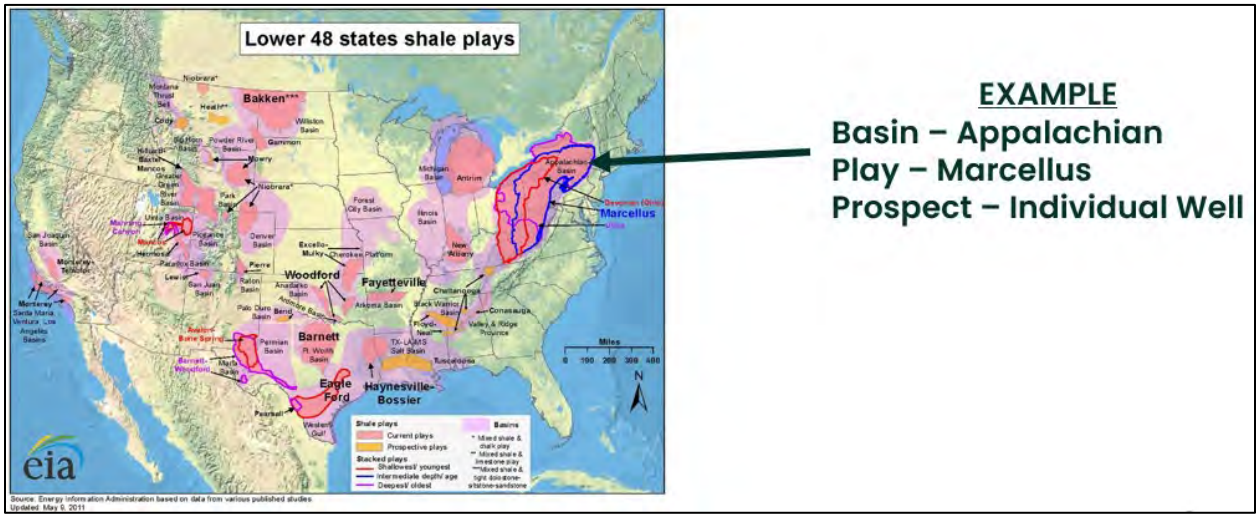

Figure 3: GPFA begins at the regional/basin scale, and progressively focuses in on the play scale (Jordan, Teresa et al., 2016).

3. Common Risk Segment (CRS) & Composite Common Risk Segment (CCRS) Maps

The outputs from the GPFA process are Common Risk Segment (CRS) & Composite Common Risk Segment (CCRS) Maps (Figure 4). CRS maps define areas that contain the same general Probability of Success (PoS) for each individual risk element based on the input data (Faulds,

James E., et al., 2021). Operator analyzed/ determined cutoff values or classes are then applied to each map with color assignments indicating high (red), medium (yellow) and low (green) risk areas for each element under consideration. Each individual CRS map is then composited into a single CCRS map. In conventional petroleum exploration, the risk elements are the reservoir, source, charge, and trap.

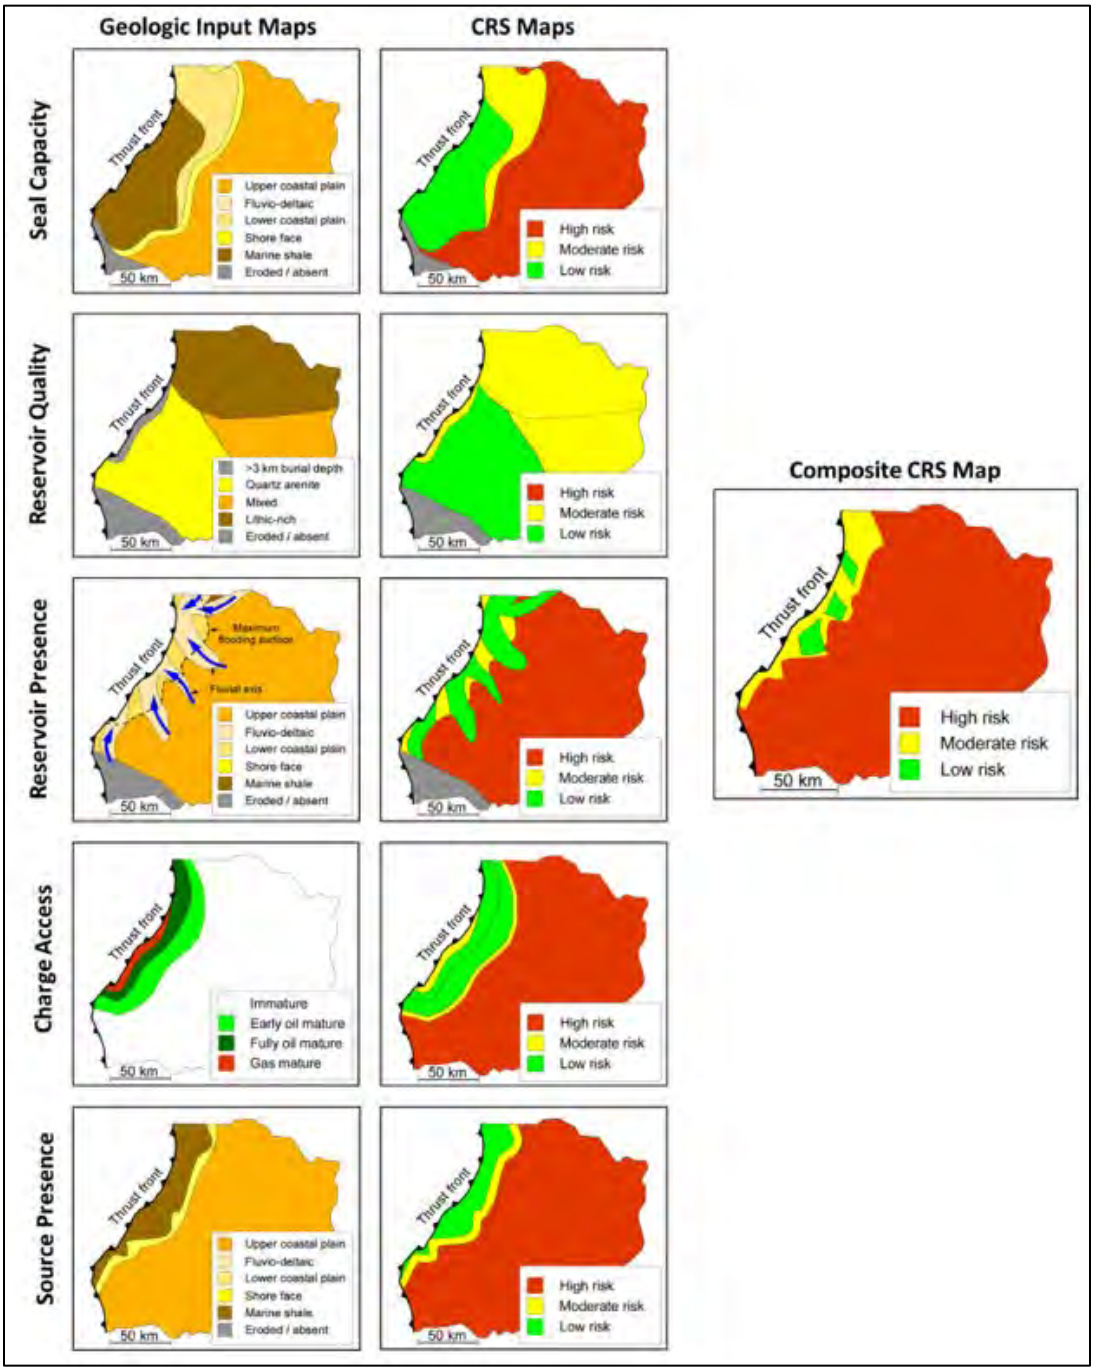

Figure 4: Common Risk Segment (CRS) & Composite Common Risk Segment (CCRS) Maps. CRS maps define areas that contain the same general Probability of Success (PoS) for each individual risk element. Source: Bump, 2021. Common risk segment mapping: Streamlining exploration for carbon storage sites, with application to coastal Texas and Louisiana

For an unconventional petroleum system, here are some examples of the critical risk elements and their associated risk cutoff values (Figure 5). Note the asterisk for EGS next to the % clay critical risk parameter. In an unconventional petroleum system that requires fracturing, if the % clay gets too high, the rock is too ductile, and the fractures will not remain open. The same would apply to EGS, which requires the generation of a fracture network.

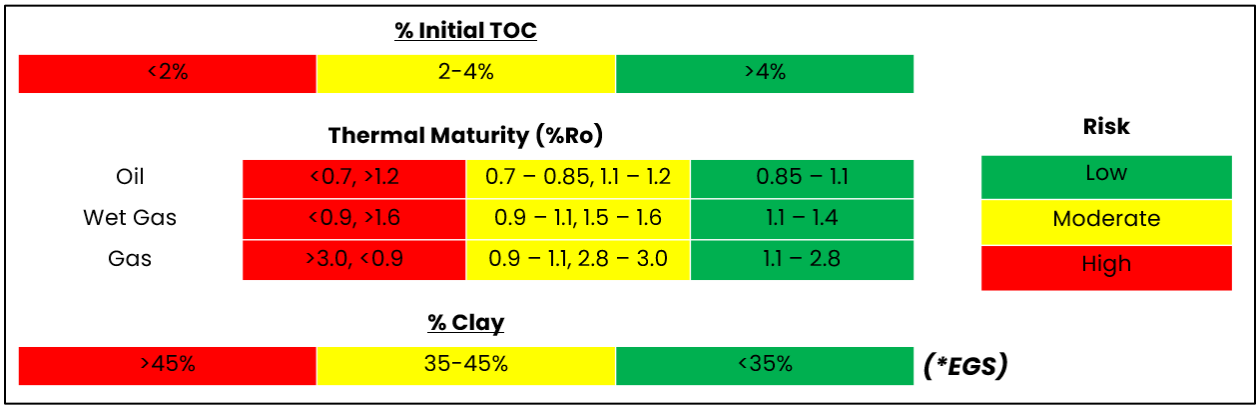

Figure 5: Critical risk elements and their associated risk cutoff values.

The CRS/CCRS workflow using heat flow (mW/m^2) as an example (Figure 6):

1. Gather risk element data
2. QC data
3. Import data into GIS system
4. Conduct interpolation to create continuous surface
5. Apply cutoff value colors (green, yellow, red)
6. Single layer risk CRS created
7. Integrate/stack individual CRS layers to create CCRS

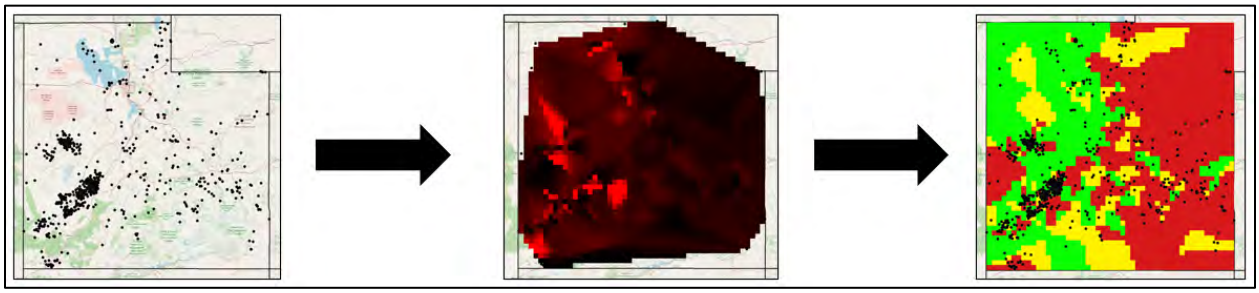

Figure 6: CRS/CCRS workflow using heat flow data (mW/m^2) as an example. Heat flow data points (mW/m^2) imported into GIS, followed by an IDW/TIN interpolation continuous surface and final risk value colors applied to form a single CRS layer.

4. Geothermal CRS Elements

In a geothermal play or system, the main exploration risk elements for this study are (a) heat resource, (b) permeability, (c) recharge and (d) seal.

a: Heat: While trivial that a high-level heat source is the principal requirement for an effective and economic geothermal system, accessibility depth for drilling and evaluation purposes, as well as interval complexity are important factors.

b: Permeability: Geothermal reservoirs are reliant on natural fracture permeability, associated with fracturing related to tectonic and magmatic processes, or through stimulated fractures if feasible.

c: Temperature recharge capacity of the migration of fluids within the geothermal system is critical to maintaining a long-lived resource with economic heatflow dynamics.

d: A seal keeps fluid from escaping or mixing with colder shallower aquifers. It also acts as a thermal insulator to the geothermal reservoir.

In the following GPFA example conducted in the Tularosa Basin (Bennett, Carlon R. et al., 2015), we see the individual CRS elements combined into a final CCRS map (Figure 7):

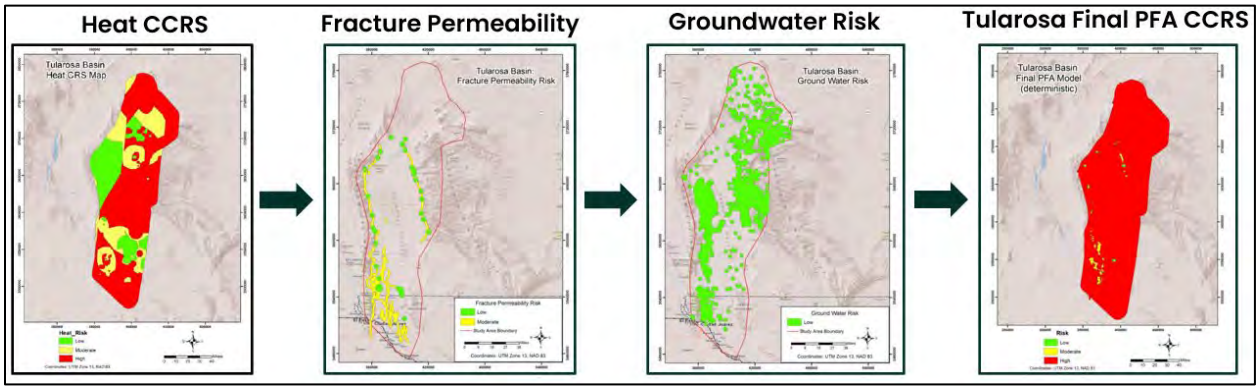

Figure 7: GPFA example from the Tularosa Basin. Source: Department of Energy, Office of Energy Efficiency and Renewable Energy (EERE), Geothermal Technologies Office DE-EE0006730; Innovative Play Fairway Modelling Applied to the Tularosa Basin.

Through the application of GPFA and screening for critical risk elements inherent to a functional geothermal system (heat, groundwater, and fracture permeability), this study was able to reduce an exploration area of approximately 6500 km2 into 8 specific high graded potential plays/target sites (Figure 8). These prospects represent areas where all the critical risk elements coincide with a low-risk determination.

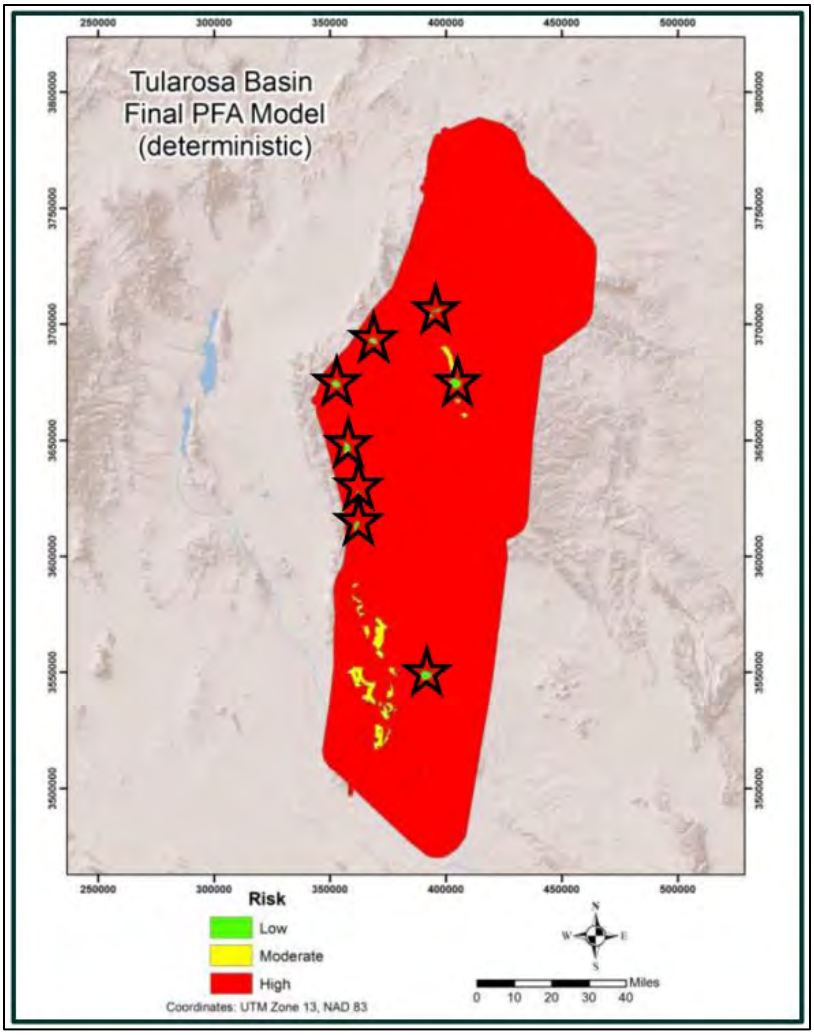

Figure 8: GPFA CCRS final map from the Tularosa Basin. Source: Department of Energy, Office of Energy Efficiency and Renewable Energy (EERE), Geothermal Technologies Office DE-EE0006730; Innovative Play Fairway Modelling Applied to the Tularosa Basin.

Here we present some example heat geothermal risk elements and their associated risk cutoff values:

1. Temp. Gradient °C/km
   - 0 °C/km – 35 °C/km = High Risk (Red)
   - 35 °C/km – 50 °C/km = Moderate Risk (Yellow)
   - > 50 °C/km = Low Risk (Green)
2. Quartz Geothermometer °C
   - 0 °C/km – 60 °C/km = High Risk (Red)
   - 60 °C/km – 80 °C/km = Moderate Risk (Yellow)
   - >80 °C/km = Low Risk (Green)
3. Heat Flow mW/m^2
   - 55 – 70 mW/m^2 = High Risk (Red)
   - 70 – 85 mW/m^2 = Moderate Risk (Yellow)
   - >85 mW/m^2 = Low Risk (Green)

The most important risk element for geothermal is heat; you can think of this as the equivalent to the source rock in petroleum systems. Without a source rock, there simply isn't a petroleum system to be investigated. Similarly, if you don't have the necessary heat resource, there is no functional geothermal system.

5. Hi-Fi Advancements

After understanding the basics of GPFA, we recommend advancing to more sophisticated and automated analysis with a high-fidelity solution. Again, leveraging the knowledge base of the petroleum industry, the results below (Figure 9) were produced using the Power Risk Optimizer from the Priemere Power Tools for ArcGIS (Help@Priemere.com). With the same data & parameters as above, the same eight Prospects (Hot/Go Spots) were identified.

However, the final hi-fi results can be classified at any desired level of detail, and there is greater resolution to consider with the six colors utilized. And as a further diagnostic aid, the polygon labels indicate the critical risk factor (CRF) as the element with the greatest impact within each area. These automated features facilitate rapid iteration on various models and parameters to achieve a more thorough and accurate understanding of the GPFA system.

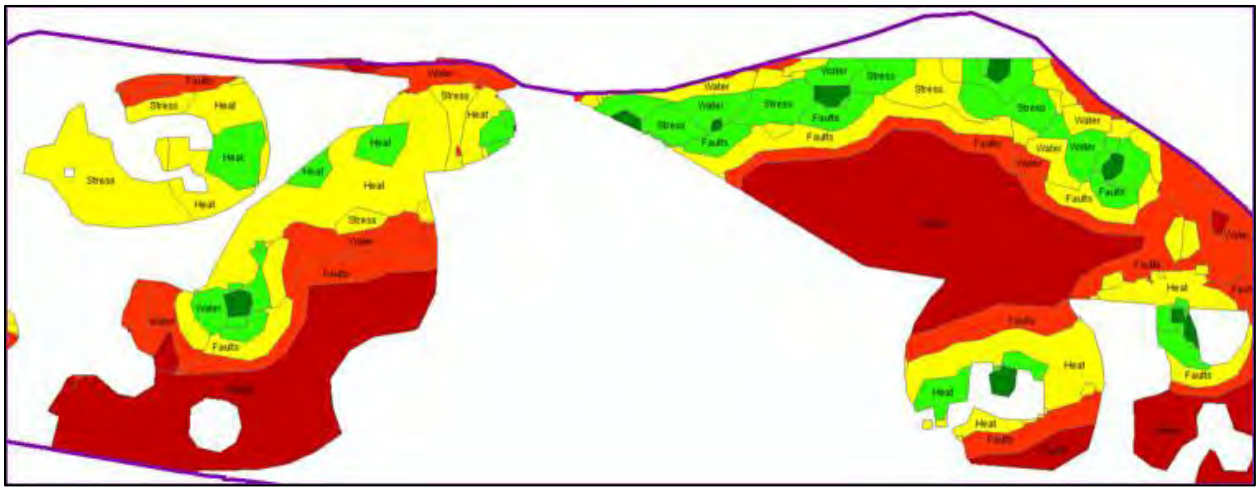

Figure 9: Hi-Fi GPFA example for the Tularosa Basin from the Priemere Power Risk Optimizer.

6. Initial GPFA Screening

When initiating an investigation into a new geothermal exploration area, a "high-level first pass" should be conducted for the heat resource before initiating the full Geothermal Play Fairway Analysis (GPFA) process or detailed feasibility assessment. This is an important first step prior to conducting a detailed study so that you can determine if there is a heat resource to be exploited prior to investing significant time and effort on an extensive study.

The initial step is to investigate for any geothermal gradient data that may be available within the exploration area. This will usually be in the form of borehole temperature logs from previously drilled oil and gas wells. In the United States, you can generally find this data across most geothermal exploration areas. An example resource for this is the Southern Methodist University (SMU) National Geothermal Data System.

This detailed database has provided the means to create some key geothermal maps in the United States, such as the Geothermal Map of North America (Figure 10), Heat Flow Map of the Continental U.S. (Figure 11) and the NREL Favorability of Deep Enhanced Geothermal Systems (Figure 12):

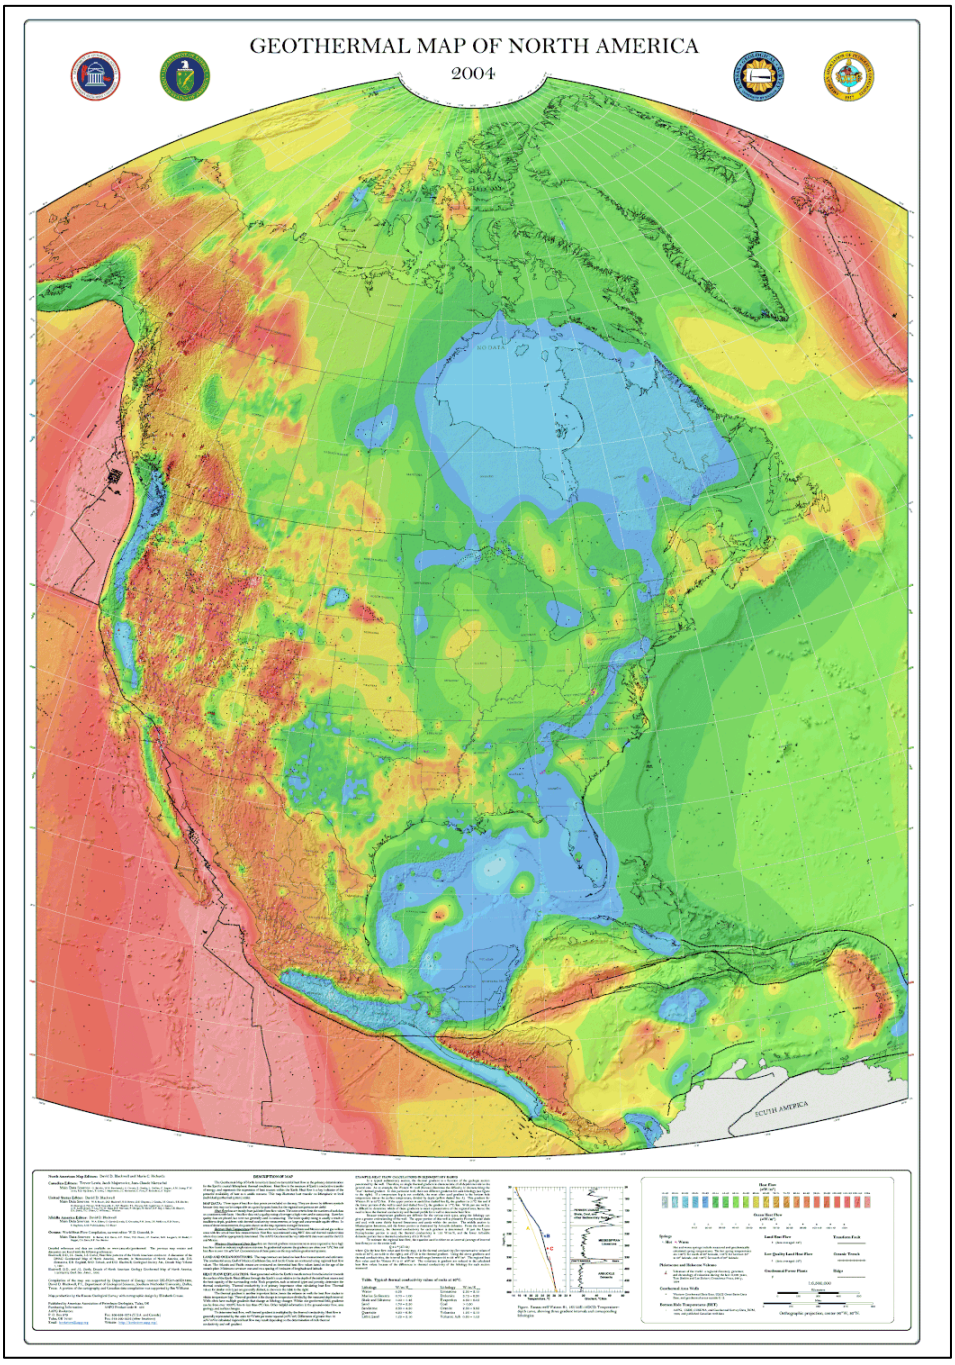

Figure 10: Geothermal Map of North America. Source: Blackwell, D.D., and M. Richards, Geothermal Map of North America, AAPG Map, scale 1:6,500,000, Product Code 423, 2004.

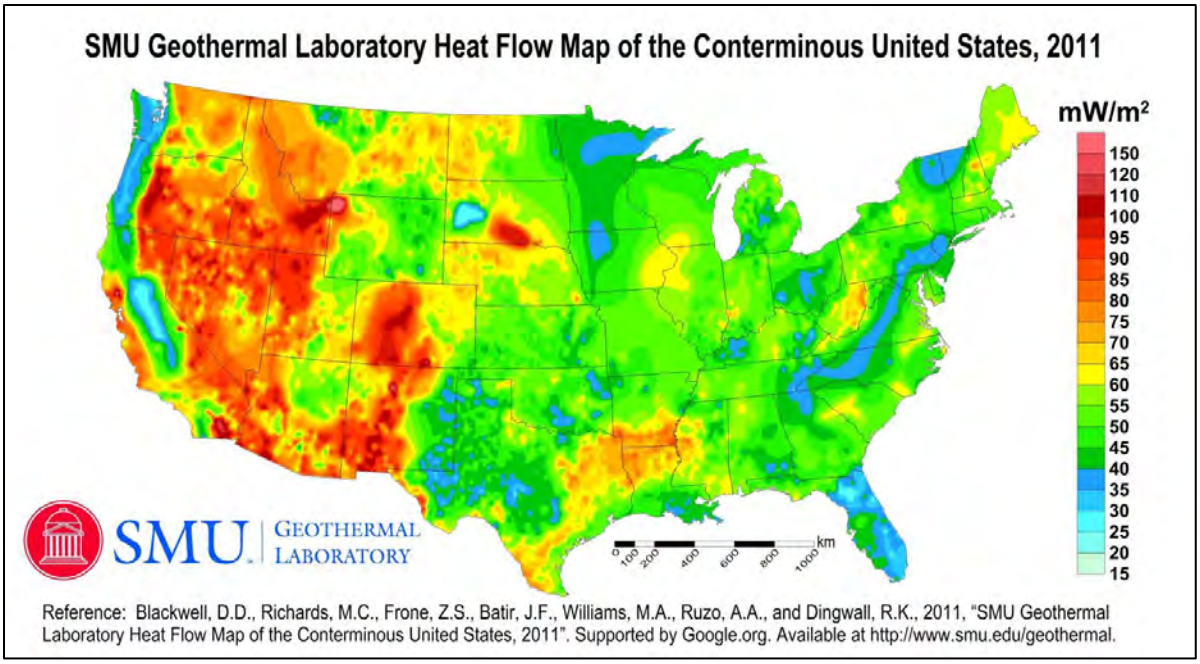

Figure 11: Heat Flow Map of the Continental U.S. Source: Blackwell, David, M. Richards, Z. Frone, J. Batir, A. Ruzo, R. Dingwall, and M. Williams 2011, Temperature at depth maps for the conterminous US and geothermal resource estimates, GRC Transactions, 35 (GRC1029452).

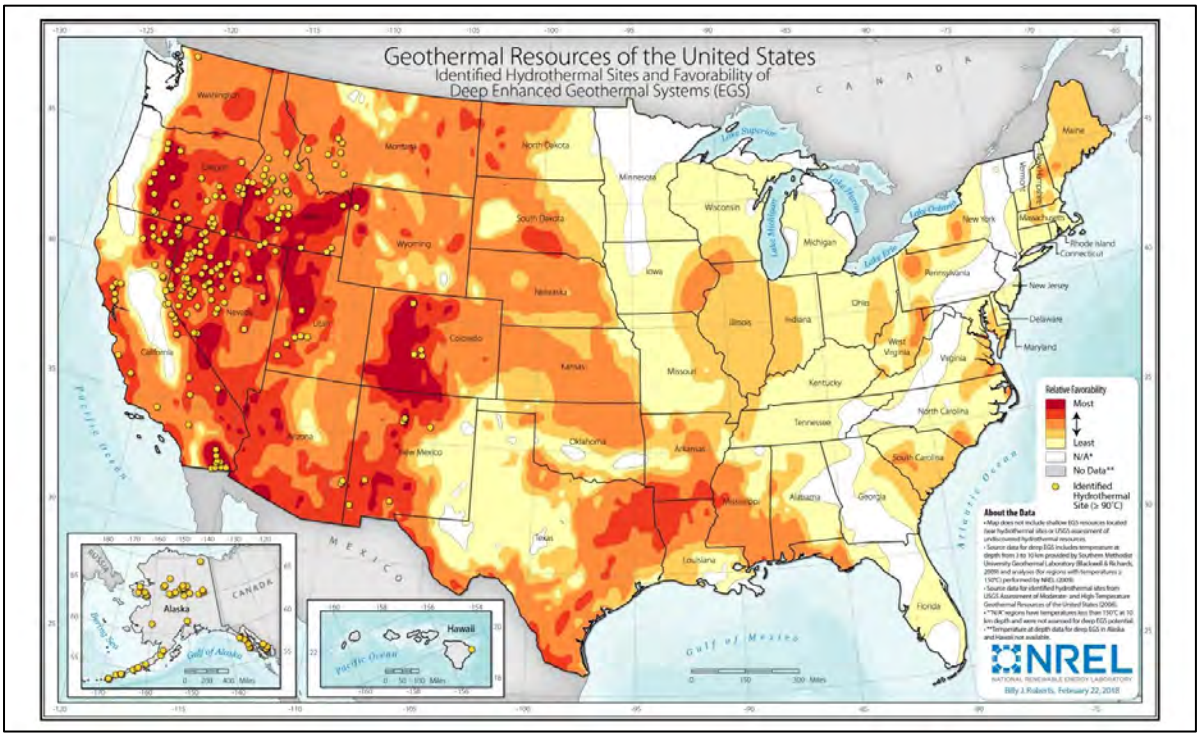

Figure 12: NREL Favorability of Deep Enhanced Geothermal Systems. Source: [NREL Geothermal Resources of the United States—Identified Hydrothermal Sites and Favorability of Deep Enhanced Geothermal Systems]

The main reason we want to look at geothermal gradients from these borehole temperature logs first is to determine if the exploration area is even suitable to geothermal development and economically feasible (Shervais, John W., et al., 2021). The previously described risk cutoffs generally applied to geothermal gradients are as follows:

Temp. Gradient °C/km

- 0 °C/km – 35 °C/km = High Risk (Red)
- 35 °C/km – 50 °C/km = Moderate Risk (Yellow)
- > 50 °C/km = Low Risk (Green)

Geothermal gradients > ~ 50 °C/km are amenable to large scale electricity/power generation and provide a temperature resource capable of supporting the full spectrum of geothermal applications. Between ~ 35 °C/km to 50 °C/km, geothermal low enthalpy/direct use applications are viable and will likely require an Organic Rankine Cycle (ORC), which includes additional costs. At gradients below ~ 35 °C/km, geothermal development is generally not viable. This is primarily due to two reasons; a) an appreciable heat resource is not present and b) you have to drill too deep to reach the required temperatures and therefore it becomes economically unfeasible since the largest cost associated with geothermal projects is drilling. For example, if you have to drill to 8-10 km just to reach 150 °C (which is the base temperature generally required for closed-loop systems and even higher temperatures for EGS), the drilling cost is too significant, making it difficult to attain an ROI within a reasonable timeframe. Notice in the NREL favorability map above, they didn't even consider areas where 150 °C were not reached by 10 km exactly for this reason.

For example, in a recent study a client was looking to investigate geothermal resource development in Louisiana (LA) for closed-loop applications. Prior to initiating a full GPFA study, a first high-level pass for the heat resource was conducted. The parish areas they were initially evaluating are shown in Figure 13.

Figure 13: Louisiana Parish Map. The exploration areas of interest are circled in red.

For the first pass, these parishes were evaluated from a temperature/geothermal gradient perspective (Figure 14 and 15):

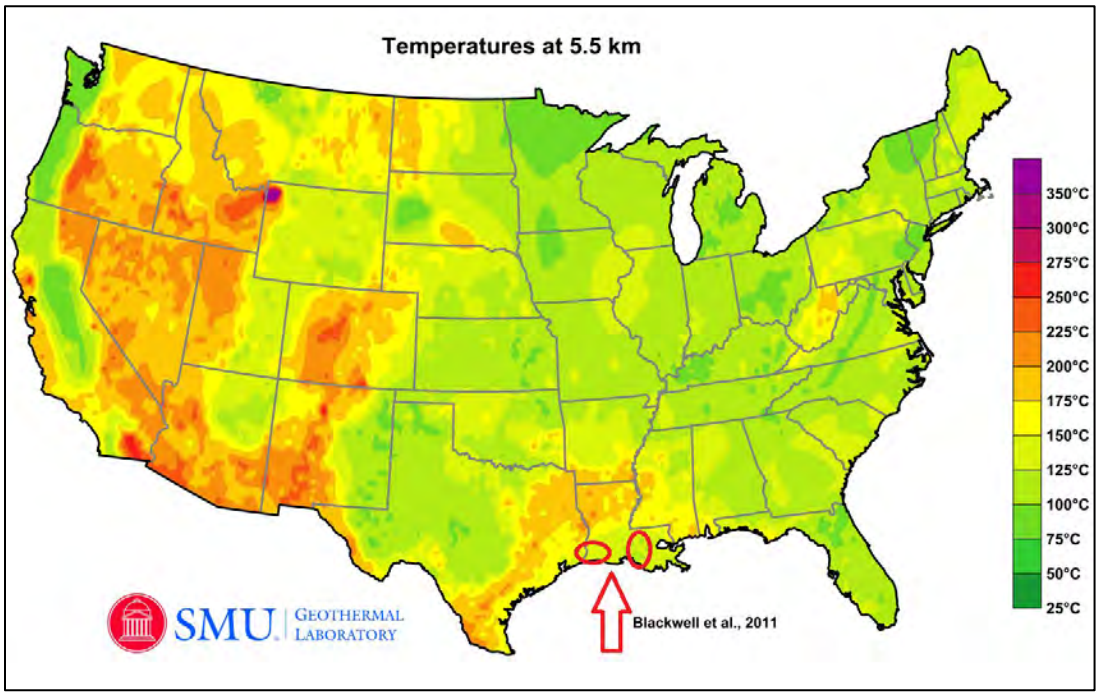

Figure 14: Temperatures at 5.5 km depth with identified counties in red. Source: Blackwell, D., Richards, M., Frone, Z., Ruzo, A., Dingwall, R., & Williams, M. (2011). Temperature-At-Depth Maps For the Conterminous US and Geothermal Resource Estimates. *GRC Transactions,* 35(GRC1029452).

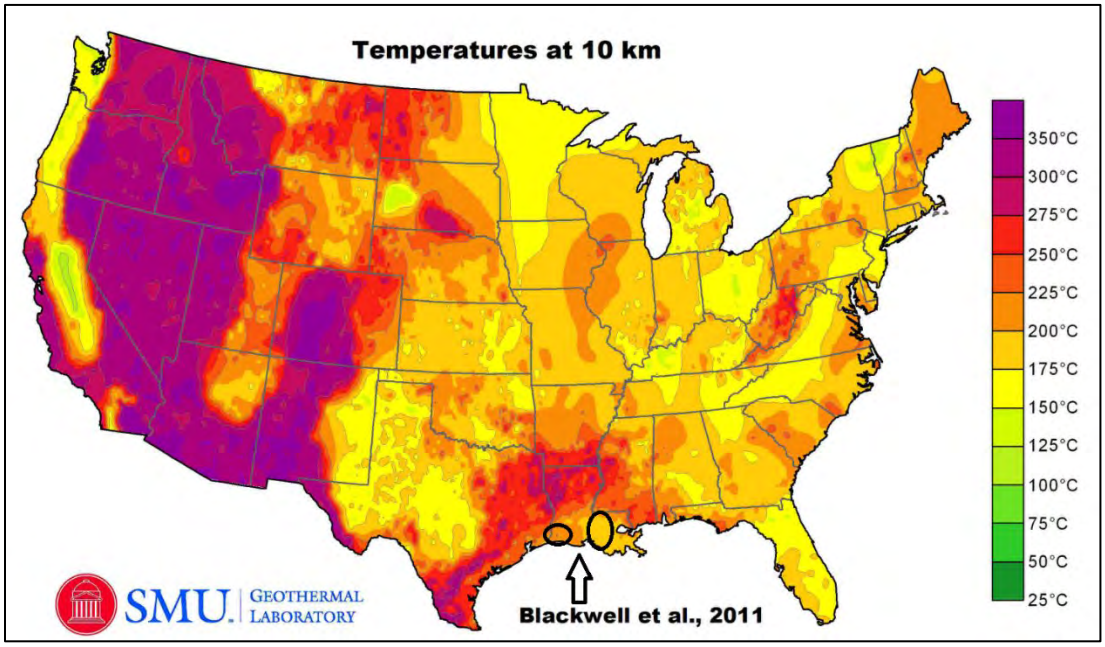

Figure 15: Temperatures at 10 km depth with identified counties in red. Source: Blackwell, D., Richards, M., Frone, Z., Ruzo, A., Dingwall, R., & Williams, M. (2011). Temperature-At-Depth Maps For the Conterminous US and Geothermal Resource Estimates. *GRC Transactions,* 35(GRC1029452).

As can be seen, the client would have to drill to ~10 km to even reach temperatures above 150 °C, base temperatures generally required for optimal closed-loop geothermal systems. This would require significant drilling costs that would make a geothermal project in the area economically unfeasible. This first-pass heat resource assessment provided the client key information that saved them significant time and money.

In this case, the client had interests across the state of LA, and as can be seen in the pictures above, the geothermal gradients in the northern part of the state are amenable to geothermal development.

The geothermal regimes between Northern & Southern LA are completely different from each other due to the Sabine and Monroe Uplifts in the north. These resulted in igneous intrusions that have higher radiogenic heat production (RHP) that provide higher heat flow and also have higher thermal conductivities, creating higher present day geothermal gradients in northern LA. These are absent to the south, where geothermal gradients are significantly lower. Additionally, there are large salt domes present in northern LA and not present in southern LA. Salt domes act as "thermal wicks" and are very efficient at wicking heat from its deeper base up to the top of the salt dome, resulting in locally higher temps at shallower depths.

7. GPFA Screening Applied to The Texas/Gulf Coast Region

Texas produces more oil and natural gas than any other state and to date remains the largest producer of these natural resources, with approximately 4 million barrels per day (MMbbl/d) of oil and more than 20 billion cubic feet per day (Bcf/d) of gas. There is no other state or region worldwide which has been as extensively explored or drilled for oil and natural gas as Texas. Currently, there are ~187,401 active oil wells and 98,709 active gas wells producing oil and natural gas in the state, according to the Railroad Commission of Texas. Additionally, over 7000 of these wells have been abandoned and require significant financial expenses to properly plug and decommission. The assessment supports the imperative need for these wells to be analyzed and assessed for their significant geothermal energy resource potential as an extension of the well life and return on investment of deployed capital, as well as benefiting corporate and societal carbon neutrality goals.

As previously stated, the most critical GPFA element is the heat resource, which is intimately tied to the existing geothermal gradient. In Texas and the Gulf Coast Region, areas with the highest geothermal gradients are found in Southwest Texas (Eagle Ford) and East Texas/Northwest Louisiana (Haynesville), as depicted in the regional geothermal gradient (°C/km) CRS map (Figure 16). The cutoffs applied in this CRS map are as follows: 0-35 °C/km (red) = no geothermal potential, 35-50 °C/km (yellow) = potential for low enthalpy/direct use applications, 50-100 °C/km (green) = electricity/power generation potential.

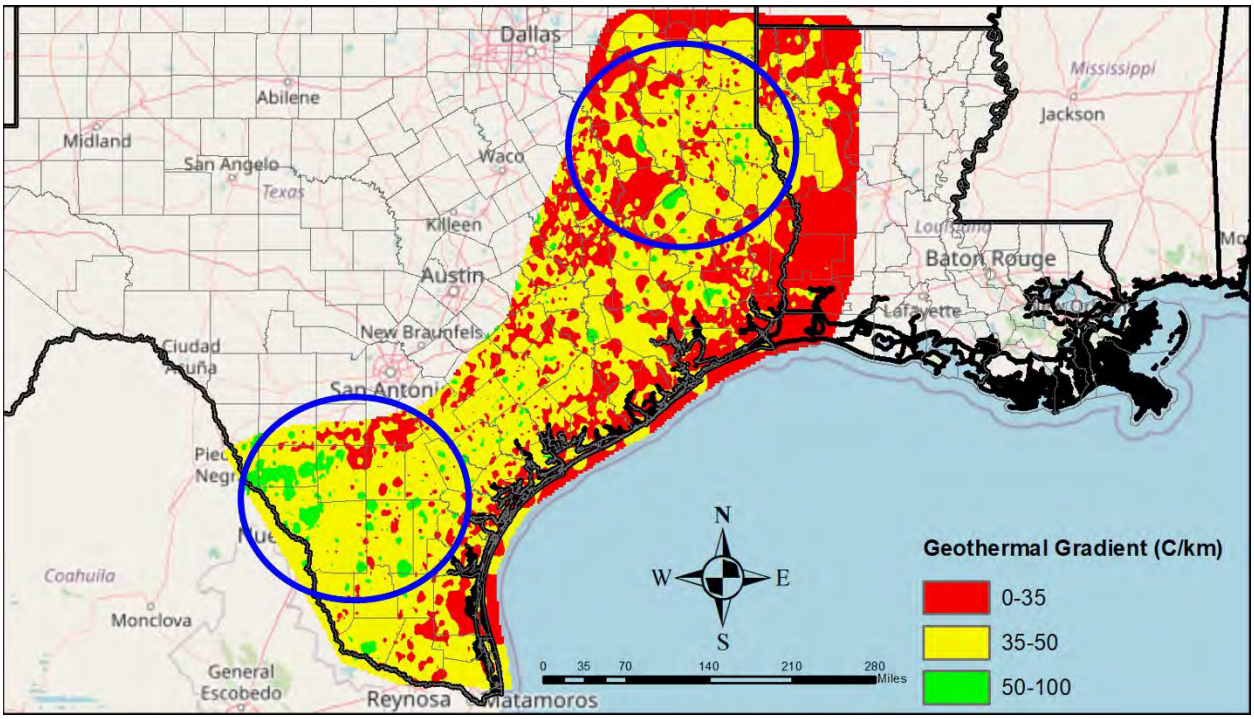

Figure 16: Regional TX/LA Geothermal Gradient CRS Mapping.

The mechanisms behind these two elevated geothermal gradient regions are different. In the Northeast, as can be viewed below (Figure 17), the Haynesville region heat flow values are in excess of 60 – 85 mW/m^2, which is anomalously high compared to the surrounding region. This higher heat flow is attributed to greater radiogenic heat production (RHP) in the igneous basement rocks and the presence of salt domes/diapirs, which have a thermal conductivity 2 to 4 times greater than any other sedimentary rocks (Gray and Nunn, 2010).

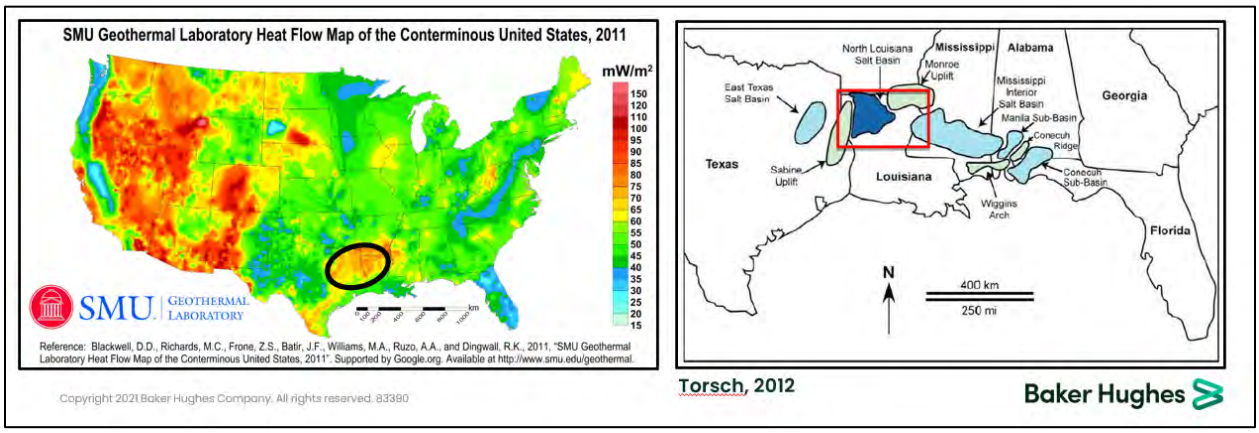

Figure 17: Haynesville Geothermal Potential.

The salt diapirs are of particular interest in geothermal development and exist across the Haynesville region, as shown in the map cross section A-A´ (Figure 18).

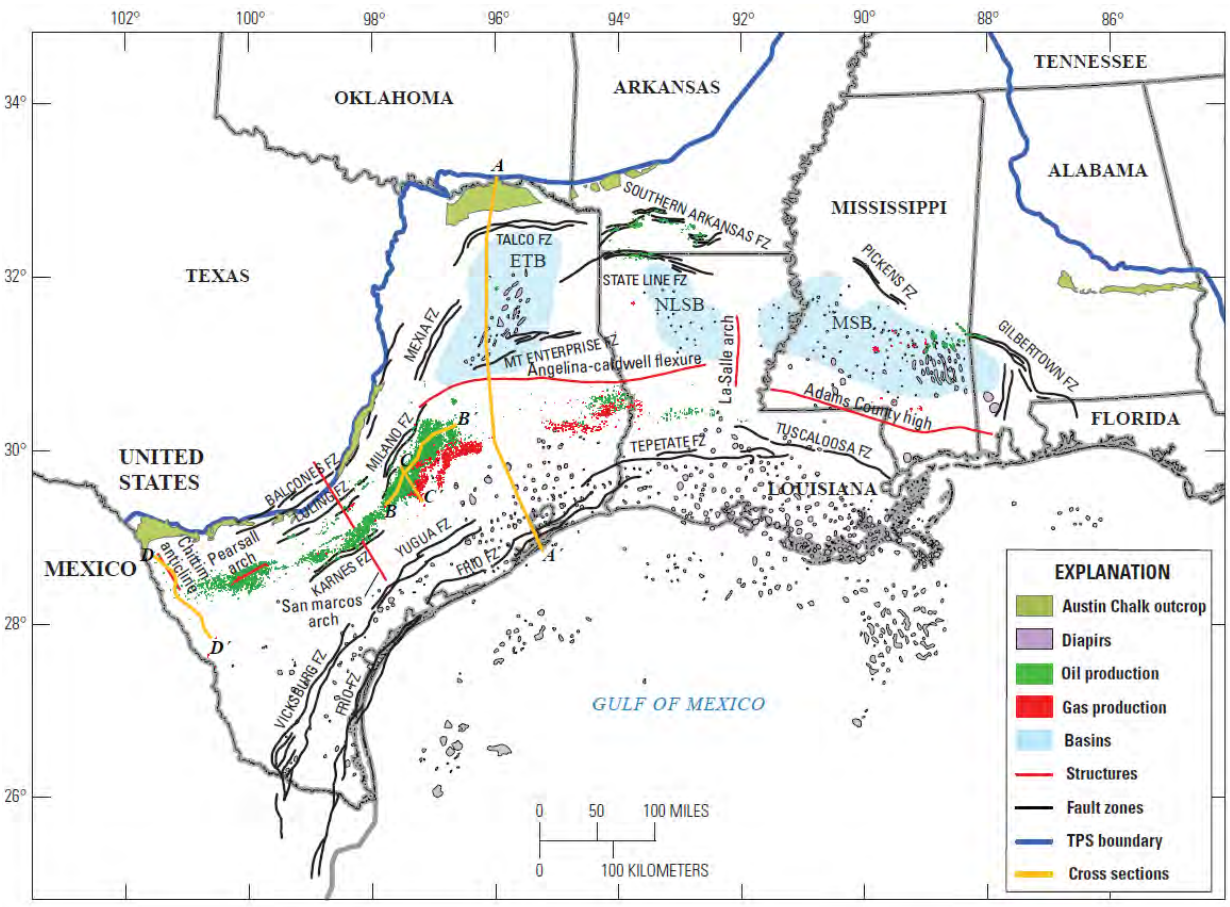

Figure 18: Map cross section A-A´ showing the location of salt diapirs (Pearson, 2012).

When viewing the cross section A-A´, it can be seen these salt diapirs are large vertical columnar structures that can extend to depths nearing 10 km and upwards to the near surface (Figure 19). These high thermal conductivity diapirs can act as “thermal wicks”, where they capture or “wick” much higher temperatures near their base to the top of the diapir. There will be some heat loss along the upward flow of the diapir but due to their high thermal conductivity/heat transfer capability, much higher temperatures can be “wicked” up to the top of the diapir, creating a localized elevated geothermal gradient that can be significantly higher than the surrounding area. In viewing individual well data, areas near these diapirs can often have geothermal gradients between 60-90 °C/km, whereas ambient background for the region is ~ 35 – 40 °C/km. While drilling into a diapir would need to be avoided due to their ductile/plastic nature, higher geothermal gradients could be exploited around them for geothermal energy. The elevated geothermal gradients would reduce drilling costs to attain required functional temperatures and provide greater energy production, although more research must be applied in understanding the extent of this localized diapir effect.

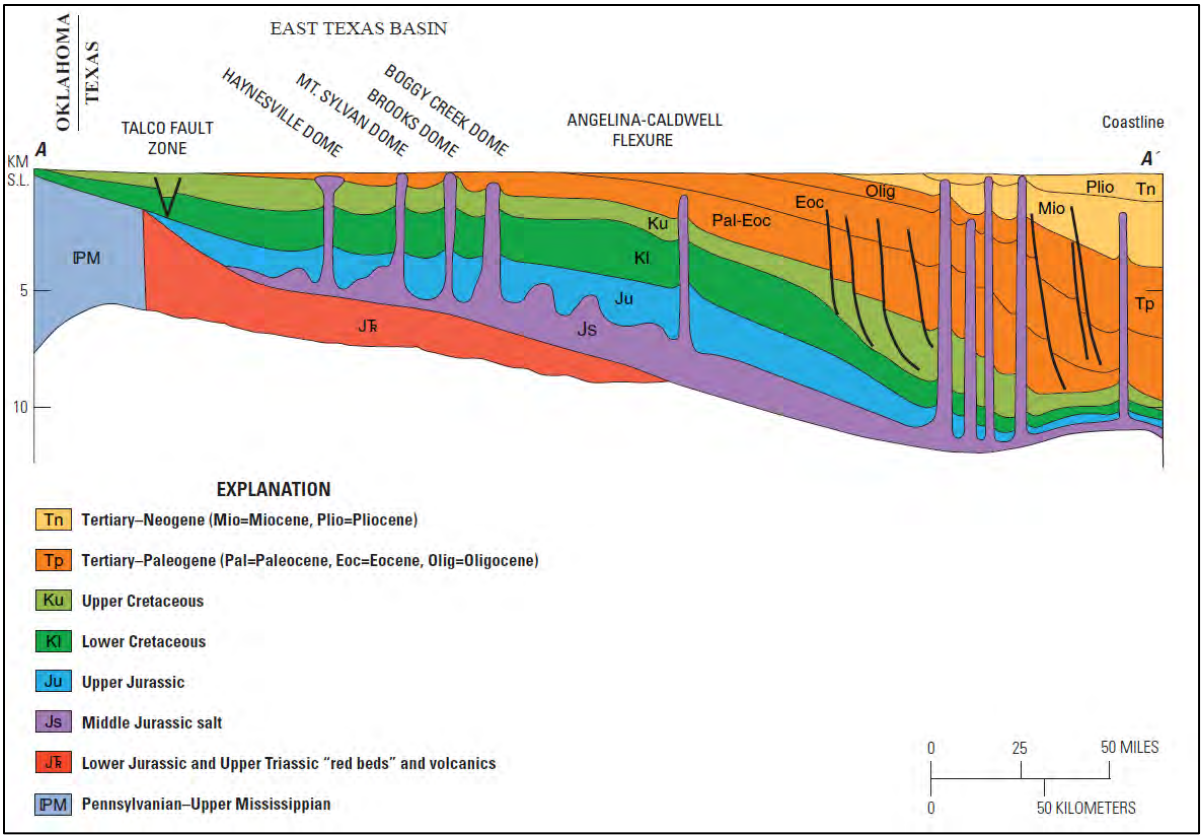

Figure 19: Cross section A-A´ with salt diapir structures from OK to the TX Gulf Coast (Pearson, 2012).

As demonstrated in the NREL Geothermal Favorability Map, the vast majority of Haynesville oil and gas wells depicted below (Figure 20) lie within a high geothermal favorability area, with bottom hole temperatures that are amenable to closed-loop applications and excellent candidates for repurposing.

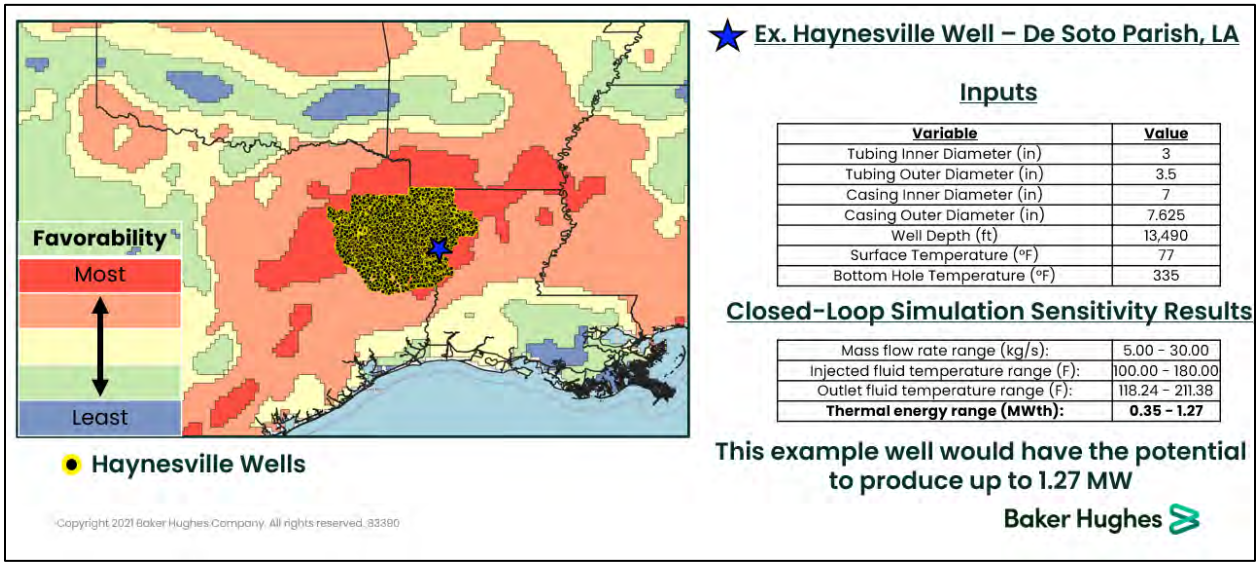

Figure 20: Haynesville Geothermal Potential – Closed-Loop Applications

The example well shows potential to produce up to 1.27 MWth and with thousands of wells like it within the Haynesville region, the potential for large scale power generation is significant.

The mechanism for the higher geothermal gradients in Southwest Texas (Eagle Ford) is likely tied to geopressured zones that are known to exist along the Texas Gulf Coast/Gulf of Mexico region. When reaching overpressure levels (>.70 psi/ft) due to rapid deposition and compaction, hot fluids can be driven upward along fault planes, resulting in elevated geothermal gradients. This was shown in the following two figures (Figure 21 & 22), where a study clearly demonstrated the correlation between depth to overpressure and geothermal gradients. Where the depth to top of overpressure was shallower, the depth to 300 °F was also less, resulting in elevated geothermal gradients.

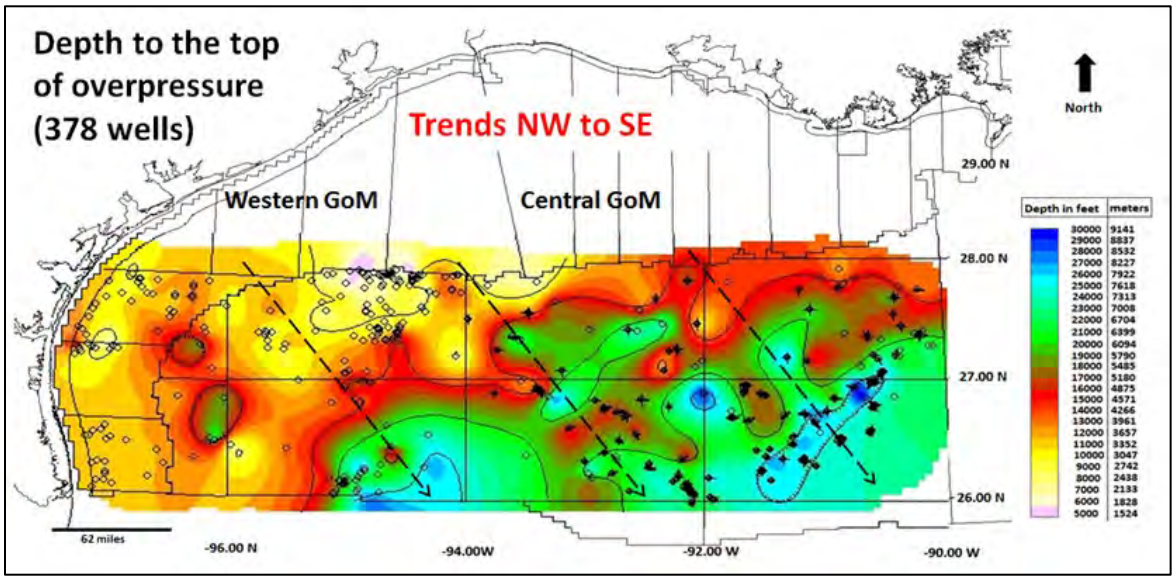

Figure 21: Depth to the top of overpressure computed from 378 GoM wells (Cornelius, 2020).

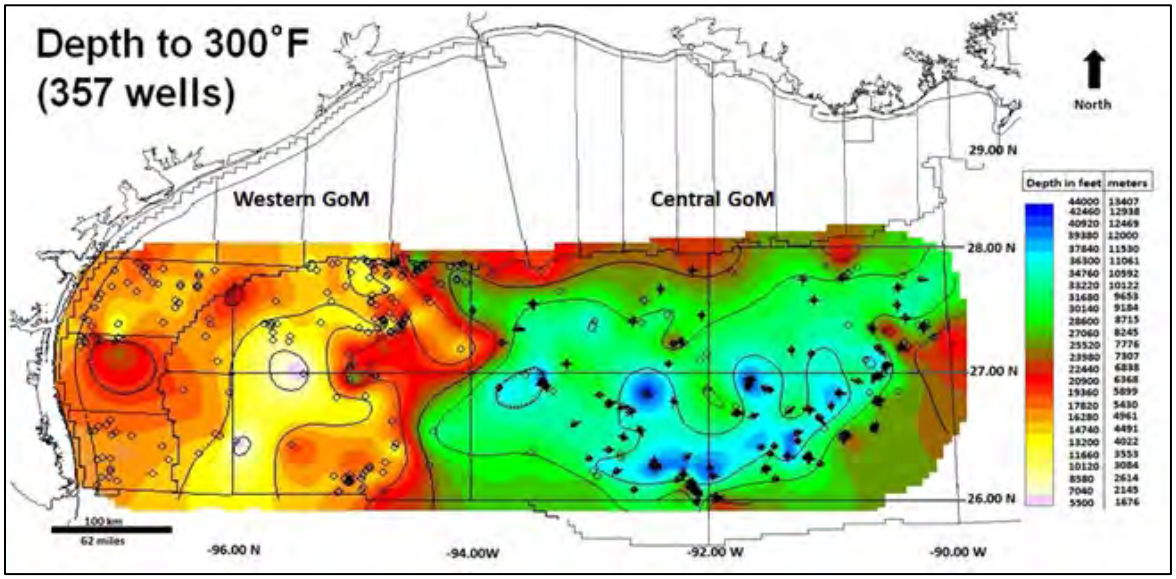

Figure 22: Depth to 300° F computed from 357 GoM wells (Cornelius, 2020).

Additionally, applying the NREL Geothermal Favorability Map to the Southwest Texas Eagle Ford Region (Figure 18) and some example well data from the Enverus DrillingInfo Database, it can be seen that many existing wells are in high geothermal favorability areas that are also amenable to repurposing from oil and gas into geothermal wells.

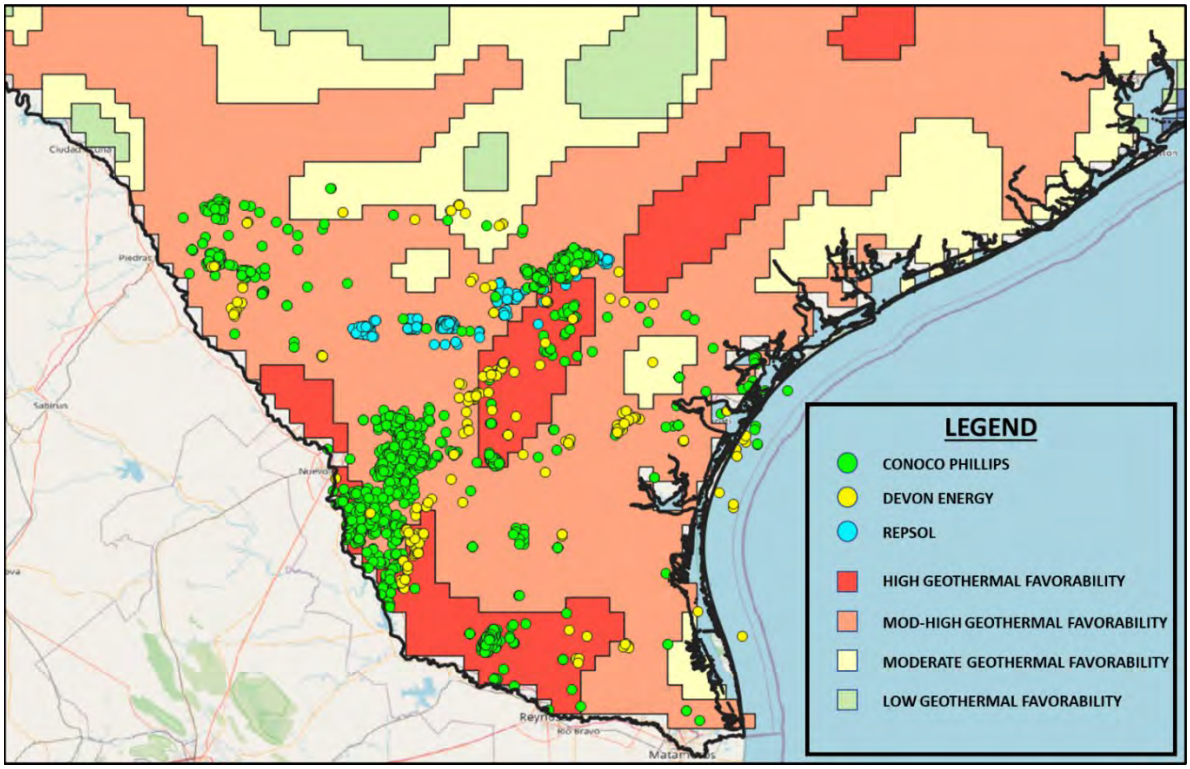

Figure 23: Southwest Texas (Eagle Ford) Geothermal Potential – Repurposing and Closed-Loop Applications

This clearly demonstrates an exploitable geothermal heat resource CRS element, which would then be combined with CRS maps for permeability, recharge, and seal to create a composite CCRS map identifying locations within these regions with functional geothermal systems that have potential for large scale power generation.

8. Conclusions

Geothermal resources have been recognized for some time as a possible significant source of energy but to date have seen marginal increases in their development and application. Much of this is attributed to the substantial upfront costs associated with geothermal projects coupled with a lack of reservoir characterization. While the resource potential is recognized, investors have been hesitant to proceed with these high risk, long return on investment (ROI) scenarios.

GPFA will provide significant value in geothermal exploration by:

- Reducing Exploration Risk
- Increasing % Probability of Success (PoS)
- Increasing the Return on Investment (ROI)

Though many cost reducing technologies are being developed in the geothermal industry right now, continued refinement and development of GPFA workflows and their associated risk reduction will continue to increase investor confidence and support the full-scale growth of geothermal in the coming energy transition.

Keywords

Basement greywacke, fractures, resistivity borehole image, outcrop, supercritical

ABSTRACT

Supercritical geothermal resources have potential to decarbonise industry and power sustainable economic growth opportunities. It is inferred that fractured, low matrix-permeability metasedimentary basement rocks (greywacke) that underly much of the Taupō Volcanic Zone (TVZ), New Zealand, could host supercritical geothermal resources. These rocks have complex fracturing patterns resulting from a long history of deposition, burial, faulting, and hydrothermal activity. Supercritical fluid circulation will likely be through fractures, so it is important to understand fracture distribution and fracture permeability in greywacke. A resistivity image from a >2 km-deep well in the Kawerau Geothermal Field provide the deepest fracture dataset collected in TVZ greywacke. The borehole observations are complemented by structural information from outcrops that are not hydrothermally altered.

Observations at two outcrops of low-grade metasediments and schist show that metamorphic veins are pervasive, of varied orientation, sometimes 10s meters long, and areal density can vary a lot over 10s meters. Parameters such as faulting seem to have a larger influence on vein density than rock type or metamorphic grade.

In the borehole image, potentially permeable fractures have orientation consistent with current tectonics. Resistive (mineralised) fractures have moderate dip magnitude and no preferred strike orientation, consistent with them being mostly of metamorphic origin. Conductive fractures are interpreted as having a combination of metamorphic and tectonic origins, with some likely to have been of metamorphic origin reactivated under current tectonics. Overall, there are more fractures in sandstone than mudstone, but this is less pronounced for conductive (potentially permeable) fractures than for resistive fractures (mineralised) or resistive fractures with conductive halo (potentially permeable). Differences between lithologies are less pronounced when considering volumetric fracture densities. Lithological controls on fracturing differ amongst the three

permeable zones. The two minor permeable zones are in intervals of sandstone, mudstone and interbedding mixes. The third, major permeable zone is in dominantly sandstone and an interbedded mixture of sandstone and mudstone. Potentially permeable fractures of high thickness (>20 mm) are more common within the two minor feed zones than outside feed zones. Fracture density is higher in the major feed zone than outside feed zones.

When considering both outcrop and borehole image fracture data, overall, faults and fractures consistent with current tectonics seem to matter more than lithology for permeability. The veins of varied orientations observed in outcrops seem to remain in the geothermal reservoir (i.e., the resistive fractures), and the permeable fractures in the geothermal system may be either new ones or metamorphic discontinuities (veins, layering boundaries) reactivated under current tectonic stresses.

1. Introduction

Future deep supercritical geothermal exploration and utilisation in New Zealand will likely be in metasedimentary basement rocks (greywacke) that underly much of the Taupō Volcanic Zone (TVZ; Te Ahi Tupua), New Zealand. Greywacke has a complex history of sedimentation, metamorphism, rifting, and hydrothermal activity, with fractures formed at various stages. Intact greywacke has low matrix porosity and permeability (Melia et al., 2022; Mielke et al., 2016) so fluids dominantly circulate through fractures. Given that greywacke is a strong rock (Melia et al., 2022), it is likely that pre-existing discontinuities that are critically stressed, i.e., well oriented for slip with regard to current in-situ stress, are being reactivated during rifting, with additional fractures potentially created. In geothermal reservoirs, hydrothermal alteration may infill and/or dissolve fracture infill. It is therefore important for current and future geothermal development in New Zealand to understand the potential effects of greywacke rock type on fracture permeability in the TVZ.

Currently, two geothermal fields production reservoirs are hosted in greywacke: Kawerau in the TVZ and Ngāwhā in Northland, where permeability is controlled by fractures and faults due to very low matrix porosity. In this paper, we assess fracture characteristics and permeability as a function of greywacke rock types interpreted from a borehole resistivity image at the Kawerau Geothermal Field. Borehole image interpretations are put in the context of outcrop observations of non-hydrothermally altered greywacke near Whakatāne and low-grade schist in the South Island at Rarangi (Figure 1).

Borehole images provide a narrow (<0.5 m width) but long (hundreds of meters) observations of layers and fractures directly in geothermal reservoirs, that can be linked to other downhole measurements to assess the fractures origin, characteristics and permeability potential. Hydrothermally altered greywacke outcrop analogues are scarce in New Zealand, hence the use of outcrops near the Kawerau Geothermal Field that have not experienced the effects of a geothermal system.

In this study, we have quantitatively assessed fractures in a 907 m-long resistivity borehole image from a >2 km-deep well in the Kawerau Geothermal Field and qualitatively assessed fractures for several greywacke outcrops.

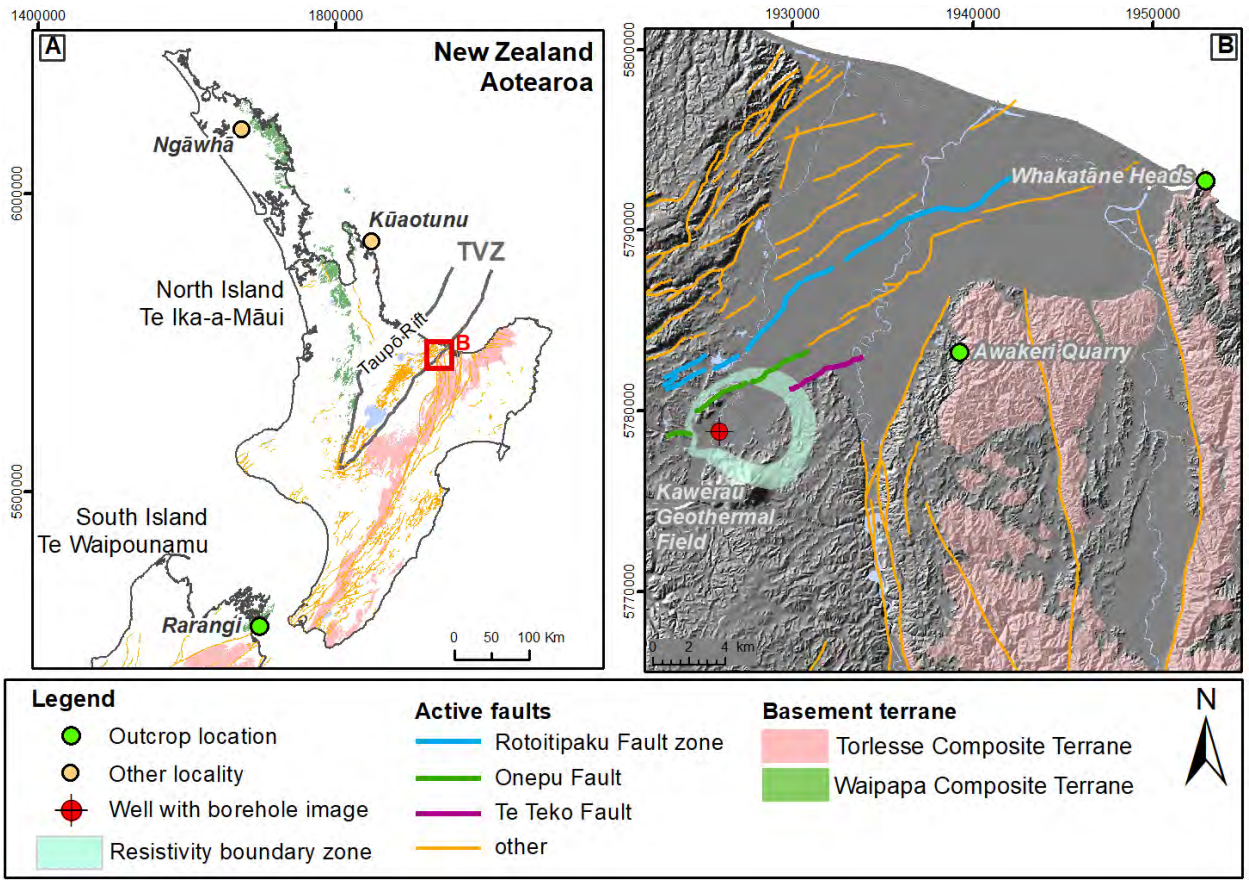

Figure 1: A) Locations with greywacke basement referred to in this study and surface outcrop of greywacke (Heron, 2023). The Taupō Volcanic Zone (TVZ; Te Ahi Tupua) hosts the Taupō Rift, an intra-arc rift with steeply dipping normal faults striking NE-SW to ENE-WSW (Villamor et al., 2017). B) Resistivity boundary zone of the Kawerau Geothermal Field at about 500 m depth with the geothermal well with borehole image in this study (bracketed by the 20 and 50 Ωm resistivity contours; after Allis, 1997), active faults (Langridge et al., 2016), surface greywacke (Heron, 2023), and location of the Awakeri Quarry and Whakatāne Heads outcrops. The subsurface greywacke at Kawerau is Waipapa Composite Terrane.

1.1 Greywacke basement rocks

The basement rocks in and around the TVZ area are greywacke, formed during the Jurassic and Cretaceous periods (about 200-100 million years ago). The sandstone and mudstone that dominate the greywacke were formed in oceans by the accumulation of coarse- to fine-grained material. Due to burial, heat and pressure, these were variably metamorphosed into metasedimentary conglomerate, sandstone and mudstone, and in some places low-grade schist (Leonard et al., 2010; Mortimer et al., 2023). Subsequent exhumation caused further fracturing and deformation. Fractures are commonly filled with minerals such as clay, quartz, and calcite. The greywackes underlying the TVZ geothermal fields comprise the Torlesse and Waipapa composite terranes (Figure 1), with the Waipapa rocks having intermediate SiO_2 (andesitic) compositions and Torlesse consisting of higher SiO_2 quartzo-feldspathic compositions (Wood et al., 2001; Mortimer et al., 2023).

The character of the greywacke varies regionally, making exploration of deep geothermal resources challenging. Basement rocks have been reached by drilling in multiple TVZ geothermal

fields. Exploration for permeability in greywacke has shown rock at Kawerau and Ngāwhā to be good hosts for geothermal reservoirs (Figure 1), with only limited success at other geothermal fields that intersect greywacke.

1.2 Kawerau Geothermal Field and Outcrop Locations

The Kawerau Geothermal Field (Figure 1) is the northeastern most of the active high–temperature geothermal fields in the TVZ (Bibby et al., 1995; Kissling and Weir, 2005; Rowland and Simmons, 2012). Kawerau wells are drilled into greywacke of the Waipapa Composite Terrane (Milicich et al., 2016; Milicich et al., 2021b) comprising primarily metasedimentary sandstone and mudstone. These rocks have very low matrix porosity but host both geothermal production and injection wells, with fluid flow localised in fault and fracture networks.

The only surface faults known in the area are the Te Teko, Onepu and Rotoitipaku faults (Figure 1), but 3D geological modelling of the subsurface indicates additional major faults (Milicich et al., 2014; Langridge et al., 2016). These are roughly striking NE-SW and steeply dipping, consistent with the Taupō Rift. In addition, faults with lesser throw than the main NE-SW faults strike NW-SE. These faults in the subsurface have a steep dip magnitude (>75°), to the NW and NE. In contrast, the metamorphic layering is likely to be much more variable, and potentially lower dip magnitude.

Wallis et al. (2012) investigated lithological controls the thickness and frequency of fractures in greywacke in wells KA50 and PK08 based on interpretation of acoustic borehole images and reported larger fracture thickness and higher frequency occurring in sandstone intervals.

Fracture patterns were observed at three locations. Whakatāne Heads and Awakeri quarry near the Kawerau Geothermal Field, and Rarangi in the northern part of the South Island (Figure 1). Whakatāne Heads and Awakeri quarry include metasedimentary sandstone, mudstone, and conglomerate, with Whakatāne Heads being located in a mélange zone, i.e., bodies of deformed rocks characterised by the inclusion of tectonically mixed fragments or blocks (Leonard et al., 2010). Rarangi is metasedimentary sandstone and mudstone with a low-grade schist overprint (Begg and Johnston, 2000).

2. Data and Method

2.1 Outcrop observations

Outcrop observations were made at three outcrops (Figure 1). Whakatāne Heads shows veins in deformed layers of sandstone and mudstone as part of the mélange (Whakatāne mélange; Leonard et al., 2010). At the nearby Awakeri quarry, lithologies comprise conglomerate, sandstone and finely layered mudstone. Although the Awakeri quarry is part of the Whakatāne mélange, rocks are less deformed than at Whakatāne Heads. One possible fault occurs in the study area but is not mapped in the New Zealand active fault database (Langridge et al., 2016) and does not show displacement. At Rarangi, the schist outcrop is dominated by sandstone with steeply-dipping foliation and includes a small fault. Observations were visual at all outcrops. For quantitative results, additional detailed vein mapping was conducted using orthophotographs acquired by drone photogrammetry at Awakeri quarry (~750 m long outcrop exposure), and hand-held cameras at Rarangi (~40 m long exposure).

2.2 Borehole image

The resistivity image obtained in 2013 using a formation micro imager (FMI) and was processed and interpreted following the methodology of McNamara et al. (2019). All orientations are with reference to geographic north, and borehole deviation (<10°) has been taken into account. Fracture thickness is corrected for both fracture and borehole orientations, i.e., it is the orthogonal distance between fracture walls. Texture and layering features were carefully differentiated from natural fractures and stress-induced features (Davatzes and Hickman, 2010; Halwa et al., 2013; Milicich et al., 2021a).

Fracture classification for the resistivity image includes natural (conductive and resistive fractures, micro-faults, halo fractures, partial fractures, and enhanced fractures; Figure 2 and Table 1) and induced (drilling induced tensile fractures and petal centreline fractures) features. Halo fractures are conductive fractures with a high resistivity halo around them (Figure 2). Enhanced fractures are ambiguous stress-enhanced fractures, many present as partial fractures and commonly with straight line sections that are not sinusoidal (Barton et al., 2010). Since enhanced fractures likely do not extend far from the borehole wall and unlikely to contribute to fluid flow, they are not considered in this fracture analysis. Conductive fractures are interpreted as most likely to be permeable (Massiot et al., 2017a; McNamara et al., 2019). McNamara et al. (2019) showed that halo fractures in ignimbrites in the Wairakei Geothermal Field, TVZ tended to be more permeable. Resistive fractures are not considered to be permeable as they are commonly mineralised (Massiot et al., 2017a).

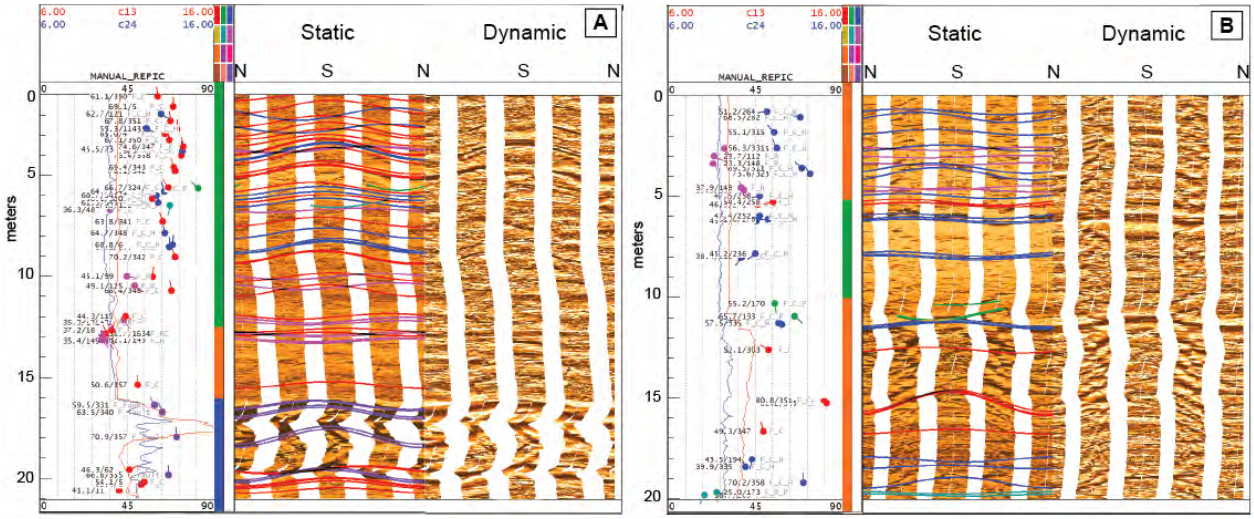

Figure 2: Borehole image examples of fractures in permeable zones. A) A feed zone with a damage zone associated with a series of micro-faults. B) A feed zone with multiple conductive fractures with halos. See Table 1 for colours. Borehole images are presented unwrapped along the north orientation, so that planar features intersecting the cylindrical borehole appear as sinusoids. From left to right: tadpole and mechanical calipers (C13 and C24), statically normalised, and dynamically normalised images (Hansen and Buczak, 2010).

Table 1: Natural fracture classification

Fracture	Definition	Trace type and acronym	Permeability potential	Number	Symbol Figure 2
Conductive	Planar conductive (dark), discordant features that can be traced around the borehole.	Full (F_C)	moderate	472	
		Partial (F_C_P)	low	202	
Conductive halo	Planar conductive (dark) discordant feature with clear indication of resistive (bright) halo.	Full (F_C_H)	high	191	
		Partial (F_C_H_P)	moderate	46	
Resistive	Planar resistive (bright) discordant feature.	Full (F_R)	none (infilled)	300	
		Partial (F_R_P)	none (infilled)	74	
Micro-fault	Planar discordant features that show obvious displacement or truncation of other image features.	Full (F_fault)	high if part of a wider fractured zone	8	

Mudstone intervals generally appear dark in statically-normalised images, whereas sandstone-dominated intervals appear bright because they are richer in quartz (Figure 3). There are many intervals with clear layering. Even though metamorphosed, there are still primary sedimentary bedding features present e.g., cross bedding. There are also bedding parallel fractures, which are commonly difficult to differentiate from bedding, although some may be included in the low dip magnitude fracture features.

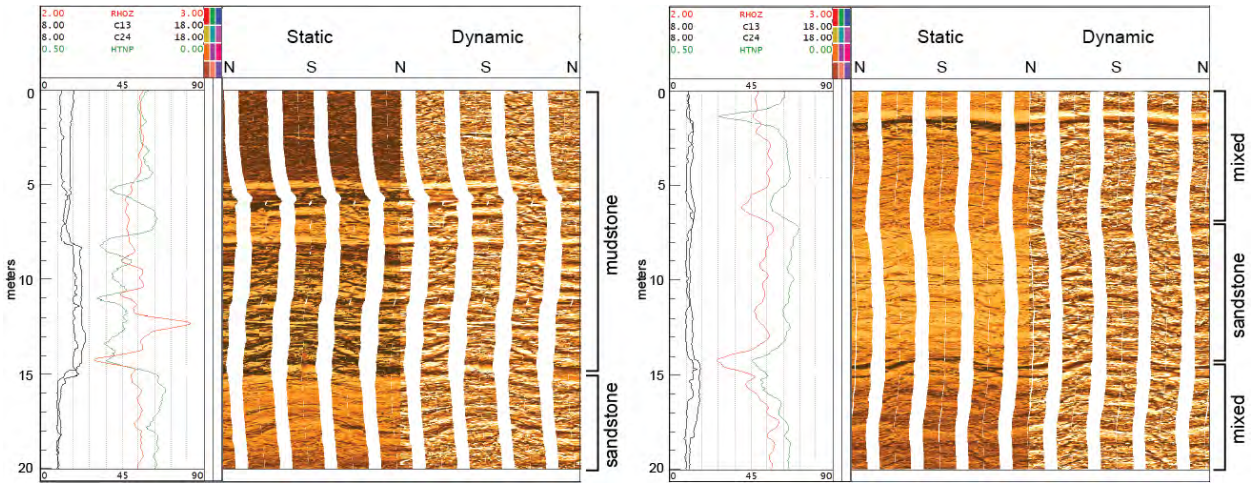

Figure 3: Representative examples of lithofacies (Table 2) in resistivity image. Left) Mudstone and sandstone. Right) Sandstone and mixed. Curves shown are mechanical calipers (C13 and C24), thermal neutron porosity (HTNP) and density (RHOZ). Images are statically normalised, and dynamically normalised (Hansen and Buczak, 2010).

Three permeable (feed) zones were interpreted from pressure, temperature and spinner logs (PTS) obtained from completion tests (Mercury pers comm, 2020). Due to commercial sensitivity, the depths and PTS data are not published here. To examine the effect of rock type on fractures, the relative abundance of sandstone and mudstone was determined. Seven lithofacies were initially determined in Schlumberger (2013) following the scheme described in Wallis et al. (2012). The classification was done with a binning technique using resistivity cutoffs applied to a scaled

resistivity image. The binning also considered neutron-density and resistivity downhole measurements. The initial seven lithofacies were simplified to three to produce a statistically meaningful lithofacies fracture analysis (Table 2).

Table 2: Greywacke lithofacies.

Lithofacies	Description	% mudstone
Sandstone	Sandstone and sandstone with very minor mudstone	0-25
Mixed	Interbedded intervals of sandstone and mudstone	25-75
Mudstone	Mudstone and mudstone with very minor sandstone	75-100

To provide reliable fracture statistics, we have only considered intervals of image where >25% azimuthal coverage was deemed reliable, i.e., where the fracture density is reliable (Massiot et al., 2017b). The 774 m of borehole image included in this analysis are made of two intervals large enough for reliable fracture statistics (125 m and 649 m, respectively). For statistical analysis, partial fractures have been grouped with continuous fractures.

3. Results

3.1 Outcrop observations: Whakatāne Heads, Awakeri quarry, Rarangi

Veins at the three outcrops show similarity of patterns with high variability over small distances (Figure 4). At Whakatāne Heads, some veins are thicker and more focused in sandstone than mudstone (Figure 4A). At all three outcrops, veins occur along, across or terminate at interfaces between layers of sandstone and mudstone (Figure 4B-D). Veins associated with faults are localised (Figure 4B-C) and commonly show splays (Figure 4B). Splaying, anastomosing, and merging of veins is common even in the absence of faulting (Figure 4E). Long (>2 m) and thin (1-3 mm) veins are common in all lithologies, and at Awakeri quarry, form connected vein groups of >10 m-long that cross interfaces between large conglomerate clasts. At all three outcrops, orientations of veins are varied and at varied angle to bedding.

Quantitative analysis of areal vein density at Awakeri quarry and Rarangi reveals that similar densities are found away from faults in different lithologies, and whether the host rock is of low-metamorphic grade or foliated schist. By contrast, density is locally increased within 1 m of a fault at Rarangi, with numerous short (<0.5 m) and thick (1-3 cm) veins; and near possible fault strands at Awakeri, presenting as a network of thin (1 mm) cross-cutting veins. A section of Rarangi outcrop presents thick (1-8 cm) veins of >1 m-long (measurement limited by the outcrop exposure) although it does not appear to be associated with a visible fault. Quantitative analysis of fractures in outcrop will be continued in future work.

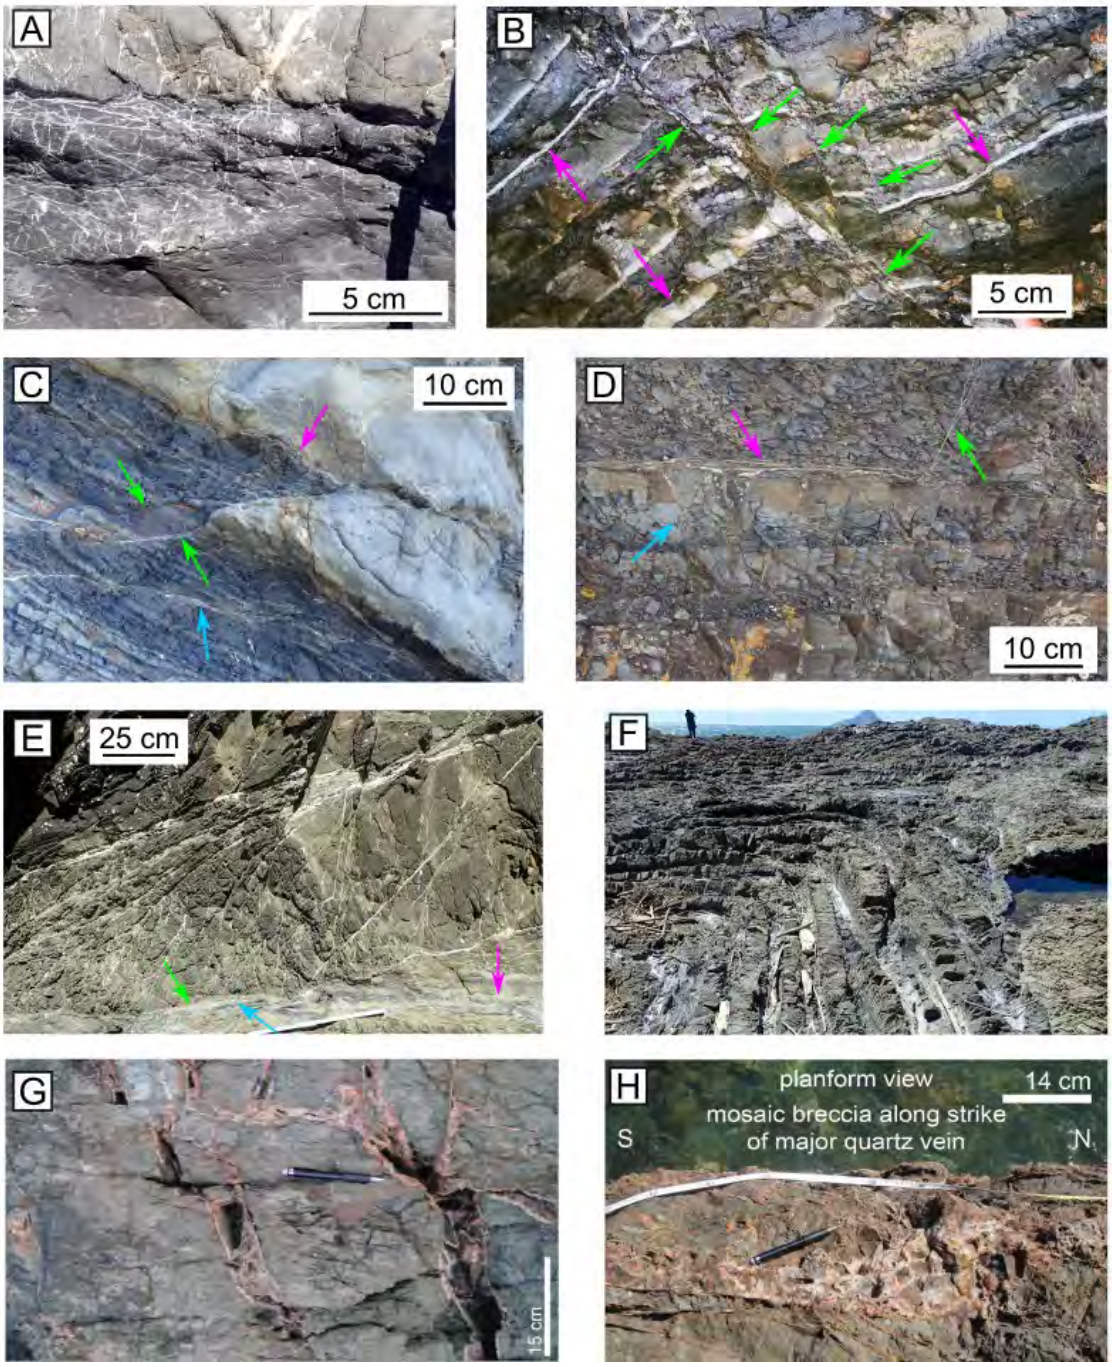

Figure 4: Veining at Whakatane Heads (this study) and Kūaotunu epithermal deposit (reproduced from Lawrence, 2015). A) Thick veins in grey sandstone and dispersed thin veins in darker mudstone. B) Fault splay (green arrows) displacing layers of sandstone and mudstone. Some veins are along layers (pink arrows). C) Fault oblique to layering displacing sandstone and mudstone layers, with veins along (pink arrow) and crossing (blue arrow) beds, and along the fault (green arrows). D) Veins along (pink arrow), crossing (blue arrow) and arresting (green arrow) on layers. E) Vein splaying in sandstone. Some veins have the same thickness and orientation modifications in the mudstone layer (blue arrow) while other become more diffuse or terminate at the mudstone interface (green arrow). Some veins are along the interface between mudstone and sandstone (pink arrow). F) Fold with veins along and across layers. G) Fractures parallel to and crossing weak cleavage parallel to pen (Lawrence, 2015). H) Localised brecciation along quartz vein (Lawrence, 2015).

3.2 Borehole image: lithology

Over the interpreted interval of the borehole image, there is more mixed lithology than pure mudstone and sandstone (Table 3). We deem the total length of sandstone intervals (178 m) to be sufficient for statistical purposes. Individual intervals of single lithologies range from 1 to 43 m-long (median of 6 m). Feed zones 1 and 2 comprise dominantly mudstone and mixed lithologies. Major feed zone 3 is dominantly in a mixed lithology with little mudstone.

Table 3: Relative percentage of lithofacies in feed zones (FZ) and the interpreted interval.

Interval	Mudstone	Mixed	Sandstone
FZ1 (minor; 33 m)	38%	41%	21%
FZ2 (minor; 82 m)	48%	35%	17%
FZ3 (major; 48 m)	11%	56%	33%
Interpreted interval (774 m)	34%	43%	23%

3.3 Borehole image: fractures

3.3.1 Orientation and thickness

Fracture orientation depends on the fracture type (Figure 5). Resistive fractures have dip magnitudes dominantly between 30° and 60° (median of 45°), and when averaged for the entire borehole image, no preferential strike orientation. In contrast, conductive fractures have a dominant strike of NE-SW to E-W dipping to NW to N, with dip magnitudes >45° (median 58°). Micro-faults have the same orientation as the dominant orientation of conductive fractures. Conductive fractures with a resistive halo have the same dominant orientation as conductive fractures, but also have more variable orientations. Orientation of halo fractures thus appears similar to both conductive and resistive fractures. These orientation patterns do not change in or outside of permeable zones.

Fracture thickness ranges from 1 to 159 mm with a median of 5 mm. Conductive, halo and resistive fractures have the same median thickness (5 mm) while the 8 micro-faults are thicker (median of 37 mm). The thickest fractures (>20 mm) consist of 18 conductive (maximum of 159 mm, likely a densely fractured zone rather than a single fracture), 16 resistive (maximum of 49 mm), 5 micro-faults (maximum of 61 mm) and 2 halo (maximum of 32 mm).

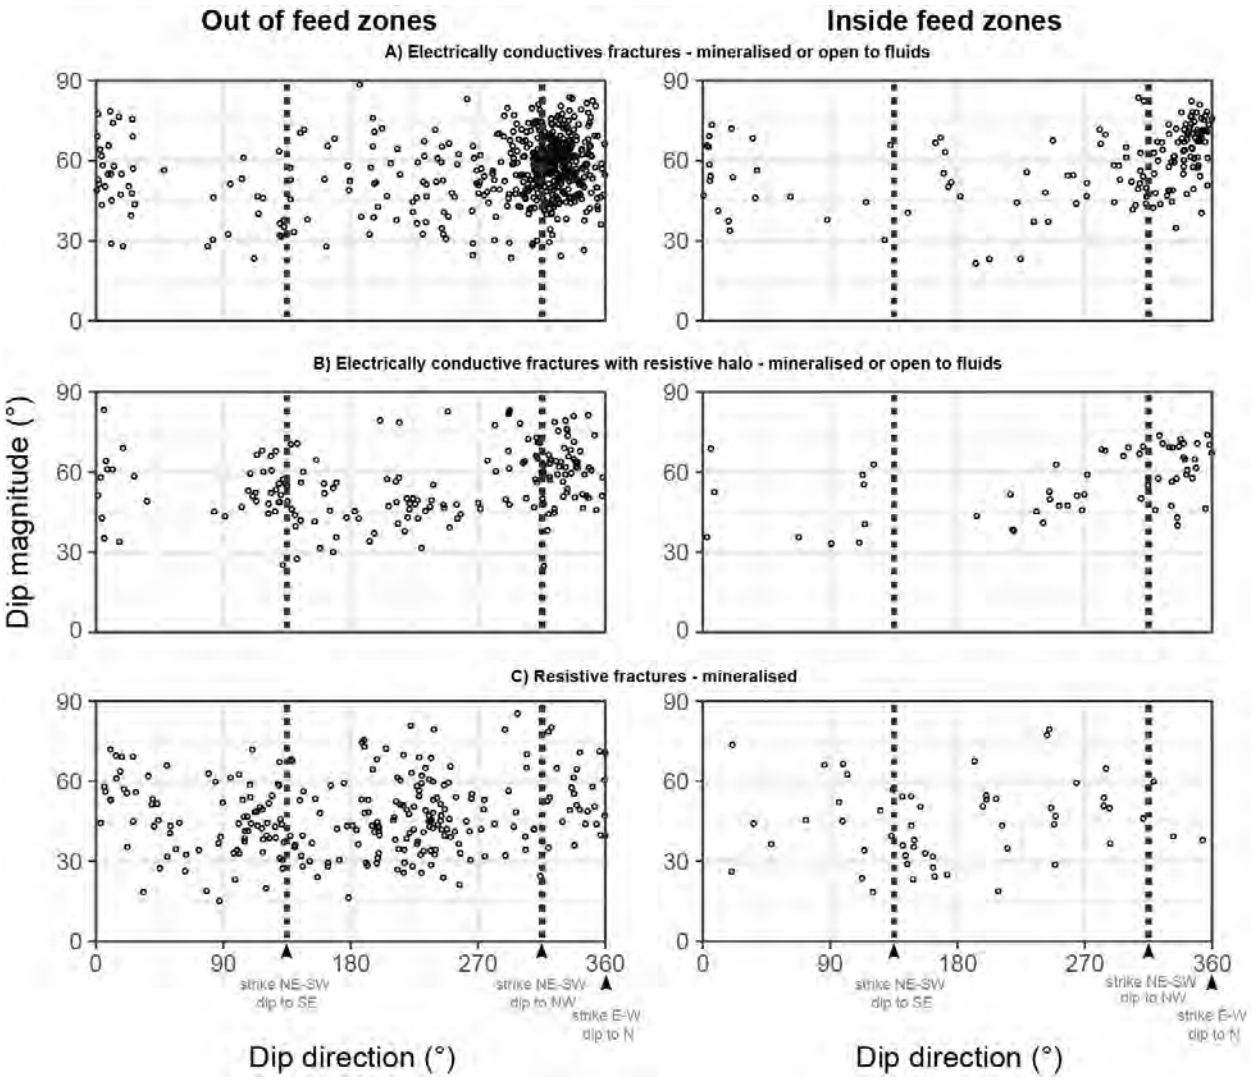

Figure 5: Dip magnitude versus dip direction for each fracture type. Left: fractures outside feed zones. Right: Fractures in feed zones.

3.3.2 Fracture density

The fractures are distributed throughout the imaged interval. Some intervals have fracture clusters with a higher density of halo, conductive and resistive fractures.

The density of natural fractures along the borehole (P10) considering all fracture types and lithologies is 1.50 m^{-1} (Figure 6A). Fracture density is twice as high for conductive (0.81 m^{-1}) than resistive (0.39 m^{-1}) and nearly three times that of halo (0.30 m^{-1}) fractures. Density is low for micro-faults (0.01 m^{-1}). The statistical difference of lithological for micro-faults is not reliable because of the small data set, with five micro-faults in mixed lithologies, three in mudstone and none in sandstone.

Fracture density is higher in sandstone (1.95 m^{-1}) than in mixed lithologies (1.52 m^{-1}) and mudstone (1.16 m^{-1}). This higher P10 for sandstone than mudstone is most clearly the case for halo fractures, but only moderately so for conductive and resistive fractures. The lithological difference

for conductive fractures is restricted to partial conductive fractures (0.32 m^{-1} in sandstone; 0.16 m^{-1} in mudstone), while continuous conductive fractures have the same density in all three lithologies (0.5-0.6 m^{-1}).

In the transformation from linear (P10 – Figure 6A) to volumetric (P33 – Figure 6B) densities, fractures of high dip magnitude and/or thickness have a relatively higher weight than other fractures. On average, fractures (open to fluid flow or mineralised) form about 2% of the rock volume. When considering all natural fracture types, P33 is slightly lower in mudstone (1.8%) than in mixed and sandstone (both 2.3%). Overall, the relative proportions of P33 by fracture types are similar to those from P10, with some slight variations. Micro-faults have higher dip magnitude and thickness than other dip types, yielding relatively higher P33.

Resistive fractures have moderate dip magnitude and have few thick fractures, yielding relatively lower P33. Some conductive fractures have high thickness, yielding relatively higher P33. Difference of P33 between lithologies are very small for conductive and resistive fractures and reduced for halo fractures compared to P10.

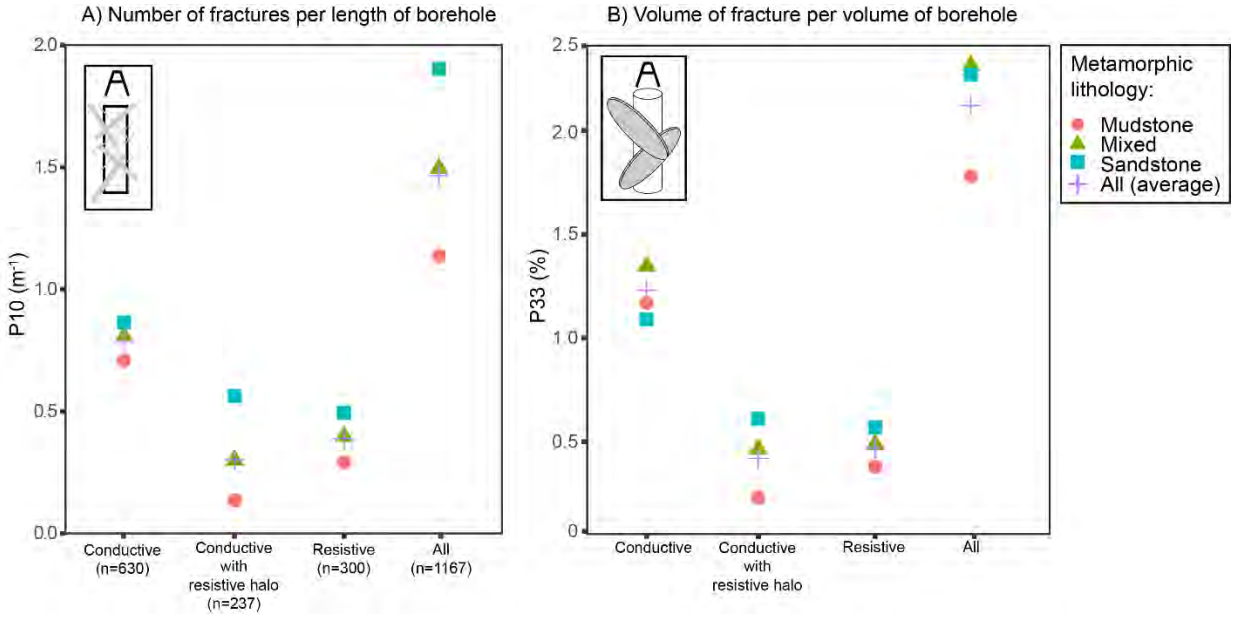

Figure 6: Natural fracture density as a function of fracture type and metamorphic lithology. A): P10, number of fractures per meter of borehole. B) P33, volume of fractures per volume of borehole.

3.3.3 Permeable zones

The orientation of potentially permeable fractures (i.e., conductive, conductive fractures with halo and micro-faults) within feed zones (FZ) is generally consistent with the Taupō Rift (steeply dipping with NE-SW strike) (Figure 7). There are some variations, in particular with FZ2 having a more ENE-WSW striking fractures. There are subordinate orientations in each feed zone (NNW-SSE and N-S strike). Resistive fractures have more varied strike, along with lower dip magnitudes. Fractures of all strike are found outside of permeable zones.

Permeability is not clearly associated with either high fracture density, high thickness, or type. Fracture density (P10) is higher in major feed zone 3 (2.2 m^{-1}) than outside feed zones (1.5 m^{-1}). This different density is not observed in the two other feed zones (1.6 m^{-1} and 1.3 m^{-1}). Density of

halo fractures is higher in major FZ3 (0.8 m^{-1}) than outside feed zones (0.2 m^{-1}), but lower in the two minor feed zones (0.1 m^{-1}). There are four micro-faults in FZ2 but none in the two other feed zones. Other fracture types have similar densities within and outside feed zones.

Potentially permeable fractures of elevated apparent thickness (i.e., >20 mm) are more common within the two minor feed zones than outside feed zones, but this is not observed for the major feed zone. There is only one resistive fracture of elevated thickness in feed zones (FZ2).

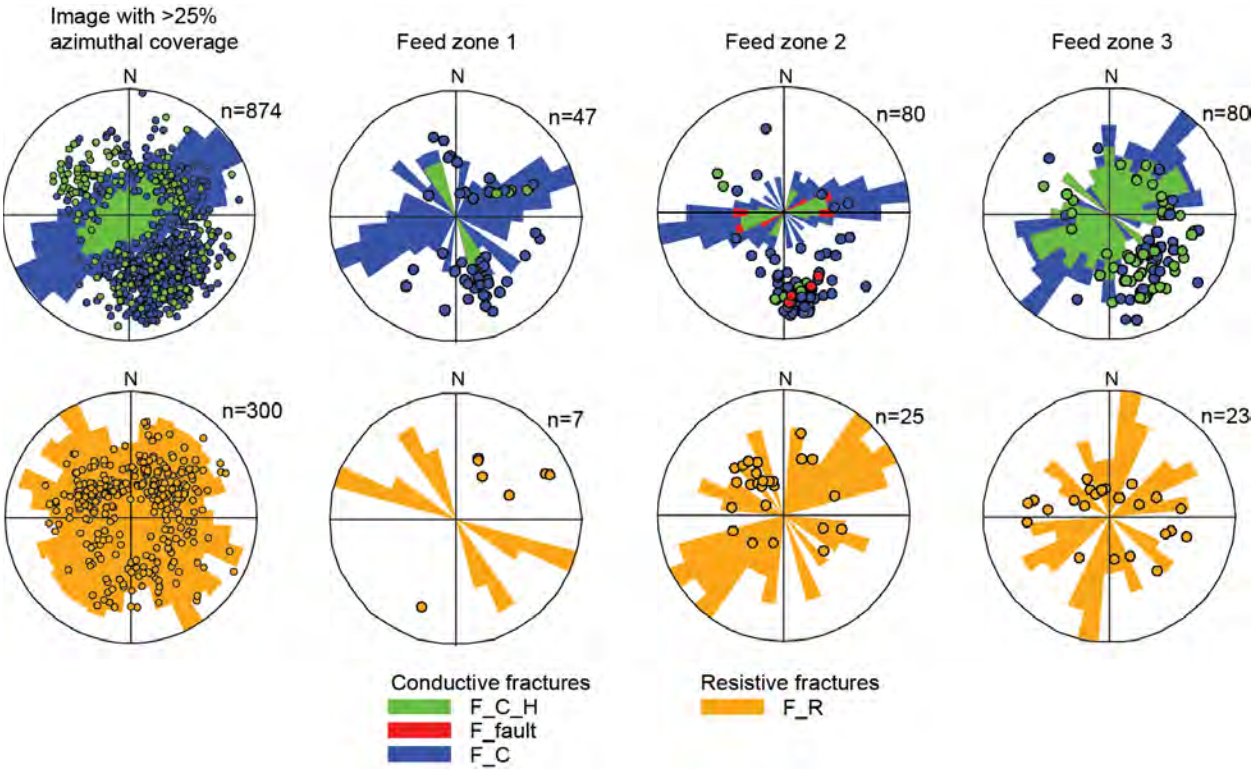

Figure 7: Fracture orientations in the imaged interval with >25% azimuthal coverage and the three feed zones. Partial and full fractures are grouped in this figure. In Schmidt projection stereonets, lower hemisphere. n = total feature count. Due to commercial sensitivity, the depths are not specified here.

4. Discussion

The high-resolution resistivity image provides an excellent detailed view of the borehole wall for lithological analysis and fracture characterisation. However, from a reservoir management point of view, it is difficult to determine which fracture is more likely to be permeable, or those resulting from either metamorphic veining or recent and current tectonic activity. Resistivity images acquired in ignimbrites at the Wairakei Geothermal Field also revealed numerous details on fracturing, layering and bedding (McNamara et al., 2019), but the metamorphic veining in greywacke adds a layer of complexity in image interpretation.

The different fracture orientation and density of different fracture types suggests different origins. Resistive fractures have moderate dip magnitude and no preferential strike throughout the entire imaged interval. In addition, resistive fractures have higher linear fracture density (P10) in sandstone than in mudstone. This suggests that resistive fractures are metamorphic veins rather

than reactivated fractures or fractures generated by current tectonics. Based on outcrop observations, some of those resistive fractures may have formed along layering in an orientation that is not well-oriented for reactivation prior to current Taupō Rift tectonics. The higher density of partial conductive fractures in sandstone compared to mudstone, and the more varied fracture orientation of these partial fractures suggest a possible metamorphic origin, similar to the varied orientations measured in outcrop.

Continuous conductive fractures have orientations consistent with steep normal faults striking parallel to the Taupō Rift faults, with linear fracture density similar in all lithologies. We infer that these fractures are tectonic-related fractures and veins. They have been formed by either reactivating metamorphic veins that are critically stressed (as defined by Barton et al., 1995), or newly formed, under the current stress regime. The localised nature of feed zones is consistent with outcrop observations of increased veining density in the near-vicinity of faults, that occur at multiple scales (Figure 4B-C-H, Seebeck et al., 2014; Ellis et al., 2023).

The higher density of halo fractures in sandstone and mudstone, combined with orientations intermediate between conductive and resistive fractures suggests that halo fractures are a mix of metamorphic veins and tectonic fractures. Contrary to the Wairakei Geothermal Field (McNamara et al., 2019), they are not as useful prediction of permeability.

In the studied well, there is a higher linear fracture density (P10) in sandstone than in mudstone; and the major FZ3 that has a high fracture density intersected more mixed and sandstone lithologies than other feed zones. However, we suggest that these observations cannot be used as a general rule that sandstone intervals are more fractured than mudstone, nor that sandstone are more permeable than mudstone. Firstly, the difference in fracture density relates only to some fracture types, including the resistive fractures that are not permeable. The density and orientation of continuous conductive fractures (some of which are permeable) is not obviously affected by metamorphic lithologies. Secondly, volumetric fracture densities (P33) show smaller differences between lithologies than linear densities (P10). This echoes outcrop observations where thinner but more numerous veins in mudstone may provide similar vein volume as the thicker but fewer veins in sandstones. Thirdly, fracturing and associated permeability also strongly depends on proximity to faults, in-situ stress (Barton et al., 1995; Townend and Zoback, 2000) and connectivity to fracture networks (Kissling and Massiot, 2023) that have not been considered in this preliminary work.

Linear fracture density (P10) in this well is high enough (1.1 m^{-1} considering conductive fractures and conductive fractures with halo) to yield a fully connected fracture network at reservoir scale (>0.3 m^{-1}), based on fracture network modelling by Kissling and Massiot (2023). The fracture density at borehole scale, and the combination of varied vein orientation and long veins (and vein groups) in outcrop suggest that, in a reservoir, some of the veins would be well-oriented for being reactivated in any stress field and could provide connectivity and/or storage for fluids. Increased veining in close vicinity of faults in outcrops suggests a very focused enhanced permeability, as suggested by other studies of greywacke in New Zealand (Seebeck et al., 2014; de Ronde et al., 2001; Ellis et al., 2023). Similarly, at Kūaotunu epithermal deposit, Lawrence (2015) made observations of veining and breccias mainly associated with faults, locally affected by the rock fabric and with high spatial variability (Figure 4G-H).

The implication from borehole and outcrop studies is that there will likely be permeable fractures in supercritical wells drilled into greywacke. In supercritical conditions, fluids need connected fracture networks, but not necessarily fractures of elevated aperture, as fluids have low viscosity (Wagner & Pruβ, 1995). As suggested by laboratory and numerical modelling of granite samples, small cloud-fracture networks may be sufficient to provide sufficient permeability (Watanabe et al., 2019; Liu et al., 2022), though granite are much more isotropic than greywacke rocks. Further studies on the effect of stress, metamorphic fabric and hydrothermal alteration are needed to confirm this, in addition to supercritical exploratory drilling.

5. Conclusion

In this resistivity borehole image acquired in greywacke at the Kawerau Geothermal Field, we interpret resistive fractures as being of dominantly metamorphic origin. Conductive fractures and micro-faults are interpreted as mostly representing fractures initiated or reactivated under the current extensional stress field. Conductive fractures with resistive halos are interpreted to result from a mixture of tectonic and metamorphic origins.

In this well, borehole resistivity image interpretation shows that there are more fractures in sandstone than mixed lithologies and again than in mudstone, but this affects some dip types more than other, and is not so pronounced when considering volumetric densities. This higher density in sandstone than in mudstone is also subtle when only considering potentially permeable fractures rather than resistive fractures (closed veins). Halo fractures are not as good indicator of permeability than they were in ignimbrites at the Wairakei Geothermal Field.

When considering fracture density and fracture patterns at both borehole and outcrop scale, there is likely to be a well-connected fracture network at reservoir scale whether drilling into either sandstone or mudstone dominated greywacke.

In future work, we will interpret data from this well in the context of nearby faults and will compare results from other wells. Future integration with quantitative outcrop observations will also strengthen findings on controls on fracture and associated permeability in TVZ greywacke.

Acknowledgement

This study is part of GNS Science's Geothermal the Next Generation research programme, led by Isabelle Chambefort, funding of which was provided as an Endeavour fund by the Government of New Zealand (Contract number CO5X1904). We thank Mercury NZ Ltd. for the provision and permission to publish well data. Thanks to J-swap for access to the Awakeri Quarry.

ABSTRACT

South-central Alaska holds significant geothermal potential due to its location along the Pacific Ring of Fire, a region globally known for its volcanic activity and geothermal resources. The Cook Inlet Region lies above the Pacific Plate subduction zone and contains active volcanoes, including Mt. Augustine.

Alaska has some of the highest residential and commercial electricity prices in the nation, while its per capita energy consumption is the second highest, in part because of the State's small population, cold climate, and energy-intensive industries. South-central Alaska houses approximately 550,000 people (75% of the entire Alaskan population). Power sales in 2020 exceeded 4,408 GWh, of which 82% came from fossil-fuel produced electricity (natural gas and coal) and 18% from renewables (primarily hydroelectric). In December 2021, the Governor of Alaska requested a study on the potential impacts of achieving an 80% renewable energy portfolio for South-central Alaska.

Mt. Augustine is an andesitic stratovolcano typical of subduction zones and located in the Kamishak Bay in the southern part of the Cook Inlet, approximately 60 miles west of Anchor Point and 175 miles SW of Anchorage. Numerous previous researchers have concluded that it contains a shallow magma chamber making it attractive for geothermal exploitation. In September 2022, GeoAlaska was awarded a permit to explore for geothermal resources across 3 onshore tracts of land, totaling 3,048 acres on the southern part of Augustine Island, primarily where the Upper Jurassic Naknek Formation outcrops.

In the summer of 2023, Acoustic Magnetotelluric (AMT) data from 28 sites and gravity data from a further 215 locations were acquired, processed, and interpreted. Additionally, 20 rock samples

were collected from cliff sections along the southern margin of the island, primarily from within the outcropping Naknek Formation.

The jointly inverted geophysical data reveal an area in the southern part of the island of low resistivity and high density strata lying above a zone of higher resistivity. We interpret this as the sub-crop of the Naknek Formation acting as a seal, trapping a potential hydrothermal system below, within the fractured basement. The Naknek Formation is likely to underly much of the southern part of the island and is such an effective seal, it has all but limited any above sea-level surface geothermal features that one would expect for a typical andesitic geothermal resource. As such, we describe this Mt Augustine resource as being an atypical blind geothermal system, suggesting a largely horizontal circulation pattern. An analogue for this system could be Cerro Pabellón GPP in northern Chile, which has a current installed capacity of approximately 83 MWe.

As a result of this collected data, additional exploration activity will be undertaken during 2024/25 including the drilling of an exploration well.

1. Introduction and Context

GeoAlaska LLC was founded in 2020 with a desire to identify and exploit geothermal opportunities in Alaska, and to provide baseload carbon-free electricity for the benefit of the Alaskan people. In March 2023 Ignis Energy Inc, a sister company to Geolog International B.V., partnered with GeoAlaska in order to provide technical and project management support. Since 2021, GeoAlaska has created a geothermal exploration position that includes 2 prospective locations on State owned land and close to the Alaskan South Central Rail Belt Region, including 10,830 acres on the southern flank of Augustine Island (geothermal prospecting permits ADL 394080 and ADL 394374) and 6,376 acres on the southern/central flank of Mt. Spurr (geothermal resource leases 394178, 394179 and 394180). This paper focuses on exploring the geothermal potential at Augustine Island.

South-central Alaska holds significant potential due to its proximity to the Pacific Ring of Fire, a region globally known for its volcanic activity and geothermal resources (U.S. Energy Information Association, 2022). The Cook Inlet basin is a NW-SE trending forearc basin lying above the Aleutian subduction zone of southern Alaska (Haeussler, *et al*., 2000) which contains active volcanoes, including Mt. Augustine.

Alaska's electricity market has been growing rapidly, with a strong recent emphasis on renewable energy. In late May 2024, House Bill 50 was passed by House Alaskan lawmakers which included more favorable conditions to encourage geothermal prospecting in the State. There are no geothermal power plants operating in the State with an installed capacity greater than 0.5 MW.[1]

Alaska's per capita energy consumption is the second highest in the nation (U.S. Energy Information Association, 2024) in part because of the State's small population, cold climate and energy-intensive industries. Alaska also has some of the highest residential and commercial

[1] The Chena power plant located at Chena Hot Springs near Fairbanks has been in operation since 2006 and has an installed capacity of 0.4MW (Erkan *et al.*, 2008).

electricity prices in the nation (U.S. Energy Information Association, 2024). Finally, 70% of the Alaskan population lies within South-central Alaska's 'Railbelt region' (Asmus *et al.*, 2023).

The 'Railbelt region' refers to the interconnected electric grid that stretches approximately 700 miles from the city of Fairbanks in the north through Anchorage to the Kenai Peninsula in the south. About 75% of Alaska's population (approximately 550,000 residents) are served by the Railbelt region. As the largest electrical grid in the State, it is vital for statewide economic and community development. Based on 2020 usage, power sales were calculated to top 4,408 GWh, of which 82% came from fossil-fuel-produced electricity (primarily natural gas and coal) and 18% from renewables (primarily hydroelectric, Dahlstrom *et al.*, 2023). In 2022, the State passed and signed legislation through the Renewable Energy Portfolio Standard (RPS) that will allow Alaska to join 30 other States and 2 Territories in creating a renewable portfolio standard, that can be applied to the Railbelt region. A key element of the Governor's RPS is a firm commitment to transitioning to 30% sustainable power by 2030 and 80% by 2040 (Dahlstrom *et al.*, 2023).

There are concerns in the Cook Inlet region over the reliability of long-term natural gas supplies, with natural gas-fired power plants currently providing the bulk of electrical production in the region. Imported LNG may become necessary in the near future, would almost certainly lead to a higher price of electricity to the consumer (ENSTAR, 2024). In a recent 2023 survey conducted by the Alaska Center for Energy and Power (ACEP) 82% of 275 respondents 'somewhat' or 'strongly' favored geothermal technology as a future carbon neutral solution for the Railbelt region (Asmus, *et al*., 2023).

Geothermal power produced at Augustine Island could replace the current coal-fired power plants operating in the interior of Alaska and within the Railbelt region. These coal fired power plants produce a total of 816,000 MWh over a typical 12 month period, emitting a total of 1.7m tonnes of CO2e per year (Goodfellow and Birnbaum, 2023).

2. Geological Setting of Augustine Island

Augustine Island (otherwise referred to as Augustine Volcano or Mt. Augustine) is located in the southwestern Cook Inlet, south-central Alaska, approximately 175 miles southwest of Anchorage and 60 miles west of Anchor Point on the Kenai Peninsula (Figure 1).

Augustine Volcano, an andesitic stratovolcano began erupting before the late Wisconsin glaciation, some 75,000 years ago (Waitt and Begét, 2009) although Waythomas and Waitt, 1998 place the timing of the initial volcanic intrusion at approximately 40,000 years ago, on a small island of upper Jurassic Naknek Formation to upper Cretaceous sedimentary rock, in the Cook Inlet, Alaska (Waitt and Begét, 2009). Augustine Volcano most recently erupted in 2006 and prior to that, during the late 20th Century (Kamata et al., 1991, Power et al., 2006, Swanson and Kienle, 1988 and Waitt and Begét, 2009).

Several have postulated that Augustine volcano contains a relatively shallow magma chamber (Koulakov *et al.*, 2023, Eichelberger *et al.*, 2023, Power, 2023 (*pers comm)*) and we concur. Koulakov *et al.*, 2023 used arrival time data from local seismicity recorded by a number of seismic stations on the island to identify a shallow rigid core composed of igneous rocks but strongly fractured and saturated with fluids and melts. Above this the authors note a zone associated with degassing of deep fluids. We explore this further. Eichelberger *et al.*, 2023 and Power, 2023 (*pers*

comm) have postulated that the Augustine Volcano magma chamber is estimated to be at a depth of only 4 km with an expected temperature of 840°C and a de-gassing zone of approximately 300°C at around 1 km below sea level.

2.1 The southern flank of Augustine Island

Outcropping on the southern flank of Augustine Volcano are a approximately 500ft thick series of approximately 1 mile^2 gently dipping sedimentary rocks attributed to the Upper Jurassic Naknek Formation (Figure 2, Detterman and Reed, 1964, Detterman and Jones, 1974, Buffler, 1976, amongst others).

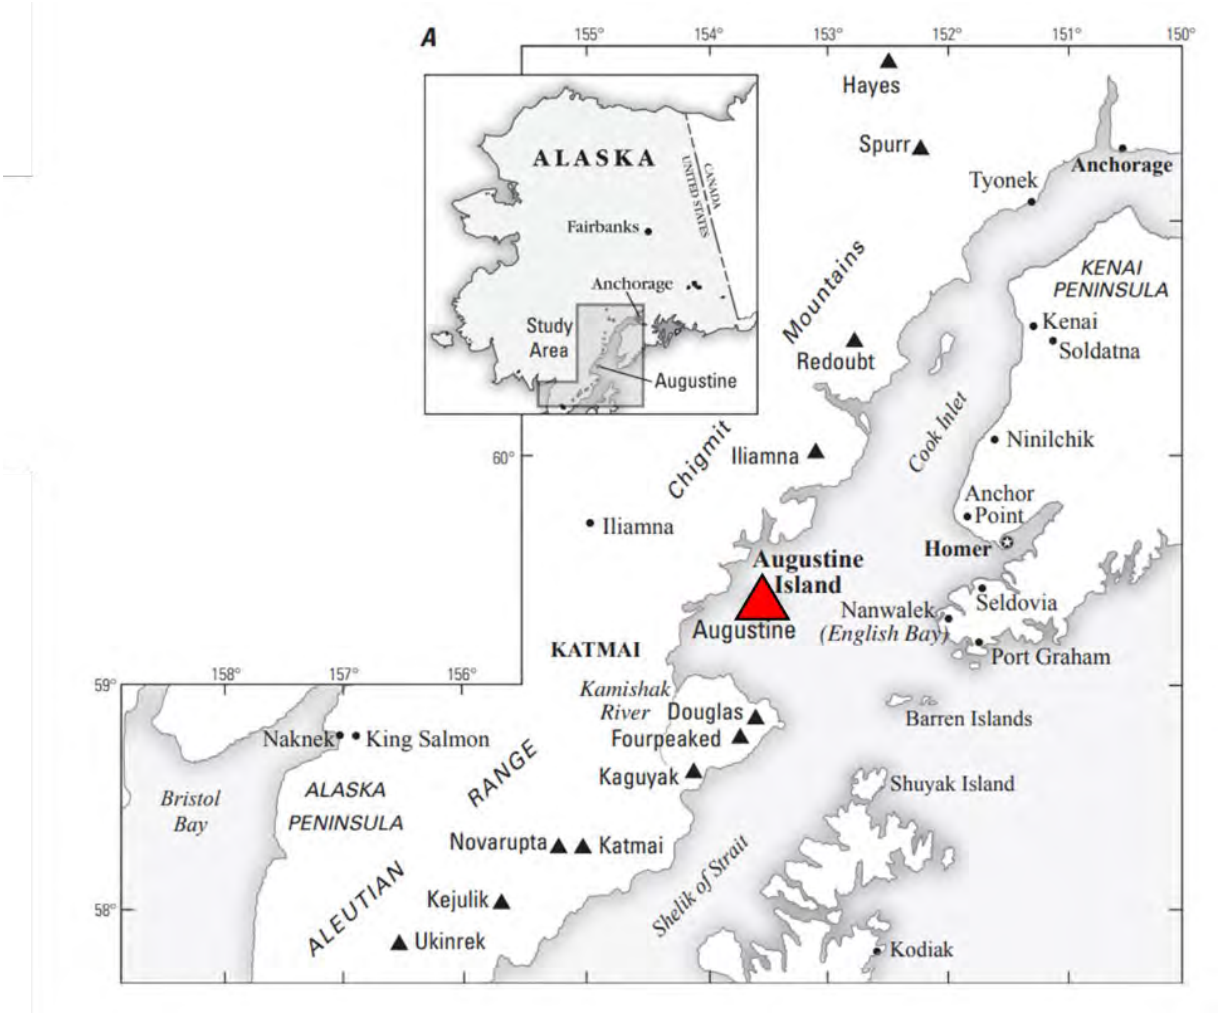

Figure 1: Cook Inlet area, Alaska; volcanoes shown as triangles, towns/cities as dots. Augustine Volcano shown as red triangle (modified from Waitt and Begét, 2009).

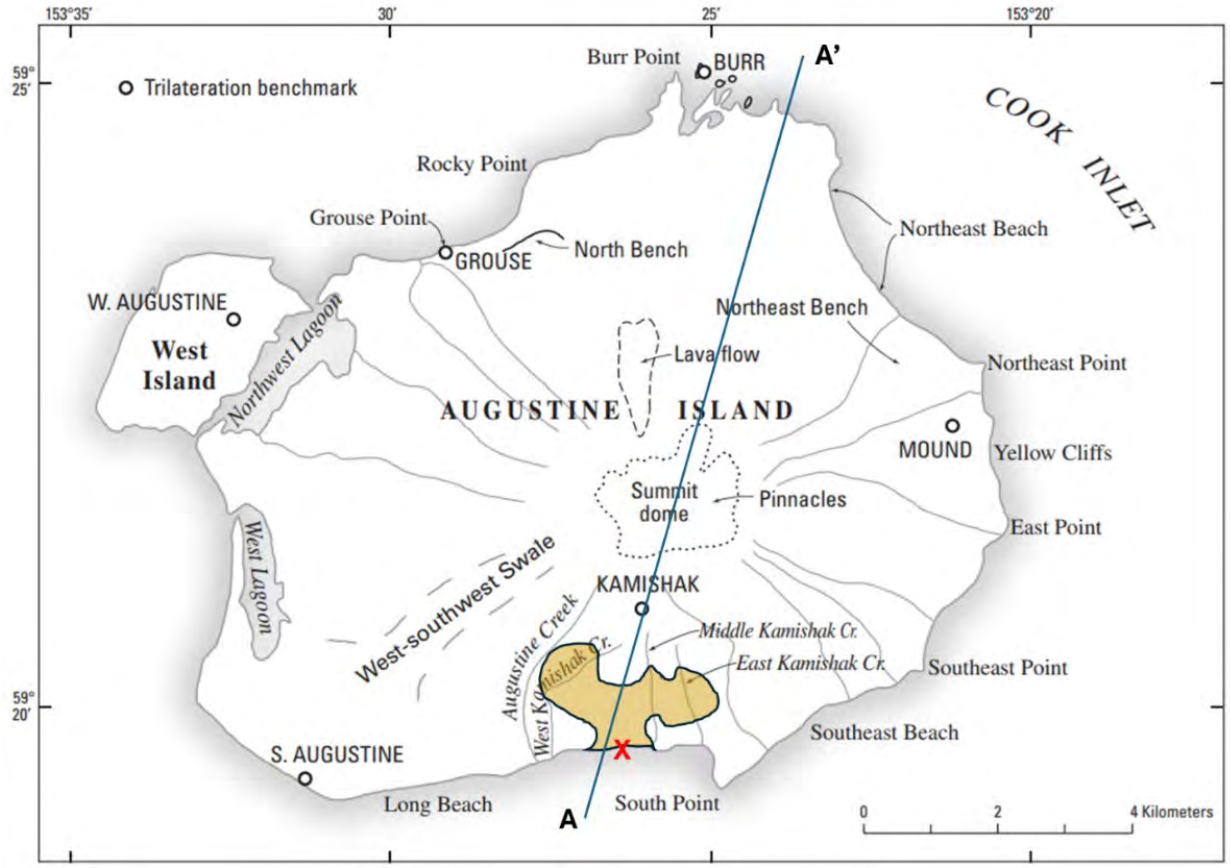

Figure 2: Approximate outcrop of Upper Jurassic Naknek Formation (brown shading) on the southern flank of Augustine Island (modified from Waitt and Begét, 2009). The red 'X' marks the location of the outcrop sampling (see below).

On Augustine Island, the Naknek Formation comprises a lower member of thin-bedded dark-gray siltstone to very fine sandstone and an upper member of thickly bedded medium to fine grained sandstone in places showing evidence of trough cross-bedding, lignite clasts and petrified wood (Waitt and Begét, 2009). The Naknek Formation on Augustine Island suggests deposition in a shallow restricted nearshore bay environment (Waitt and Begét, 2009). Interestingly, approximately 80 miles further north at Chisik Island, the Naknek Formation consists of deep-water channel deposits in sub-marine canyons (Herriott, T., *et al.*, 2016). Other workers (*e.g.* Koulakov *et al.*, 2023b and Syracuse *et al.*, 2011) have reported that the uplifted Jurassic section is commonly zeolitized.

2.1.1 Outcrop sampling

During the Fall of 2023, GeoAlaska sub-sampled various sedimentary strata exposed in the beach and cliff section at the eastern extent of Long Beach (see Figure 2 for location). In total, 15 samples were collected of which 13 are of a sedimentary origin and 11 likely representative of different facies within the Naknek Formation (Figure 3 and Table 1). These sedimentary samples ranged from well cemented siltstone containing calcite cemented fractures to well cemented medium to coarse grained oxidized sandstones. Abundant bivalves were identified in some of the samples. XRD and XRF data from these outcrop samples indicate a clay mineralogy indicative of

chlorite and smectite (up to 29% in sample 20) with minor illite, throughout. In addition, in samples 13, 19 and 21 zeolites were identified ranging from 7.6 weight% (sample 21, Clinoptilolite) to 17.9 weight% (sample 13, Laumontite). Sample 19 was found to contain 10.7 weight% Heulandite.

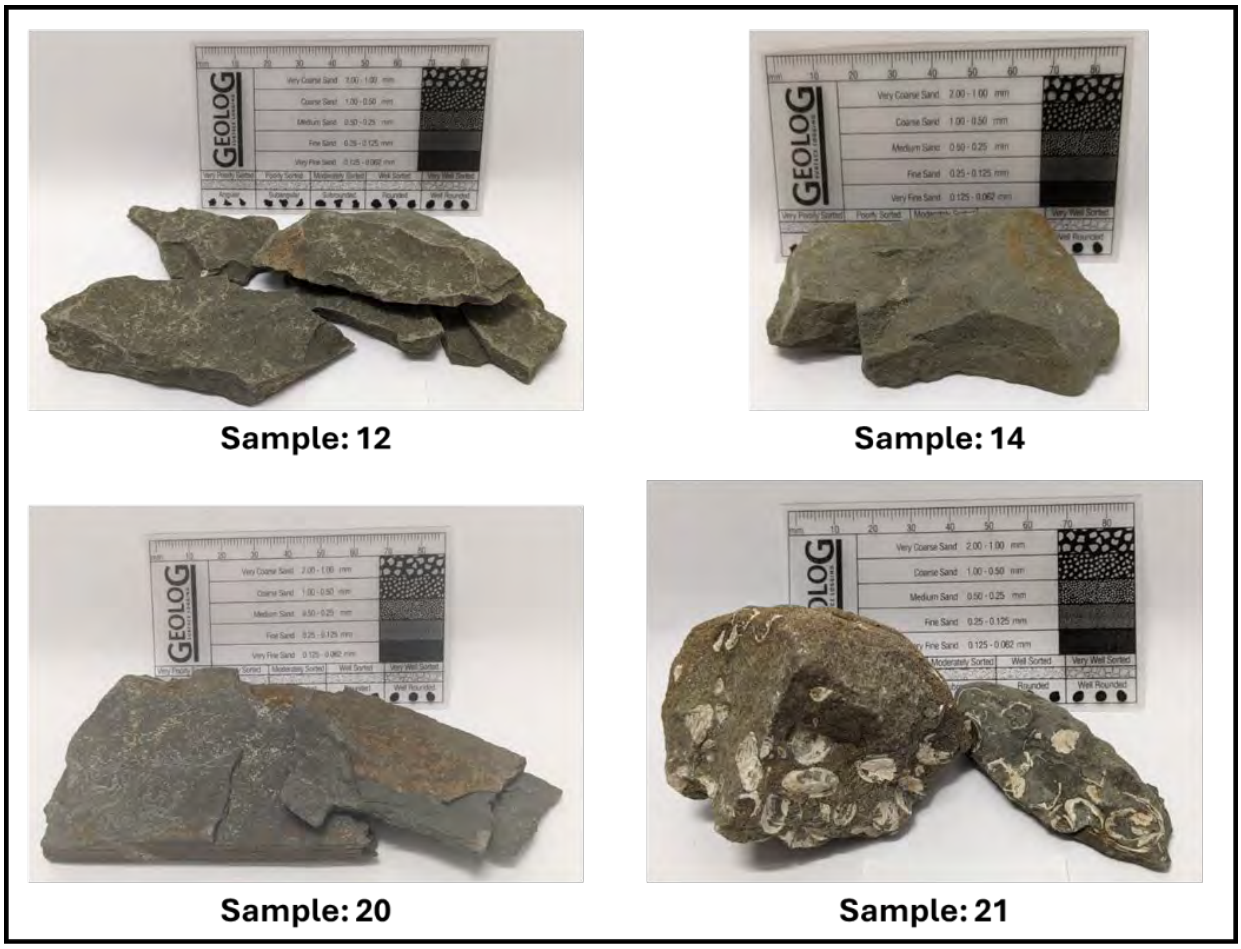

Figure 3: Outcrop samples from Long Beach, south Augustine Island. See Figure 2 for location of sampling.

2.1.2 Cross section

In their 2009 publication, Waitt and Begét include a NNE/SSW cross section of Augustine Island (see Figure 1 for cross section line) the southern portion of which is displayed in Figure 4 below. Note their assumptions of the Jurassic sub-crop, which this paper will explore further based on new MT, gravity and seismic data. It is the location, extent and composition of this Jurassic sub-crop that is a key component of the geothermal resource potential of the southern flank of Augustine Island.

3. Available Database

Table 2 summarizes the available data utilized for the exploration campaign to-date. In addition to the outcrop samples collected during the Fall of 2023, an initial Acoustic Magnetotelluric

(AMT) and Gravity survey was commissioned by GeoAlaska during the summer season of 2023 covering the entire ADL 394080 permit area. The MT survey consisted of 28 MT stations (Figure 5A) while the Gravity survey consisted of 215 stations (Figure 5B).

Table 1: Outcrop samples from Long Beach, south Augustine Island, sedimentological description. Highlighted rows refer to samples displayed in Figure 3.

Sample	Lithology	Colour	Density (g/cm^3)	Notes	Interpretation
1	Porfyric lava	Medium Grey (N5)	2.33	Hard, visible femic minerals (and some Obsidian), plagioclases and feldspars in a greyish groundmass.	Probable volcanic deposits
4	Porfyric lava	Grayish Red (10R 4/2)	2.52	Hard, millimeter sized feldspars and reddish femic crystals in a reddish groundmass.	
2	Claystone	Moderate Yellowish Brown (10YR 5/4)	1.94	Loose clay.	Probable recent Pleistocene to Late Holocene deposits
3	Claystone	Moderate Brown (5YR 4/4)	1.86	Soft claystone with some volcanic and sedimentary grains	
10	Sandstone	Dark Grey (N3)	2.42	Medium hard layered sandstone with cleavage. Presence of black fossils.	Probable Upper Jurassic sandstone and shale Naknek Formation
11	Sandstone	Olive Grey (5Y 4/1)	2.37	Hard coarse sandstone, reddish oxidation on some sides of the rock sample.	
12	Sandstone	Dark Grey (N3)	2.30	Hard fine grained sandstone. Presence of thin veins.	
13	Sandstone	Olive Grey (5Y 4/1)	2.33	Poorly well cemented coarse grained sandstone. Presence of fine-grained layers. Presence of dark micas.	
14	Sandstone	Olive Black (5Y 2/1)	2.15	Moderately hard. Presence of localized oxidation.	
15	Sandstone	Olive Black (5Y 2/1)	2.30	Hard fine grained layered sandstone. Presence of veins.	
17	Calcite veins in sandstone	Dark Grey (N3)	2.42	Pseudo-acicular/prysmatic veins witihn a fine grained sandstone. Calcite veins are coated by iron oxides.	
18	Siltstone	Dark Grey (N3)	2.52	Very hard cemented siltstone. presence of veins (calcite?).	
19	Sandstone	Olive Grey (5Y 4/1)	2.24	Moderately hard coarse grained sandstone. Slightly layered.	
20	Siltstone/Sandstone	Dark Grey (N3)	2.25	Moderately hard laminated coarse grained siltstone/fine grained sandstone . Slightly cemented.	
21	a) CG Sandstone; b) FG Sandstone	a) Light Olive Grey (5Y 5/2); b) Dark	2.42	a) Moderately hard, cemented, abundant fossils (bivalves) ; b) Hard, presence of fossils (bivalves) and veins.	

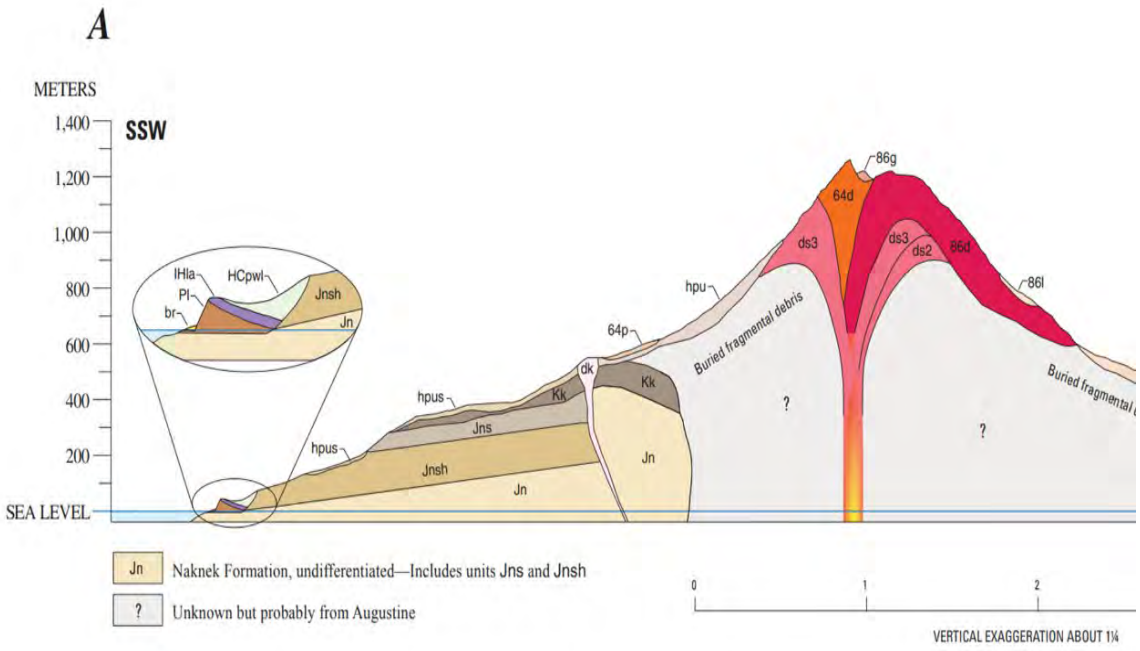

Figure 4: Cross section of the southern flank of Augustine Island (after Waitt and Begét, 2009).

Table 2: Summary of the available data utilized to-date for the exploration campaign on Mt. Augustine.

Data Type	Raw Data	Output Data	Interpreted Data	Notes	Reference
Geologic Structure	Yes	Yes	Yes	-	(Waitt and Begét, 2009) (Syracuse et al., 2011) (Koulakov et al., 2023b) Field studies, 2023

Eruptions	Yes	Yes	Yes		(Kamata et al., 1991; Power et al., 2006; Swanson and Kienle, 1988)

In addition, GeoAlaska used catalog data provided by the Alaska Volcano Observatory (AVO) which includes arrival times of seismic *P* and *S* waves recorded by permanent seismic networks operating on the volcano. In this study we used data from January 2001 to December 2017, which included 6624 events recorded by 15 permanent stations deployed on the flanks of the volcano.

4. Geophysical Data Interpretation and Modelling

4.1 AMT and Gravity Data

From the AMT and Gravity data, a combined 3D inversion model was built using Geotools and RLM-3D code. The resulting 3D resistivity and density volumes were uploaded into Leapfrog Energy software where depth and vertical slices were extracted to visualize any low-resistivity and high-density anomalies. The visualizations were complemented by uploading the geological map of Mt. Augustine including the location of any potential geothermal elements.

The generated model revealed a sector with a convergence of low resistivity and high-density volumes on the southern flank of Augustine Volcano that could represent a working hydrothermal system, underlying a geothermal clay cap.

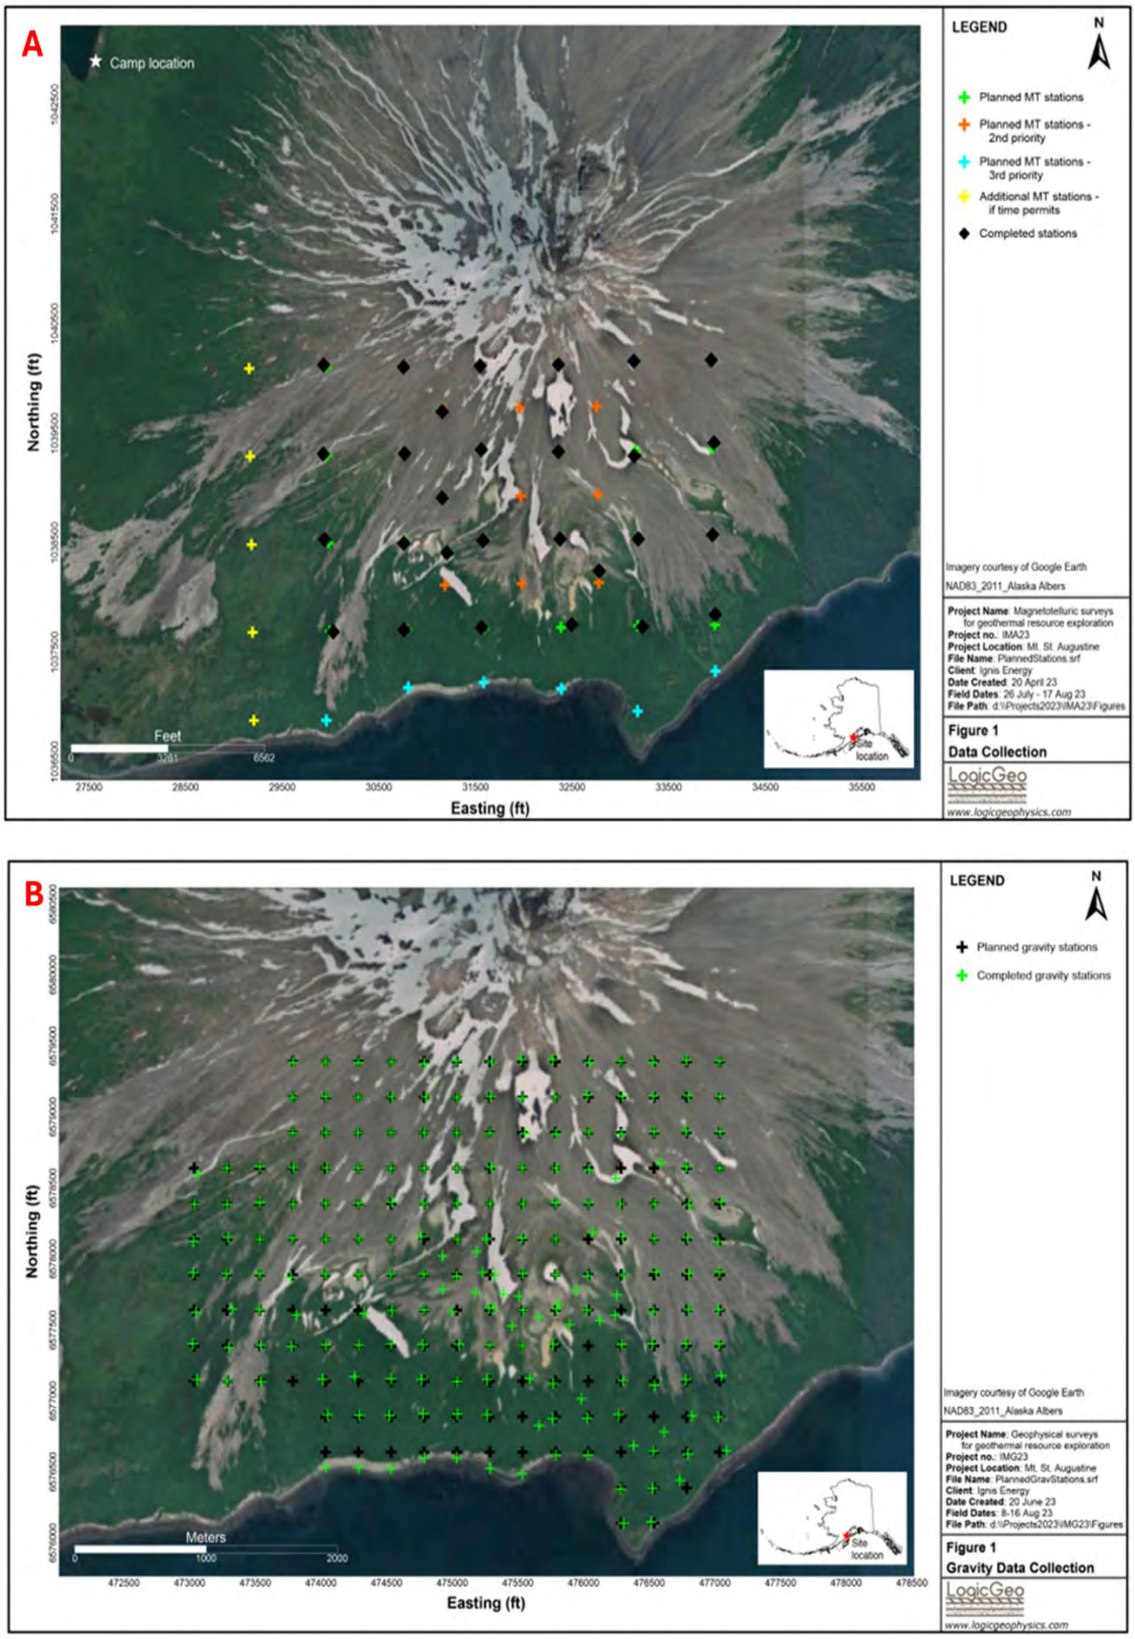

Figure 5: Maps showing the location and number of collected data from AMT (A) and Gravity (B)

4.2 Seismic Data

LOTOS code has been used for the seismic inversion and to construct the 3D visualization of Mt Augustine seismic data (Koulakov, 2009). The *P* and *S* wave velocities have been analyzed to get an insight on the potential geothermal reservoir tomography. The limitation and details of the code are beyond the scope of this article so the reader is referred to Koulakov, (2009); Koulakov et al., (2023b); Koulakov, (2020) for more information. The 3D inversion was sliced into 4 vertical cross-sections Figure 6) and 5 horizontal cross-sections. The data filtration was based on the approach of Koulakov, *et al.* 2023 which resulted in a total of 3,127 events with 10,680 P-wave picks and 11,080 S-wave picks. Although our approach is similar to Koulakov *et al.* (2023), their main focus was the volcanic pluming system, while our main focus is identifying a potential geothermal resource. Figure 7 shows the absolute P (V_P) and S (V_S) waves velocities for vertical and horizontal cross-sections. Also, the anomalies in P (dV_P) and S (dV_S) wave velocities are presented in Figure 8. The relatively similar count for P-wave picks and S-wave picks made it easier to obtain the ratio of dV_P/dV_S (shown in Figure 8). It is noted that in each of the cross-sections displayed in Figures 7 and 8, the lack of seismic events away from the central region is due to a limited number of seismic stations over the flanks of the volcano.

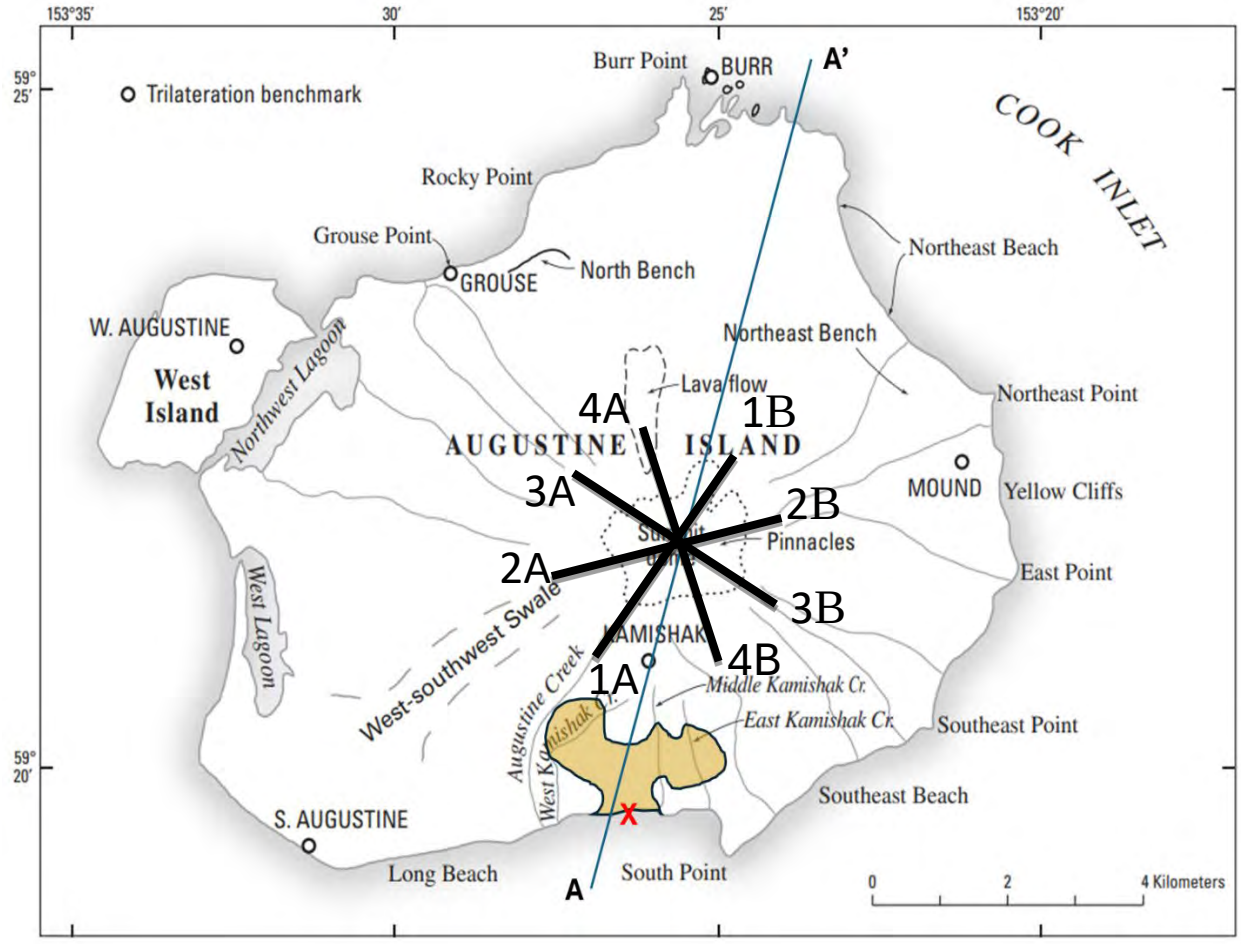

Figure 6: Locations of the 4 vertical seismic sections across Mt Augustine. Sections 1A-1B and 4A-4B are most relevant to this paper and will be discussed further.

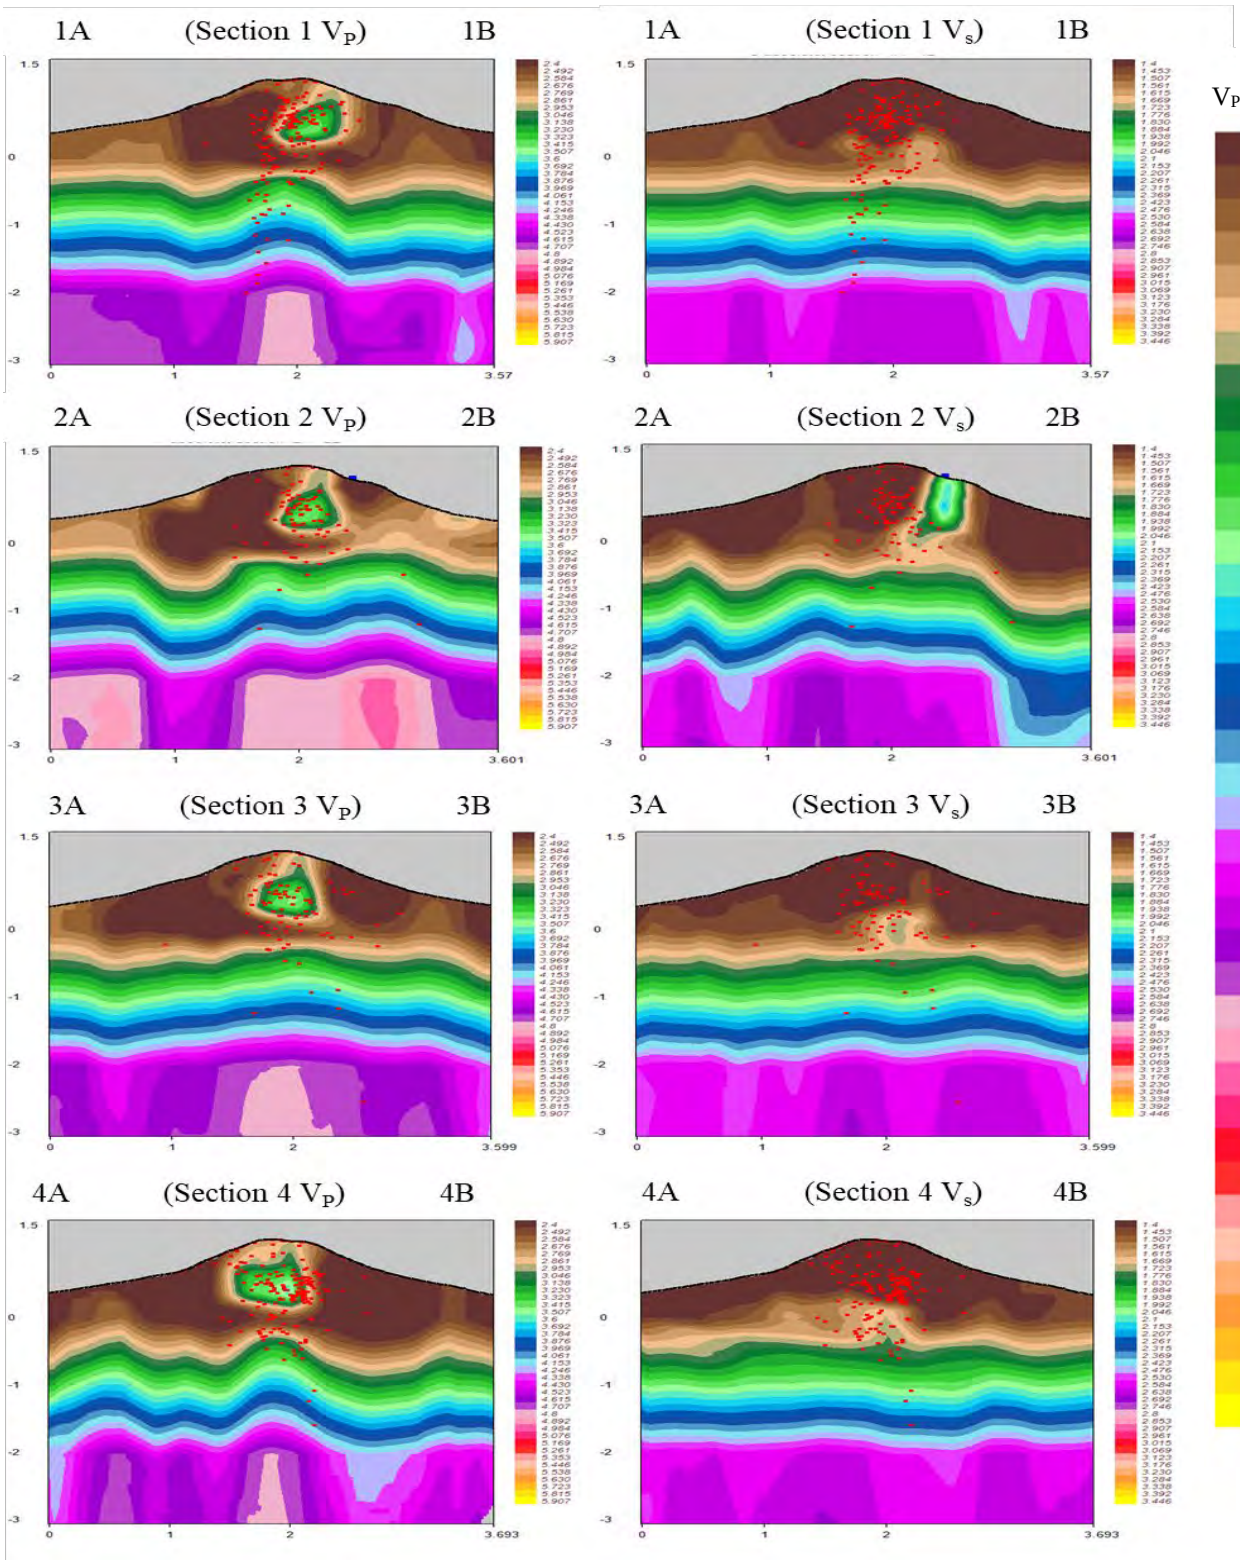

Figure 7: V_P (left column) and V_S (right column) measured in Km/sec for the 4 vertical sections (1 to 4) shown in Figure 6. The red dots represent measured seismic events, Y-axis is the elevation/depth above/under sea-level in Km and X-axis is horizontal displacement in Km along the 4 vertical seismic sections (shown in Figure 6) starting from 0 at point A and ending at point B in all subfigures.

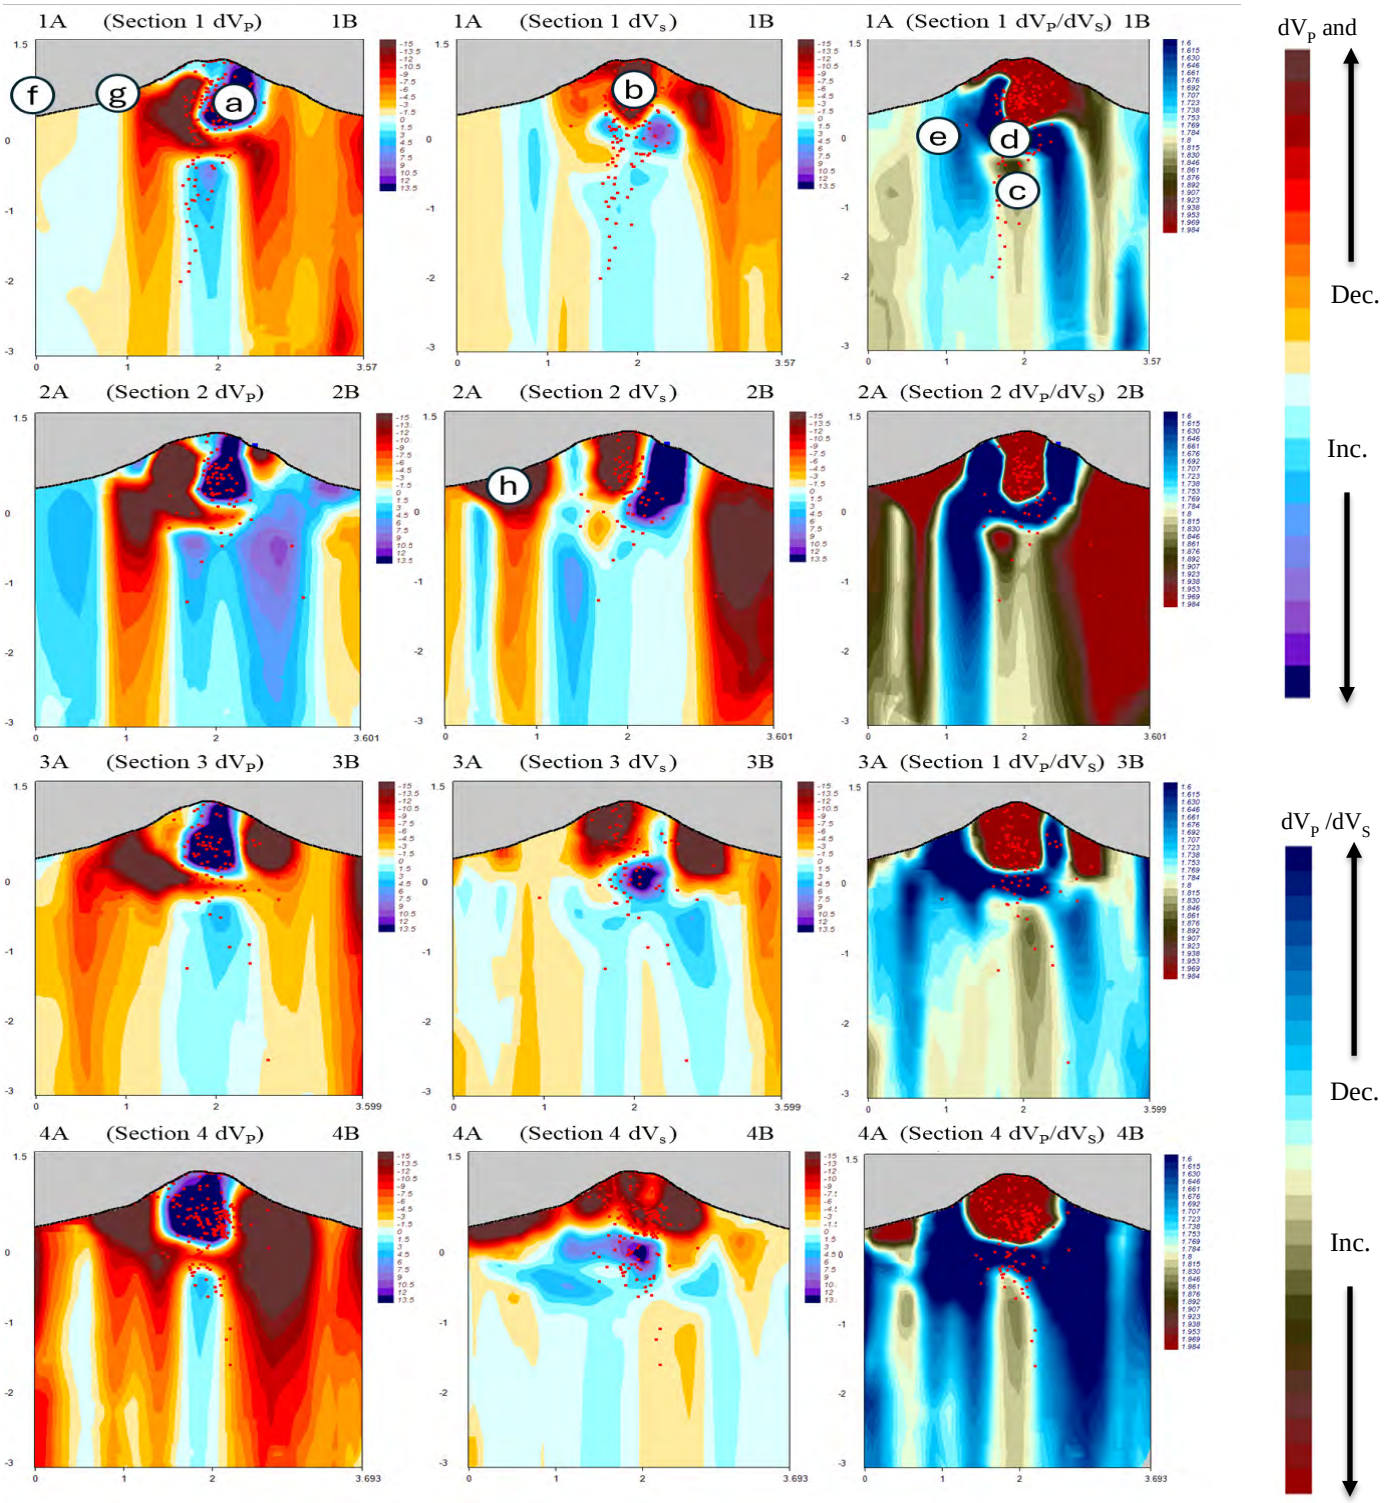

Figure 8: Shows dV_P (%) in the left column, dV_S (%) in the middle column and dV_P/dV_S (dimensionless) in the right column for the 4 vertical sections (1 to 4) shown in Figure 6. The red dots, Y-axis and X-axis are the same as described in Figure 7. See text for explanation of annotations a through h.

5. Subsurface Modelling

5.1 Geological Model (incorporating the AMT and Gravity data)

Figure 9 below is adapted from Waitt and Begét, 2009 and illustrates the geological model of the potential geothermal resource below the southern flank of Augustine Volcano. Outcrop data suggests that the Upper Jurassic sedimentary pile (light brown color on Figure 9, and acronyms Jnsh and Jns) has been faulted due to compression, probably as a result of the initial volcanic intrusion. These faults are likely to have been clay smeared reducing their effectiveness to form conduits to vertical fluid flow. It is more likely that any downward meteoric fluid flow occurs through or at the contact between the more porous volcanic sediments that onlap the Jurassic sub-crop.

XRD data from outcrop samples reveals that the Jurassic sediments can contain up to 29% smectite. In the sub-surface where there is interaction between super-heated brines and the sedimentary rock (yellow surfaces in Figure 9) this percentage volume is likely to be more and thus the Jurassic sub-crop is predicted to form an excellent seal or clay cap to any underlying hydrothermal system contained within the fractured basement (pink polygons in Figure 9). In fact, we believe the Jurassic sub-crop is such a good seal, it is preventing any upward movement of hydrothermal fluids, resulting in a more horizontal circulation pattern for the trapped hydrothermal fluids (Figure 9). A working hypothesis is that hydrothermal fluids could be reaching the surface on the sub-sea lower flanks of Augustine Island, although as of yet, there is no direct evidence to corroborate this.

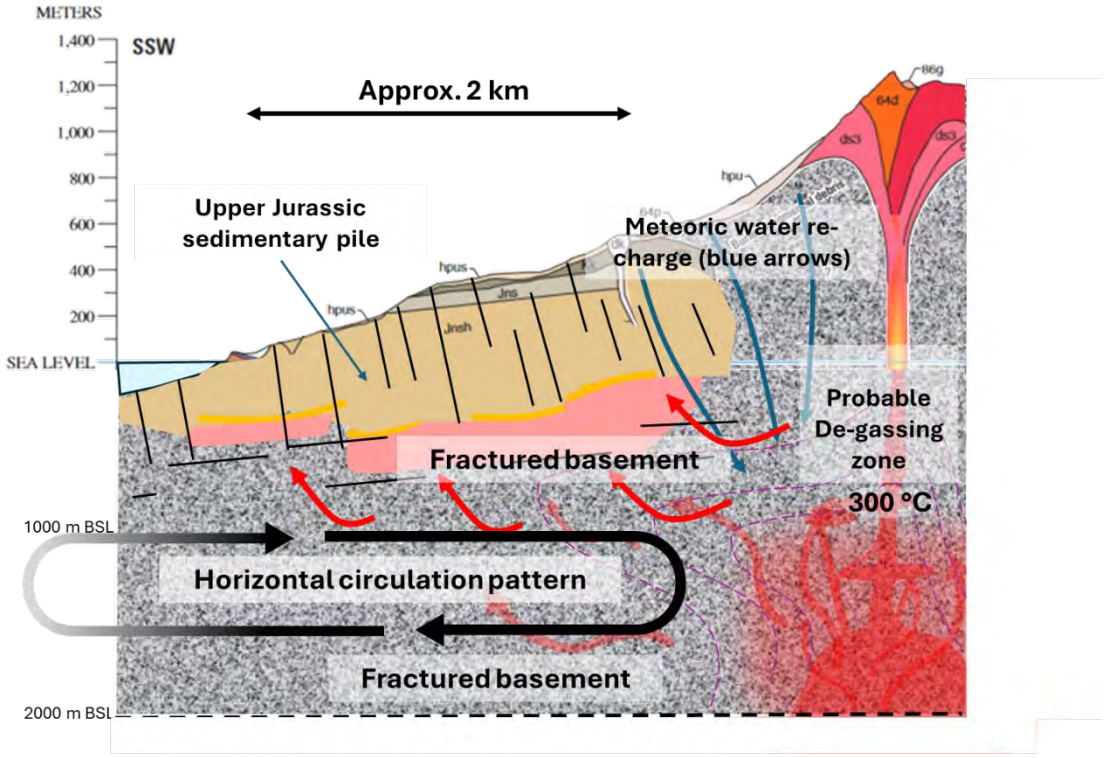

Figure 9: Geological model of potential geothermal resource under the southern flank of Augustine Volcano. See text for further information (modified from Waitt and Begét, 2009, see reference for acronym explanation).

The combined resistivity and density data from the 3D AMT/gravity datasets corroborates the above findings. The convergence of low resistivity and high density volumes on the southern flank of the island represents the Upper Jurassic sediment seal or geothermal clay cap sitting above a higher zone of resistivity which is likely to represent the hydrothermal system. (Figure 10).

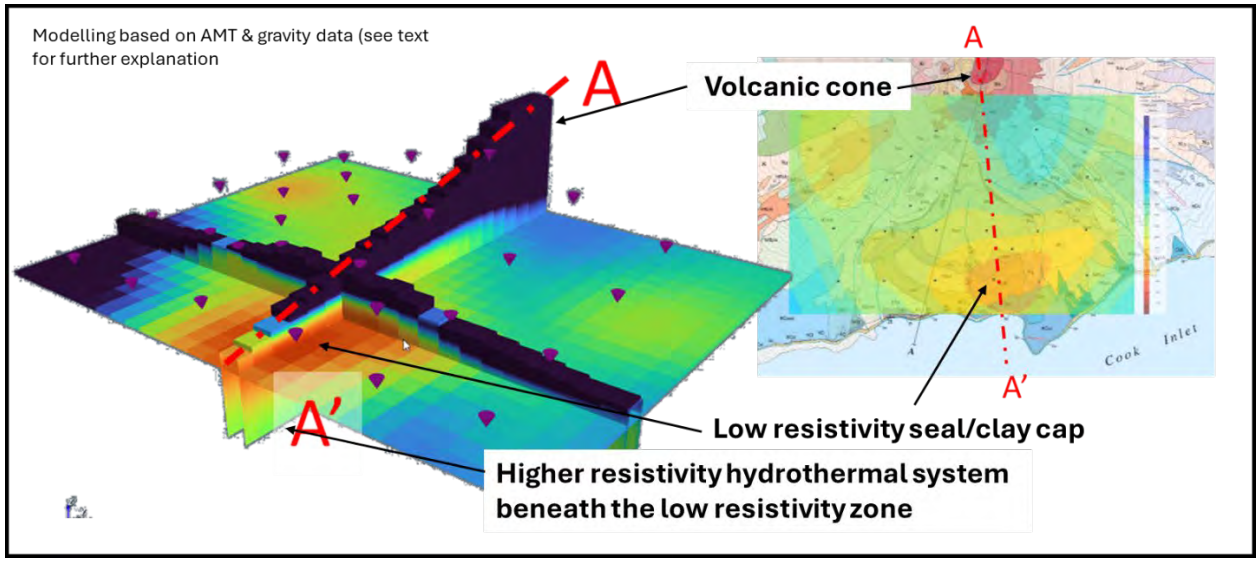

Figure 10: 3D modelling of AMT and Gravity data revealing a volume of low resistivity and high-density within the southern part of Augustine Island

5.2 Seismic model

In all vertical sections a strong anomaly of very high dV_P was observed within the edifice of the volcano which is interpreted as the igneous rock structure within the edifice (see Figure 8, point a). Conversely a very low dV_S was observed within the edifice which can be interpreted as fractures filled with fluids and melts (see Figure 8, point b). Also, the data reveals a high dV_P, low to moderate dV_S columnar anomaly associated with high dV_P/dV_S observed at a greater depth below the edifice which is interpreted as a slender magma conduit (see Figure 8, point c). In addition, a sudden change in dV_P/dV_S from high to low values is observed between the edifice and the magma conduit. This behavior is associated with high, dense seismicity and could be the result of a zone of degassing region (see Figure 8, point d).

The Southern flank of Mt Augustine represents a high potential for geothermal resource development. In section 1A-1B we observe the presence of a columnar anomaly of relatively high dV_P, high dV_s and relatively low dV_P/dV_S (see Figure 8, point e). This anomaly could be interpreted as a brittle zone where degassed fluids form fractures and quickly propagate upwards (Koulakov et al., 2023a). Also, in section 1A-1B both dV_P and dV_S increase as we go further away from the shoreline (see Figure 8, point f to g). This increase could be due to the decrease in the saturation of water further away from the shoreline. Aside from the magma conduit and edifice, the Upper Jurassic silts and sands were observed to have a higher V_P and V_S. This observation coincides with the theory of having a thermally altered clay layer that works as a seal between the fractured saturated basement below and the silts and sands, above. Similar anomalies were observed for section 4A-4B and the interpretation of these anomalies is the same.

In section 2A-2B, a relatively high dV_P associated with low dV_S which results in high dV_P/dV_S anomaly is observed under the southern flank of the volcano (see Figure 8, point h). Our interpretation is that dV_P is less in this region because of the Upper Jurassic sedimentary lithology (Takei, 2002; Waitt and Begét, 2009) when compared to the igneous structure of the edifice. On the other hand, another reason for dV_P to increase is the presence of water. This assumption is verified by the low dV_S and high dV_P/dV_S in the area (Adam and Otheim, 2013).

Combining the geological, resistivity, gravity and seismic data, the basis of a working hydrothermal system is identified under the southern flank of Augustine Volcano (Figure 11). The geological, resistivity and gravity data support the identification of an effective seal/clay cap, while the seismic data identifies a fluid filled zone of fractured basement directly beneath this. The areal extent of the seal/clay cap has been calculated as 3000 m^2 while the underlying hydrothermal resource volume has been calculated as 1,200,000 m^3 (based upon currently available data).

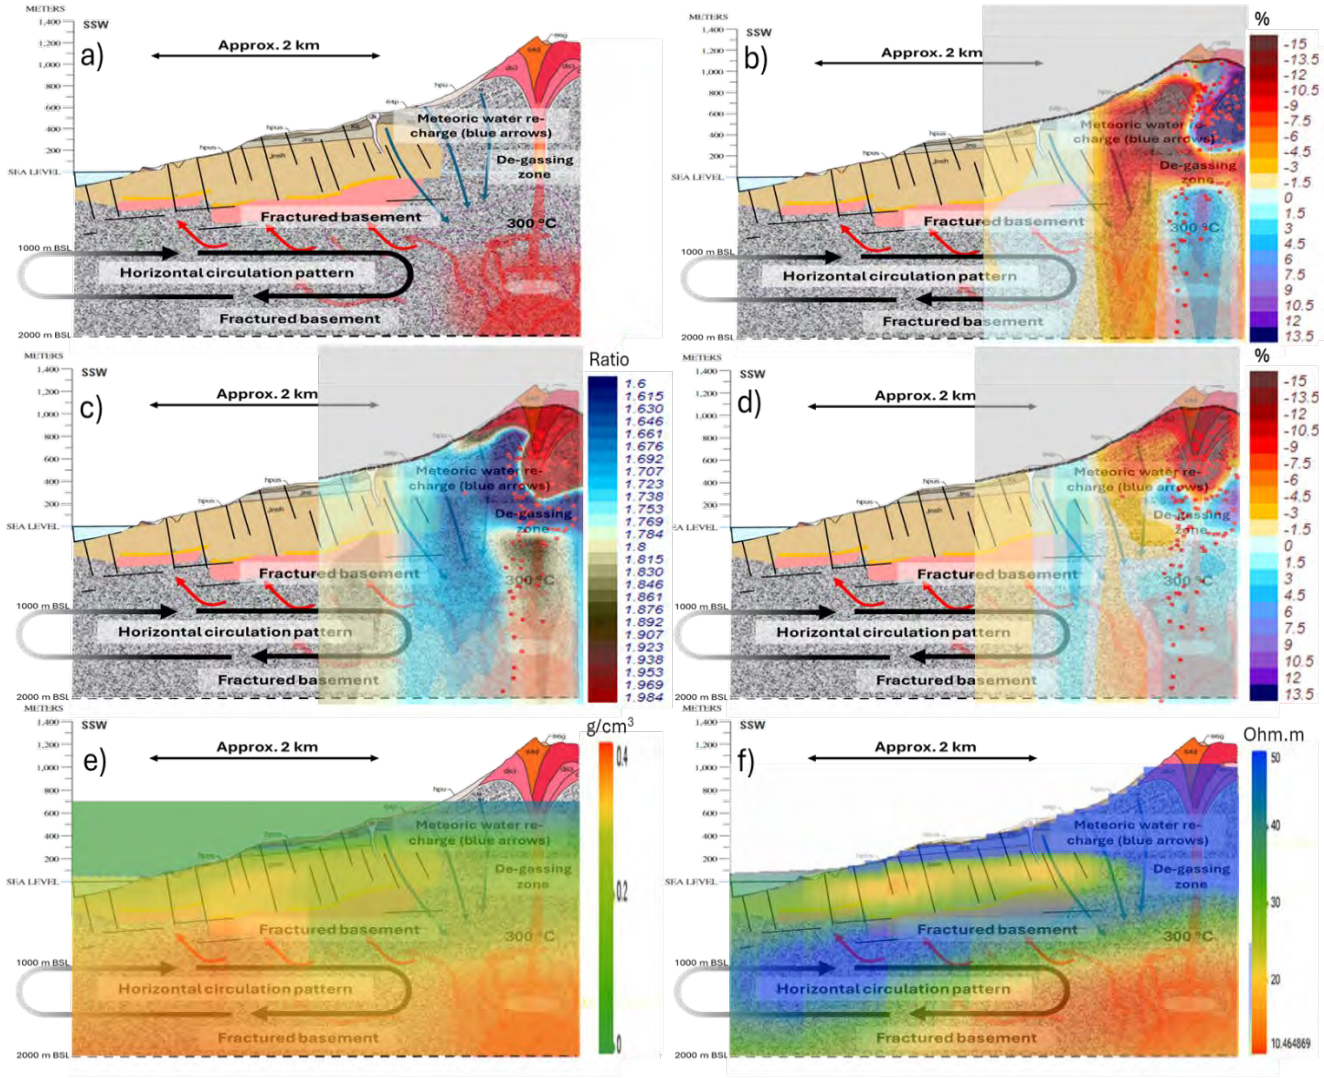

Figure 11: Full sub-surface model combining the (a) geologic model with (b) dVP, (c) dVP/ dVS, (d) dVS, (e) gravity and (f) AMT data.

5.3 Discussion

Due to the presence of the Jurassic seal/clay cap, we describe this geothermal resource as 'atypical'. A typical geothermal resource on a volcanic flank normally requires hydrothermal alteration of volcanic sediment/basement in order to create an effective seal. In addition, and due to the absence of identified surface manifestations, the potential geothermal resource identified at Augustine Volcano could be described as 'blind'. Blind geothermal systems are hydrothermal systems that lack surface thermal features (*e.g.* hot springs, mud volcanoes, *etc*). However, they share many features in common with conventional identified hydrothermal systems. Dobson, 2016 identifies a number of geologic factors that could prevent the rise of hot, buoyant fluids from reaching the surface including,

- Blind systems may have thicker, better developed seals
- Faults associated with blind systems may not reach the surface or may be fault-sealed
- Blind systems may contain depressed water tables that result in no surface thermal manifestations
- Blind systems may be obscured by an overlying cold-water aquifer
- Blind systems may be smaller than identified hydrothermal systems in the same geologic setting
- Blind systems may be deeper than their identified geothermal counterparts

There are good examples of blind geothermal systems located in volcanic zones that have been developed for geothermal power production including Puna Geothermal Venture, Hawaii and Cerro Pabellón Geothermal Field, Chile. Cerro Pabellón is located in a subduction zone volcanic center and is located on the eastern flank of the Apacheta volcano, and thus has a similar geological setting to Mt. Augustine. A thick altered clay seal consisting of smectite-illite mix has formed over the geothermal reservoir, blocking any vertical migration of fluids, thus resulting in a dominant horizontal circulation pattern (Maza *et al.*, 2021, Baccarin *et al.* 2021). Despite the lack of surface manifestations, Cerro Pabellón geothermal system has a current installed power capacity of 83 Mwe.

Based on the data collected from Augustine Volcano to date, we believe that the potential identified geothermal resource shows many similarities with Cerro Pabellón which could represent a good analogue for future development.

6. Volumetrics and Uncertainties

Based on the results from the seismic, AMT, gravity, and geological data, a potential hydrothermal resource was identified in the southern part of the island and within the original permit area. In order to volumetrically evaluate this potential hydrothermal resource, two reservoir estimation methods (the volumetric method and the power density method) were evaluated.

The volumetric method is widely used to quantify geothermal resource capacity. Equation 1 is used to estimate the megawatts of electric power that can be generated from a geothermal resource (Muffler, 1979). Equation 2 is used to determine the thermal energy (q) measured in joules (J) (Garg and Combs, 2015; Muffler and Cataldi, 1978).

$$MWe = \frac{qXR_fX\eta_{\text{conv}}}{FXL} \quad (1)$$

$$q = q_r + q_f = Ah(T_i - T_f)[(1-\varphi)\rho_R c_R + \varphi(X_L \rho_L c_L + X_V \rho_V c_V) \quad (2)$$

X_L and X_V can be calculated using Equation 3 (O'Sullivan and O'Sullivan, 2016). While the rock is considered fully saturated where $X_L + X_V = 1$ and their entropies are obtained using the steam tables for two-phase saturated fluid. All the variables and their units are summarized in Table 3.

$$X_V = \frac{S_{L@Ti} - S_{L@Tr}}{S_{V@Tr} - S_{L@Tr}} \quad (3)$$

Table 3: Variables and corresponding units for parameters used in Equations 1 through 3.

Symbol	Name	Unit
MWe	Power Potential	Mwe
Q	Thermal energy	MJ
R_f	Recovery factor	%
L	Power plant lifespan	Seconds
η_{conv}	Conversion factor	%
F	Load factor	%
A	Area	m^2
H	Thickness	m
T_i	Initial reservoir temperature	°C
T_r	Reference Temperature	°C
T_f	Final abandonment temperature	°C
$\rho_i c_i$	Volumetric heat capacity	$J/m^3°C$
X_L	Liquid fraction	%
X_V	Vapor fraction	%
S_L	Entropy of liquid phase	J/K
S_V	Entropy of vapor phase	J/K

The power density method is another way to estimate potential power generation per area (Mwe/Km^2). The simple calculation and the few assumptions for power density make it a favorable choice especially in an early exploration phase. Wilmarth and Stimac, (2015) have developed Figure 12 for 53 geothermal fields based on tectonic settings in correlation with reservoir temperature.

Based on the current dataset, potential power generation was calculated using both power density and volumetric methods and averaged for further calculations. Since there are a lot of uncertainties associated with any green field prospect like Mt Augustine, Monte Carlo simulation (MCS) with 10,000 iterations was utilized to reduce the level of uncertainty. Figure 13 shows the histogram distribution for the potential MWe for Mt Augustine. The P_{50} has been calculated as 70 MWe with a P_{90}-P_{10} range of 49 MWe to 93 MWe. These numbers will change as GeoAlaska collects additional quantitative data.

Once the power production potential is calculated it can then be used to estimate the number of wells required to effectively produce the resource. The MWe/number of wells is assumed to be 3.5 MWe/well for slim wells (Alarcón, 2023) and 8.5 MWe/well for conventional wells, both of which agree with the Cerro Pabellón Field full field development plan (Lobos Lillo et al., 2023). Tables 4 and 5 summarize all the key data and assumptions used in the power production potential calculation. Once the optimum number of wells is calculated, the technical assessment is concluded, and the economic assessment can commence.

Based on the current dataset and the results of the volumetric modelling, the optimal number of wells required to develop the prospect is 11 conventional wells or 27 slim wells.

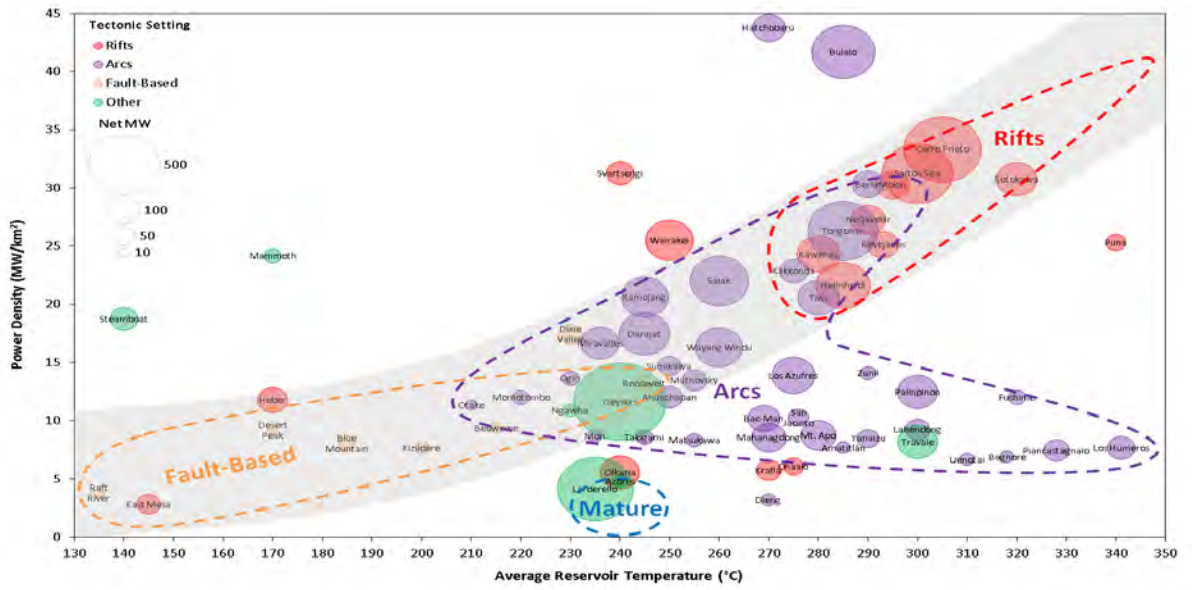

Figure 12: Clusters of geothermal wells and the correlation of their power density with measured reservoir temperature, (Wilmarth and Stimac, 2015).

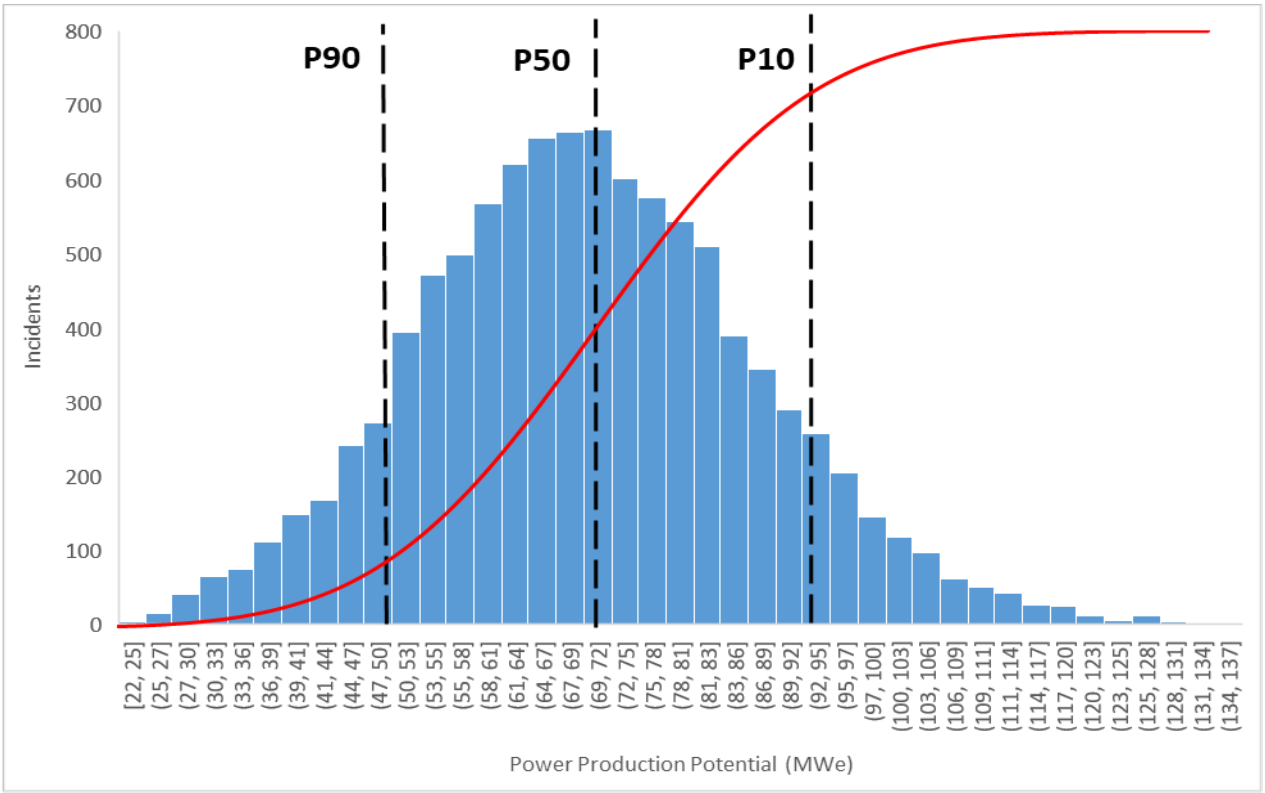

Figure 13: MCS histogram distribution for power production potential in MWe. 70 MWe is the P50 and a P90-P10 range of 49 MWe to 93 MWe. CDF is the cumulative distribution function of power production potential to be equal a certain value or less.

Table 4: Summary of the variable data utilized for MCS modelling.

Parameter	Most Likely	Minimum	Maximum	Unit	Reference
Rock porosity (φ)	10	5	15	%	(Ciriaco et al., 2020)
Recovery Factor (Rf)	15	5	20	%	(Garg and Combs, 2015)
Conversion efficiency (η_{conv})	75	70	80	%	(Garg and Combs, 2015)
Abandonment temperature (T_f)	100	100	151.831	°C	(Aravena et al., 2016)
Area	3.5	3	4	Km^2	2023 AMT Data
Thickness	400	200	600	m	2023 AMT Data
Production decline rate	0.15	0	0.5	%	(Alarcón, 2023)
Cost Increase rate	2	0	10	%	(Alarcón, 2023)
Power Density range	15	10	25	MWe/Km2	(Wilmarth and Stimac, 2015)

Table 5: Summary of the fixed data utilized for MCS modelling.

Parameter	Value	Unit	Reference
Reference Temperature	15	°C	(Sanyal et al., 2004) (Williams 2004) (Basel et al. 2010)
Initial Reservoir Temperature	280	°C	(Eichelberger et al. 2023)
Volumetric heat capacity of the rock ($\rho_R c_R$)	2700	$KJ/m^3°C$	(Aravena et al., 2016)
Lifespan (L)	30	Years	(Ciriaco et al., 2020)
Capacity factor (F)	95	%	(Aravena et al., 2016)

The economic assessment assumes the delivery of electrical power to the shoreline of Mt. Augustine and does not consider transfer of power to the mainland. It is divided into three main parts, CAPEX, OPEX and Revenue. Firstly, CAPEX can be divided into development costs and construction costs. The development cost includes surface exploration, project management, testing and reservoir management, infrastructure (well pads, etc.), drilling of production wells, drilling of injection wells, design and engineering, land, permitting, environmental management and contingency reserve. The construction cost includes powerplant engineering, procurement and construction (EPC), insurance, management and others (Martínez Ruiz et al., 2022; Osorio Luna, 2018). Powerplant EPC can be calculated using Equation 4 (Martínez Ruiz et al., 2022; Sanyal, 2005).

$$EPC = KW * CC = KW * CPP * e^{-0.0025(MW-5)} \quad (4)$$

Where, CC is the capital cost in USD/kW, CPP is the cost per kW of the powerplant, and W is the gross power output of the power plant in MW. The cost per kW of the powerplant (CPP) varies depending on the type of powerplant and any changes in the technologies involved. CPP ranges between 1,700 USD/kW to 2000 USD/kW (Alarcón, 2023).

OPEX calculations also include such costs as insurance, easements, concession leases, selling and administrative expenses, environmental mitigation, utilities, auxiliary power, OandM externalization and royalties. The net potential generation capacity is calculated by subtracting the parasitic loads shown in Table 6 from total potential capacity. Based on Table 6 calculations, the net potential generation capacity is 89% of the total potential capacity.

Based on the current dataset and assumptions the economic modelling predicts a total CAPEX investment to range from \$181 to \$287 million USD as P_{10} and P_{90}, respectively. P_{50} for total CAPEX is \$234 million USD which represents a 3.4 million USD/MWe CAPEX investment per power generation. Figures 15 shows the range of P10 to P90 for CAPEX investment per MWe.

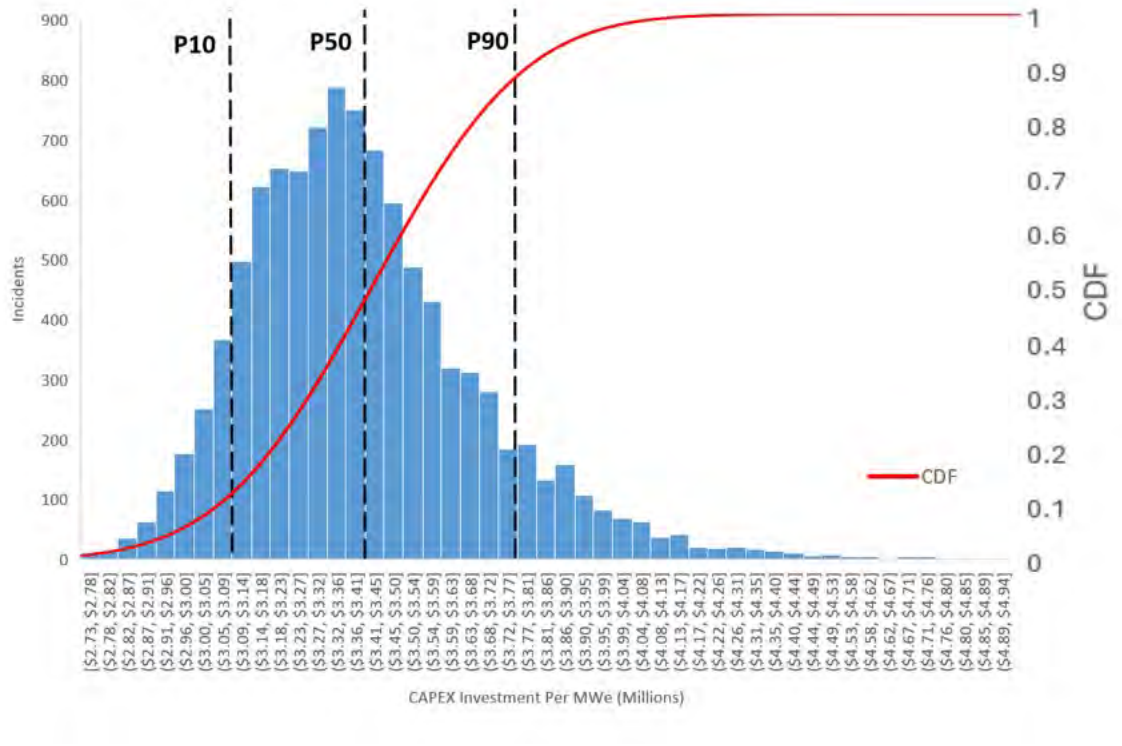

Figure 15: MCS histogram distribution for CAPEX investment per MWe. \$3.4 million /MWe is the P50 while P90-P10 range from \$3.1 to \$3.8 million/MWe. CDF is the cumulative distribution function of CAPEX investment per MWe to be equal a certain value or less.

7. Full Field Development Plan

Any development efforts are accompanied by an underlying business plan that relies on carefully derived assumptions and is updated as new information is revealed. Economic evaluation criteria include the internal rate of return (IRR) and net present value (NPV). Current assumptions in determining the viability of this project neglect beneficial tax breaks, carbon offset credits, and debt leverage from project finance. The location also warrants high capital expenditure and operating cost to mitigate against geohazards, as well as costs associated with the remote location. Finally, the financial calculations assume a zero-terminal value for the power plant after 35 years even though other geothermal plants around the world operate long after their design life spans., Figure 16 plots undiscounted cumulative net cash flow for the full project life cycle versus time.

Lastly, an overview of the full evaluation process for Mt Augustine is presented in Figure 18 and Table 7.

Based on the results obtained from the full field evaluations, the payout time for Mt Augustine is between the year 2034 to 2035, assuming a start date of January 1st 2022. The IRR for the project has an 80% probability to be between the range of 16.44% and 20.42% with P50 equal to 18.48%. Figure 17 show the histogram distribution for IRR as it calculates today.

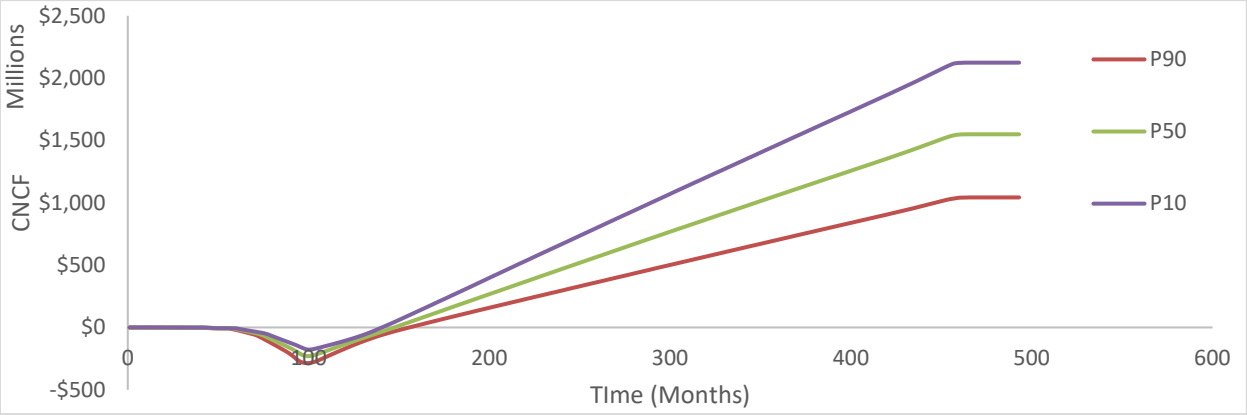

Figure 16: Undiscounted CNCF before tax versus time for different scenarios.

Table 6: Summary of the parasitic loads (Alarcón, 2023).

Type of Load	Percentage of the total capacity
Average powerplant consumption	6%
Average reinjection pumps	2.75%
Average contingency systems	2.25%
Total	11.00%

Table 7: Summary of the undiscounted economic results before tax, credits, depreciation, and project finance considerations.

Output	10%	50%	90%
Total Installed CAPEX	$ 181,496,071	$ 233,861,921	$ 287,315,152
Net Power Production Potential (MWe)	49	70	93
Number of Wells	8	11	14
Number of Slim Wells	18	27	36
CAPEX Investment Per MW	$ 3,091,623	$ 3,402,422	$ 3,771,093
IRR (35 Years)	16.44%	18.48%	20.42%
NPV (35 Years)	$ 71,403,695	$ 126,446,230	$ 185,064,641
Payout (Months)	140	147	155

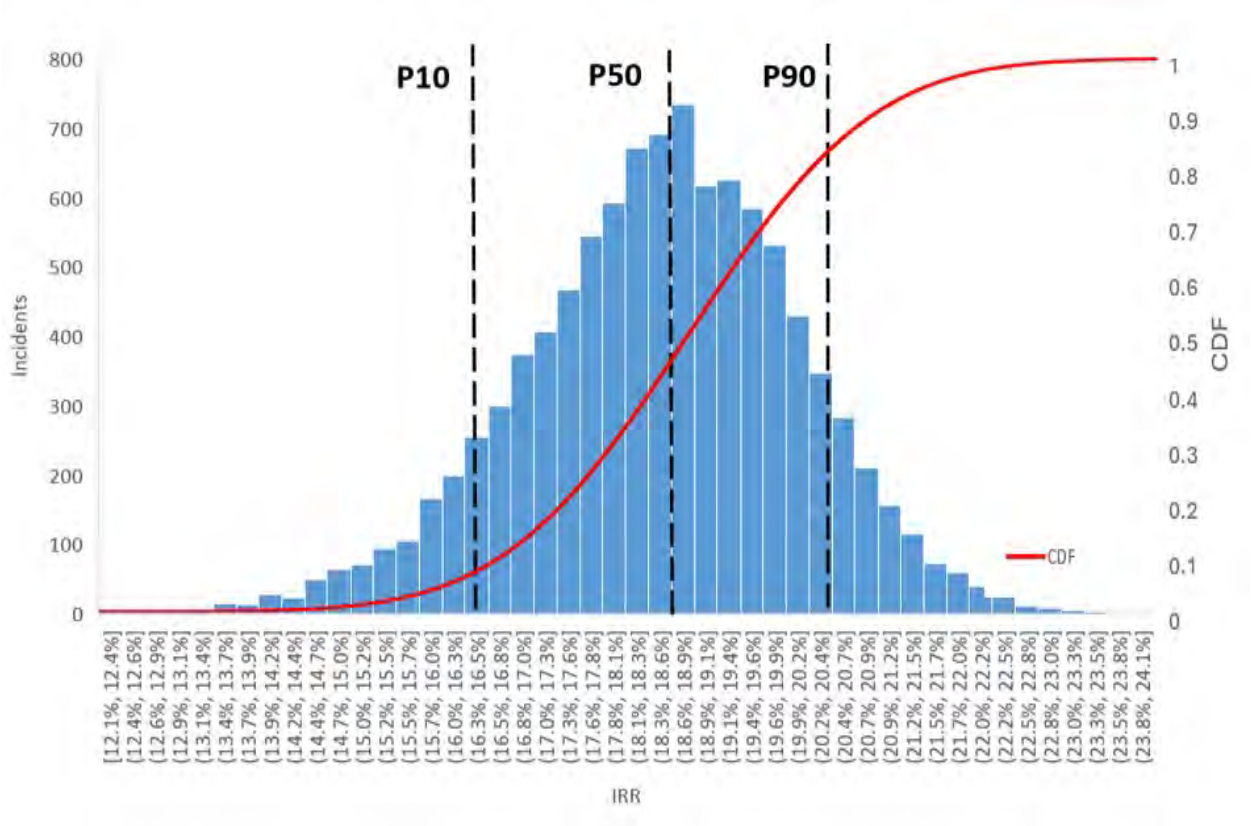

Figure 17: MCS modelling histogram distribution for IRR after 35 years. 18.48% is the P50 while P90-P10 range from 16.44 to 20.42%. CDF is the cumulative distribution function of IRR to be equal a certain value or less.

8. Next Steps

Figure 19 displays GeoAlaska's plans for exploration, appraisal. and development of the Augustine Volcano's potential geothermal resource. Our aim is to contribute to a 24/7 reliable baseload energy supply for Alaskans residing within the Railbelt Region of South-central Alaska.

GeoAlaska has commissioned additional MT data collection, processing and 3D modelling to further resolving the depth to base of the Jurassic seal, and the volume of the potential hydrothermal system identified from the 2023 dataset. GeoAlaska has expanded the survey area with the recent lease expansion; additional data will be collected across the entire south of Augustine Island to delineate the spatial extent of this and other potential prospects. During 2025, GeoAlaska intends to drill its first exploration well, the location of which will be determined by the results of the MT data analysis. The intention of the exploration well will be to penetrate beyond the base of the Jurassic seal and into the reservoir to gain information on the reservoir, fluid type, fluid flow, and temperature. This data should enable GeoAlaska to improve plans for development drilling.

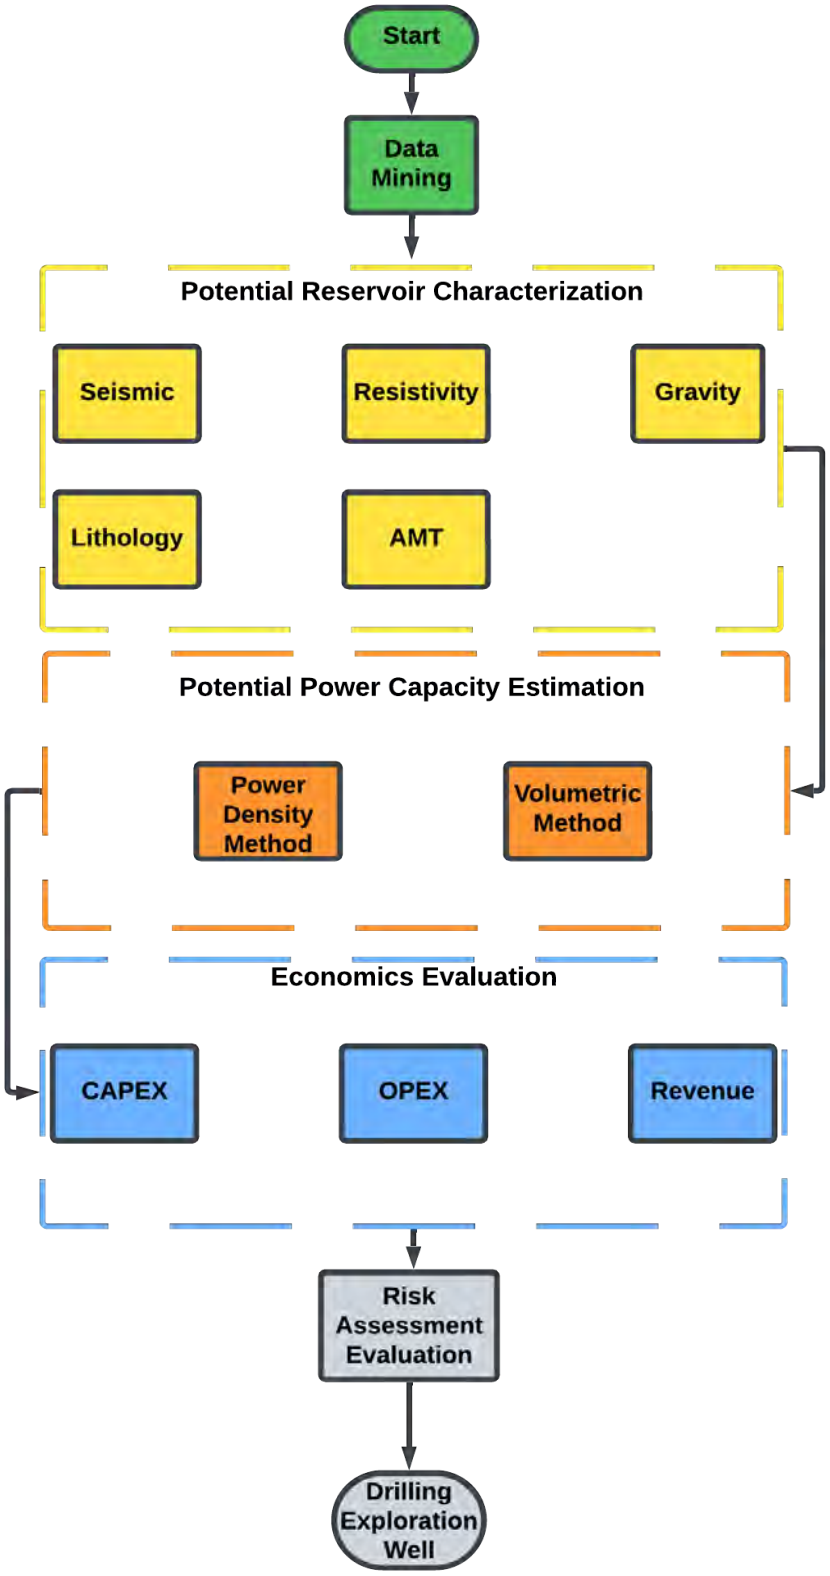

Figure 18: Mt Augustine full evaluation process.

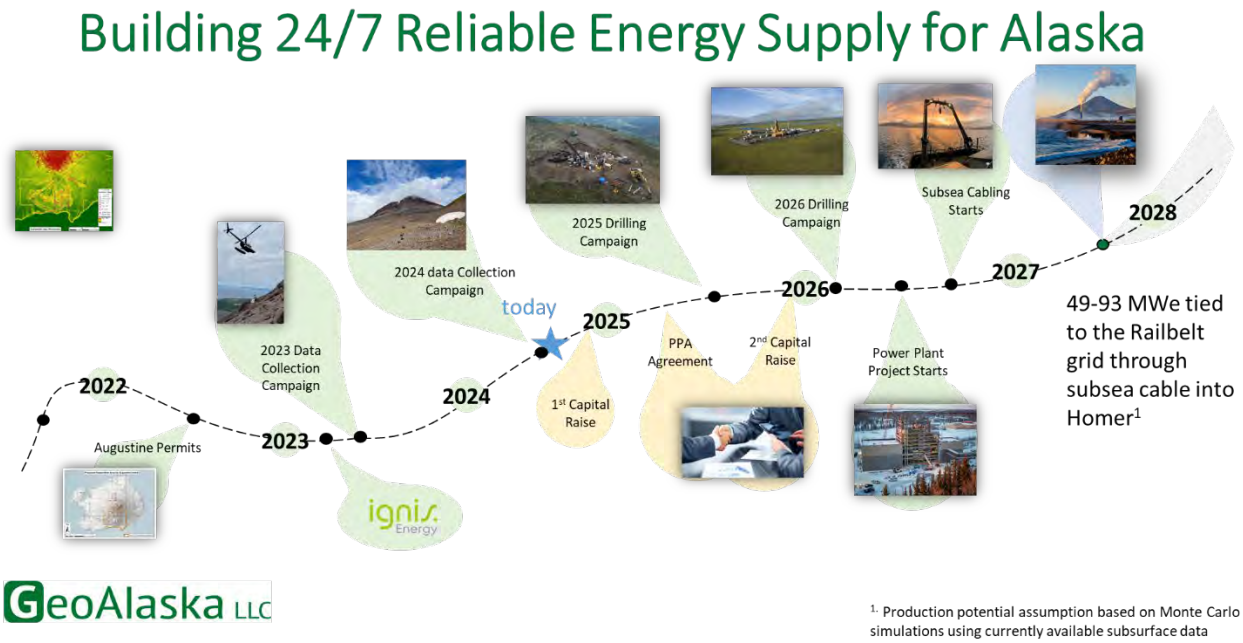

Figure 19: Expected exploration, appraisal and development timeline for Augustine Volcano geothermal project.

9. Conclusions

1. Augustine Volcano (Mt. Augustine) is an active stratovolcano located in the southwestern Cook Inlet, South-central Alaska, approximately 60 miles west of Anchor Point, Kenai Peninsula, and adjacent to the Railbelt Region of Alaska which houses approximately 550,000 residents whose current power generation is dominated by natural gas and coal.
2. The Governor of Alaska recently requested a study on the potential impacts of achieving an 80% renewable energy portfolio for South-central Alaska including any potential geothermal resource.
3. Since 2021, GeoAlaska and its partner Ignis Energy have permitted 10,830 acres and extended the original lease holding on the southern flank of Mt Augustine, with a view to explore its full geothermal potential.
4. Outcropping on the southern flank of the island are a series of silt-grade to coarse-grained Upper Jurassic Naknek Fm. sediments. Outcrop studies confirmed that these sediments can contain up to 29% smectite.
5. During the summer of 2023, AMT and Gravity data were collected over a portion of the southern flank of the island, corresponding to the first tract of geothermal prospecting permits.
6. Inversion and 3D modelling of these data suggest the presence of a low resistivity and high density seal or clay cap, corresponding to the Upper Jurassic sub-crop overlying a zone of higher resistivity which is likely to represent the underlying hydrothermal system. Based on these data, the area of the clay cap is measured at 3 km^2, while the thickness of the underlying reservoir is thought to be around 400 m.

7. GeoAlaska utilized catalog seismic data provided by the Alaska Volcano Observatory. These data corroborate the identification of a sedimentary clay cap overlying a fluid-filled zone of fractured basement.
8. Based on the assumed reservoir temperature of 280° C and all other assumptions, the potential power production was estimated using two methods, the volumetric method and the power density method. A Monte Carlo simulation predicts a P50 of 70MWe and a range (P90-P10) of 49MWe to 93MWe.
9. According to the above-mentioned economic analysis the development of Mt Augustine will require around 3.4 million USD per MWe. The IRR ranges between 16.44% to 20.42% with a payout time of 12 years from project start.
10. GeoAlaska continues to collect additional sub-surface data as a means of further de-risking the geothermal prospect(s) and to identify a suitable location to drill its first exploration well during 2025.

ABSTRACT

Targeting structurally controlled permeability in geothermal fields remains a challenge due to the difficulties in characterizing subsurface structures in terms of their hydraulic behavior within the reservoir. Measurement sensitivity in combination with approximately 80% circumferential coverage (in an 8-1/2-inch wellbore) makes the Borehole High-Resolution Resistivity Imaging Tool useful for identifying subsurface structures and providing direct data on in-situ stress orientations in the formation intersected in the logged interval. Accurate, high-resolution wellbore images paired with skilled image interpretation enables fractures and faults to be characterized as open (hydraulically conductive) or closed (non-conductive, typically due to mineral deposition). Knowledge of the depths and orientations of permeable structures is beneficial at the local scale (within the logged wells) and at the reservoir scale. The improved understanding of permeability distribution is used to optimize operations and improve decisions about future well targets in conventional hydrothermal projects.

In 2020, two exploration wells were logged on behalf of CPC Corporation Taiwan utilizing the Borehole High-Resolution Resistivity Imaging Tool, the Advanced Neutron-Gamma Logging Tool, the High-Resolution Resistivity Array Tool, and the Pressure-Temperature (PT) Logging Tool. The exploration wells are located in the Tuchang Geothermal Prospect Area, Yilan County, Northeastern Taiwan. These logs were run mainly in the 8-1/2-inch diameter production interval of the wells, and the results have been analyzed and interpreted. This has enabled improved classification of fractures and faults, including basic properties (direction), and determination of whether the fractures and faults are open or healed.

Conductive fractures and faults are observed in much of the logged interval in each exploration well; together, they show a dominant strike orientation of NE-SW, with dips measured in the range of 5°-90°. Drilling-induced fractures and borehole breakouts are also observed, with a dominant strike orientation of NNE-SSW to NE-SW for drilling induced fractures and NW-SE for borehole breakouts. The interpretation of the logging results is consistent with the predominant structural / tectonic trend in the area as most mapped faults are oriented NE-SW. conductive fractures and faults are important contributors to permeability in both exploration wells. Large conductive fractures and faults with NE-SW, NW-SE, and N-S strike orientations have been correlated to permeability indicators such as the presence of thermal plumes and sudden increases in temperature.

1. Introduction

Fluid flow in geothermal reservoirs in active tectonic regions like Iceland, Indonesia, Taiwan, the Philippines, and New Zealand is controlled mainly by permeable structures (fractures and faults) in the subsurface. Therefore, examining the location and characterization of permeable structures is an important step towards estimating the productivity of a reservoir (Brehme et al., 2016).

Targeting structurally controlled permeability remains a challenge in geothermal fields, because of the difficulties in characterizing subsurface structures and their behavior within the reservoir. The sensitivity of measurement in combination with approximately 80% circumferential coverage (in an 8-1/2-inch wellbore) makes the Borehole High-Resolution Resistivity Imaging Tool useful for identifying subsurface structures and providing direct data on in-situ stress orientations in the formation in the logged interval. Accurate, high-resolution resistivity borehole images (hereinafter referred to as 'borehole images') paired with skilled image interpretation enables fractures and faults to be characterized as conductive (possibly “open”, hydraulically conductive) or resistive (“closed”, non-conductive, typically due to mineral deposition).

In 2020, CPC Corporation Taiwan (“CPC”) drilled two deep exploration wells (X-1 and X-2) in the Tuchang Geothermal Prospect Area, Yilan County, Northeastern Taiwan (Figures 1, 2, and 3). The wells were drilled from the same well pad because it is difficult to find flat surfaces for drilling. Well X-1 (completed on 31 May 2020) was deviated SSE, with a maximum deviation of about 47° from vertical; well X-2 (completed on 15 September 2020) was deviated WSW with a maximum deviation of approximately 38° from vertical (Figure 3). Wells X-1 and X-2 encountered bottom-hole temperatures of 151°C and 134.5°C, respectively; the highest temperature measured in well X-2, however, was 150°C (at a depth of 550 meters measured depth [mMD]). Well X-1 shows a gradient of approximately 6°C/100 m at 2,000 mMD, and well X-2 encountered a slightly higher gradient of 7°C/100 m at 1,500 mMD. The temperature profiles of wells X-1 and X-2 suggest, to varying degrees, a “thermal plume” in the approximate interval of 450 to -100 m a.s.l. No losses of circulation were reported during drilling. The temperature profiles of wells X-1 and X-2 are presented in Sub-Section 4.3.

Production wells X-1 and X-2 were logged on behalf of CPC using Borehole High-Resolution Resistivity Imaging Tool, the Advanced Neutron-Gamma Logging Tool, the High-Resolution Resistivity Array Tool deployed by SLB, and Pressure-Temperature (PT) logging tool deployed by Industrial Technology Research Institute (ITRI). The Borehole High-Resolution Resistivity Imaging Tool was run mainly in the 8-1/2-inch-diameter intervals, which pass through Tertiary-age metamorphic rocks.

For the intervals where borehole image data were collected, we conducted the following analyses: borehole image processing, borehole image interpretation, and integrated fracture interpretation. This integrated analysis utilized borehole images, temperature and pressure logs, caliper logs, standard open-hole logs (including gamma ray [GR], resistivity, neutron-porosity, and density), lithological log plots from cuttings analysis, and lost circulation intervals (from drilling reports). The primary objective of this study was to deliver a comprehensive analysis of subsurface structures, encompassing fracture and fault classification, as well as the determination of the orientation and density of subsurface fractures and faults.

2. Geologic Setting

2.1 Regional Geologic Setting

The Tuchang geothermal prospect area is located approximately 30 km southwest of the city of Yilan in Yilan County, northeastern Taiwan (Figure 1). It lies in a mountainous area (known as the Central Mountain Range) with the valleys of the TuoWen and TienKuJen rivers running through it (Figures 1, 2, and 3). It is also near the Yilan plain, a major plain in northeastern Taiwan. The prospect area is approximately 1.5 km northeast of the JenTse prospect area and about 15 km southwest of the operating geothermal field at Chingshui which has a total installed capacity of 4.95 MW as of June 2024 (Figure 1).

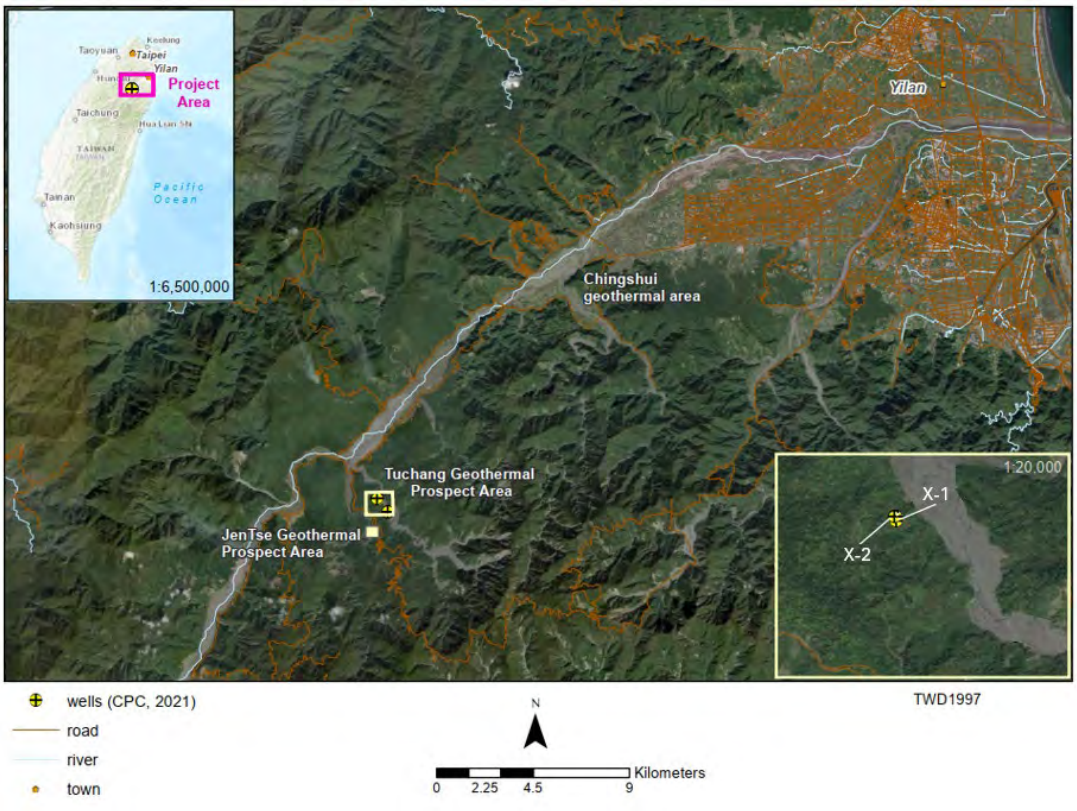

Figure 1: Location map of the Tuchang Geothermal Prospect Area, Yilan County, Northeastern Taiwan

Taiwan is a site of active orogenesis caused by the northwestward movement of the Philippine Sea Plate and its collision with the Eurasian Plate (Shyu et al., 2005; Teng, 1996) (Figure 1). The

Philippine Sea Plate subducts beneath the Eurasian Plate, leading to the formation of the Ryuku Arc in Northern Taiwan. The Okinawa Trough, extending from southwestern Kyushu Island in Japan to the Yilan Plain, is a back-arc basin in the Ryuku Arc-Trench system (Figure 2). To the south of the Yilan Plain, the northern Central Mountain Range (where the Tuchang prospect is located) has undergone a transition from a tectonic compressional regime to an extensional regime (Teng, 1996) (Figure 2). The earlier tectonic collision formed the high mountains and metamorphic rocks. The later eastward extension of the Okinawa Trough has caused the regional extension and the development of the Yilan Plain (Lai et al., 2009). The latest extension that may have occurred within the past million years in the southwestern portion of the Okinawa Trough is characterized by normal faults with vertical to sub-vertical offsets that have existed since the Late Pleistocene (Shih et al., 2018; Shyu et al., 2005).

Abundant hot springs indicate the existence of geothermal potential in the Yilan Plain and the northern Central Mountain Range (Liu et al., 2015). Borehole data and geochemical studies suggest that the temperature of the geothermal systems in the northern Central Mountain Range is on the order of 200-230°C at depths of 2,000 to 3,000 m (Liu et al., 2015; Tong et al., 2008).

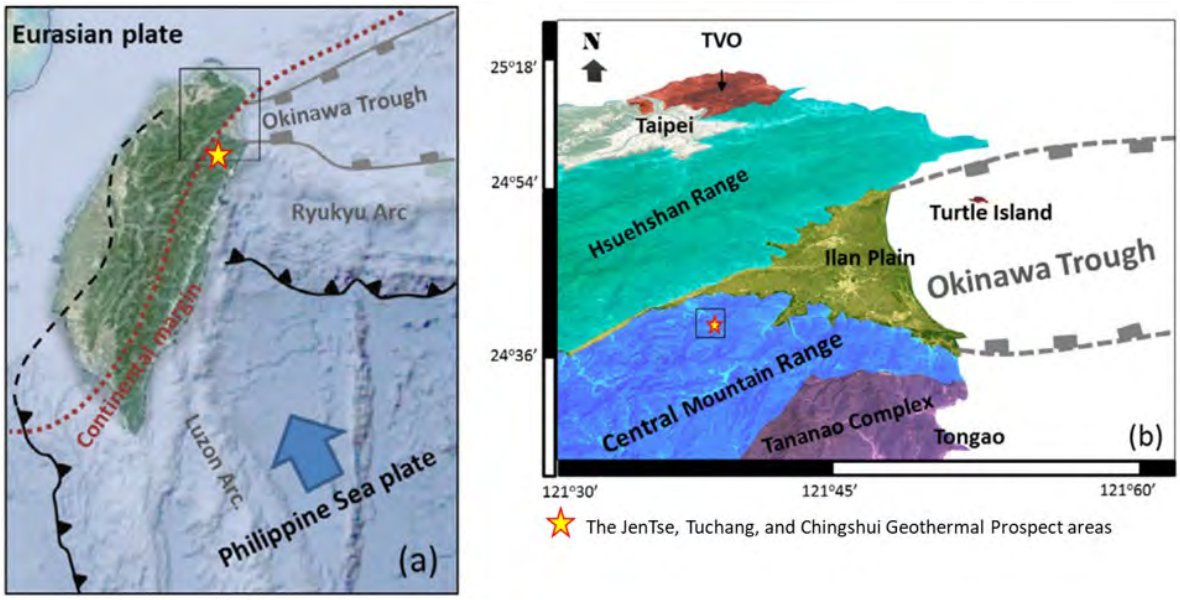

Figure 2: Regional geologic setting of the Yilan Plain and Northern Central Mountain Range (modified from Lu et al., 2017)

The primary heat source of the geothermal systems of the northern Central Mountain Range is believed to be the high-temperature metamorphic rocks in the rapidly uplifted mountain belts (Lin, 2000). In this model, the heat source of the geothermal system is the residual heat of rock formations in the Central Mountain Range which have been rapidly uplifted in the past 5 million years. Lu et al. (2017) indicated that the hydrogen and isotopic compositional data of natural hot springs and thermal water has a meteoric origin with a recharge area located at an altitude above 1,000 m, and circulates to deep levels through a fracture network controlled by regional fault systems. The meteoric water infiltrated into, and was heated by, deep rocks with a high geothermal gradient and then rose to the shallower reservoir or to the surface as hot springs.

Some geophysical and geochemical studies, however, suggest that there may be a deeper magma-related heat source in this area (Lu et al., 2017; Tong et al., 2008). Based on geologic and geophysical data, there is a possibility that the high heat flow and geothermal gradient may result from the existence of a magma chamber within the shallow crust or from shallow intrusive dikes underneath the Tuchang prospect area. There is an E-W trending high magnetic anomaly onshore (in the Yilan Plain) and a low-velocity zone underneath the offshore crust that indicate possible magmatic intrusion related to the back-arc opening of the Okinawa Trough (Lu et al., 2017 citing Tong et al., 2008; Yu and Tsai, 1979).

Geologically, the Tuchang and JenTse geothermal prospect areas are in a tectonically active region that has undergone a transition from compression to crustal extension. In principle, a graben structure in this setting would be an area of crustal thinning that is favorable for magmatic intrusion into the crust, providing a heat source for the formation of geothermal systems. A series of normal faults and opening fractures demonstrate an extensional structural setting (e.g., the NE-SW trending Dashi Fault). These faults may provide conduits for magma to rise easily and erupt at the surface as a volcano (e.g., Kueishantao to the NE of Yilan Plain), and to intrude beneath the Tuchang prospect area and the Yilan Plain. Lu et al. (2017) inferred that the fluid for hydrothermal alteration in the area was probably related to the magmatic source; this is also supported by oxygen and carbon isotopes.

The "Slate Belt" of the northern Central Mountain Range is one of the regions of high geothermal potential in Taiwan. It is mainly comprised of tight host rocks (slate formations) which have low primary porosity; these host rocks are also impermeable if they are not faulted and/or fractured (Liu et al., 2015; Song and Lu, 2019). Fault-related and/or fracture-related permeable structures are believed to be the main migration paths for geothermal fluid in the northern Central Mountain Range (Chang et al., 2014; Lu et al., 2017, 2020; Tong et al., 2008; Chiang et al., 2015). However, studies suggest that not all the faults (and their associated fractures) in this region are effective geothermal fluid conduits (Chang et al., 2014; Chiang et al., 2015; Lu et al., 2018, 2020; Tong et al., 2008). It has also been demonstrated that Tertiary-age metamorphic rocks of the Central Mountain Range have lost their original porosity; thus, fault and/or fracture permeability is essential for production of thermal fluids (Chen, 1985). Several explored geothermal reservoirs in the Central Mountain Range area are hosted by Tertiary-age metamorphic rocks, with production from faults and/or fractures in slate and metasandstone; the latter is generally more productive, having higher fracture permeability than slate (Chen, 1985).

2.2 Lithology and Structural Setting of the Tuchang Prospect Area

2.2.1 Lithology

The slightly fractured sub-metamorphic slate of the Miocene Lushan Formation is the predominant rock widely exposed in the Tuchang geothermal prospect area. The Miocene Lushan Formation is part of the "Slate Belt" discussed above. The Lushan Formation can be divided into three members based on lithological differences: the Kulu Member (which exhibits good development of slaty cleavage, with a few beds of fine-grained metasandstones; it does not crop out in the prospect area); the Chingshuihu Member (mainly composed of slate or phyllite with thin beds of metasandstones; it crops out in the western and northwestern portions of the prospect area); and the JenTse member (composed mainly of very-fine-grained metasandstone intercalated with slate,

with some fine-grained to medium-grained metasandstones [up to 35 m thick] on the bottom; it is highly fractured, and crops out in the central and eastern portions of the prospect area) (Figure 3).

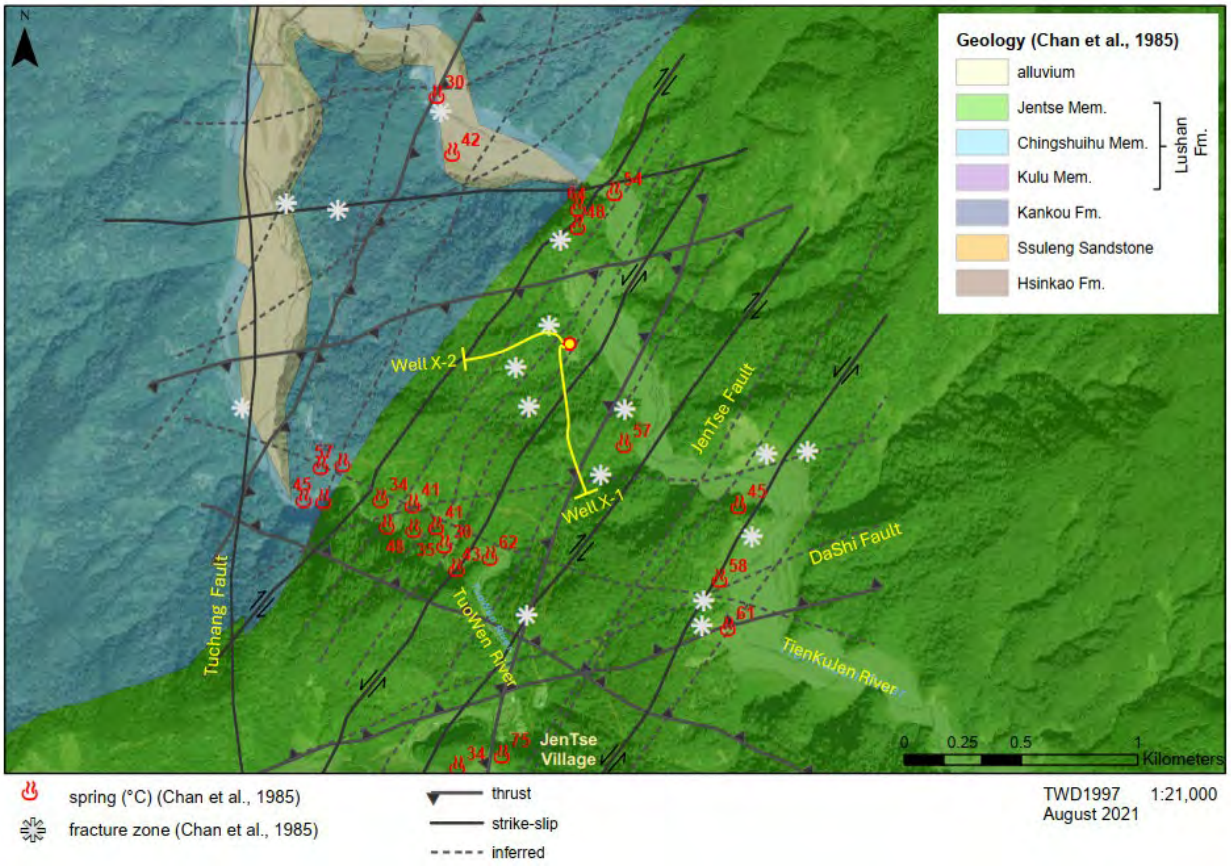

Figure 3: Geologic map of the Tuchang Geothermal Prospect Area

2.2.2 Structural Setting

The Tuchang geothermal prospect area is transected by prominent faults trending NE-SW, with some faults trending NW-SE, N-S, and ENE-WSW also present in the area (Figure 3). The widths of the fault zones range from less than one meter to tens of meters on outcrops; their offsets, however, are minor. The extensions of the faults / fault zones are difficult to determine due to poor continuity of the outcrops.

Some low- to high-temperature springs and fracture zones in the Tuchang geothermal prospect area are associated with certain faults and/or areas of fault intersections (Figure 3). Some major right lateral strike-slip faults, thrust faults, and normal faults have been identified from surface geologic mapping (Figure 3).

Outcrop data indicate that fractures are well developed in the Tuchang prospect area, mainly along faults or fault zones (Figure 3). Mapping by previous investigators (e.g., Hsiao and Chiang, 1979) indicates that fractures are well developed mainly in the JenTse Member of the Lushan Formation. Two dominant fracture sets in the area were reported: (1) NE-SW striking fractures dipping 70° to 80° to the southeast; and NW-SE striking fractures dipping 60° to 90° to the southwest.

The rugged terrain in the Tuchang area may be related to the development of fracture systems (Hsiao and Chiang, 1979). Rivers and valleys in the area trend almost parallel to the faults and/or fractures (N-S, NW-SE, and NE-SW) (Figure 3).

2.2.3 Geothermal Manifestations

The important geothermal manifestations in the Tuchang prospect area consist of several low- to high-temperature springs with minor associated hydrothermal alteration. They appear mainly along the banks of the TuoWen and TienKuJen Rivers and rock cliffs (Figure 3). Temperatures of the springs range from 30°C to more than 75°C with pH from 7.0 to 8.0. The springs issue mainly from the JenTse Member of the Lushan Formation, and are associated with faults, areas of fault intersections, and fracture zones (Figure 3).

3. Borehole Image Processing and Interpretation

3.1 Data

Wells X-1 and X-2 were logged using Borehole High-Resolution Resistivity Imaging Tool, the Advanced Neutron-Gamma Logging Tool, the High-Resolution Resistivity Array Tool, and PT logging tool. In well X-1, these logs were run in the intervals of 10 to 300 mMD (17-inch section of the well), 300 to 747 mMD (12-1/4-inch section), and 753 to 1,980 mMD (8-1/2-inch section). In well X-2, they were run in the interval of 250 to 1,480 mMD (8-1/2-inch section).

3.2 Borehole Image Processing

The primary purpose of computer processing of resistivity data is to convert the raw data into the best visual representation of the borehole. Proper conditioning of the data is achieved using certain correction algorithms, prominent examples of which are:

3.2.1 Image Correction / Equalization

Processing of the borehole image data was carried out on the SLB's Techlog* wellbore software platform using the Well Bore Imaging (WBI) workflow. A basic quality control test of the inclinometry data from raw images was used to determine if the borehole image is correctly oriented. This test computed the offsets needed to correct accelerometer and magnetometer variables and determined if correction was required. The main Speed correction module in Techlog was used, using frame time and Z-axis acceleration to compute tool acceleration and tool velocity at every depth. Tool sticking is detected to avoid incorrect computation of the variables when the tool is temporarily stuck. The speed-corrected image is then normalized using the Histogram Equalization module.

3.2.2 Image Orientation

The image is oriented with respect to the north of the borehole.

* Mark of SLB

3.2.3 Image Depth Shift / Depth Match

When logging tools are run in sequence, differences occur in depth from tool to tool and from run to run due to differential cable stretch. Stretch can be pronounced when the logging string sticks or temporarily hangs up in the hole. All logging measurements must be adjusted to a common depth reference before data processing can continue. All depths should be referenced to a base log selected from a logging tool where strong or forceful tool positioning is not used (e.g., GR log from the Advanced Neutron-Gamma Logging Tool). Free-moving tools travel through the borehole more smoothly than tools that are pushed with great force against the borehole wall. For this reason, logs run with strongly centralized tools (e.g., Borehole High-Resolution Resistivity Imaging Tool) are not selected as the base log.

3.2.4 Image Normalization

The image is normalized by assigning a color spectrum of user-defined bins to the resistivity data to obtain image pixels that are representative of a particular bin size. When all pixels are viewed together the normalized image is produced. Two types of normalization – static and dynamic – are performed.

In static normalization a preferred spectrum of colors, in this case 128, is distributed over the data interval. This technique provides a good overall representation of the data, highlighting major resistivity variations. Higher resolution normalization is achieved through the process of dynamic normalization, where a preferred spectrum of colors (up to 128) is distributed over a 1-meter window length. A sliding window method is applied to the whole data interval. The normalized images produce an optimized image of the resistivity data and are usually presented side-by-side on interpretation plots.

3.2 Borehole Image Interpretation

The processing of borehole images was followed by interactive dip picking and feature classification using normalized images. The dip picking enabled computation of the dip angle of lithological boundary, fracture, fault, and/or any other planar features. Drilling-induced fractures and borehole breakouts were also easily recognizable in most situations. Interactive dip picking was performed manually using a sine wave, with its amplitude and azimuth fitted to planar features on the image.

3.3 Integrated Fracture Interpretation and Analysis using Borehole Images and Standard Open-Hole Logs

Integrated fracture interpretation and analysis using borehole image and standard open-hole logs (e.g., GR, resistivity, neutron-porosity, density, pressure, and temperature) are conducted to better classify the natural fractures, to get the fracture properties (direction and density / intensity), to better determine whether the fractures are (possibly) open or closed, and to assess the permeability of the subsurface fault or fracture. With the sensitivity of the measurement of borehole imaging (in combination with their circumferential coverage), the natural fractures, possible faults, beddings / foliations, drilling-induced fractures, and borehole breakouts are reliably characterized.

4. Results of Borehole Image Processing and Interpretation

4.1 Borehole Image Log Quality and Borehole Conditions

Borehole log inclinometry data from wells X-1 and X-2 (collected using the General-Purpose Inclinometry Tool, or GPIT) show good coherency with the wells' deviation and azimuth data, indicating that the tools were correctly oriented in the boreholes and that the calculated dips are correct.

The borehole conditions of both wells are generally good, with only a few large and minor washouts, and the image quality is generally good to excellent.

The Borehole images are in general on-depth with standard open-hole logs.

4.2 Borehole Image Manual Dip Classification

Structural features were picked manually using sine waves, with their amplitudes and azimuths fitted to planar features on the borehole image. The lowest point of the sinusoid troughs defines the dip azimuths, and the amplitude of the sinusoids define the dip magnitudes.

All dip interpretations have been made using a combination of static and dynamic normalized images, along with gamma-ray, resistivity, and neutron-porosity logs, and results of cutting analysis.

In resistivity images, the fractures that have conductive traces (represented by dark colors) are termed conductive fractures. The fractures are further classified into three types based on their appearance and continuity across the borehole diameter:

- Conductive Fractures: the predominant fracture type, they appear as low- to high-angle planar features with good continuity across the borehole and strong contrast with the surrounding rock (Figure 4[a]).
- Bedding Fractures: rare compared to the conductive fractures, mostly recognized in or near the fault zones. These fractures appear as medium- to high-angle planar features with good continuity across the borehole and strong contrast with the surrounding rock. Due to their similarity to bedding planes, these features are classified as Bedding Fractures (Figure 4[b]).
- Fissures: these fractures appear as low- to moderate-angle planar features with relatively poor continuity across the borehole and weak contrast with the surrounding rock (Figure 4[a]).

The study focused especially on conductive fractures which, due to conductive drilling mud, are conventionally assumed to be open and hydraulically conductive, although care must be taken with such an assumption because conductive fractures can also be clay-filled or pyrite-filled.

Fractures with resistive traces (represented by white / light colors) are termed resistive fractures. Resistive fractures are generally considered to be closed or healed (filled with resistive minerals such as calcite and quartz) (Figure 4[c]).

Conductive faults or possible faults have also been identified (Figure 4[d]), with diagnostic features including (but not restricted to): indications of large conductive events developed across

the wellbore (Figures 4[d] and 5[c]), enlarged hole at faults, abrupt termination of fractures and/or bedding surfaces on the fault plane (Figure 5[c]), sharp facies changes, dip magnitude and / or azimuth changes of beddings (Figure 5[c]), and the presence of fractures around the fault (Figure 4[d]).

Drilling-induced tensile fractures and borehole breakouts were identified where they occur on opposite sides of the borehole wall (Figures 5[a] and 5[b]). Although these features do not have a dip direction or dip magnitude, their strikes can be defined and used to indicate the maximum and minimum horizontal stress directions.

The intervals logged in wells X-1 and X-2 are comprised of metamorphic rock formations. The lithologies are mainly slate and metasandstone of the JenTse Member of the Lushan Formation. Bedding of these lithologic units can be observed on the borehole image (Figures 4[b] and 5[d]).

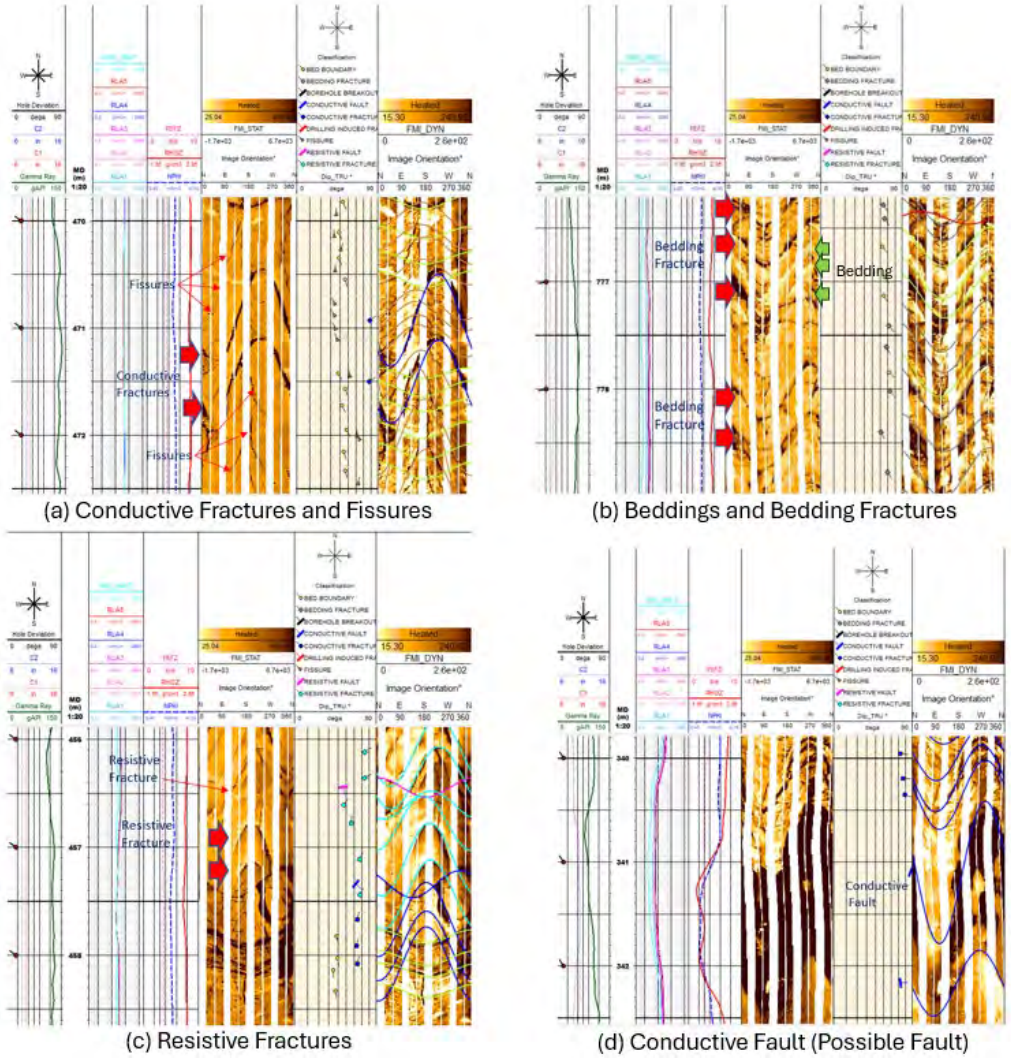

Figure 4: Borehole image examples of conductive fractures and fissures (a), beddings and bedding fractures (b), resistive fractures (c), and conductive fault / possible fault (d) from wells X-1 and X-2

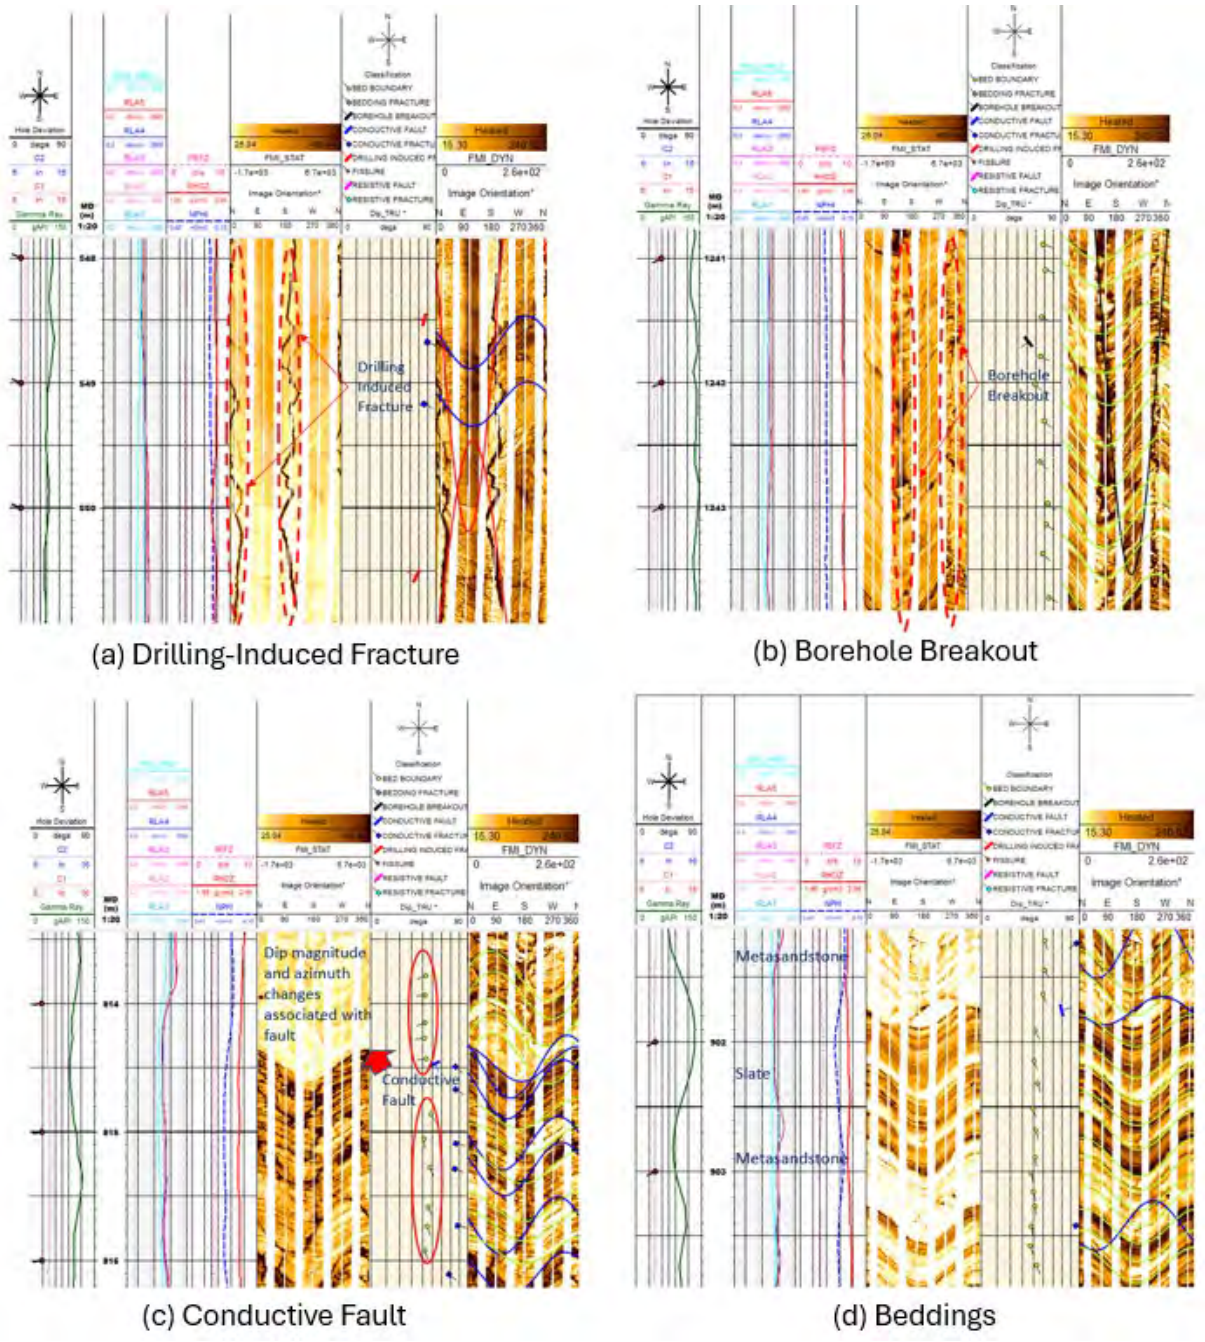

Figure 5: Borehole image examples of drilling-induced fracture, borehole breakout (b), conductive fault (c), and bedding (d) from wells X-1 and X-2.

4.3 Borehole Structural Interpretation

4.3.1 Borehole Image Structural Interpretation of Well X-2

Structural interpretation includes identifying and determining the orientation of fractures and faults and determining the present-day tectonic stress field orientation from drilling-induced features and borehole breakouts. Detailed structural analysis was performed for the interval of 250 to 1,480 mMD (within the 8-1/2-inch section of the well).

Bedding is observed on the borehole image; it is developed mainly in the slate and appears as a repetitive layering (which can be conductive and/or resistive) (Figure 5[d]). Bedding dip statistics in the interval show a dominant azimuth orientation of southeasterly, though some northwesterly dips are also present. Bedding dip magnitudes are from approximately 5° to vertical. High-angle bedding is usually associated with faults / fault zones. These bedding orientations reflect the major structural / tectonic trend in the area.

Fractures are well developed over almost the entire interval logged. The fractures identified from borehole images are almost exclusively conductive (considered to be open). Some resistive (considered to be closed) fractures were also recognized. Fracture types and morphology in well X-2 are described below:

- Conductive Fractures: the predominant fracture type. Conductive-fracture dip statistics over the interval show dominant strike orientations of NE-SW, NW-SE, and N-S with NE, SE, E, and W azimuths (Figures 6 and 7). Dip magnitudes for this fracture type are highly variable, from approximately 5° to vertical. These conductive fracture orientations reflect the major structural / tectonic trend in the area as discussed in Section 2.
- Bedding Fractures: bedding-fracture dip statistics in the interval indicate dominant strike orientations of NE-SW with SE azimuth. The dip magnitudes of the bedding fractures vary from approximately 10° to nearly vertical. These bedding fracture orientations reflect the major structural / tectonic trend in the area, as discussed in Section 2.
- Fissures: in well X-2, fissures were recognized in a few intervals near the fault zones. Fissure dip statistics in the interval indicate dominant strike orientations of ENE-WSW, NNE-SSW, and WNW-ESE with W, NNW, and N azimuths. The dip magnitudes of the fissures are from 30° to 40°.
- Resistive Fractures: resistive-fracture dip statistics over the interval demonstrate dominant strike orientations of NW-SE with NE azimuths. Dip magnitudes for this fracture type are highly variable, from approximately 10° to vertical.

Conductive faults (or possible faults) were recognized on the borehole images. Their dip statistics show dominant strike orientations of NE-SW with SE and NW azimuths (Figures 6 and7). Dip magnitudes for conductive faults vary from approximately 15° to vertical. These orientations reflect the major structural / tectonic trend in the area as discussed in Section 2. Well X-2 was drilled near some mapped NE-SW trending faults; in the subsurface this well might encounter some of these faults / fault zones.

The temperature data of well X-2 suggest a thermal plume at 50-600 mMD, and large conductive fractures and faults are well developed within this interval (Figure 7). Conductive-fault and conductive-fracture dip statistics over the interval of 250 to 600 mMD demonstrate dominant strike orientations of NE-SW, N-S, and NW-SE, with SE, E, NE. and W azimuths (Figure 7). Dip magnitudes for conductive fault and conductive fracture over the interval of 250 to 600 mMD are highly variable, from approximately 15° to vertical.

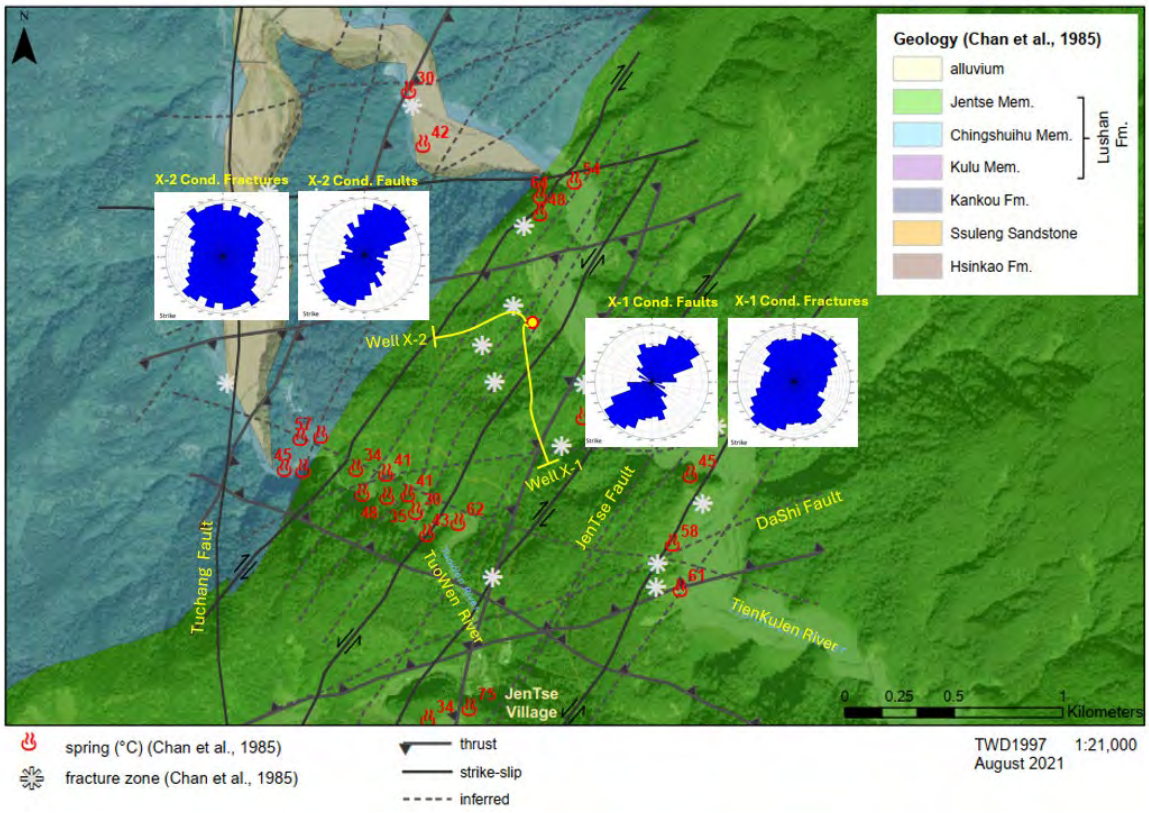

Figure 6: Geologic map of the Tuchang Geothermal Prospect Area showing surface geologic structures and strike orientations of conductive fractures and faults from wells X-1 and X-2.

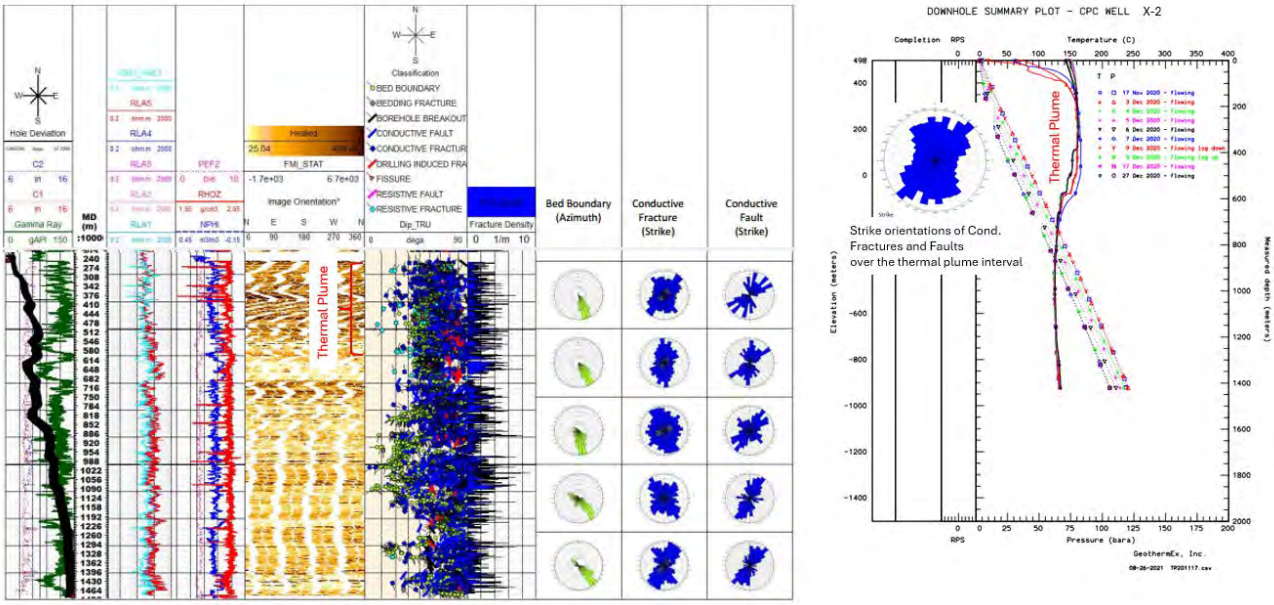

Figure 7: Integrated fracture interpretation and analysis of well X-2. The temperature data suggests a thermal plume in an interval of 50-600 mMD, and large conductive fractures and faults are well developed within this interval. Conductive-fault and conductive-fracture dip statistics over the interval of 250 to 600 mMD demonstrate dominant strike orientations of NE-SW, N-S, and NW-SE.

4.3.2 Borehole Structural Interpretation of Well X-1

Detailed structural analysis of well X-1 was performed for the intervals of 10 to 300 mMD (17-inch section of the well), 300 to 747 mMD (12-1/4-inch section), and 753 to 1,980 mMD (8-1/2-inch section).

Like X-2, the interval logged in well X-1 is comprised of metamorphic rock formations, mainly slate and metasandstone of the JenTse Member of the Lushan Formation. Bedding is observed on the borehole image, with dip statistics showing dominant azimuth orientations of southeasterly and northwesterly. Main dip magnitudes are from approximately 30° to 50° and 65° to 85°. High-angle foliation surfaces are usually associated with fault(s) / fault zone(s). These foliation surface orientations reflect the major structural / tectonic trend in the area. A major change in bedding dip azimuth is observed at a depth of approximately 1,450 mMD; this change is associated with a major fault / fault zone.

Fractures are developed over almost the entire interval logged in well X-1. The fractures identified from borehole images are almost exclusively conductive (considered to be open). Resistive fractures were also recognized in the studied interval.

- Like well X-2, conductive fractures are the dominant fracture type in well X-1. Conductive-fracture dip statistics over the interval demonstrate dominant strike orientations of NE-SW and NW-SE, with NW, NE, and SE azimuths (Figure 6). Dip magnitudes for this fracture type are highly variable, from approximately 5° to vertical. These conductive fracture orientations reflect the major structural / tectonic trend in the area as discussed in Section 2.
- Bedding fractures are rare compared to the conductive fractures. Bedding-fracture dip statistics in the interval indicate dominant strike orientations of NE-SW with SE and NW azimuths. The dip magnitudes of the bedding fractures vary from approximately 20° to vertical. These bedding fracture orientations reflect the major structural / tectonic trend in the area as discussed in Section 2.
- In well X-1, fissures were recognized in some intervals near the fault zones. Fissure dip statistics in the interval indicate dominant strike orientations of NW-SE with NE and SW azimuths. The dip magnitudes of the fissures vary from approximately 10° to vertical.
- Resistive fractures were also recognized on the borehole image, with dip statistics indicating dominant strike orientations of E-W and NW-SE, with N, NE, and SE azimuths. The dip magnitudes vary from approximately 15° to vertical.

Conductive faults (or possible faults) were recognized on the borehole images. Conductive-fault dip statistics over the interval demonstrate dominant strike orientations of NE-SW with SE and NW azimuths (Figure 6). Dip magnitudes for conductive fault vary from approximately 5° to vertical. These orientations reflect the major structural / tectonic trend in the area as discussed in Section 2.

Temperatures measured in well X-1 suggests a thermal plume in an interval of 60 to 650 mMD. Some large conductive fractures and faults are developed in this interval. Conductive-fault and conductive-fracture dip statistics over the interval of 60 to 650 mMD demonstrate dominant strike orientations of NE-SW and NW-SE, with NW, SE, NE, and N azimuths. Dip magnitudes for conductive faults and conductive fractures over the interval of 250 to 600 mMD are highly

variable, from approximately 10° to vertical. However, a 9-5/8-inch casing has been set in this interval, thus, the well currently produces from a deeper reservoir whose top is at a depth of approximately 1,450 mMD. A major fault / fault zone is observed at about 1,450 mMD; it is associated with a major dip azimuth change of the bedding and good development of conductive fractures. Well X-1 also demonstrates a "positive" deflection of temperature (to higher readings) in this fault / fault zone, which might be associated with permeable fractures and/or fracture network. Conductive fractures around 1,450 mMD depth show dominant strike orientations of NW-SE and NE-SW, with dip magnitudes from about 10° to near vertical. Conductive faults around this depth show dominant strike orientation of NE-SW with dips mainly steeper than 80°.

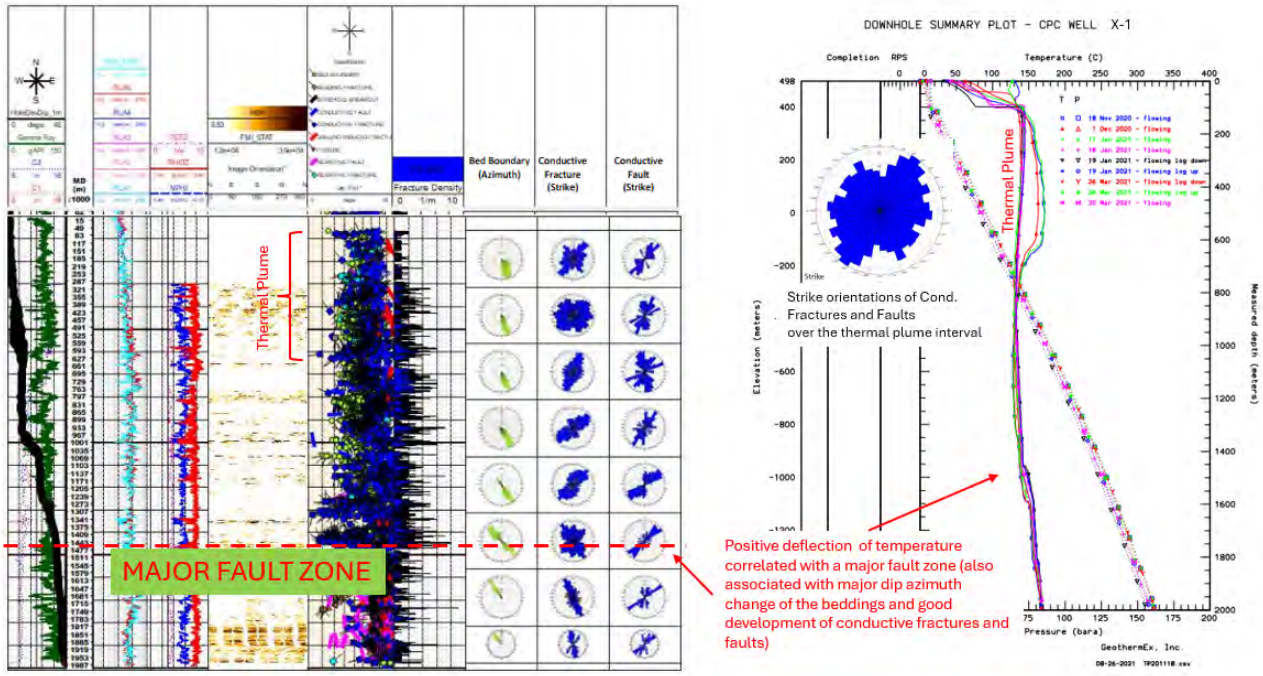

Figure 8: Integrated fracture interpretation and analysis of well X-1. The temperature data suggests a thermal plume in an interval of 60-650 mMD, and large conductive fractures and faults are well developed within this interval. Conductive-fault and conductive-fracture dip statistics over the interval of 60 to 650 mMD demonstrate dominant strike orientations of NE-SW and NW-SE. A "positive" deflection of temperature (observed at a depth of 1,450 mMD) is correlated with a major fault zone (that is associated with a major dip azimuth change of the beddings and good development of conductive fractures and faults. Conductive fractures and faults around 1,450 mMD depth show dominant strike orientations of NW-SE and NE-SW).

4.3.3 Analysis of *In-Situ Stress Orientations*

The Earth's crust rarely stays in a lithostatic stress condition (with stresses equal in all directions; that is, $\sigma1 = \sigma2 = \sigma3$). The equilibrium of the stress state is generally disturbed by movements of tectonic plates, leading to the formation of a regional stress system, which may itself be partially or completely overprinted by localized stresses associated with faults, folding, diapirism, volcanism and so forth. The orientation of such local stresses may change abruptly over short distances in any area.

Wells drilled in areas subjected to unbalanced stresses often exhibit two types of borehole failures (shear failure and tensile failure) when the rocks they penetrate are replaced by drilling fluid. The

rocks can bear both compressive and shear stresses, but the fluid filling the borehole can bear only compressive stress. Consequently, concentration of stresses takes place around the borehole in the form of hoop stress or tangential stress. When the mud weight is too low (i.e., radial stress = mud weight minus pore pressure), the maximum hoop stress becomes much higher than the radial stress. Consequently, a shear failure of rocks exposed to the borehole takes place; this appears as borehole elongation on the orthogonal calipers and as long dark regions on the borehole images that are 180 degrees apart.

Conversely, when the mud weight is too high, the radial stress increases and the hoop stress decreases; consequently, the rock around the borehole comes under tension and fails in tension. The fractures thus created are called drilling-induced fractures, which appear as fractures seen in the borehole images oriented at 180 degrees from each other.

Generally, in vertical to near-vertical wells, the axis of borehole elongation is aligned with the trend of minimum horizontal stress, and the strike of drilling-induced fractures is aligned with the trend of maximum horizontal stress. However, this may not be the case for deviated wells, particularly those that are not aligned with either of the two horizontal stresses. In such wells, the orientations of borehole breakouts and drilling-induced fractures may not represent the true orientation of the two horizontal stresses, because all three principal stresses (vertical and two horizontal) act obliquely to the borehole.

In the intervals logged in well X-1, both drilling-induced fractures and borehole breakouts are developed. Drilling-induced fractures demonstrate a strike orientation of NNE-SSW/NE-SW, and borehole breakouts show a strike orientation of NW-SE.

Both drilling-induced fractures and borehole breakouts are also developed in the interval logged in Well X-2. Some drilling-induced fractures demonstrate a strike orientation of NNE-SSW/NE-SW (Figure 5[a]). Some borehole breakouts show a strike orientation of NW-SE (Figure 5[b]).

Wells X-1 and X-2 have maximum deviations of approximately 47° and 38° from vertical, respectively; thus, the strikes of drilling induced fractures and borehole breakouts may not align with the trends of maximum and minimum horizontal stress, respectively, though in general they agree with the major structural / tectonic trend. The maximum horizontal stress direction (S_{Hmax}) observed in the image logs aligns with the dominant structural strike trend (NNE-SSW/NE-SW) observed in the prospect area.

5. Conclusions

Surface exploration indicates that the Tuchang geothermal prospect area is transected mainly by faults trending NE-SW, with some faults trending NW-SE, N-S, and ENE-WSW also present. Outcrop data indicate that fractures are well developed in the prospect area, mainly along faults or fault zones. There are two dominant fracture sets in the area: NE-SW and NW-SE.

Subsurface data (i.e., borehole images) indicate that fractures are well developed over almost the entire intervals logged in exploration wells X-1 and X-2. Conductive fracture is the predominant fracture type. Conductive-fracture dip statistics over the intervals logged in wells X-1 and X-2 demonstrate dominant strike orientations of NE-SW, NW-SE, and N-S with NW, NE, SE, E, and

W azimuths. Dip magnitudes for this fracture type are highly variable, from approximately 5° to vertical. These orientations reflect the major structural / tectonic trend in the area.

Conductive faults (or possible open faults) were also recognized on the borehole images, with dip statistics that show dominant strike orientations of NE-SW with SE and NW azimuths. Dip magnitudes for conductive faults are highly variable, from approximately 5° to vertical. These orientations reflect the major structural / tectonic trend in the area. Wells X-1 and X-2 were drilled near some NE-SW trending mapped faults; in the subsurface the wells might encounter some of these faults / fault zones.

In general, the *in-situ* horizontal stress orientations agree with the major structural / tectonic trend. The maximum horizontal stress direction (S_{Hmax}) observed in the image logs aligns with the dominant structural strike trend (NNE-SSW/NE-SW) observed in the field.

Conductive fractures and faults (or possible faults) are important contributors to permeability in both wells. Large conductive fractures and faults have been correlated with permeability indicators, e.g.:

- Thermal plume intervals observed in Tuchang's exploration wells X-1 (at 60 to 650 mMD) and X-2 (50-600 mMD / 250-600 mMD [the Borehole High-Resolution Resistivity Imaging Tool was not logged from 50-250 mMD]) are associated with good development of large conductive fractures and faults which trend mainly NE-SW, NW-SE, and N-S.
- A "positive" deflection of temperature (to higher readings) in well X-1 (observed at a depth of 1,450 mMD) is correlated with a major fault zone, which is associated with a major dip azimuth change of the bedding and good development of conductive fractures and faults. Conductive fractures and faults around 1,450 mMD depth show dominant strike orientations of NW-SE and NE-SW.

Lahendong, geothermal system, reservoir characteristic, reservoir compartment

ABSTRACT

Lahendong geothermal field is located in North Sulawesi Province about 30 km south from Manado City. The exploration of geothermal resources in Lahendong and surrounding area has been initiated since early 1980's by PT. Pertamina and identified two prospects which are Lahendong and Tompaso on north and south part of the field respectively. Lahendong geothermal field is the pioneer of geothermal power generation in North Sulawesi region and currently is operating 4 x 20 MW.

39 (thirty-nine) wells have been drilled in Lahendong Geothermal field to support the power generation. Integrated geoscientific and reservoir data from the wells reveal interesting fact that the reservoir in Lahendong is compartmentalized with discrete reservoir characteristics. There are at least 2 (two) main upflows which are upflow from beneath Linow volcanic crater lake and upflow from beneath Kasuratan volcano. The later hydrology is also divided into 2 (two) blocks which are North Kasuratan and South Kasuratan. They also having distinct characters.

Identification of discrete reservoir within Lahendong geothermal system is manifested in the conceptual model and later provided the foundation for numerical model. This knowledge is also important for determining production and injection strategy for sustainable exploitation of geothermal fluid.

1. Introduction

Lahendong geothermal prospect is located within two administrative areas which are Minahasa County and City of Tomohon, North Sulawesi Province (Figure 1.1). Exploration of geothermal resources in Lahendong has been initiated since 1982-1983 by conducting geoscientific surveys (geology, geochemistry and geophysics). There are 2 prospects identified in Lahendong Geothermal Concession which are Lahendong and Tompaso on North and South part of the field respectivley. Both prospects have their own geothermal system although they are located within greater Tondano Caldera volcanic complex.

Currently Lahendong geothermal field is operating 4 x 20 MW geothermal power plants (GPP) and delivering 80 MW to North Sulawesi electricity grid system by PT. Pertamina Geothermal

Energy Tbk (PGE). Understanding of geothermal system and reservoir characteristic of Lahendong field is crucial as the basis for managing sustainable reservoir for years of contract lifetime.

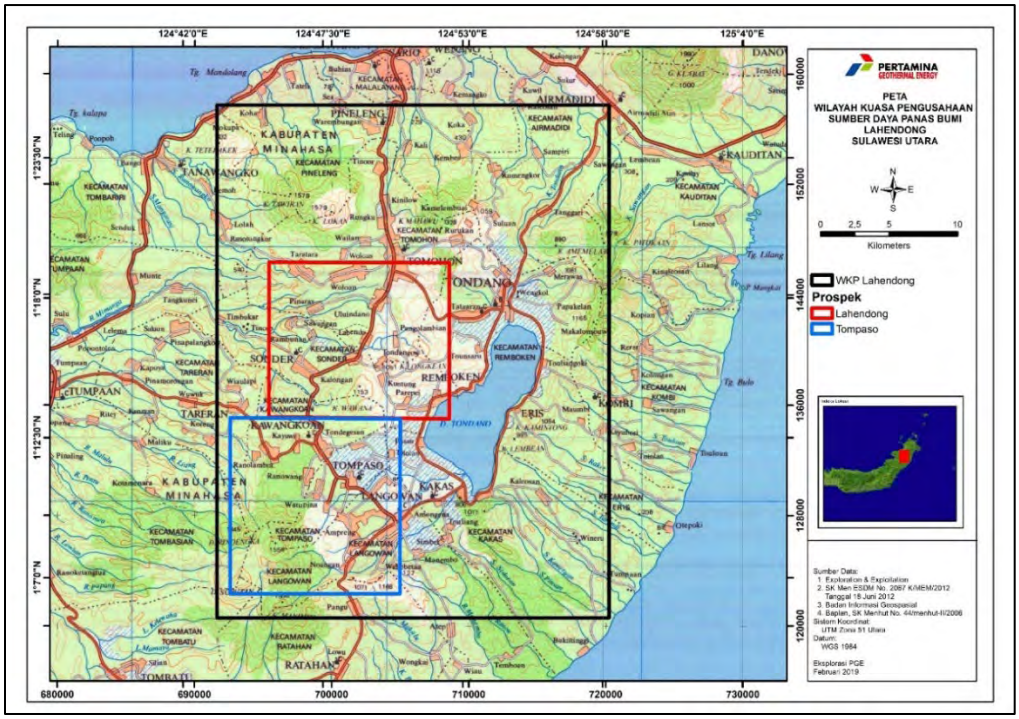

Figure 1. Map of Minahasa geothermal concession map consisting of Lahendong and Tompaso on north (red box) and south (blue box) respectively.

2. Lahendong Geothermal System

Lahendong Prospect lies in Pangolombian Caldera which is located within Tondano Caldera. The caldera is about 4 km wide, and it erupted about 0.45 mya according to the latest dating of its deposits. It is located on the west side of Tondano Lake and inside of the Pangalombian Caldera. Several younger quaternary volcanic edifices may act as potential heat sources of Lahendong geothermal system, such as Mount Kasuratan, Mount Tampusu, Linau Crater Lake and Mount Lengkoan. They are volcanoes related to the Pangalombian Caldera.

The lithology in Lahendong consists of predominantly Quaternary volcanic rocks. Although there are some Tertiary Volcanics and carbonate rocks intersected by deep exploration wells in Lahendong, those rocks are not found on the surface. The rock composition in Lahendong is mainly andesitic to rhyolitic. Pyroxene andesite is common as the product of andesitic lavas from volcanoes such as Kasuratan and Tampusu. while pumice, pumiceous tuff, obsidian is some of the products from rhyolitic volcanoes.

The structural geology of the field is mainly affected by the subduction of Halmahera Plate beneath the Sulawesi plate on the east. Although the local stress regime may be modified due to the resultant of regional stress regime. The main structural trends in Lahendong consist of NE-SW and NW-SE with minor N-S directions.

The components of geothermal system of Lahendong field consist of: 1. Potential heat sources from diorite intrusions beneath Mt. Kasuratan and Linow lake; 2. The hydrothermal activity in shallow part resulting impermeable argillic clay cap mainly developed inside Pangalombian Caldera and extent toward north and south; 3. The reservoir rocks consist of primary permeability from Tuff, Lapilli Tuff and volcanic breccia whereas NE-SW and N-S faults provide secondary permeability from fractures; 4. The origin of fluid is coming from meteoric water sources mainly from Mt. Lengkowan area in the south-west.

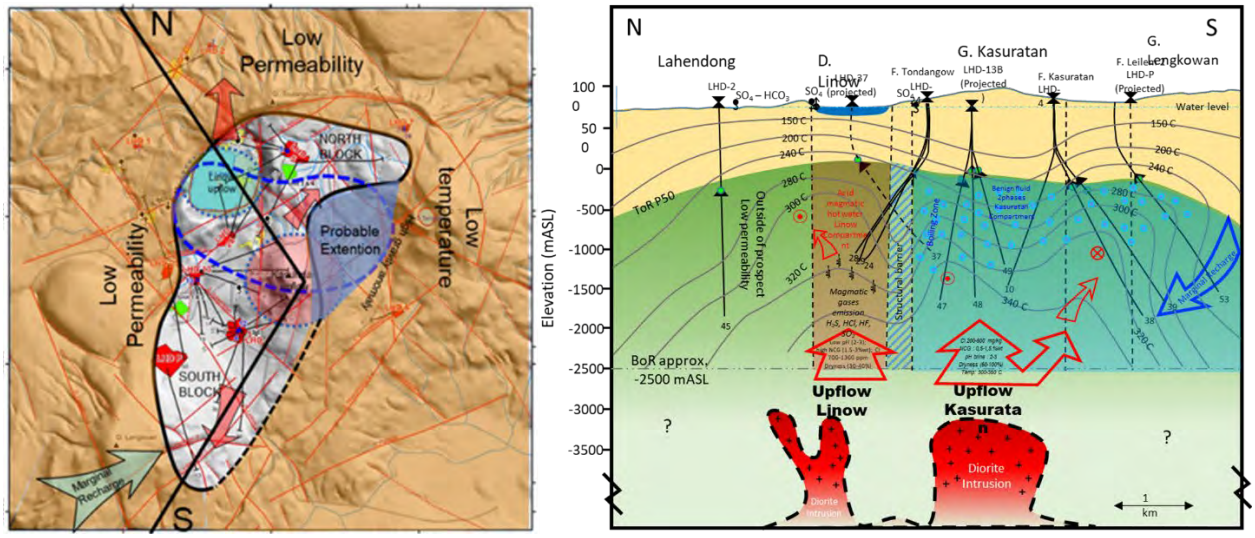

Figure 2. Hydrology and conceptual model of Lahendong geothermal system.

There are two upflows in Lahendong which are rising from beneath Mt. Kasuratan and Linow crater lake. Both have been confirmed by wells and geochemical characteristics. The fluid up flows from Kasuratan and moves laterally toward north and south. Hydrothermal fluid also rises beneath Linow crater lake and outflows to the north. The later system is young and influenced by magmatic components.

3. Reservoir Characteristics

Lahendong Geothermal field is naturally a water-dominated geothermal system which has relatively shallow water table. It has very high temperature characteristics with a range of 250 to 360^{0}C. The highest temperature anomaly distribution lies in the middle and south, especially around the Mt. Kasuratan area with measured temperature range of 320 to 360^{0}C. The reservoir pressure of the Lahendong is in the range of 100 to 160 bar with the reservoir water level at an elevation of about 750-800 masl. The feedzone depths around -300 s.d -1100 mdpl with range of permeability medium to high. The dryness has also wide range numbers between 11 – 100 % with current production decline of 4%/year. This wide range of numbers in reservoir parameters is mainly due to compartmentalized reservoir.

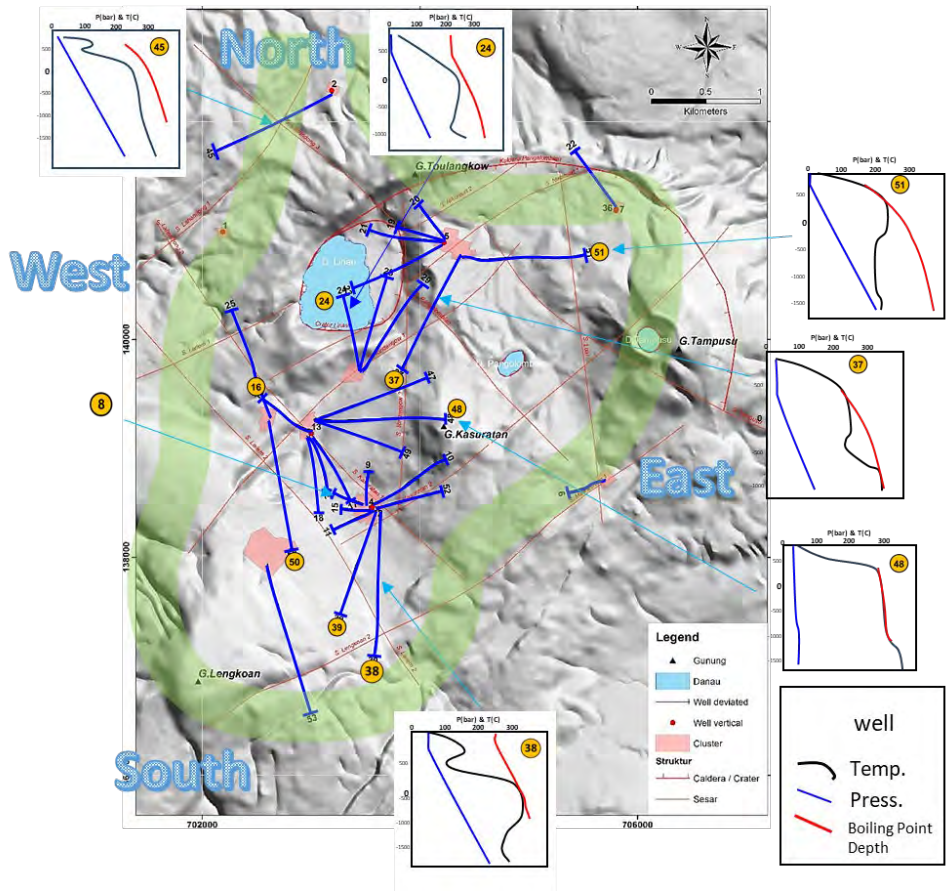

Figure 3. Distribution of temperature across Lahendong reservoirs.

3.1 Reservoir Compartmentation

Mainly there are 2 reservoir compartments inside the Pangalombian Caldera which hosts Lahendong geothermal system, they are:

Linow Compartment

Linow reservoir is located in Linow eruption crater at the North West edge of Pangalombian Caldera. The reservoir compartment is restricted by the collapse rim of Linow Lake. The main feature of this compartment is the influence of acid magmatic fluid. The characteristics of this reservoir compartment are as follow:

- Hot water dominated system with initial dryness of 40-60%
- Reservoir temperature ranges of 280-300 C and enthalpy of 1500-1800 kj/kg
- High permeability but located in limited area around LHD-23 and 28
- The chemistry of fluid shows low pH (2-3), High NCG (1.5-3%wt), and chloride concentration of 700-1300 ppm.

Kasuratan Compartment

Kasuratan reservoir is located around Mt. Kasuratan as the main upflow zone. It is divided into 2 blocks which have distinct characterics. The blocks are as follow:

- *North Block:* covers the area of Pangalombian and east of Linow lake. The characteristics of this reservoir block are: Hot water dominated reservoir (dryness 11-15%), Temperature range of 230-250 C and enthalpy of 900-1000 kJ/kg; high permeability (ii=80-2000 lpm/ksc); the chemistry of fluid shows benign (pH 7-8), NCG (0.2-0.5%wt), and chloride concentration of 300-400 ppm.
- *South Block:* covers area of Mt. Kasuratan, South and South West flank of Mt. Kasuratan, and E – SE flank of Mt. Lengkowan. This block is characterized by its 2-phase vapor dominated reservoir (60-100% dryness); high temperature and enthalpy (300-360 C and 1900-2600 kJ/kg respectively); low to medium permeability (ii 0.025 – 336 lpm/ksc); The chemistry shows benign fluid (pH 6-7) with NCG (0.2-1.3 wt%) and Chloride concentration of 300-500 ppm.

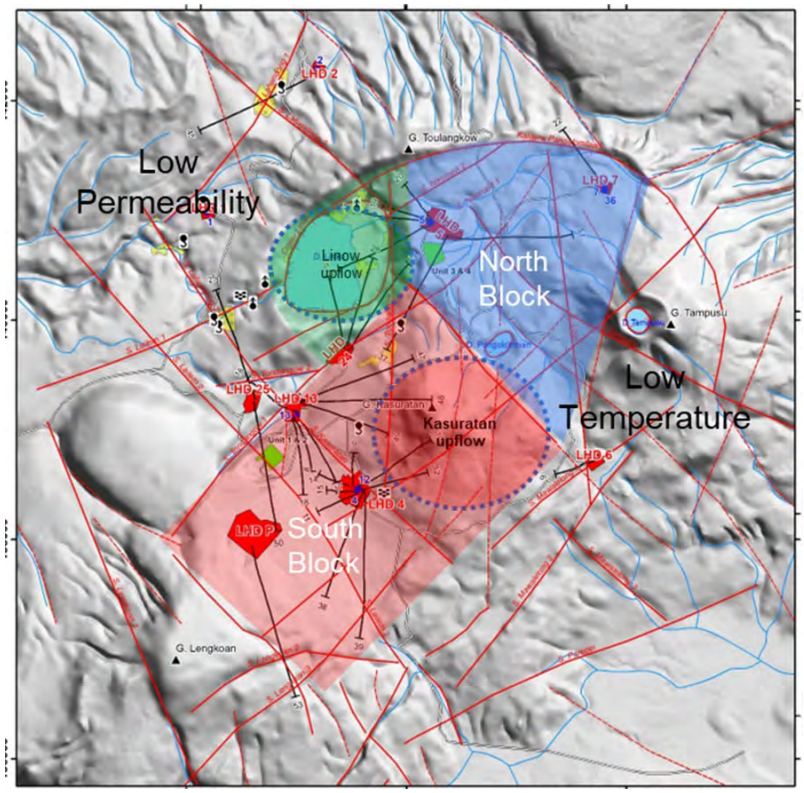

Figure 4. Reservoir compartments of Lahendong geothermal system.

4. Discussion

Lahendong geothermal field features a unique system that combines both two-phase high enthalpy and lower enthalpy reservoirs within Mt. Kasuratan reservoir compartment. Additionally, an acid magmatic upflow rises beneath Linow Lake, isolated from other compartments. The boundaries between these compartments and reservoir blocks are governed by geological structures. The Linow Lake compartment is bounded by the crater rim of Linow Lake, while the North and South blocks of Mt. Kasuratan are divided by the Kasuratan Fault. These geological structures play a crucial role in distinguishing the reservoir characteristics.

The overall heat anomaly in the Lahendong prospect is notably high. The temperature in the south block of Mt. Kasuratan reaches a maximum of 360°C, the highest recorded temperature among PGE fields. This high temperature correlates with low to medium permeability. However, due to

the high enthalpy of the two-phase system, well output remains substantial. Conversely, the north block of Mt. Kasuratan has a lower temperature but higher permeability, resulting in lower enthalpy and dryness. This also necessitates significant brine management or injection.

5. Conclusion & Recommendation.

Understanding reservoir characteristics in a geothermal field is crucial for its development. When a field has discrete characteristics, effective reservoir management is necessary to sustain production and identify opportunities for expansion.

In the Lahendong field, the south block of Mt. Kasuratan serves as the main production zone, while the north block is used for injection. Some wells in the north block can flow at low pressure, presenting an opportunity to install low-pressure turbines and binary plants in the future. Linow Lake wells continue to be used for production, with appropriate treatment of acid magmatic fluid.

Acknowledgement

We would like to express our appretiation to the management of PGE for the opportunity to publish this paper.

Geology, Drilling, Conceptual Model, Image Log Analysis

ABSTRACT

The Puna Geothermal Venture (PGV) is a 38-MW combined cycle power plant producing from a two phase, liquid-dominated, 280-320°C (±535-610°F) resource located at a prominent left-step in Kilauea's East Rift Zone on the Island of Hawai'i. Drilling results and interpretation of available geoscientific datasets reveal a deep reservoir with fracture-dominated permeability controlled primarily by rift-parallel fractures with some contribution from rift-cutting features.

The 2018 Kilauea eruption forced plant shutdown and resulted in a recovery campaign which brought the plant back online in 2020. Following plant restart a new drilling campaign was completed, adding two new wells to the production field and one new well to the injection field and bringing PGV generation to over 32 MW for the first time since the eruption. An acoustic borehole image log was successfully acquired for the first time at PGV during this drilling campaign, providing new insights into subsurface conditions and permeability controls. In this paper we integrate available geologic, geophysical, and geochemical to provide a conceptual framework for the PGV system.

1. Introduction

Exploration for naturally occurring geothermal systems as a source of independent power production has been ongoing in the state of Hawai'i since at least the early 1960s. Numerous state and federally funded projects have studied Hawai'i's geothermal potential through a variety of geological, geophysical, and geochemical surveys, as well as exploration drilling to test hypotheses resulting from surface exploration (e.g., Furumoto et al., 1977; Thomas, 1986; Lautze et al., 2017; Warren et al., 2023). The Island of Hawai'i was the focus of early exploration efforts due to its active volcanism and the presence of surface manifestations of geothermal systems, such as hot springs, which other islands lack. Kilauea volcano and its associated rift zones are the most favorable regions for Hawaiian geothermal exploration due to the colocation of necessary elements for the formation of hydrothermal systems: elevated shallow heat flow (from young volcanism), a

fluid-saturated subsurface (implied by the high annual rainfall and location on an oceanic island), and permeable fluid pathways to support natural convective processes (suggested by active tectonic dilation along the rift zones).

Geothermal exploration on the Island of Hawai'i began in 1961 with the drilling of four exploration wells by Hawaii Thermal Power Company in Kilauea's Lower East Rift Zone (LERZ) near a prominent left step in the rift zone's fissures. The wells (TH-1, -2, -3, & -4) encountered elevated groundwater temperatures ranging from 109° to 203°F (43° to 95°C) at depths from 216 to 686 ft but were plugged and abandoned, lacking temperatures high enough for energy production (DPED, 1982). Following an extensive geophysical survey of the LERZ from 1973-1975, the Hawai'i Geothermal Project utilized federal, state, and county grant funds to drill the HGP-A resource discovery well near Pu'u Honua'ula, the initial eruptive fissure for the 1955 LERZ eruption. HGP-A was completed in April 1976 to 6450 ft (1966 m) measured depth (MD) with a bottom hole temperature of 676°F (358°C) (Takahashi et al., 1985). The well produced 110 kph at 166 psig with ~43% steam fraction to a 3MW turbine generator from 1981-1989, marking the onset of geothermal energy production in Hawai'i. Additional exploration drilling along the LERZ during the 1980-1990s by competitor companies and the State of Hawai'i/University of Hawai'i demonstrated the existence of high temperatures along the LERZ, but high permeabilities were never encountered and production was not sustained from any of the Lanipuna, Ashida, or Scientific Observation Hole (SOH) locations (Figure 1).

Figure 1: Regional map of Kilauea's Lower East Rift Zone. The PGV lease area is shown in hatched blue, with faults shown in black (Moore and Trusdell, 1991) and fissures from the 2018 eruption in red (Zoeller et al., 2020). Geothermal exploration wells are shown in white, and warm springs in orange.

PGV was the first and only commercially productive geothermal power plant in Hawaii and provided 31% of the island's electrical demand in 2017. PGV began commercial operation of a >600°F (315°C) naturally occurring geothermal system with an Ormat-supplied 30 MW combined cycle power plant with 100% reinjection of produced fluids in 1993. The project was acquired by Ormat in June 2004, and over the years generation has increased by upgrading the facility, through resource development, and with the addition of two bottoming OECs (Ormat Energy Converter) which produced more energy from the brine. As of 2012, the facility was comprised of a combined cycle (steam turbine with binary condenser) air cooled plant and two brine binary units with a nameplate capacity of 38 MW. The plant operated continuously from startup in 1993 until plant shutdown in May 2018 due to a volcanic eruption along the LERZ. Recovery efforts to the facility began in early 2019 following cessation of the eruption in late September 2018. The plant was brought back online in November 2020 after an extensive campaign to restore both the power plant and wellfield, which included workovers, re-drills, and initially the drilling of 3 new wells.

Following plant restart, a drilling campaign from 2022-2023 successfully three new wells, with the additional production brine helping to increase PGV's generation to >32 MW for the first time since the eruption. As part of the planned completion testing for the campaign an acoustic borehole image log was acquired in the northernmost well, the first successful image log at PGV.

As of this writing (June 2024), there have been 20 full-sized "KS" (Kapoho State) wells drilled at PGV with a total of 39 discrete legs considering original holes (OH), twins (e.g., KS-1A), multi-leg completions (ML), redrills (RD), and sidetracks (ST). Production wells are primarily clustered on the southern side of the wellfield, with injection wells primarily on the northern side of the field (Figure 2).

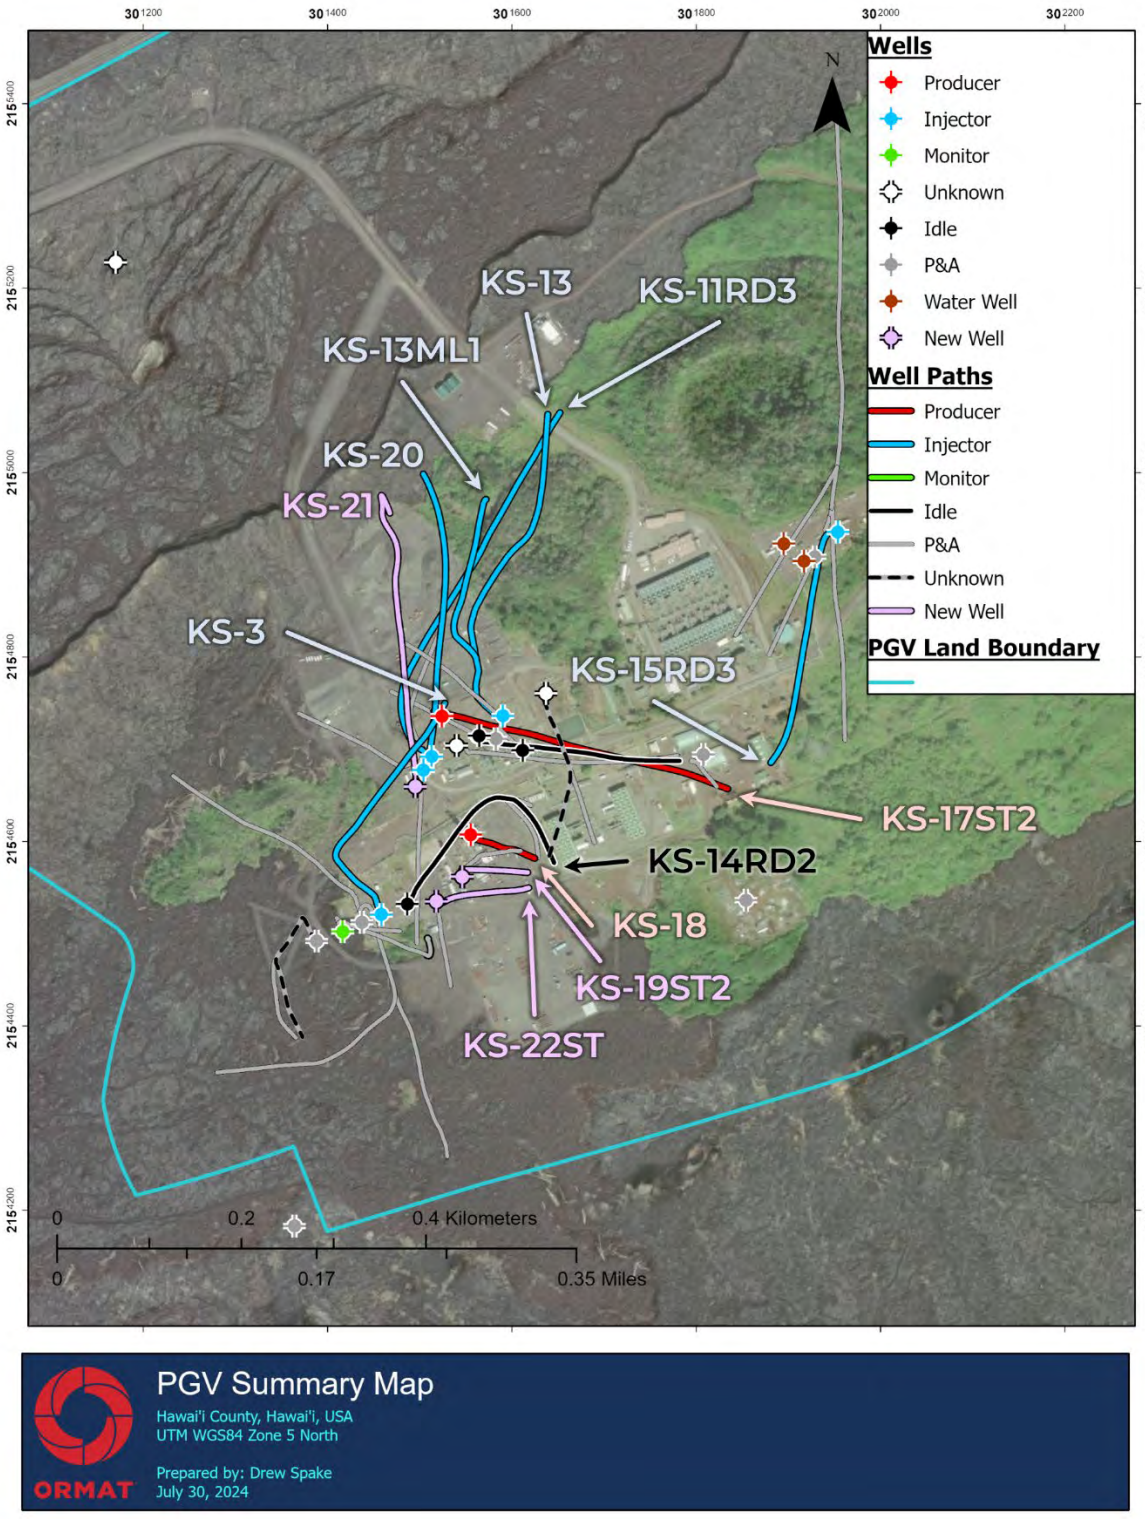

Figure 2: PGV wellfield map. Directional well paths are shown with colors corresponding to the well's status, with new wells completed during the 2022-2023 drilling campaign indicated separately. The bottom hole location of new wells and active production/injection wells are labeled (other wells left unlabeled for clarity).

2. Geology

2.1 Regional Geology and Tectonic Setting

The hydrothermal system at PGV is located in a volcanic rift zone associated with the Kilauea volcano on the Island of Hawai'i. The Hawaiian-Emperor island chain is a string of 8 major and 129 minor islands and seamounts formed by a mantle plume hot spot over the past ±70 MA (Wilson, 1963). The Island of Hawai'i is the youngest, southernmost member of the archipelago and encompasses five major shield volcanoes (from oldest to youngest: Kohala, Mauna Kea, Hualālai, Mauna Loa, & Kilauea). An older, sixth volcano, Māhukona, lies beneath sea level off the northwestern tip of the island, while Kama'ehuakanaloa (formerly Lō'ihi), represents active growth of the newest volcano in the chain southeast of Kilauea (Sherrod et al., 2021).

Magma supply to Hawaiian volcanoes originates with upwelling of mantle melt at an intraplate "hot spot" (Wilson, 1963; Morgan, 1971). On the Island of Hawai'i, Kilauea and Moana Loa share magma supply from the hot spot but likely have separate, though proximal, storage chambers (Poland et al., 2014). The general model for Kilauea's magma plumbing system is that magma generated in the mantle at 30-60 km depth ascends and is stored at neutral buoyancy in reservoirs that are 2-4 km beneath the summit and almost wholly molten rift zones at 3-10 km beneath the surface (Eaton and Murata, 1960; Ryan, 1988) (Figure 3).

Hawaiian volcanoes are built through successive stages of volcanism, quiescence, and erosion. An idealized model of Hawaiian volcano evolution involves four eruptive stages: (1) a pre-shield submarine alkalic stage, (2) a tholeiitic shield-building stage, depositing ≥95% of the volume of the volcano, (3) a post-shield alkalic stage which deposits a thin cap of alkalic basalt and differentiated lavas, and (4) an alkalic rejuvenation stage characterized by isolated vent eruptions following several million years of dormancy and erosion (Clague and Dalrymple, 1987). Deposits found on the Island of Hawai'i represent stages 1-3, with the active Mauna Loa and Kilauea depositing primarily tholeiitic basalts through shield-stage volcanism (Sherrod et al., 2021).

Kilauea's oldest deposits are ±275 ka alkalic, pre-shield submarine basalts which were sampled from the southern slope of the volcano by remotely operated submersibles, presumably representing submarine lava flows (Lipman et al., 2002). The SOH-1 exploration core hole drilled on the eastern flank of the volcano records a transition from subaerial to submarine deposits at ±551 m below sea level in a sequence comprised entirely of tholeiitic lava flows and dikes (Trusdell et al., 1999; Sherrod et al., 2021). Surface mapping shows that Kilauea's subaerial stratigraphy is composed of three major units (oldest-youngest): (1) the Hilina Basalt, (2) the Pahala Ash, and (3) the Puna Basalt (Sherrod et al., 2021). The Hilina Basalt is exposed only in fault scarps located along the southern flank of the volcano, while the Puna Basalt covers nearly the entire surface of Kilauea (Langenheim and Clague, 1987; Sherrod et al., 2021).

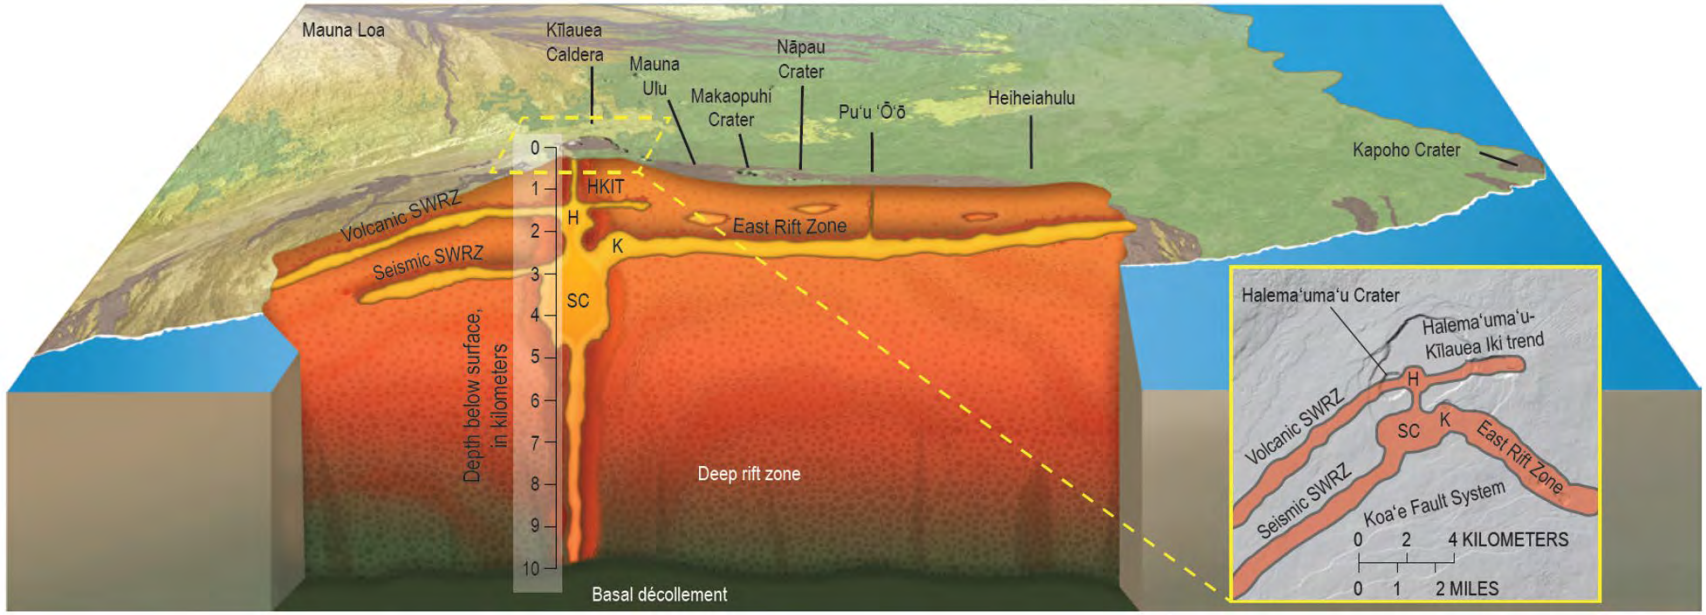

Figure 3: Illustration of Kilauea's magma plumbing system. Schematic cross section depicts the magma pathways and storage areas (exaggerated in size). K, Keanakāko'i reservoir; SC, south caldera reservoir; SWRZ, Southwest Rift Zone. Schematic viewing direction is from south to north. Plan view gives the relations of magma pathways to surface features and topography in the vicinity of Kilauea Caldera. (Figure and text reproduced from Poland et al., 2014).

Kilauea is cut by two rift zones which emanate from the summit caldera: the East Rift Zone (ERZ) and Southwest Rift Zone (SWRZ) (Figure 4). The two rift zones are bridged by the Koa'e Fault and Hilina Fault zones, deeply rooted normal fault systems accommodating southeastward displacement along the rift zones (Lipman et al., 1985, Duffield, 1975). Beginning in the 1950s, the ERZ became the most active part of Kilauea's magmatic system (Poland et al., 2014). Magma movement along the rift is facilitated by seaward extension of Kilauea's mobile southern flank, which acts to dilate the rift zone (Patrick et al., 2020). Motion of the south flank is likely accommodated by slip along a basal decollement 6-11 km deep at the interface between pre-Mauna Loa oceanic crust and the overlying volcanic edifice (Lipman et al., 1985).

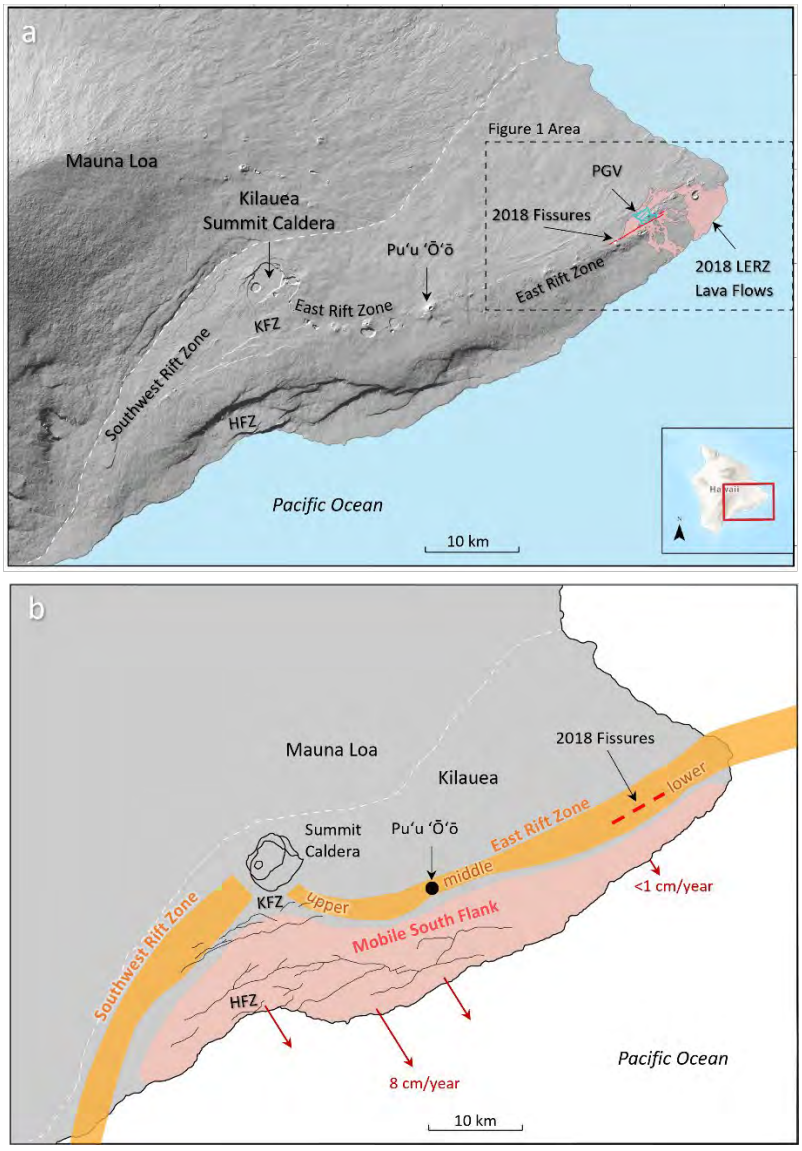

Figure 4: (a) Map of Kilauea volcano. The approximate boundary between Mauna Loa and Kilauea lavas is denoted by the dashed white line and the area of Figure 1 is shown by the black dashed box with PGV's location indicated in hatched blue. (b) Schematic structural map of Kilauea volcano showing the summit region and two rift zones. The mobile south flank exhibits steady southeast motion and is tightly coupled with the rift magmatic system. KFZ: Koa'e Fault Zone. HFZ: Hilina Fault Zone. (Figure modified from Patrick et al., 2020).

The East Rift Zone extends southeast from the summit caldera for approximately 7 km, then trends ±063° (N63°E) toward and beyond the end of the land surface. The rift is loosely subdivided into upper, middle, and lower sections and is one of the main conduits for lateral migration of magma from the holding chamber beneath Kilauea's summit caldera, with eruptions in the lower portion of the rift having occurred as recently as 1790, 1840, 1955, 1960, 1961, and 2018 (Moore and Trusdell, 1991).

The subaerial portion of the LERZ strikes 063°, is 3-4 km wide and about 23 km long, extending for an additional 70 km offshore as the submarine Puna Ridge. The LERZ is a constructional ridge characterized by low spatter deposits and cones up to ~200 ft (60 m) high (Moore and Trusdell, 1991). Its elevation gently decreases from southwest to northeast and ranges from a high of 1,713 ft (522 m) above sea level at Heiheiahulu to sea level at Cape Kumukahi (Swanson et al., 1976). The overall vent and fracture lineaments align strongly along the 063° trend and typically exhibit a pattern of en echelon step-overs.

Underlying the surface expression of the ERZ is a much broader (±12- 20 km wide) intrusive dike complex inferred by gravity (Broyles et al., 1979) and magnetic data (Kinoshita et al., 1963). This complex is thought to consist of an aggregate of closely spaced, parallel to subparallel, vertical to steeply dipping dikes intruded into a sequence of Mauna Loa and Kilauea lava flows. Individual dikes are likely <1 m to 5 m in width, though may be vertically and laterally extensive (Swanson et al., 1976; Wilson and Head, 1988).

2.2 Local Geology and Structure

All the rocks in the vicinity of PGV are Holocene tholeiitic basalts with varying abundances of olivine and pyroxene phenocrysts reflecting the relative amount of fractionation of magmas in subsidiary magma chambers along the rift zone (Moore and Trusdell, 1991; Langenheim and Clague, 1987). Pahoehoe and a'a lava flows as well as spatter deposits and small cinder cones dominate the landscape, representing eruptive events from about the year 1601 up to the most recent eruption in 2018, which overran part of the PGV wellfield and covered older deposits. Two small cinder cones and associated spatter deposits known as Pu'u Honua'ula from an eruption ±373 years before present form prominent hills on the PGV property. The power plant is constructed on a small topographic high formed by flows from the 1955 eruption which emanated from fissures at the base of the two cones. This small plateau prevented the plant from being consumed by the 2018 lava flows.

Eruptive vents on the southern side of the LERZ are commonly en echelon and right-stepping in the region west of Puulena Crater (~800 m southwest of the PGV lease). The linear alignment of vents abruptly terminates here, shifting left (northwest) by ~1 km, where they resume the 063° trend but are organized in left-stepping en echelon arrangement. The left step is well documented by seismic and magnetic datasets, however no transverse faults striking perpendicular to the main rift trend have been identified. The differential motion of the southern flank may result in failure of structural blocks bound by NW-striking faults, causing the stepover (Moore, 1992).

2.3 Downhole Geology and Structure

Subsurface geology is informed by the relatively high-density drilling over the small areal extent at the PGV project area, with additional context and regional constraints provided by publications on the early exploration wells, particularly HGP-A and the SOH holes.

Wells drilled at PGV document 3 major correlatable units, in order from shallowest to deepest: l) subaerial basalt flows 2) a transitional, near-shore assemblage dominated by hyaloclastites, and 3) submarine pillow basalts. Diabase dikes are found throughout the stratigraphic sequence but increase in frequency and width with depth. These lithologic assemblages are not internally homogeneous, and geologists working at Puna have divided the basalt stratigraphy into the following primary divisions based on physical characteristics: scoria (cinders), lavas (vesicular, aphanitic), hyaloclastite, diabase dikes (porphyritic), highly altered (observable parent texture i.e., vesicular or aphanitic) and clay (indistinguishable parent texture commonly associated with hyaloclastite and/or tephra). The hydrothermal reservoir is hosted within fractured submarine basalt flows and diabase dikes starting about 4200 ft (1280 m) below ground level (bgl) (approximately -3600ft/-1100 rSL (relative to sea level)).

The depositional environment directly affects the physical appearance of all three basalt types. Subaerial basalts, mostly a'a and pahoehoe, occur as solid flows separated by rubblized interflow breccias or sometimes totally fragmented and rubblized flows. Submarine basalt flows occur as dense conglomerates of pillows and pillow fragments infilled by ocean floor clays and silica. Dikes are typically coarser grained tabular bodies that intruded pre-existing flow basalts. Hyaloclastites are deposits of grit to sand sized granular glass fragments formed when hot, fluid basalt flows into the ocean creating phreatic explosions. The hyaloclastite material may be deposited off or near shore as black sand beaches or on shore as littoral cones and tuff rings depending on the prevailing winds and intensity of the lava-water reaction. Primary olivine tholeiites as well as differentiated basalts can be found as subaerial, submarine, hyaloclastite, or intrusive dike deposits.

Permeable fractures are commonly, but not ubiquitously, associated with the intersection of diabase dikes. Dike rock is recognized by its relatively coarse grained, hypidiomorpic, subhedral texture, its fresh, unaltered appearance, and general scarcity of secondary mineralization. In many wells the permeable fractures were encountered in the footwall side of a diabase dike after drilling through several tens of feet of diabase.

Dikes and permeable fractures are primarily interpreted to be aligned with the local strike of the LERZ (063°) and subvertical or steeply northwest dipping. Permeable fractures at PGV are generally named for the first well to have intersected the feature, e.g., the KS-5 Fracture hosts current production from the KS-19ST2 and KS-22ST wells. Key production fractures include the KS-5, KS-8, and KS-14 Fractures, and injection is hosted in the 1955 Fissure (distinguished by discrete North and South fracture zones), KS-3, and KS-20 Fractures.

In addition to the SW-NE striking features, the conceptual and numerical models include permeable pathways oriented perpendicular to the rift (NW-SE) (Murphy et al., 2024), which is supported by observed tracer return pathways and consistent with PGV's location at the major left-step in the LERZ (Figure 5). A key purpose for image log acquisition during the 2022-2023 drilling campaign was to establish if such fractures are identifiable in the subsurface.

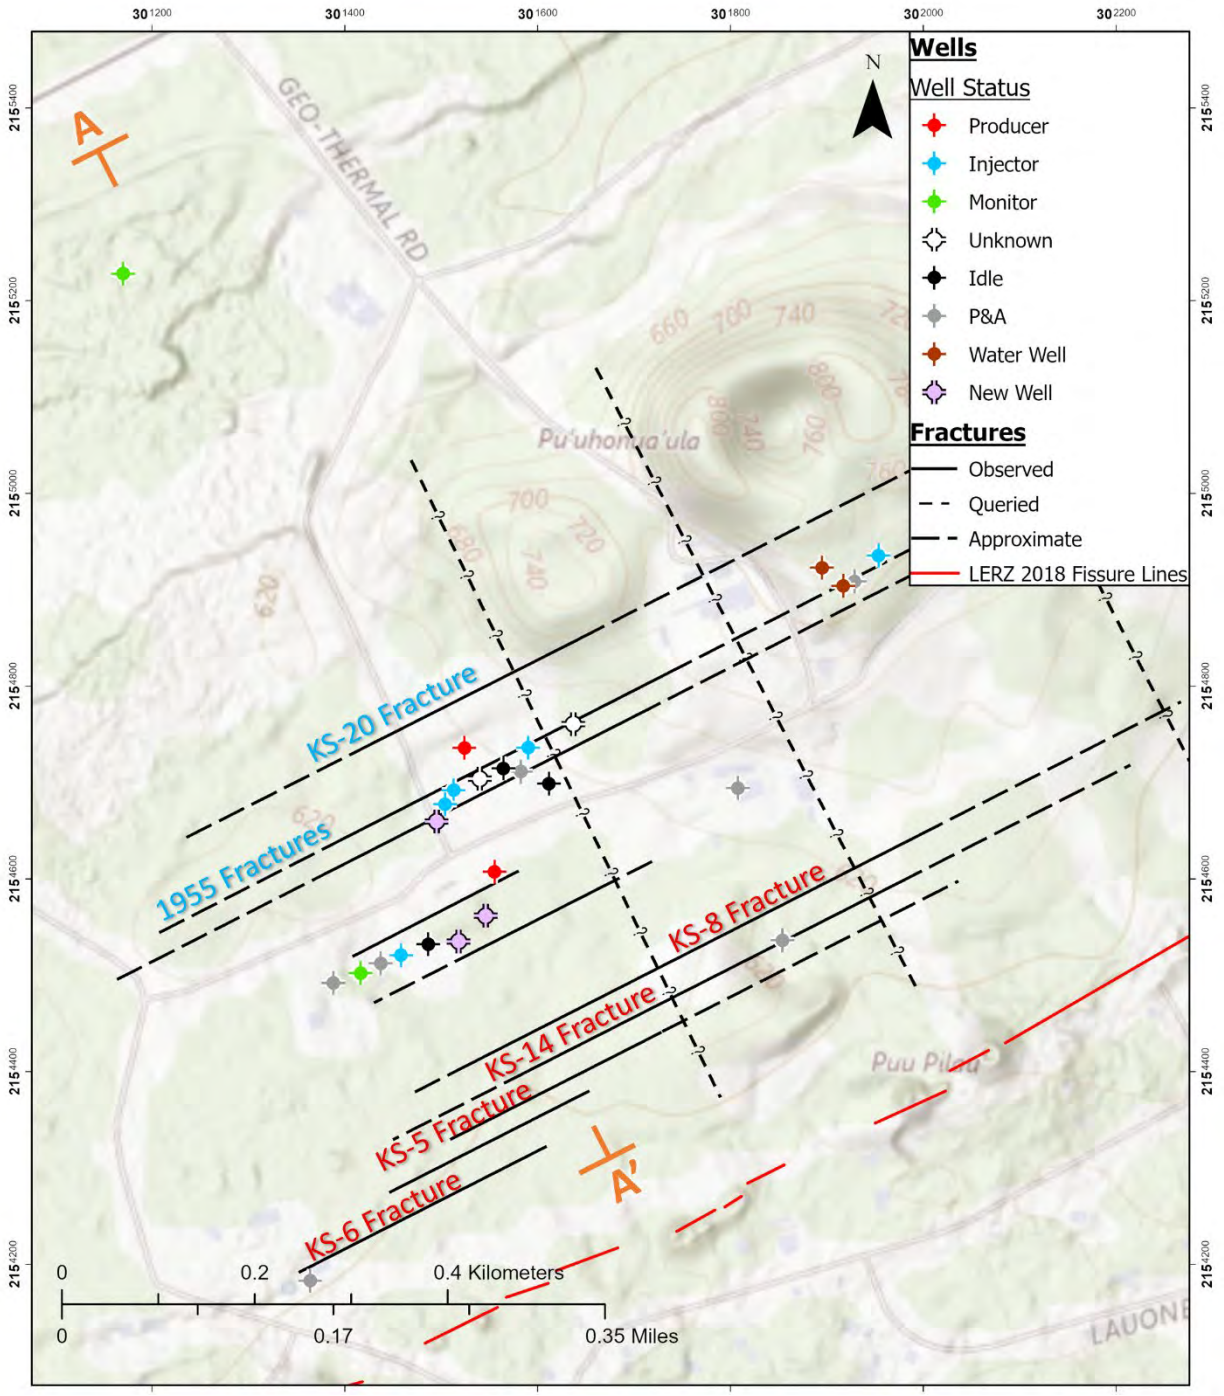

Figure 5: Map of the PGV wellfield showing known and hypothesized subsurface fracture pathways. Key production and injection structures are labeled in red and blue, respectively. Figure 10 cross section extents indicated by A-A' line (orange symbology).

2.4 Image Log Results

Borehole image logs are an invaluable dataset which allow quantification of fracture attitudes and in some cases the orientation of the stress field, data points which allow ground truthing of key elements of a conceptual model, and for this reason acquisition of an acoustic image log was an important component of the logging and testing plan for the northernmost well drilled in the 2022-2023 campaign. The borehole geometry and stability conditions were considered continuously throughout drilling and the decision-making process of calling TD, and these components were essential to making an informed, risk-based plan and decision for log acquisition. For example, below 6900 ft MD the borehole "inverts", changing azimuth by ~180° as designed to re-cross the target fracture zone, and this geometry was an important component of selecting the image log interval. With no significant fill on bottom observed during drilling or reaming (which could indicate borehole sloughing or collapse), the borehole was considered to be in stable condition and approval was granted to run a PTS survey followed by image log acquisition. However, to maintain borehole stability throughout logging operations it was decided that the wellbore would remain filled with drilling mud rather than switching over to water, as is common for acquisition of acoustic image logs.

The image log was successfully acquired from the casing shoe (3634 ft) to 6900 ft MD. The image quality is poor overall due to suspended solids in the fluid column from the drilling mud causing attenuation of the acoustic signal, but interpretation of important features is still possible. Analysis of the image log identified 248 discrete features over the 3266 ft log interval. Most structures identified are rift-parallel and sub-vertical, dipping both NNW and SSE (supporting key elements of the conceptual model), with a minor population of NW-trending, SW-dipping features identified.

Southeast-striking (rift-cutting) fractures captured in the image log have strikes ranging from ±105°-160°, with the mode of the population oriented approximately 112°/75° (strike/dip) (Figure 6). Mapped surface representations of these features, represented as queried fractures in Figure 5, strike 154°; this attitude is based on combined analysis of regional to local gravity and magnetic surveys, LiDAR lineaments, and tracer studies, and is consistent with the range of fracture attitudes implied by image log interpretation. Whether there are throughgoing, high permeability fractures present in the field, as the mapped traces imply, or if NW-SE trending fractures are found as a distributed population throughout the subsurface, as they manifest in the image log interval, is a remaining uncertainty in the conceptual model with important implications for reservoir management and well targeting.

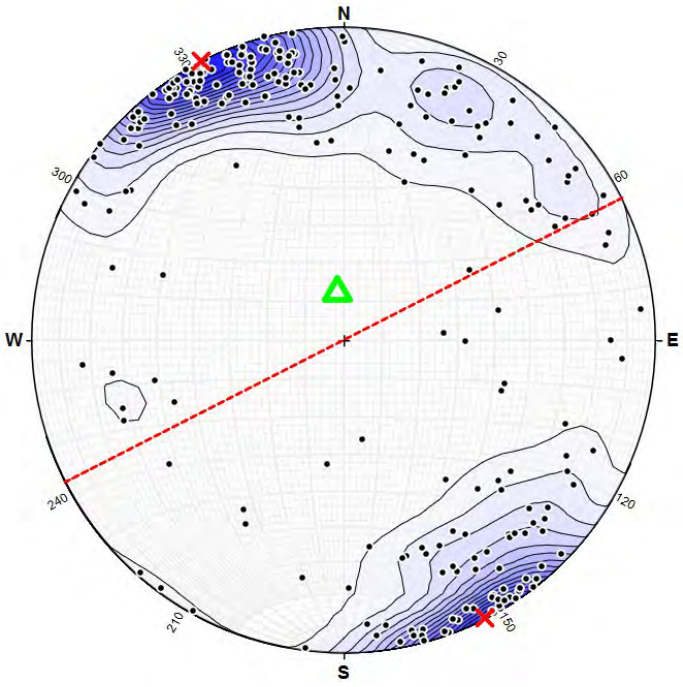

Figure 6: Lower hemisphere stereonet with poles to planes plotted and contoured for all fractures identified in the image log (n=248). The trend of the LERZ (063°/243°) is indicated by the dashed red great circle, and poles to that vertically dipping plane are indicated by red X's. The average (median) attitude of the borehole through the imaged interval is plotted as a bold green triangle.

Drilling induces damage to the borehole wall may be preserved as borehole breakouts (BO), petal-centerline fractures (PCF), or drilling induced tensile fractures (DITF), structures which can be used to infer the orientation of the modern stress state in the subsurface (e.g., Davatzes and Hickman, 2010; Moos and Zoback, 1990, Zoback et al., 1985). Three pairs of DITFs were identified in the image log. DITFs at ±3650 ft and 4450 ft are oriented NE-SW, indicating that S_{Hmax} is roughly aligned with the trend of the LERZ (Figure 7) and fractures subparallel to the rift should be well-oriented for dilation and fluid flow (e.g., Heffer, 2002). However, the final pair of DITFs identified at ±6270 ft are oriented NW-SE (116°/299°), an approximately 60° shift from the shallower pairs, which would place rift-parallel fractures under compression and preferentially favor fluid flow along NW-SE trending structures. This rotation may be local, with the attitude of S_{Hmax} reverting to a NE-SW orientation beyond the logged interval. Alternatively, this stress field rotation may imply that deep permeable zones in the northern wellfield are more likely to be channelized along rift-perpendicular fractures, which may facilitate rapid breakthrough of injectate back to the production field and thus unfavorable cooling of the reservoir. Additional testing, particularly a long-term reservoir tracer test, is required to better understand the fluid pathways from the injection to production fields.

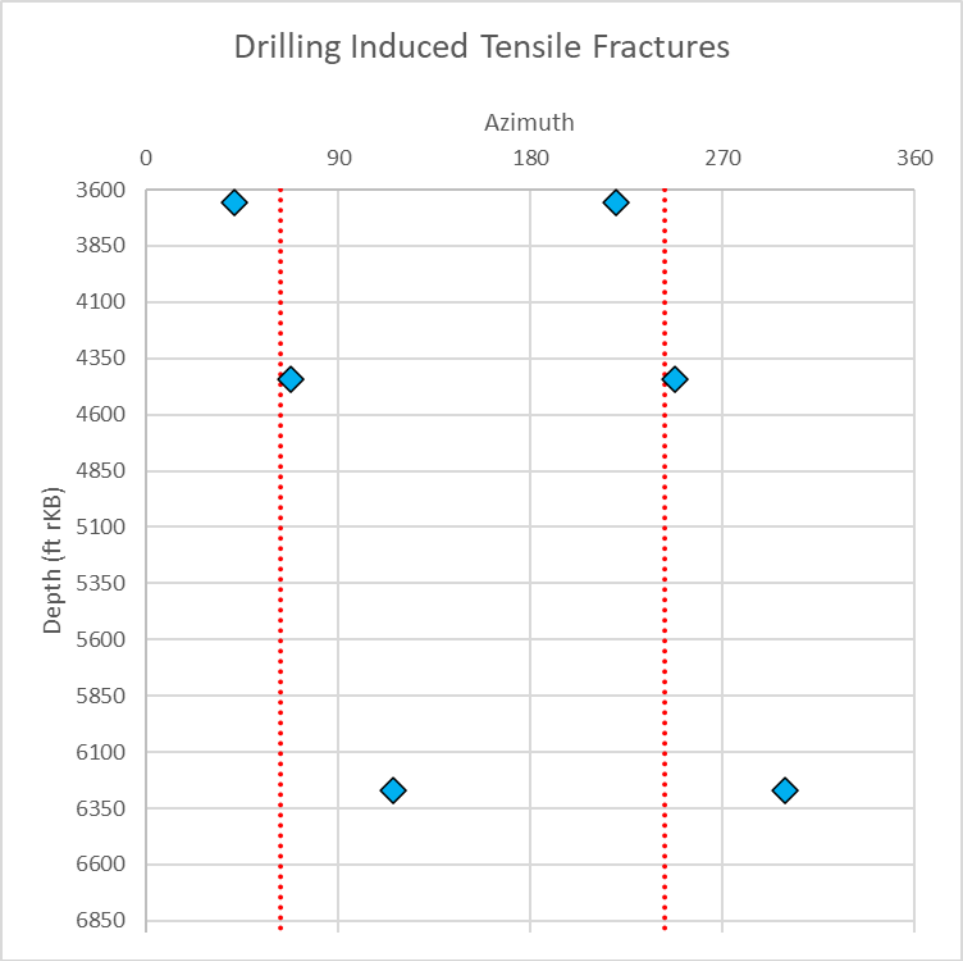

Figure 7: Drilling induced tensile fractures (blue diamonds) identified in image log plotted against borehole depth. The trend of the LERZ is plotted as red dotted lines.

2.5 Alteration Systematics

Hydrothermal alteration of basaltic to diabasic host rocks occurs as replacement mineralization and fracture or vesicle filling secondary mineral deposits. Replacement minerals include clays, chlorite, and disseminated pyrite, with replacement mineralization first appearing at ±1500 ft MD (±455 m) and becoming more pervasive below ±4000 ft MD (±1220 m).

High clay content logged in drill cuttings is a function of both temperature-dependent alteration processes and host rock lithology, with abundant clay found in glassy hyaloclastites of the transitional zone/near shore depositional environment. Widespread clay begins at ±2600 ft (792 m) bgl (-1110 ft/ -580 m rSL) and is logged to variable depths that are interpreted to represent the size and shape of the clay caprock overlying the convective hydrothermal system. Thick expanses of clay are interbedded with unaltered basalt flows and hyaloclastite deposits, indicating the incomplete alteration of the host rock and imperfect nature of the caprock. This incomplete alteration combined with structural discontinuities from tectonic fracturing allow minor leakage of fluids and steam from the underlying hydrothermal system in the natural state. This phenomenon is well-documented in geothermal systems around the world where surface manifestations

overlying the reservoir document leakage of steam and fluids through the caprock (e.g., Rowland and Simmons, 2002).

Four distinctive fracture filled mineral assemblages are recognized. The stratigraphically highest, lowest temperature assembly consists of amorphous silica (opaline silica and chalcedony) + anhydrite + pyrite ± clay/chlorite ± zeolite(s) ± calcite. A moderate to high temperature assemblage is composed of anhydrite + pyrite + quartz + chlorite ± garnet ± chalcopyrite. The highest temperature, deepest stratigraphic assemblage consists of quartz + epidote + chlorite ± actinolite ± anhydrite.

A quantitative relationship between reservoir temperatures and these mineral assemblages has not been well established due to the propensity of higher temperature fluids from deep in the reservoir to flow upwards within the wellbore and mask the flow from the upper, cooler entries. From mineralogical and fluid temperature correlations from other known geothermal fields, the low temperature mineral assembly probably represents reservoir temperatures of 300-400°F, the moderate temperature assembly represents temperatures of 400-550°F, and the high temperature group ≥550°F.

Mineralogical precursors to entry into high-temperature production zones are not well-developed in the Puna field. In shallower portions of the high-temperature system, such as that encountered in KS-7, a hydro-fractured texture consisting of brecciated basalt, re-cemented with silica and anhydrite, may be present along with bladed pyrrhotite. Below 3500 ft depth, minor occurrences of euhedral epidote have been noted within 100 feet of entry into producing fractures. However, it is stressed that mineralogical precursors may be rare or absent immediately prior to entry into a producing fracture.

3. Geophysics

Geophysical data acquired near PGV reveal that measurable variations within the rocks of the LERZ are subtle, primarily due to the island's lithologic homogeneity. Gravity data indicate a lack of significant density contrast between rock units, resulting in a relatively attenuated gravitational signature. Several generations of resistivity surveys have been completed with varying degrees of success, including 4 CSAMT lines in 1993 and a regional magnetotelluric (MT) survey focused on imaging magma reservoirs and conduits within Kilauea and the East and Southwest rift zones. While the CSAMT data is of limited use due to the high levels of anthropogenic noise near the power plant, Hoversten et al. (2022) demonstrates that MT resolves the rift zones as extensive low resistivity anomalies and provides insight into successful MT acquisition in the challenging field conditions found near Kilauea.

An airborne magnetic survey collected in 1978 with flight line spacings of 0.8 and 1.6 km demonstrated that magnetics is a useful tool for imaging the regional structure of the LERZ (Flanigan & Long, 1987). Ormat collected an airborne magnetic survey over PGV which enhances the resolution of key features, revealing strong magnetic highs that correlate with mapped eruptive vents and faults along the LERZ (Reynolds et al., 2024). The survey shows that sharp magnetic highs aligned with the trend of the LERZ, interpreted as shallow dikes with high magnetic susceptibility, make a left-step near PGV, consistent with the rift geometry implied by vents and fissures. Lineaments linking the two main rift segments in this area trend approximately perpendicular to the rift, supporting the existence of NW-SE (±333°/153°) trending fractures in

the vicinity of the geothermal system. It should be noted that the survey is not interpreted as imaging alteration and destruction of magnetic minerals associated with the upper portions of the hydrothermal system due to the depth to the resource (>3000 ft). Rather, breaks in magnetic highs associated with the rift trend are interpreted as possible structures which may extend into the subsurface and influence permeability pathways (Figure 8).

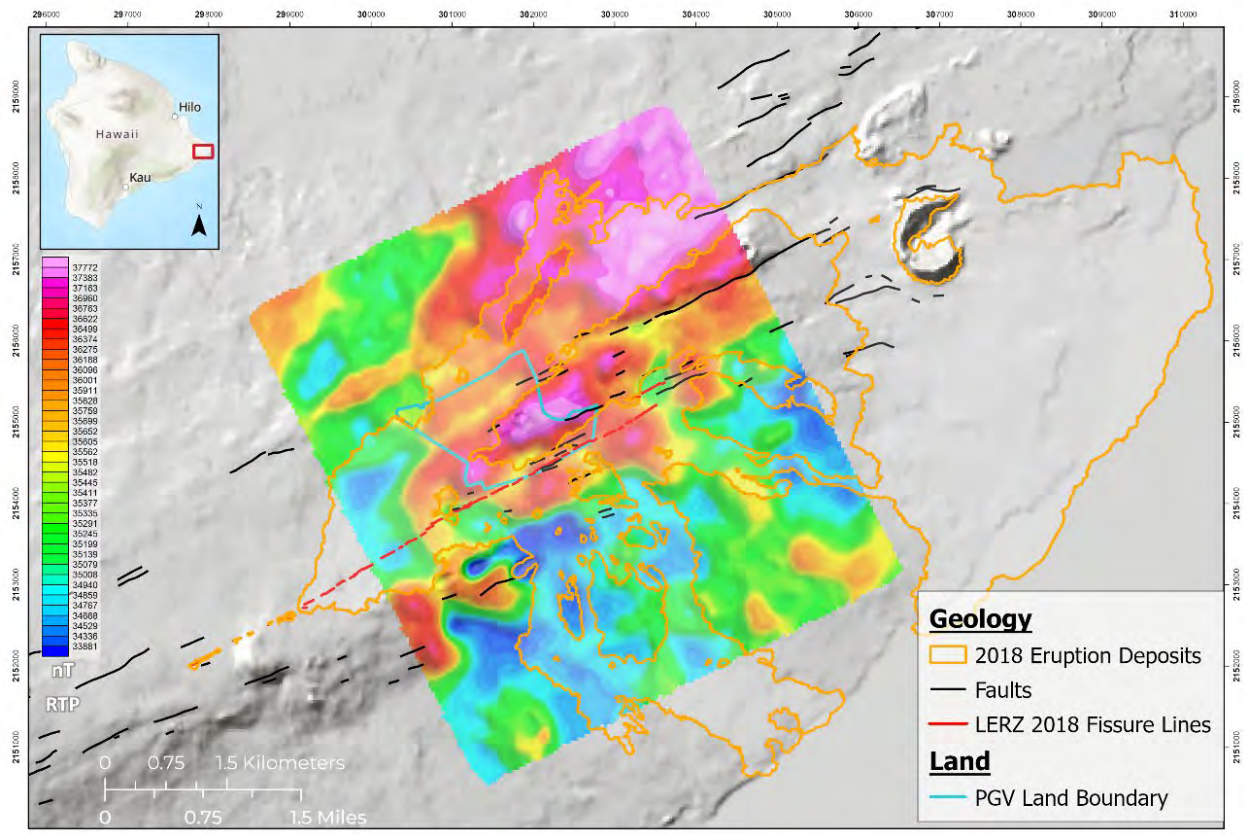

Figure 8: RTP (reduced to pole) magnetic data overlain on a 30 m DEM of the LERZ and PGV. Basalt deposits from the 2018 eruption are shown outlined in orange; mag anomalies do not follow the deposits, indicating that deeper structures are resolved by the method.

4. Geochemistry

Production fluids from PGV are a combination of two-phase flow from intra-wellbore boiling, as well as two-phase brine and steam in the reservoir based on enthalpy measurements and quarterly tracer flow tests (TFTs). Reservoir brines at PGV are moderate TDS (up to ±23,000 ppm), Na-Cl fluids with reservoir pH generally estimated between 5-6. The fluids are variably mixed, thermally altered meteoric-modified seawater brine with up to 70% modified seawater (Figure 9). Gas composition is dominated by H_2S and CO_2 with total discharge of less than 0.5 wt.%.

The basal groundwater aquifer above the PGV hydrothermal resource is predominantly a mixture of meteoric and altered seawater, with temperatures ranging between 30-65°C. The basal aquifer within the LERZ experiences a high degree of natural spatial and temporal chemical heterogeneity. This is likely a result of near well structures, such as highly permeable lava flows being intersected with impermeable dikes, which may isolate shallow aquifers and limit fluid flow. In addition to

structural controls, changes in the rates of recharge into these aquifers varies the degree of input from seawater versus meteoric water sources (Novak, 1995; Thomas, 1987 and Sorey and Colvard, 1994). Further, some minor degree of natural steam leakage into the system is inferred based on slightly depressed pH values and elevated sulfate concentrations in some monitoring wells such as MW-1.

There are no surface manifestations related to the PGV system. There are, however, a series of warm springs and seeps that occur to the SSE along the coast and isolated steam vents within the rift associated with the 1955 and 2018 fissure eruptions. Based on lower expected resource temperatures inferred from geothermometery and differences in the degree of seawater dilution, the springs are hypothesized to be related to a separate hydrothermal system (Janik et al., 1994).

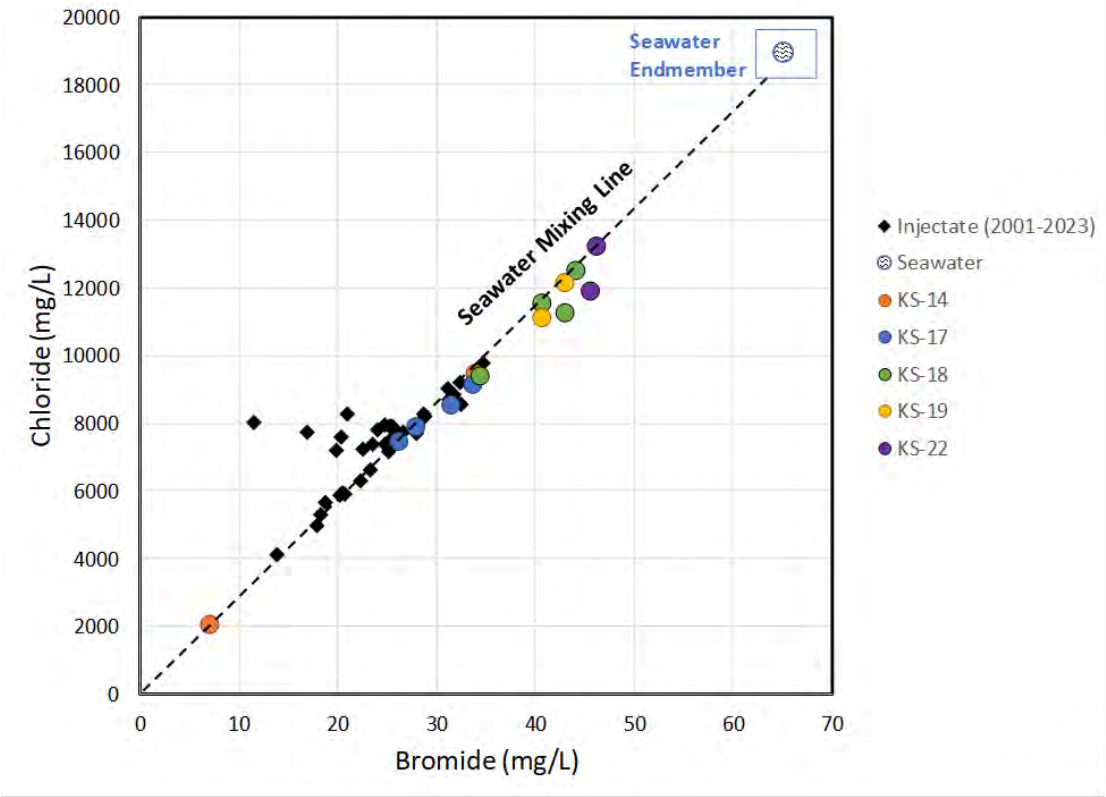

Figure 9: Chloride/Bromide cross plot showing the relationship between PGV brines and seawater. Production brines and injectate plot on the seawater mixing line.

5. Conceptual Model

The Puna reservoir is a high temperature, two-phase, liquid-dominated system with a varying steam fraction confined within Kilauea's Lower East Rift Zone. Heat for the system is supplied by active magma migration and the very high heat flow through the rift. Intrusion of magma into the rift zone displaces the southern flank of the volcano, promoting dilation along the rift. A prominent left step in the rift in the vicinity of PGV generates and maintains a zone of locally enhanced permeability in basalt flows and dikes with low natural porosity and permeability. The high permeability production and injection structures are subvertical, rift-parallel fractures that often associate with diabase dike margins, with fractures perpendicular to the rift formed as a function

of the stepover facilitating injection returns to production. The system is overlain by a caprock formed by hydrothermal alteration of pahoehoe & a'a flows, hyaloclastite, and pillow basalts which alters mafic minerals and volcanic glass to smectite-rich clay. The glassy groundmass characterizing hyaloclastite makes them particularly susceptible to clay alteration and the caprock is largely coincident with the extents of these transitional marine deposits. Departures of the clay caprock from the modeled extents of the transitional zone are interpreted based on the distribution of the natural state temperatures of the system, with the caprock closely following the 200°C isotherm due to the instability of smectite clays above that temperature (e.g., Reyes, 1990). Clay alteration is not homogenous and the caprock is likely breached in places by tectonic dilation over the lifecycle of a long-lived geothermal system, but naturally occurring leakage into overlying strata is thought to be relatively minor and transient in nature as the leaking structure self-seals due to hydrothermal alteration. Surface manifestations are suppressed by the deep resource depths, the clay caprock, and the vigorous groundwater system overlying the reservoir, all working in conjunction to keep the system hidden at surface. The water table within the resource area occurs at an elevation of approximately sea level (0 mRSL), corresponding to a depth of 188m (620 ft).

The distribution of interpreted static-state temperatures in PGV suggest that upflow originates along steeply northwest-dipping fractures. Note that the isotherms displayed in Figure 10 represent the post-eruption conditions, not the natural state of the system, and reflect significant cooling of the northern reservoir by a long history of injection.

Steep NW-SE thermal gradients through the field are a function of high permeability and convection along sub-vertical fractures within the rift zone versus unfractured zones adjacent to the rift to the north and south. The occurrence of permeable rift-perpendicular fractures as integrated into the conceptual and numerical models based on surface geology and tracer returns, a hypothesis which has been further substantiated by a recent airborne magnetic survey, which clearly images the left-step in the LERZ, and analysis of an acoustic borehole image log, which demonstrates the existence of NW-SE trending fractures throughout the logged interval. However, a key uncertainty remaining in the conceptual model is whether (a) there are large, high permeability NW-SE pathways (as the queried faults in Figure 5 would imply), or (b) NW-SE trending fractures represent a distributed fracture set that is present throughout the field but not localized into a handful of high permeability pathways.

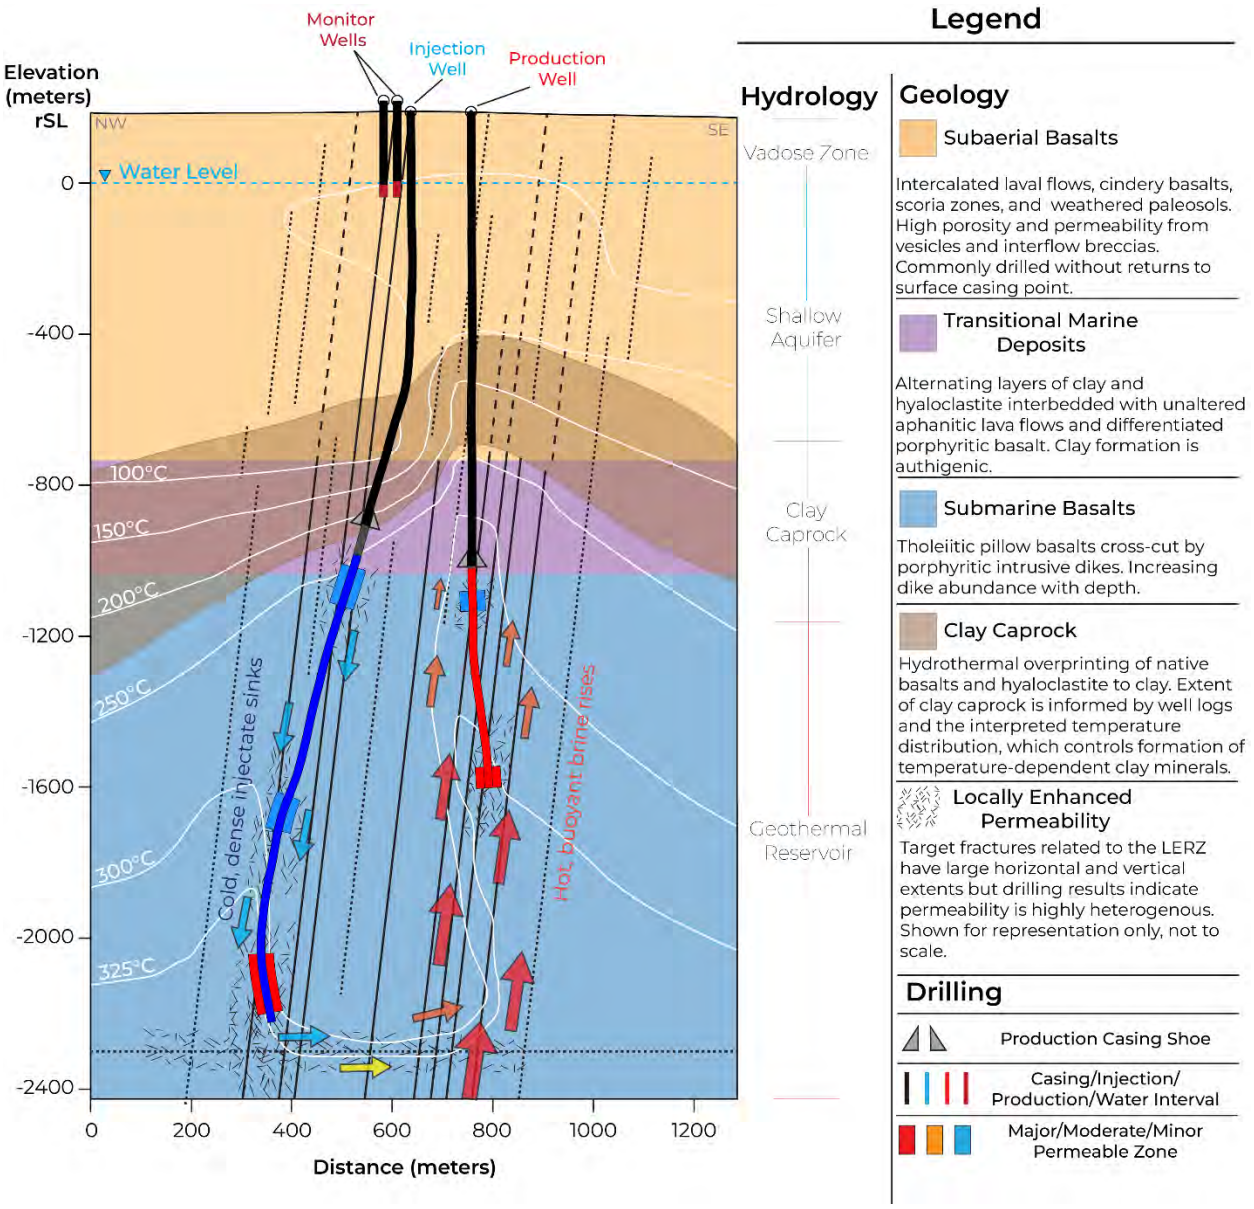

Figure 10: Schematic diagram of the PGV hydrothermal system conceptual model, including interpreted post-eruption natural state isotherms which depict significant cooling of the reservoir at injection depths. Vertical exaggeration 0.75x.

6. Conclusion

The Puna Geothermal Venture represents a high-temperature, naturally occurring geothermal system found in the active Lower East Rift Zone of Kilauea. The geothermal system's location is due in part to the occurrence of a prominent left-step in the rift zone which creates locally enhanced permeability. Fracture-dominated permeability and upflow of thermal fluids at PGV are controlled primarily by rift-parallel fractures. Rift-perpendicular permeability pathways were previously hypothesized based on surface mapping, geophysical datasets, and reservoir tracer studies, and have been confirmed for the first time at PGV by analysis of an acoustic borehole image log. Additional reservoir testing is required to understand the impact of rift-perpendicular fractures and

the connection between production and injection following the successful completion of a recent drilling campaign.

7. Acknowledgements

We would like to thank the PGV operators, Ormat's Wellfield and Resource staff who contributed to post-eruption recovery effort and who continue to operate and maintain PGV as a flagship geothermal power plant, as well as Peter Drakos for his more than 15 years of geoscience contribution to the field.

Identifying Sedimentary Geothermal Play Types in the Cretaceous Strata of South Texas Through High-Resolution Temperature-Depth Mapping Based on Corrected Bottom-Hole Temperature Measurements

J. Eric Stautberg and Steven A. Sonnenberg

Department of Geology and Geological Engineering, Colorado School of Mines

Keywords

Sedimentary basins, Texas Gulf Coast, bottom-hole temperature correction, temperature mapping, isotherm, time since circulation

ABSTRACT

Accurate formation temperature is a pivotal part of geothermal resource assessments in sedimentary basins. Bottom-hole temperature (BHT) measurements from well logs are an abundant data set in these basins but are also notoriously unreliable because of several reasons such as the vintage of the measurement, type of tool used, ambient surface temperature at the time of logging, thermal properties of the drilling mud, time since circulation (TSC), rate of penetration (ROP) while drilling, human error, and the thermal conductivity of the formation and formation fluids (oil, natural gas, or brine) where the temperature is measured. Consequently, BHT correction methods vary depending on the basin and available data. In south Texas, where oil and gas wells dominate the landscape, the Waples et al. (2004) correction method is commonly used because it incorporates TSC data and ambient surface temperature to correct for the cooling effects of drilling mud on the formation while the well was being drilled.

A 12,500 square mile area in south Texas was designated for BHT correction and temperature-depth mapping because it contains most of the key sedimentary geothermal elements of the Texas Gulf Coast. These elements include: 1) the location of geopressured reservoirs in Paleogene formations, 2) the location of the Aptian and Albian shelf margins, 3) the type of transitional crust beneath the sedimentary section, 4) the location of salt diapirs, and 5) the shallowest depth to 250º F in Texas. To help identify geothermal play types in the Cretaceous strata of south Texas, BHT measurements from 826 wells north of the Aptian and Albian shelf margins were corrected for temperature-depth mapping. Of these 826 wells, 267 had TSC data and were subsequently corrected using the Waples et al. (2004) BHT correction methodology. This method resulted in an average temperature increase of 19.66%, which aligned with temperature measurements from

cement bond logs, drill stem tests (DSTs), and regional BHT correction studies completed by other researchers.

Corrected BHT measurements for 267 wells were then used to calculate a temperature log from the surface to 25,000 ft for each well. Using IHS Markit's Petra cross section and mapping software, temperatures were correlated from well to well across the research area at 25º F increments from 200º F to 500º F. This methodology resulted in two important products for geothermal play type identification: 1) a high-resolution series of temperature-depth maps for play fairway identification and 2) a set of temperature logs that can be incorporated into petrophysical analysis for temperature-based reservoir characterization calculations.

1. Introduction

The Texas Gulf Coast region of the greater Gulf of Mexico Basin contains the necessary geothermal elements for low-temperature geothermal development for both utility scale electrical power generation and direct use applications. Deposition of thick Mesozoic and Cenozoic sedimentary rocks, coupled with passive margin tectono-stratigraphic relationships provides the necessary geologic framework to support geothermal exploration here. Previous researchers from the Bureau of Economic Geology at the University of Texas in Austin (BEG), the Department of Energy (DOE), Southern Methodist University (SMU), the National Renewable Energy Lab (NREL), the U.S. Geological Survey (USGS), and many others have laid the groundwork for the development of clean, renewable, stable, dispatchable, baseload electricity in this basin and others across the United States.

Despite decades of subsurface research completed by these researchers and others, however, no commercial scale geothermal development has yet occurred on the Texas Gulf Coast. Consequently, the focus of this project is to provide a detailed subsurface characterization of an approximately 12,500 square mile area in south Texas to: 1) encourage geothermal exploration along the Texas Gulf Coast and in other sedimentary basins, 2) provide an exploration-based workflow for identifying and characterizing geothermal reservoirs, and 3) pinpoint specific geothermal play fairways in this region through high-resolution temperature-depth mapping.

To achieve these goals, understanding the distribution of subsurface temperatures across the basin is extremely important but often very challenging because of the inaccuracy in bottom-hole temperature measurements from wireline logs. These temperature measurements are the most common datasets used in sedimentary basins for subsurface temperature mapping because of their abundance but are also notoriously unreliable for many reasons including: 1) the vintage of the measurement, 2) type of tool used, 3) ambient surface temperature at the time of logging, 4) the thermal properties of the drilling mud, 5) time since circulation (TSC), 6) rate of penetration (ROP) while drilling, 7) human error, and 8) the thermal conductivity of the formation and formation fluids (oil, natural gas, or brine) where the temperature is measured. For these reasons, multiple different types of correction methodologies have been developed in sedimentary basins across the world. Subsequent correction methods and mapping techniques are discussed here, with the goal of building a high-resolution and comprehensive set of temperature-depth maps across a region of south Texas that can be used as a case study for further temperature-depth mapping across the Texas Gulf Coast.

2. Methods

2.1 Geothermal Elements of the Texas Gulf Coast

Understanding the basinwide geologic controls on the spatial and temporal distribution of potential geothermal play types along the Texas Gulf Coast is the first step in exploring for these resources. Fortunately, oil and gas exploration and development over the past century has provided an excellent subsurface dataset for geothermal explorers to use to characterize the potential resources here. Combining the results from previous researchers in this region yields five major structural and stratigraphic features that appear to have the most significant controls on the location of potential geothermal targets. These features are: 1) the location geopressured reservoirs in Paleogene formations (Bebout et al., 1978; Loucks et al., 1978; Bebout et al., 1979; Bebout et al., 1982), 2) the location of the Aptian and Albian shelf margins (Ewing, 1991), 3) the composition of the crust that underlies the sedimentary formations (Ewing and Galloway, 2019), 4) the location of salt diapirs (Condon and Dyman, 2006), and 5) the depth to 250º Fahrenheit (F) (Figure 1). Combining all these elements together shows that the south Texas region contains all of these overlapping geologic elements and was consequently chosen to be the focus of this study.

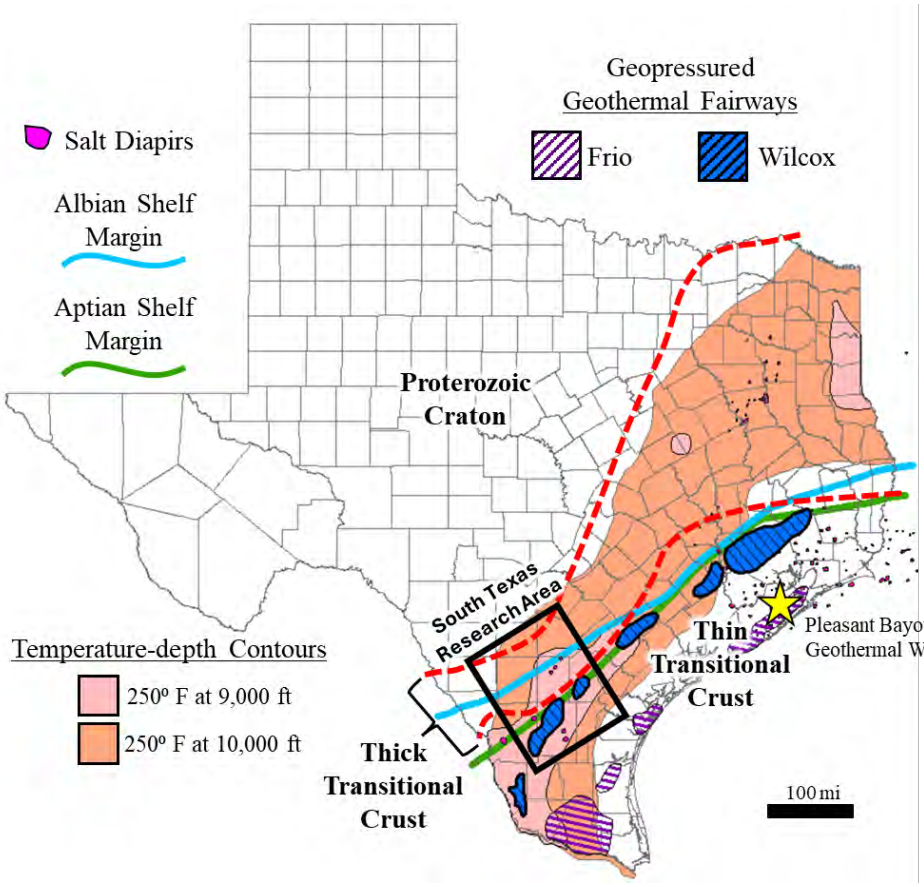

Figure 1: Location of the basinwide geologic elements of the Texas Gulf Coast that influence the location and types of potential geothermal reservoirs. Map elements from Bebout et al., 1982; Blackwell et al., 2010; Condon and Dyman, 2006; Ewing, 1991; and Ewing and Galloway, 2019. Modified from Stautberg and Sonnenberg, 2024.

An approximately 12,500 square mile area covering 10 counties was selected to identify and characterize all the major geothermal play types in this region that then could be applied to the rest of the Texas Gulf Coast (Figure 2A). The research area is cross-cut by both the Aptian and Albian shelf margins, the main Wilcox fault zone, the boundary between thick transitional crust to the north and thin transitional crust to the south, it contains six salt diapirs, and there are two geopressured-geothermal zones in the Wilcox Formation previously identified by Bebout et al. (1982). Additionally, the approximate depth to 250° F is represented by the color-filled contours as previously mapped by Blackwell et al. (2010). This temperature is important because it is often considered the lowest temperature that can be used for electrical power generation, although there are other controlling factors that ultimately affect the minimum temperature required for the power generation process.

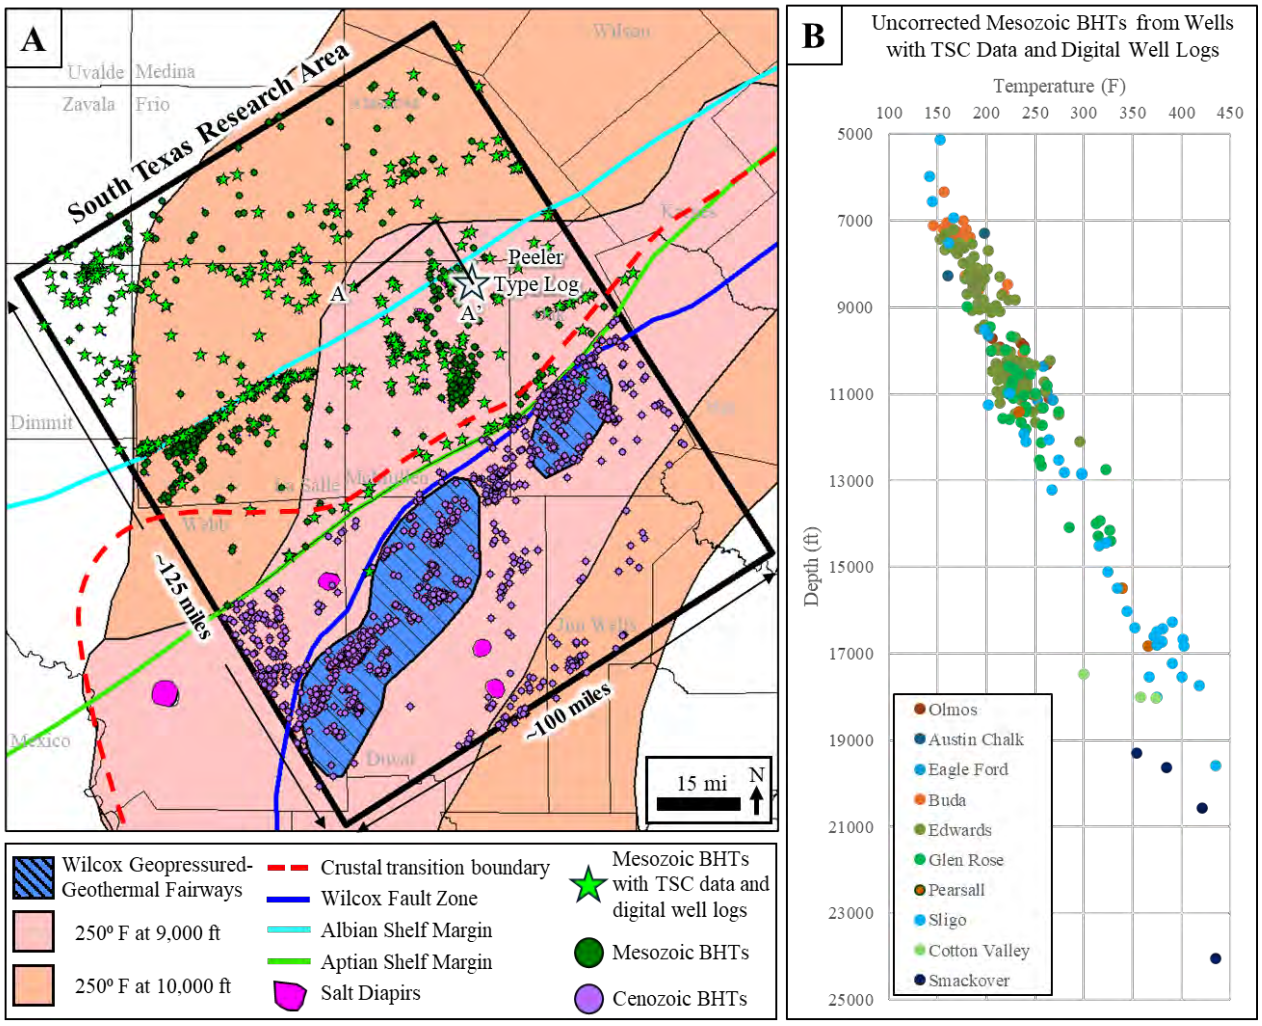

Figure 2: A) Location of the south Texas research area showing the location of geologic elements that control the location and type of geothermal play types along with the location of wells with BHT measurements in Mesozoic and Cenozoic formations. B) Temperature versus depth plot for 267 wells with BHT measurements in Mesozoic formations and that also contain digital well logs. Map elements from Bebout et al., 1982; Blackwell et al., 2010; Condon and Dyman, 2006; Ewing, 1991; and Ewing and Galloway, 2019.

2.2 Bottom-hole Temperature Data

A dataset of 1,864 wells with one or multiple BHT measurements was compiled from the National Geothermal Data Systems website for BHT correction and subsurface temperature mapping (Figure 2A). This dataset was then divided based on the age of the formations that the BHT measurement was taken in (Mesozoic versus Cenozoic) and the crustal type underlying those subsequent formations. In the northern half of the research area, the Mesozoic sedimentary rocks are underlain by thick transitional crust, whereas the southern half of the research area is underlain by thin transitional crust and contains thick Cenozoic formations. Consequently, the BHT dataset is divided based on boundary between these two crustal types from Ewing and Galloway (2019). These two geologic elements influence the basal heat flow from the underlying basement, heat flow within different sedimentary packages, thickness and age of the sedimentary packages, and thermal conductivity of the different formations. However, for this study only the BHT correction methods and temperature-depth mapping for the Mesozoic formations will be discussed.

The Mesozoic dataset contains 826 wells with BHT measurements and was subsequently divided again based on the availability of both digital well log and TSC data. Of these wells, 267 were selected for temperature mapping because they contain both TSC times and digital well logs that cover most of the Cretaceous and Jurassic formations (Figure 2B). The location of these wells is shown in Figure 2 along with the relationship between uncorrected BHT measurements and depth for the Cretaceous and Jurassic formations. Bottom-hole temperature measurements for these 267 wells are from the Olmos, Eagle Ford, Buda, Edwards, Glen Rose, Pearsall, Sligo, Cotton Valley, and Smackover formations (Figures 2 and 3).

2.3 Bottom-hole Temperature Correction

One of the cruxes of subsurface temperature mapping in sedimentary basins is accurately correcting the BHT measurements for external variables that affect the quality and accuracy of the temperature measurement. In sedimentary basins, most subsurface temperature data comes from measurements from wireline logging tools when the well was logged. Subsurface temperature measurements can also come from drill stem tests (DSTs), cased-hole temperature logs, and cement bond logs, however, these types of data are less common and will be discussed in the following section. Temperature measurements from these three other sources are considered to be best representative of true formation temperature because they are typically collected long after the well was drilled, so the temperature of the wellbore is back to its original temperature.

Temperature correction is required for BHT measurements obtained from wireline logs for the many reasons discussed previously. In the Gulf of Mexico Basin, a BHT correction methodology from Waples et al. (2004) is commonly used because it incorporates depth, TSC, and ambient surface temperature when the well was logged to correct for some of the variables that affect the temperature at the bottom of the wellbore. This correction methodology was adopted and applied to the dataset used in this study. Other correction methodologies (Blackwell and Richards, 2004; Corrigan, 1997; Crowell et al., 2010; Forster et al., 1995; and Kehle et al., 1970) rely mainly on depth of the temperature measurement for correction and were developed in other basins, so their correction method is not directly applicable to the south Texas region of the greater Gulf of Mexico Basin.

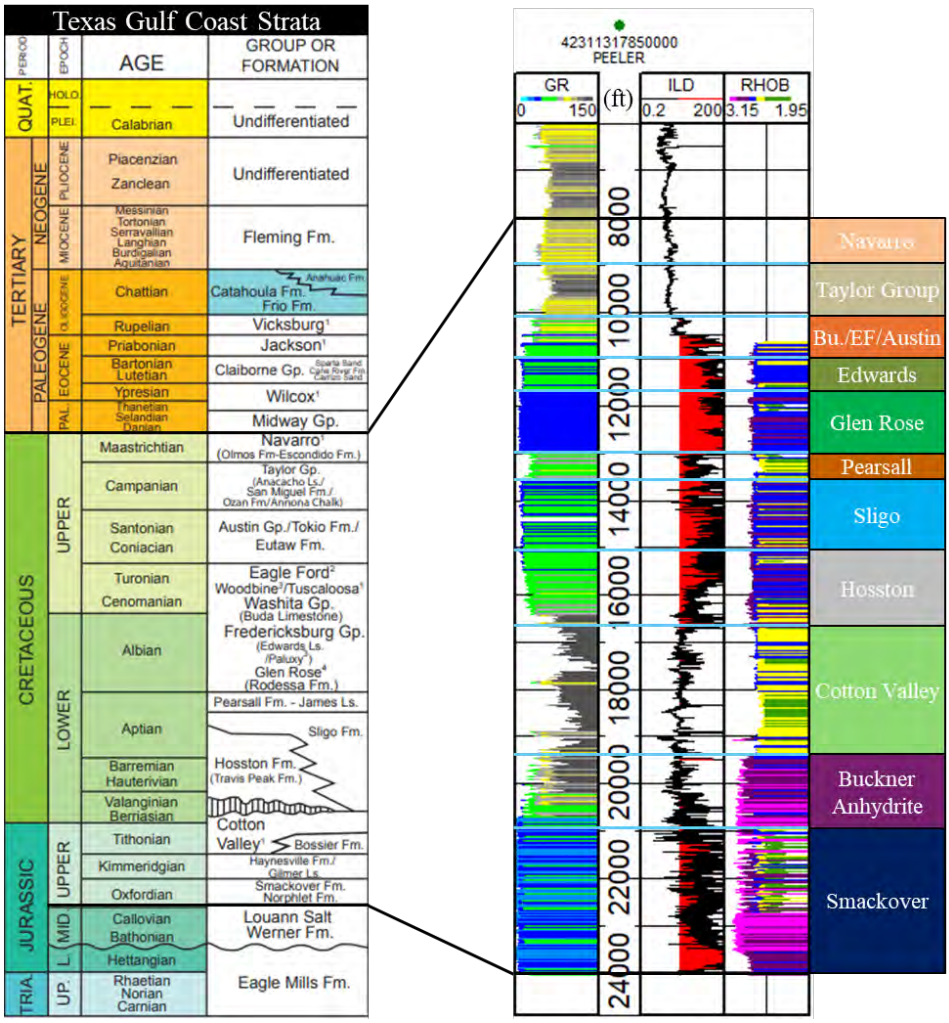

Figure 3: Stratigraphic column for south Texas tied to the Peeler#1 well in northeastern McMullen County. Gamma-ray (GR), resistivity (ILD), and bulk density (RHOB) were used to correlate Cretaceous and Jurassic formation tops across the 267 wells that contain digital well logs and BHT measurements. Stratigraphic column is modified from Swanson et al., 2013.

Equation 1 shows the formula derived by Waples et al. (2004) where the true formation temperature (T_{true}) is a product of the ambient surface temperature in Celsius at the time of logging ($T_{surface}$), the formation factor (f) which incorporates the TSC data, the measured BHT in Celsius ($T_{measured}$), and the depth in meters (Z). Temperatures and depths were converted from Celsius and meters to Fahrenheit and feet after the BHT correction was completed.

$$T_{true} = T_{surface} + f * (T_{measured} - T_{surface}) - 0.001391 * (Z - 4{,}498) \quad (1)$$

Depths, BHT measurements, and TSC times were obtained from well headers of raster logs for 267 wells with both temperature measurements and digital log data in the Cretaceous and Jurassic formations. Ambient surface temperature for the month, county, and year in which the well was logged came from the National Oceanic and Atmospheric Administration (NOAA) database (Figure 4A). Ambient surface temperature at the time of logging ranged from 49° F to 89° F, and the average was 70° F. All these variables were recorded in an Excel spreadsheet so they could be input into Equation 1 for accurate BHT correction.

3. Results

3.1 Corrected Bottom-hole Temperature Measurements

Using the Waples et al. (2004) correction methodology discussed above yields on average a 19.66% increase in temperature for the 267 wells in the Mesozoic BHT dataset (Figure 4B). Temperature correction ranges from an increase of 26.24% to a decrease of 4.65%. The resulting corrected BHTs for this entire dataset are shown in Figure 4C and are compared to the uncorrected values (shown in black). To calibrate the accuracy of the Waples et al. (2004) correction method, temperature measurements from 10 cement bond logs and 22 cased-hole temperature logs are shown in Figure 4C. Most of these equilibrium temperature measurements fall within the cloud of corrected temperature measurements, which suggests that this methodology of BHT correction is valid. A linear best fit line (green) that more closely follows the slope of the equilibrium temperature data points (red and orange dashed lines respectively) was applied to the corrected BHT data by adjusting the y-intercept to intersect the average ambient surface temperature (70° F) and 0 ft measured depth (MD). Consequently, the origin of this graph represents the average surface temperature when these wells were logged.

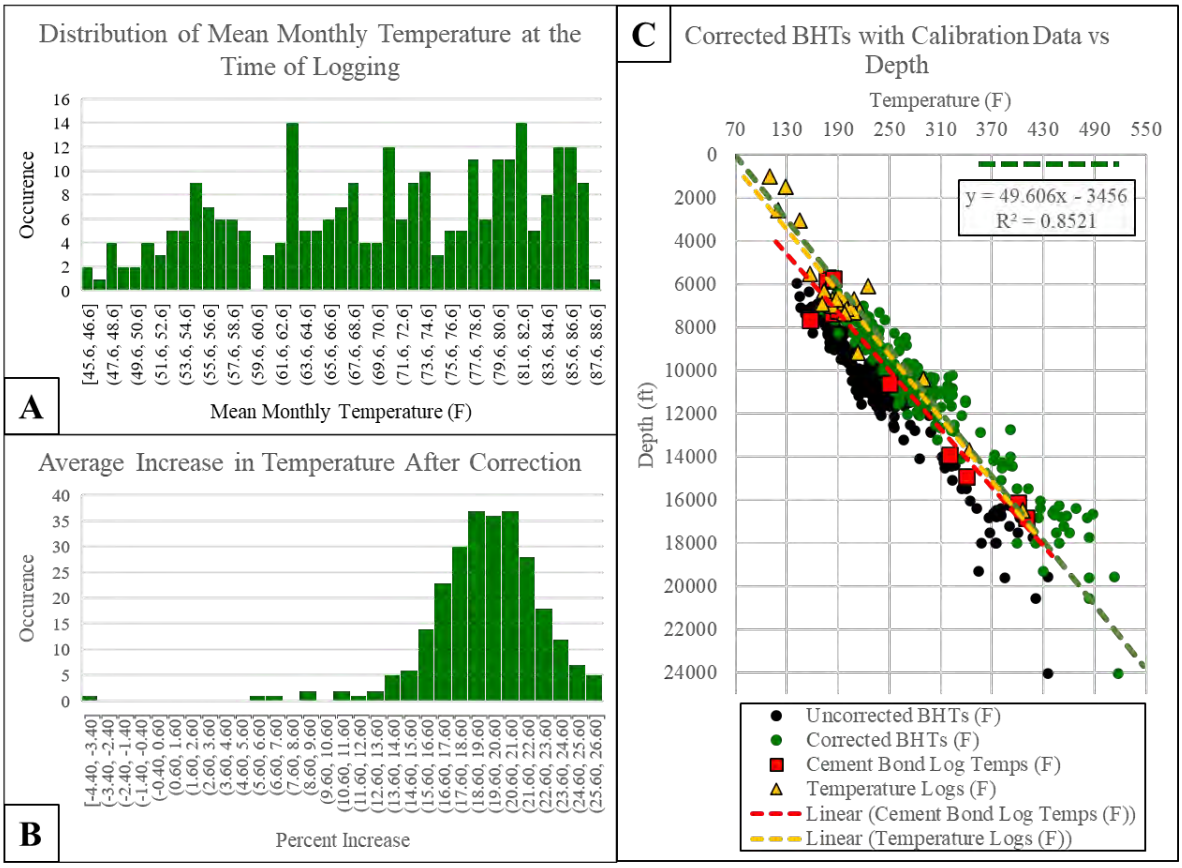

Figure 4: A) Distribution of the mean monthly temperature for the 267 wells with TSC data based on the county and year in which the well was logged. Wells with multiple logging runs at different dates have multiple different ambient temperatures based on the dates of each logging run. B) Average percent increase in temperature using the Waples et al. (2004) method shown in Equation 1. C) Uncorrected versus corrected BHT measurements with calibration data in the form of temperatures from cement bond logs (red squares) and cased-hole temperature logs (orange triangles).

Some of the temperature measurements between 16,000 ft and 18,000 ft in the Sligo Formation are elevated compared to the cement bond logs and cased-hole temperature logs at equivalent depths. This suggests that the Waples et al. (2004) correction methodology might be overestimating true formation temperature at deeper depths. More calibration datapoints are needed below 16,000 ft to verify this but only a few other wells penetrate these depths in the study area. Despite this observation, this method of BHT correction seems valid for the south Texas region of the greater Gulf of Mexico Basin.

3.2 Corrected Bottom-hole Temperature Logs

For geothermal exploration in sedimentary basins, building a comprehensive set of subsurface temperature-depth maps is the main goal of correcting BHT measurements. One of the additional challenges with using BHT measurements for temperature mapping is that they usually span a wide range of depths and are not measured in the same formation. In the Mesozoic dataset, temperature measurements are found in eight Cretaceous and two Jurassic formations and represent discrete points in each well (Figure 2B). Consequently, geothermal gradients from the corrected BHT measurements need to be calculated to estimate the true formation temperature in formations above and below where these datapoints were collected. Using both the ambient surface temperature at the time of logging and the corrected BHT measurement, temperature can be estimated between the base of the well and the surface using the geothermal gradient calculated for each well. In doing so, a series of temperature-depth logs can be created for mapping temperature between wells and within each formation of interest.

Corrected BHT measurements, the depth at which the measurement was acquired, and the ambient surface temperature at the time of logging for the Mesozoic BHT dataset was loaded into IHS Markit's Petra software to calculate a temperature-depth log for each well. Equation 2 shows the relationship between these variables and how Petra creates temperature-depth logs for these wells.

$$T_{depth} = ((T_{true} - T_{surface})/Z_1)*Z_2+T_{surface} \quad (2)$$

In this equation T_{depth} is the temperature calculated at any depth between the surface and 25,000 ft, T_{true} is the corrected BHT, $T_{surface}$ is the ambient surface temperature at the time of logging, Z_1 is the depth of the BHT measurement, and Z_2 is a depth log in 0.5 ft increments from surface to 25,000 ft. With this equation, the corrected BHT and the depth of that measurement is converted into a geothermal gradient for each well and the ambient surface temperature at the time of logging becomes the shallowest temperature for each calculated temperature log. Geothermal gradients for the Mesozoic BHT dataset range from 2.15-3.27° F/100 ft with an average gradient of 2.66.

These variables are then used to calculate a temperature at any given depth throughout the wellbore at a 0.5 ft increments. Subsequent temperatures are stored in the depth log (Z_2 from Equation 2) and Petra creates a LAS file for each well that this equation is run on. This produces a corrected temperature log for each well with a corrected BHT measurement at a 0.5 ft increment from surface to 25,000 ft (Figure 5). These corrected temperature logs can then be displayed in a cross-section, where isotherms can be physically correlated from well to well like a formation top. Additionally, since the corrected temperature logs are at 0.5 ft increments, they can be incorporated into petrophysical calculations or models to be compared to other petrophysical variables (porosity, permeability, water saturation, mineralogy, etc.).

Figure 5 is a well log cross section that contains corrected temperature logs (CTDL) for each well. The color pattern on the temperature logs is at 25° F increments and the black lines are the Cretaceous and Jurassic formation tops. Using this methodology, the relationship between temperature and depth can easily be mapped in the subsurface and at any temperature increment that is desired. This results in a temperature-structure map that shows the depth to the desired temperature measurement.

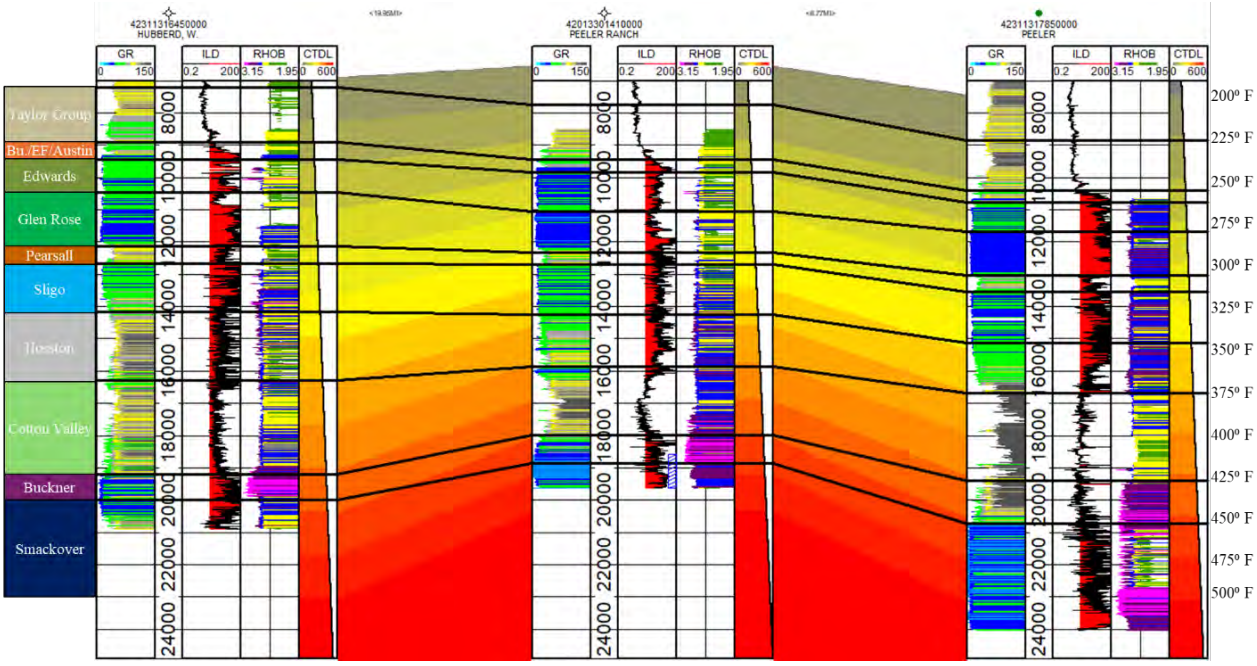

Figure 5: Cross-section A-A' (shown on Figure 2A) showing the relationship between structure and temperature. Calculated temperature-depth logs (CTDL) are displayed in track four of each well and the color fill between each well shows the temperature in Fahrenheit (F). Formation tops for Cretaceous and Jurassic formations are displayed in black.

3.3 Temperature-depth Mapping

Using the cross-section display above, isotherms can easily be correlated from well to well resulting in a series of temperature and depth values for each isotherm in every well. Consequently, either a computer based contouring method or hand contouring method can be used to map the relationship between temperature and depth. Figure 6 shows the depth to 250° F across the research area, contoured with a combination computer contouring and hand contouring method.

This map shows a similar trend to the Blackwell et al. (2010) contours from Figure 2A, where the depth to 250° F is shallower to the south and deeper to the north (Figure 5). However, the depth to 250° F using the methodology discussed above shows that the depth to the 250° F isotherm is slightly shallower than the Blackwell et al. (2010) map to the south and slightly deeper to the north. This is likely a result of differing BHT correction methodologies and a different dataset. Between the Aptian and Albian shelf margins the depth to 250° F ranges from 7,000-9,000 ft, whereas north of the Albian shelf margin the depth is consistently greater than 9,000 ft. This is similar to the depth trends observed in temperature-depth maps from Blackwell et al. (2010) and Gardner and Birdwell (2023), however, their maps are on a much more regional scale that spans the entire Texas Gulf Coast.

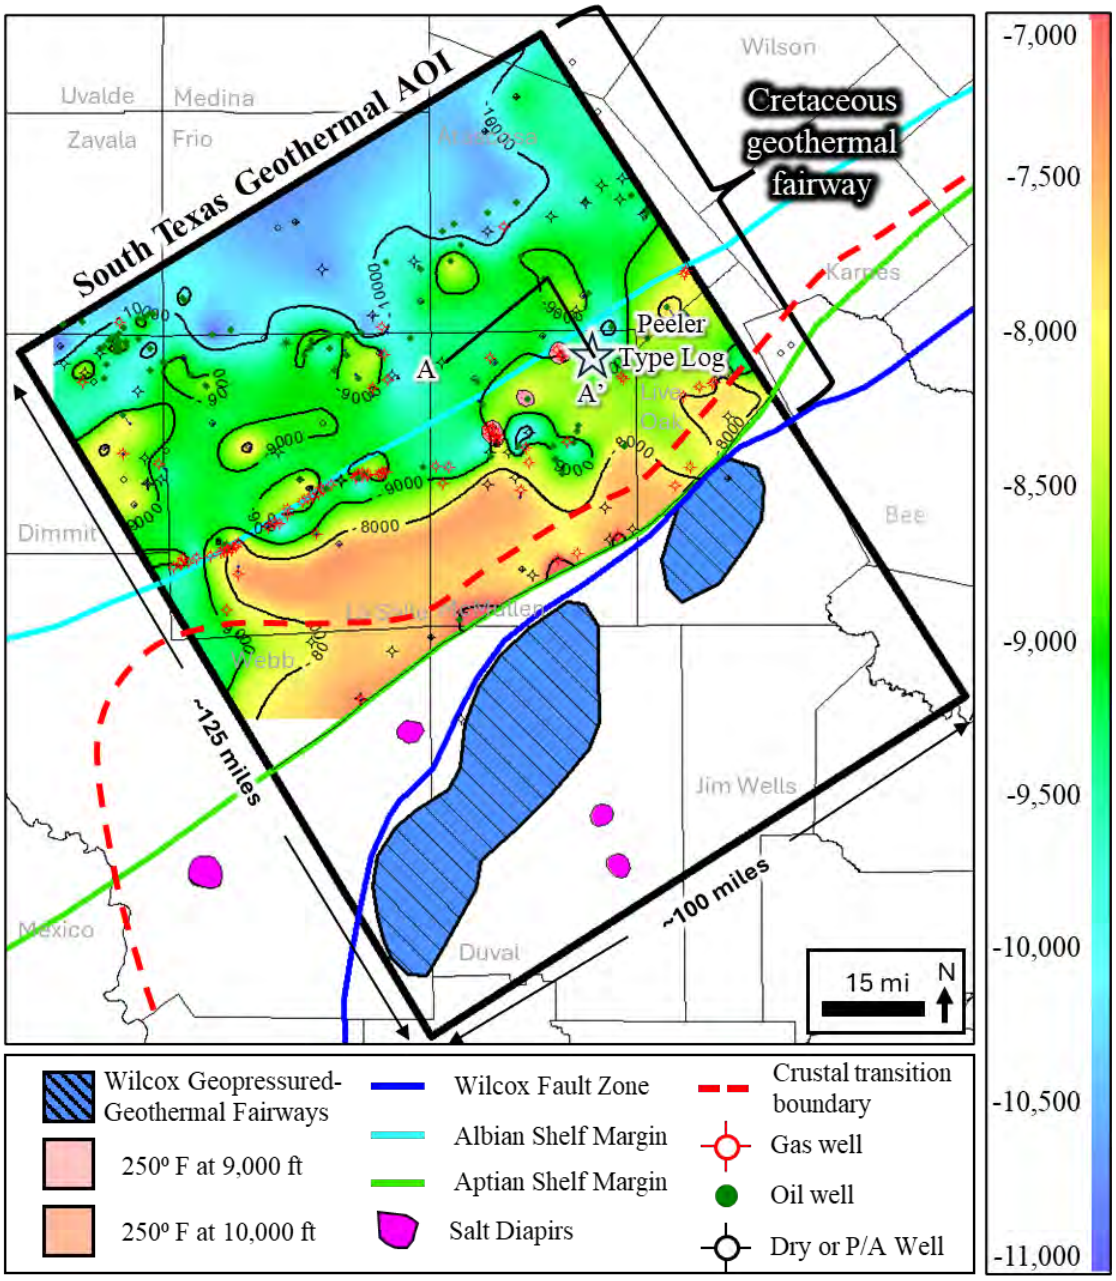

Figure 6: Temperature-depth map for the 250º F isotherm based on 267 wells with BHT measurements in Cretaceous and Jurassic formations that overly thick transitional crust. This temperature surface dips to the north and ranges in depth from about 7,000 ft to almost 11,000 ft.

4. Conclusions and Future Work

Temperature mapping is a fundamental part of geothermal exploration in sedimentary basins but often is one of the most challenging reservoir properties to calculate and map. Many external factors at the time of logging ultimately affect the accuracy of the BHT measurement and careful consideration of these factors is required when compiling a BHT dataset for correction and mapping. The Waples et al. (2004) correction methodology used here, combined with calibration

temperatures from cement bond logs and cased-hole temperature logs, appears to be a valid method for correcting BHTs in the Mesozoic strata of south Texas.

Temperature mapping based on temperature-depth logs calculated from corrected BHT measurements is one approach to high resolution temperature mapping in the subsurface. Using this method, geothermal explorers can easily hand contour temperature-depth maps and correlate temperature between wells in any formation of interest. However, comparing this method of temperature mapping to other methods, such as basin modeling, would help to compare the accuracy of each temperature mapping method. The next step in temperature-depth mapping in this research area is to repeat the methodology discussed here but on the wells with BHT measurements in Cenozoic formations (Figure 2A). This will show if there are any differences between the BHT measurements in Mesozoic formations compared to Cenozoic formations, and if the underlying type of crust is the cause these differences. Temperature mapping and BHT correction in sedimentary basins is a challenging aspect of geothermal exploration, but using the concepts and methodologies discussed above will help to ensure the accuracy and legitimacy of subsequent maps and resource estimates produced from corrected BHT measurements.

Acknowledgement

Funding for this project was provided by the Mudrocks and Tight Oil Characterization Consortium (MUDTOC) in the Department of Geology and Geological Engineering at Colorado School of Mines. Digital and raster log data was graciously provided by TGS.

ABSTRACT

The Sorik Marapi Geothermal Field is a volcano-hosted geothermal system located in North Sumatra, Indonesia. The project has been developed in four phases by PT Sorik Marapi Geothermal Power (SMGP) for a total of 180 MWe installed capacity of power generation. Wells drilled to depths of 1500 to 2715 m have proven a commercial geothermal resource at 245 – 320°C with neutral pH in an approximately 3 km (N-S) x 2 km (E-W), irregularly shaped area along the Sumatran Fault System (SFS). Like other geothermal resources, the base of the argillic cap provides a good marker for the top of the reservoir in some areas of the reservoir (mainly under Pad A and some Pad T wells). However, across much of the reservoir, the reservoir top does not align with the smectite cap and is instead commonly capped by phyllic or overlapping phyllic and propylitic alteration. In all areas across the field the appearance of wairakite, rather than epidote which is typical of volcanic-associated geothermal systems, is most diagnostic of the top of the reservoir. Vein paragenesis determined from thin section petrography illustrates that where wairakite is observed, it is consistently the most recent vein filling mineral observed throughout the reservoir. In this paper, we examine the spatial patterns between permeability, alteration mineralogy and paragenesis, and present conceptual model and alteration elements in map, 1-D, and 2-D cross-section views to illustrate these relations. This work was done as part of Geologica supporting SMGP develop the Sorik Marapi geothermal field (Sorik Marapi).

1. INTRODUCTION

Sorik Marapi is located on the northeast flank of Sorik Marapi volcano and along a major strand of the Sumatran Fault System (SFS) in North Sumatra (Figure 1). Unlike some other geothermal systems in the world adjacent to active volcanoes that have been impacted by magmatic acid vapor cores or supergene acid influx, there is no evidence that the Sorik Marapi geothermal reservoir has

experienced either, rather the reservoir is geochemically similar to many other entirely neutral systems developed worldwide. Sorik Marapi Geothermal Field can therefore be considered an example of paired (but separate) acid vapor core and neutral systems. The first thorough geothermal assessment of Sorik Marapi was completed by Sinclair Knight Merz (SKM) in 2011 (SKM, 2011), which concluded that up to four possible resource areas were present along distinct parts of the SFS northeast of Sorik Marapi volcano. Starting in 2016 and continuing into 2024, Sorik Marapi Geothermal Power (SMGP) has drilled >40 wells in Sibanggor, the southernmost of the four prospect areas identified (Figure 2) that have proven a ~245° to 325°C geothermal resource extending over an area of approximately 3 x 2 km. Between 2019 and 2023 SMGP constructed and is currently operating multiple power plants with a installed capacity of 180 MWe.

In this paper, we examine the spatial patterns between geometry of the productive reservoir, permeability patterns within the reservoir, alteration mineralogy and paragenesis, and present conceptual model and alteration elements in map, 1-D, and 2-D cross-section views to illustrate these relations. Below is a list of the key datasets used for this evaluation.

- Mud Logs: During development drilling, cuttings were collected approximately every 3 meters and analyzed under a binocular microscope. The first 25 wells were relogged by binocular scope to refine lithologic units (Hinz et al., 2021).
- MeB: Methylene Blue (MeB) estimates of the smectite clay content were completed at 9 m intervals in all production and injection wells.
- Thin Sections: Cuttings from intervals of interest were selected for thin section preparation and analysis (~10 samples per well). The thin sections were prepared by Wagner Petrographic and analyzed by Jim Stimac. Samples were stained for K-feldspar and calcite to simplify estimating abundance of these minerals (Stimac, 2023).
- Well Testing: Upon the completion of drilling, temperature and pressure (±spinner) logs were run by wireline as part of completion tests.

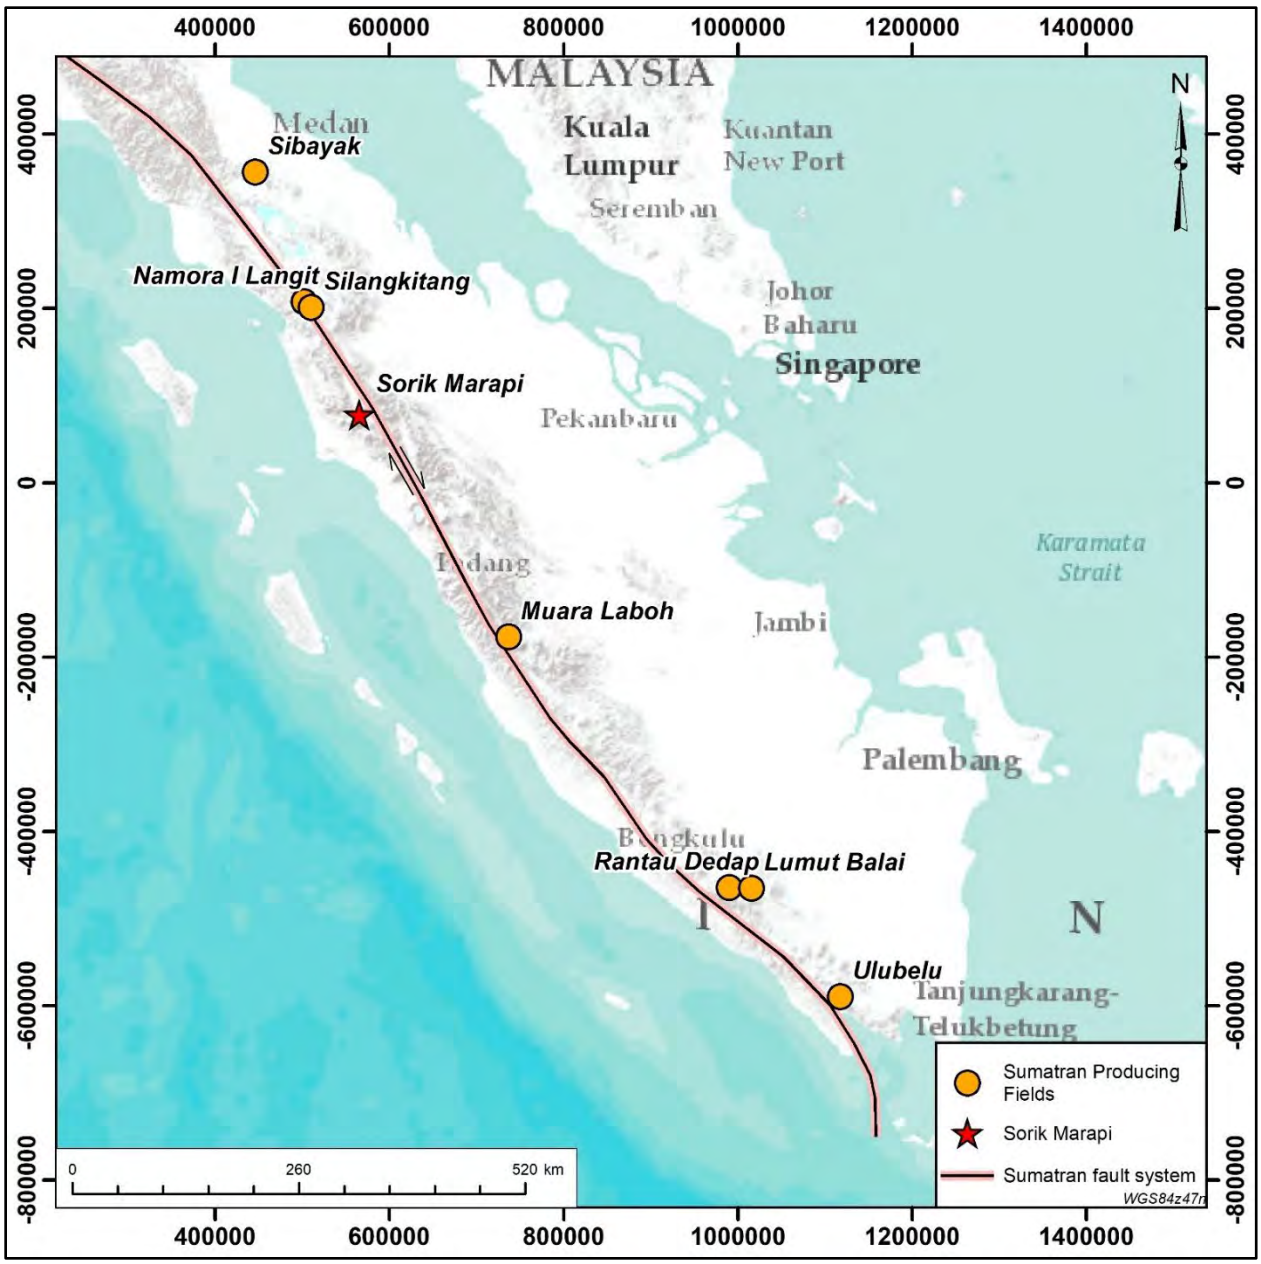

Figure 1. Overview map of Sumatra showing location of the Sorik Marapi and other operating geothermal fields.

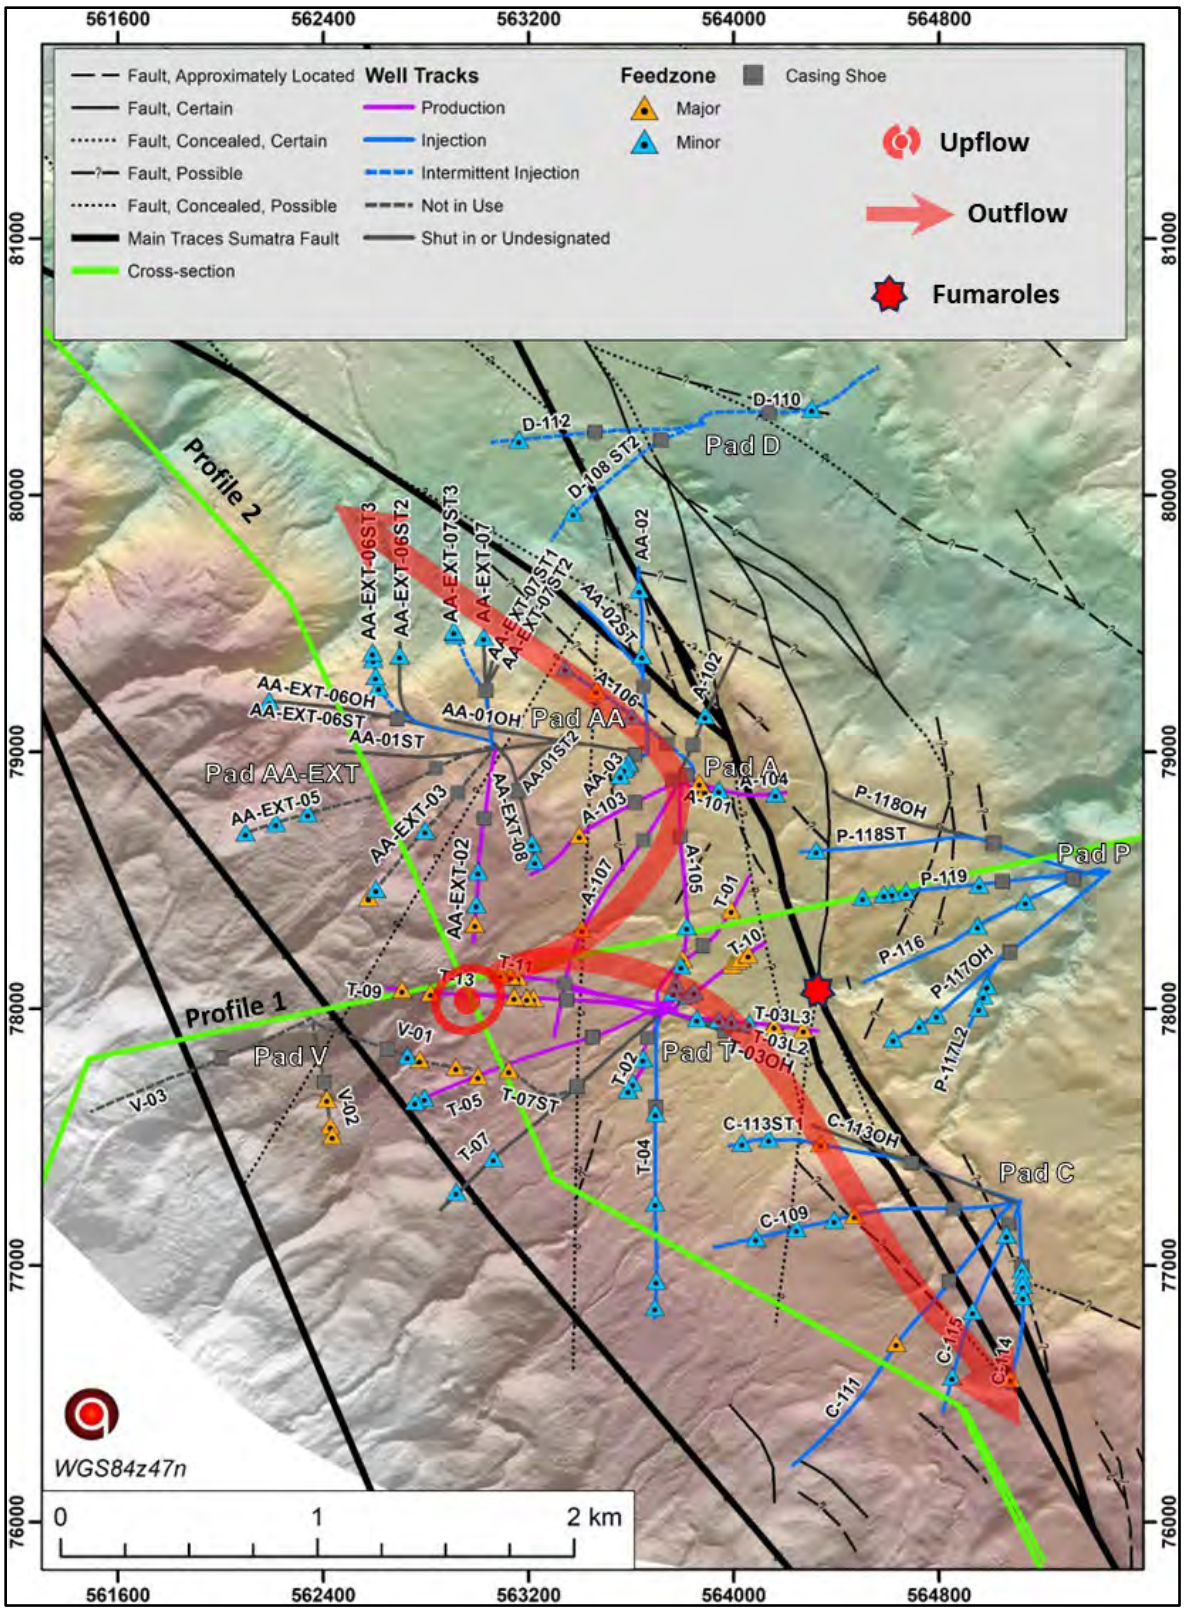

Figure 2. Wells drilled within the currently developed Sorik Marapi Geothermal Reservoir. Heavy black lines are NW-SE trending faults of the SFS. Key conceptual model elements include upflow (arrowed circle) and outflow pathways (red arrows). The green lines correspond to the cross-sections in Figures 4 and 5.

Through the development of the resource, the conceptual model has been continuously updated to incorporate geologic and well testing data from new wells. The most recent published conceptual model was in Hinz et al. (2021). This paper presents a summary of the current conceptual model used to guide ongoing development through 2024 and discusses the patterns among the initial appearance of wairakite, hydrothermal vein paragenesis, and the commercial reservoir as determined from temperature profiles and feedzones in the wells.

2. CONCEPTUAL MODEL SUMMARY

The conceptual model for the Sorik Marapi reservoir remains largely unchanged from that published in Hinz et al. (2021). In this previous conceptual model, a neutral >320°C upflow zone separate from the acid core occurs about 750 m west of Pad T (Figure 2). The inferred upflow area is based on well temperature data, fluid geochemistry, locally elevated noncondensable gases (NCG), and permeability patterns. Overall, the convective upflow appears to be elongated NE-SW and inclined upward towards the E from the area between Pads T and V towards Pad A at a moderate angle beneath a west-dipping cap rather than a subvertical upflow (Figure 4). This apparent elongate orientation of the upflow is likely associated with a NE-striking fault zone. One option for such a fault zone is a NE-striking fault that connects the major western and eastern strands of the Sumatra fault zone in this area. There is an initial eastward rollover and lateral outflow from the upflow zone which fans out eastward across Pad T and A wells, which intersect 260 to 280°C fluids. This eastward flow is under an inclined cap dominated by phyllic (sericite/illite-quartz-pyrite) to mixed-layer clay (illite-smectite, chlorite-smectite) to argillic (smectite) alteration assemblages, rising from below -1,100 masl west of Pad T to >100 masl beneath Pad A. As the outflow approaches the main strand of the SFS, it branches to the southeast and north-northwest. The southeast branch of outflow carries 250 to 260°C fluids southeast through the T-04, C-113ST, and C-109 area at -600 to -1,100 masl under a phyllic to phyllic-propylitic alteration assemblage cap (Figure 5). The north-northwest branch of outflow is inferred to carry <260°C fluid NW of A-106 within fractured metasediments and between major strands of the SFS between -600 and 0 masl below a mixed clay to argillic cap (Figure 2 and Figure 5). The zones of highest permeability in the reservoir are associated with the upflow and the outflow where it forks north and south along the SFS in the shallow Pad A wells and eastern Pad T wells.

The top of the reservoir (TOR) has been determined by the top of isothermal intervals in stable static temperature logs and feedzones identified through analysis of PT(S) surveys taken after completion testing. Throughout the productive reservoir, the depth to the TOR varies from ~250 masl to -1,200 masl. In this previous model, the base of the argillic cap provides a marker for the top of the reservoir near the eastern parts of the Pads A and T wells. However, across much of the reservoir outside this area, the reservoir top does not immediately coincide with the base of the argillic cap and is instead commonly capped by transitional/mixed clay, phyllic or phyllic-propylitic alteration area (Figures 4 and 5). This, along with paragenetic analysis suggests that reservoir permeability and temperature may have extended further than today.

The 2024 conceptual model includes two updates. One is that there are likely two major splays of SFS along the western part of the well field (Figure 2 and Figure 4). The interpretation for these splays is the variation in elevation of the contact between Tertiary volcanics and the underlying metamorphic rocks. The other conceptual model update is that there is an ~1-km diameter

hypabyssal intrusion under Pad V that is similar in size to the intrusion under Pad A but is intermediate in composition rather than felsic (Figure 4). The inferred upflow area under T-09 is inferred to be between these intrusions. The intrusions pre-date the modern reservoir and feedzones are distributed both within and outside the intrusions.

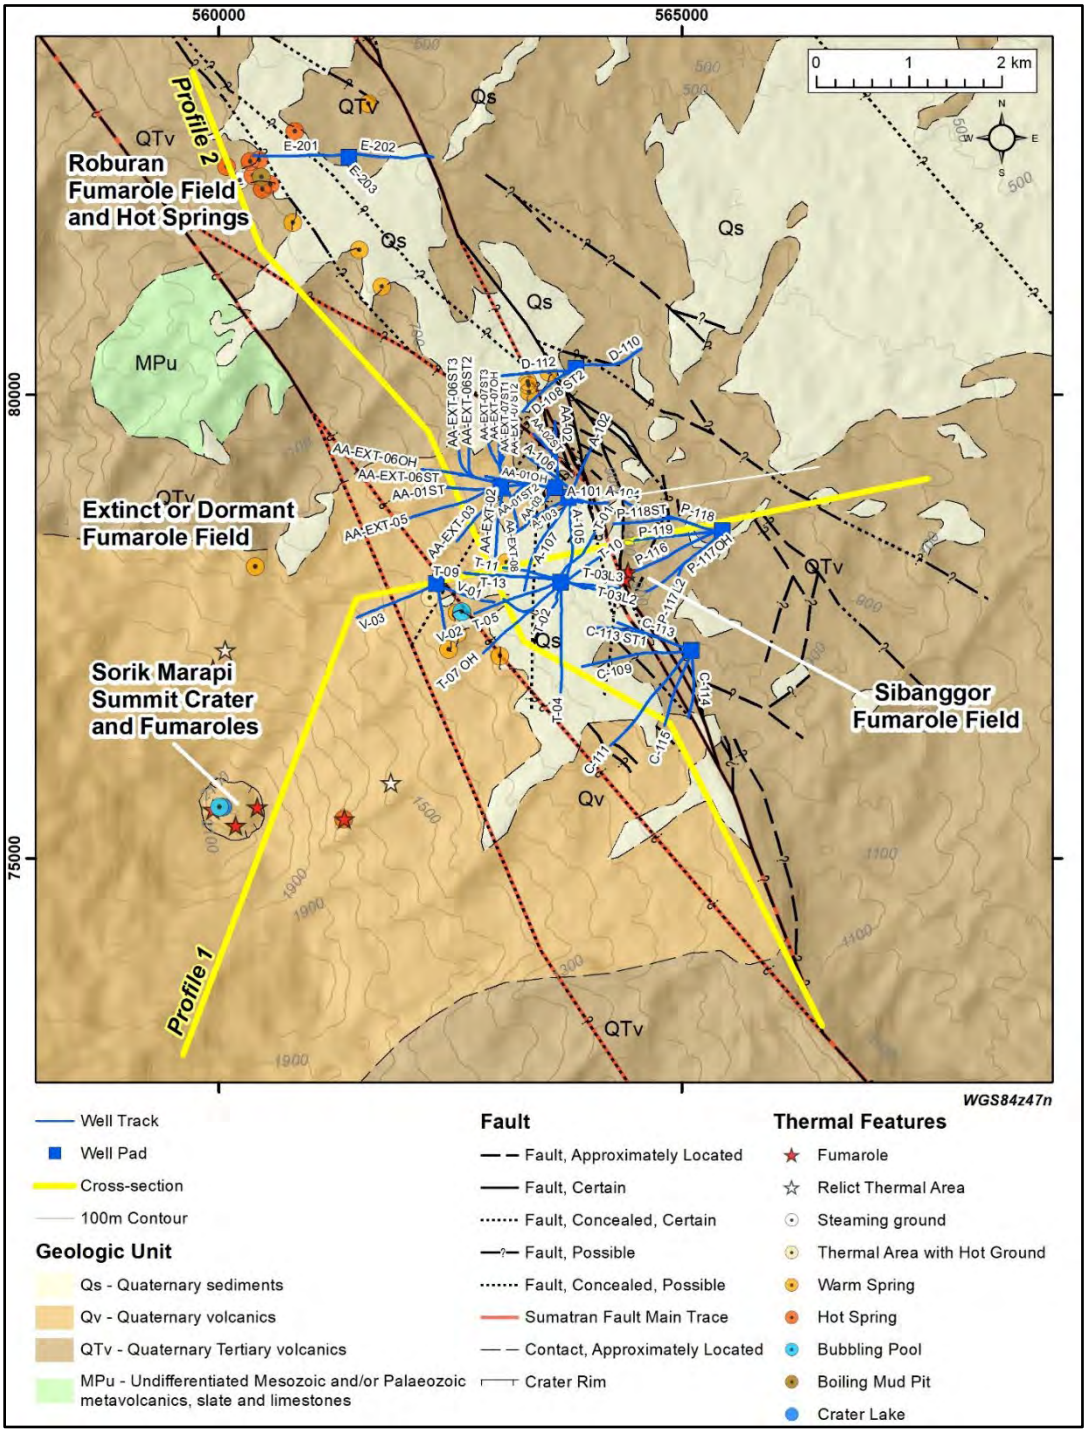

Figure 3. Map of Sorik Marapi with well tracks and conceptual model cross-section lines. The summit crater and associated magmatic fumaroles and the active solfataric (acid core) system are located about 3 km southwest of the wellfield. Modified from Hinz et al. (2021).

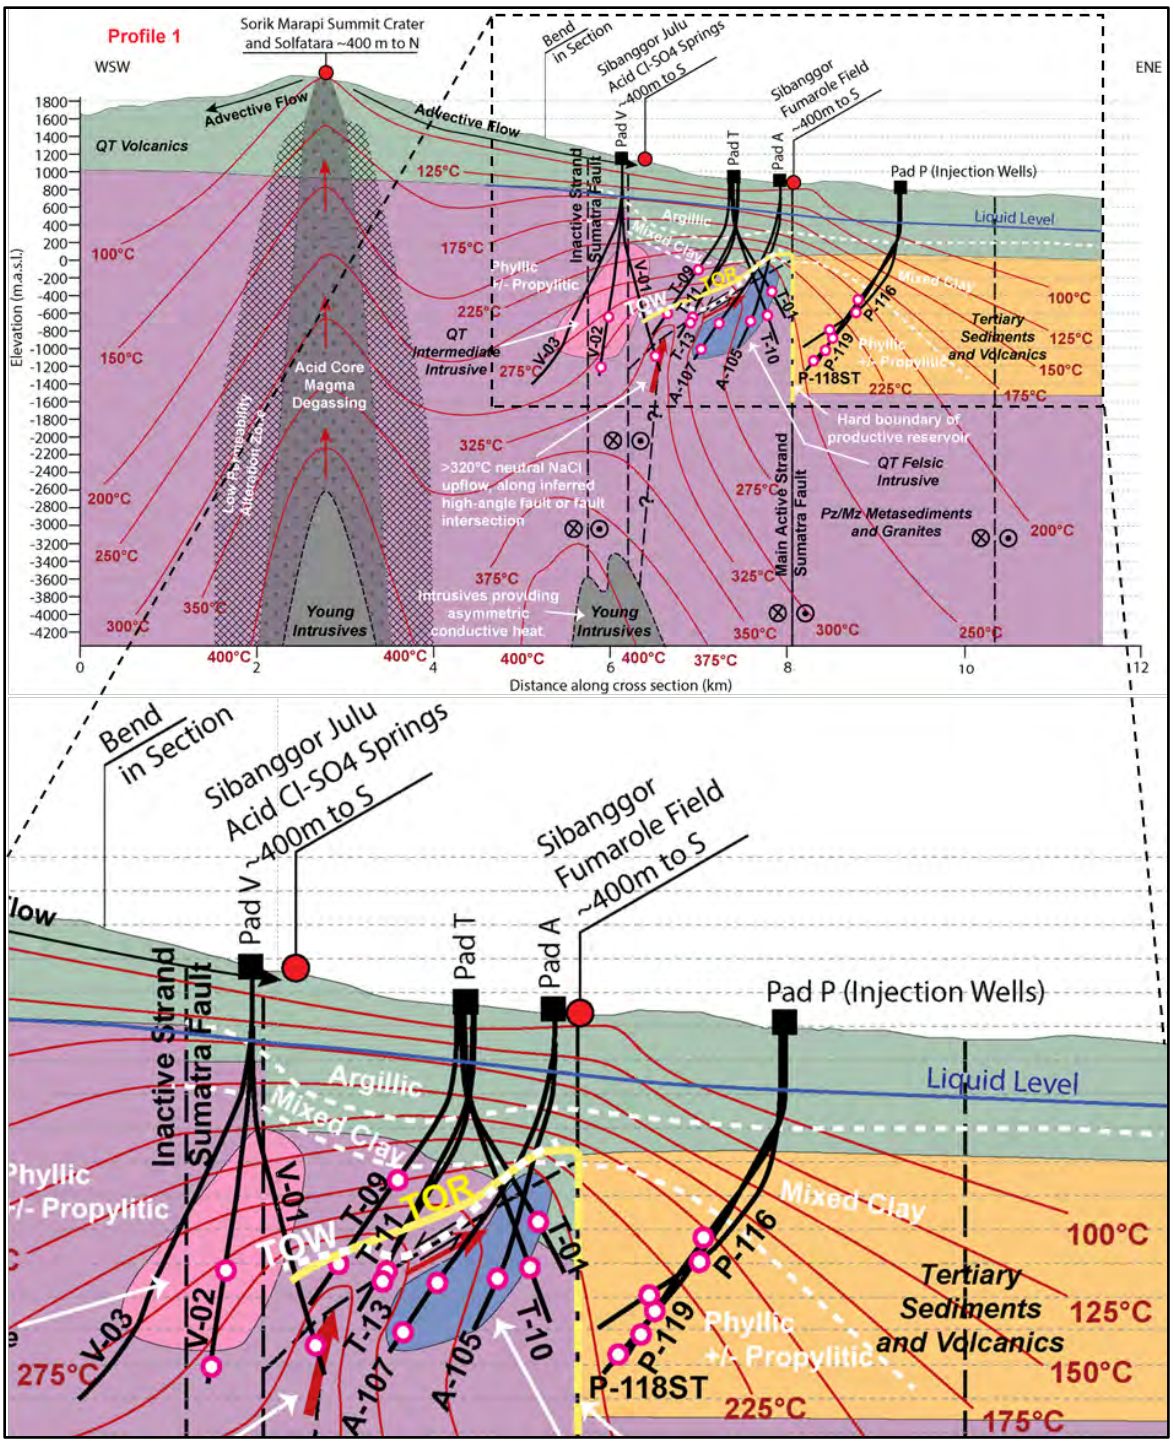

Figure 4. Top - Conceptual model cross-section along Profile 1 (location shown in Figures 2 and 3). The key features of the model include simplified geologic units, temperature isotherms, the top of the reservoir (TOR) shown as a yellow line, the top of wairakite (TOW) shown as a heavy dashed white line, major structures (dashed black lines), and hydrothermal alteration zones (white dashed lines and text). Well courses are solid black lines, and major feedzones are shown as open red circles. Bottom – a zoomed in view of the conceptual model cross-section showing the relations between the TOW, TOR, and feedzones. Modified from Hinz et al. (2021). The acid core system beneath Sorik Marapi volcano is based on surface observations and modeled after Reyes et al. (1993).

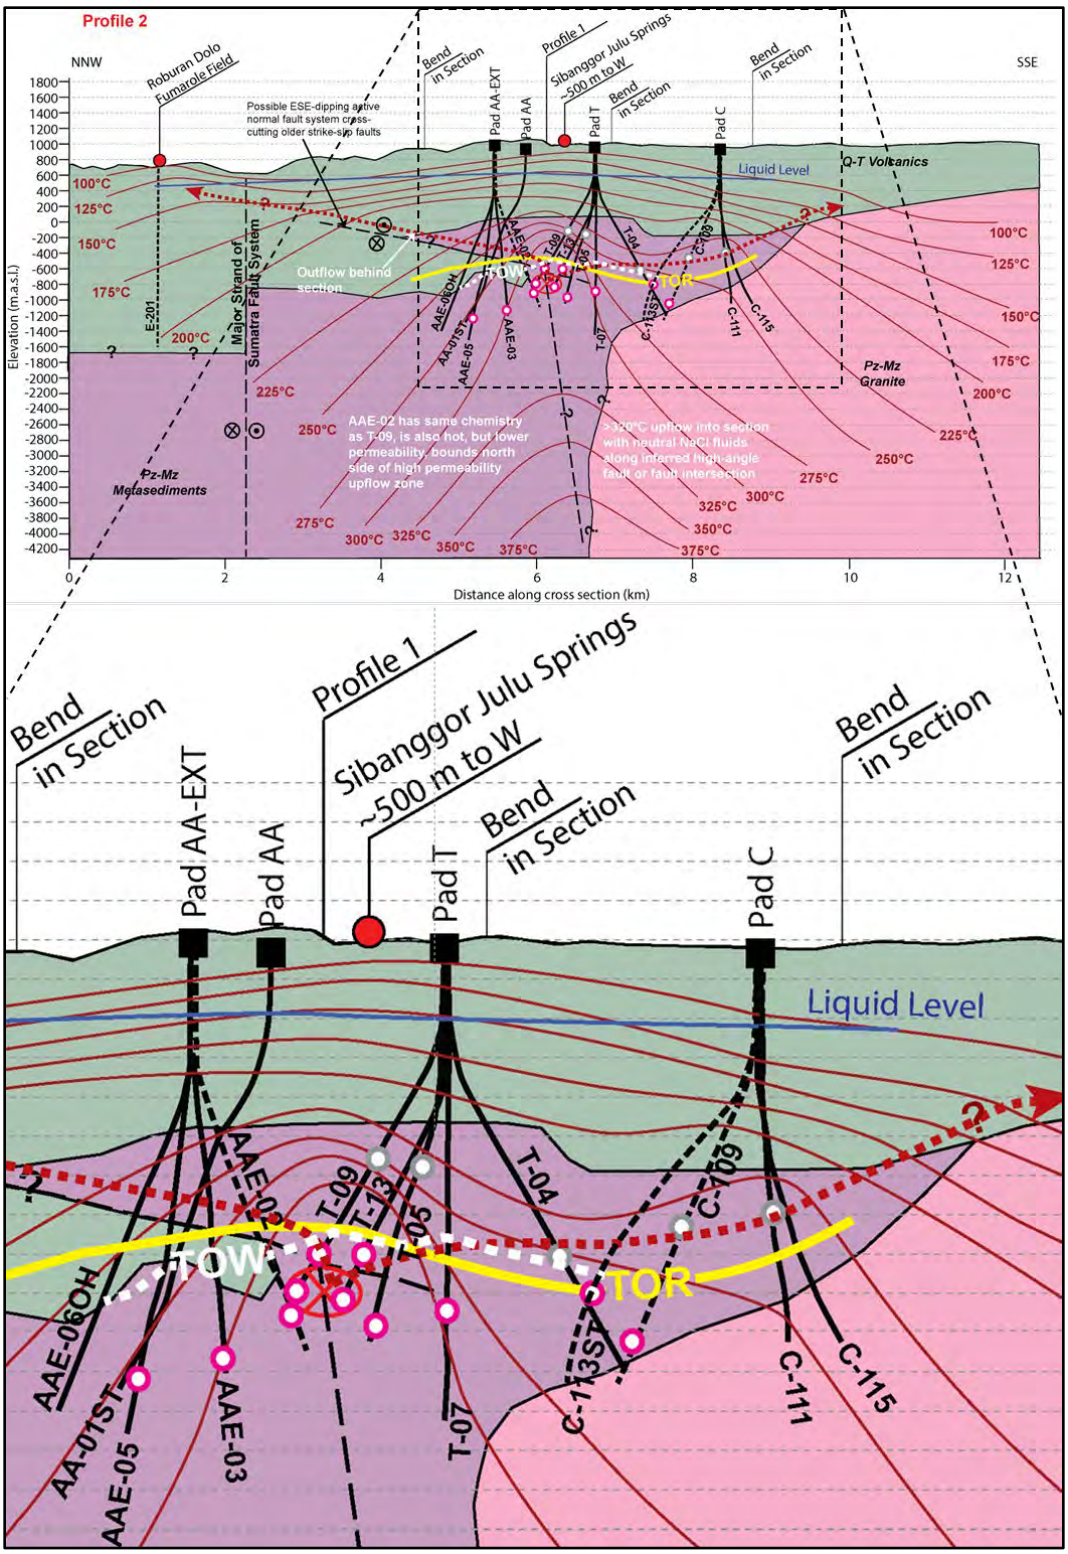

Figure 5. Top - Conceptual model cross-section along Profile 2 (location shown in Figures 2 and 3). The key features of the model are shown in the same manner as in Figure 4. Outflow to N and S are shown as dashed red lines and portray flow behind section. Bottom – a zoomed view of the conceptual model cross-section showing the relations between the top of wairakite, top of the reservoir, and feedzones. Modified from Hinz et al. (2021).

3. HYDROTHERMAL ALTERATION

Hydrothermal alteration in geothermal systems is well understood and can be separated into distinct mineral assemblages based on the chemistry of circulating fluid (e.g., Browne, 1978; Reyes, 1991). Evaluation of mineral paragenetic sequence in veins provides an additional level of understanding of system evolution and status (Stimac, 2023). In particular, comparison of the formation sequence of key calc-silicate minerals and the abundance of open space in veins to measured temperatures and well permeability provides insight into the evolution of the system to its current state.

Analysis of well temperature and alteration mineralogy data has identified that the alteration of the cap overlying the reservoir varies from argillic (smectite) to mixed-layer clay (smectite-illite and smectite-chlorite) to phyllic-propylitic (Hinz et al., 2021). Phyllic-propylitic alteration consists of overlapping dominant quartz-sericite-pyrite and subordinate quartz-chlorite-epidote-pyrite. Where both epidote and illite/sericite are present in a sample, we determine the dominant assemblage by which key mineral is more abundant.

The metasedimentary rocks such as phyllite and schist are atypical reservoir rocks in volcanic systems but are important in the Sorik Marapi system. Their presence favors formation of illite/sericite-quartz-titanite-pyrite-calcite, rather than epidote and other calc-silicates. Conversely the assemblage epidote-adularia-chlorite-quartz-pyrite is more prevalent in plutonic rocks that form another important reservoir lithology in the Sorik Marapi system. In these rocks epidote is distributed as matrix alteration or in filled veins where it is encapsulated in later quartz, calcite, or prehnite. This contributes to the poor correspondence between epidote and the current reservoir top of this system. More broadly this suggests the existence of precursor hydrothermal systems that formed in the same area as the modern system or earlier stages of fluid-rock interaction in this geothermal system.

The cap geometry over major feedzones in production wells on Pads A, AA, AA-EXT, T, and C shows that the reservoir top deepens to the southwest from Pad A and is deepest in the T-05 and T-09 area. In general, decreases in MeB values provide the most consistent marker for the top of the reservoir in the Pad A area, coupled with the appearance of chlorite replacement of phenocrysts; this is typical of the argillic to transitional/mixed-layer clay transition. Note the argillic alteration is correlative to the volcanics and is not observed in the underlying metamorphic rocks. As the cap further deepens to the SW in the west-directed Pad T wells (i.e., T-05 and T-09), it transects below the volcanic rock and enters the metamorphic rock and is characterized by phyllic-propylitic alteration, and the underlying reservoir is most consistently marked by the appearance of wairakite.

3.1 Implication of Wairakite in Analogue Systems

In typical high-temperature (> 240°C) neutral-chloride volcano-hosted geothermal systems, the first vein minerals to form upon fracture initiation and upflow of heated meteoric water circulation are epidote ± adularia ± quartz (Stimac, 2023). As temperatures decline, prehnite ± quartz commonly form. Wairakite ± calcite ± anhydrite commonly form later as temperature declines or pH declines due to admixture with steam condensate (Moore et al., 2004; Figure 7). Calcite ±

anhydrite may also form from descending peripheral steam-heated waters as system temperatures and pressures wane. Secondary mineral growth tends to result in permeability loss unless fractures are being reopened or new ones are being formed. Progressive infilling of veins records the life of the system, although rejuvenation and repeated paragenetic cycles are possible.

Moore et al. (2004) summarized characteristics of wairakite at Tiwi, Bulalo (Philippines) and Karahabodas (Indonesia) geothermal fields. Constraints from fluid inclusions in coprecipitated phases gave temperatures of about 235 to about 300°C. Similarly, at Copahue (Argentina), quartz coexisting with wairakite had fluid inclusions temperatures of 240 to 280°C (Mas et al., 1995). These authors interpreted that the coexistence of vapor- and liquid-rich inclusions in the same quartz crystal as suggesting that boiling was taking place when wairakite was precipitated.

Moore et al. (2004) highlighted that wairakite typically forms late, commonly after epidote and prehnite, but before calcite and anhydrite. However, at Bulalo episodes of epidote and wairakite alternated. At Karahabodas, wairakite postdates early epidote, then prehnite and later anhydrite + calcite. In these examples Moore et al. (2004) noted that wairakite typically forms from lower pH or lower aCa^{+2} fluid than epidote (i.e., lower aCa^{+2}/aH^{+}). They emphasized that, based on phase relations, a decrease in temperature favors prehnite over epidote but a decrease in pH favors wairakite relative to epidote.

Although epidote is typically used to define high-temperature geothermal reservoir volumes, in some cases wairakite may be the most reliable indicator of the reservoir top and extent. Wairakite is common in high-temperature geothermal systems (>220°C) dominated by propylitic alteration (Browne and Ellis, 1970; Moore et al., 2004). They observed wairakite forming after epidote ± prehnite and either before or after late anhydrite ± calcite. They interpret this sequence of deposition to indicate evolution from system initiation and upflow (epidote), to minor cooling (prehnite), to mixing with descending steam condensates (wairakite), and descent of sulfate and bicarbonate-rich steam heated waters (anhydrite ± calcite). This general sequence, or variations on it, is extremely common, especially in the upper portions of geothermal reservoirs (Moore et al., 2004; Stimac, 2023). Wairakite is stable at relatively low concentrations of dissolved CO_2. At higher concentrations of CO_2, it is replaced by calcite (Browne and Ellis, 1970; Thompson and Thompson, 1996; Moore et al., 2004).

3.2 Wairakite at Sorik Marapi

At Sorik Marapi wairakite is commonly the most abundant calc-silicate mineral (Figure 6 and Figure 8). It is found partially filling late-stage veins that appear to have formed at or near current system conditions. It is particularly useful in determining the top of the reservoir since epidote is commonly distributed above and/or laterally away from the reservoir or is sparse to absent. Wairakite locally encapsulates needles of earlier formed epidote, actinolite, or prehnite, and it is found in close association with quartz, calcite, and anhydrite.

Geochemical data from wells indicate that the Sorik Marapi reservoir fluid is a dilute (TDS ~1500-1900 mg/kg) neutral Na-Cl brine (Hinz et al., 2021) with low non-condensable gas (up to 0.1 wt% total NCG) primarily composed of CO_2, with minor proportions of H_2S and trace amounts of NH_3, N_2, CH_4, and H_2. Steam is formed from depressurization of these reservoir fluids and condensed would likely be an acid sulfate fluid. However, steam zones at the current Sorik Marapi reservoir

appear to be production induced and limited to shallow parts of the reservoir. Wairakite is found deeper in the reservoir at high temperature as well as at the top of the reservoir. Alternating episodes of boiling and cooling, rupture, and down flux of condensed steam may be the processes which yielded the formation of wairakite at Sorik Marapi and the association of wairakite with quartz and bladed calcite or anhydrite. Such ruptures may be related to the close spatial relationship of the reservoir to active splays of the SFS.

Figure 6. Wairakite found at 1635 m-MDRF in well T-09. The depth at which this wairakite was observed coincides with an increased loss rate of drilling fluids, indicating that an open-fracture was intercepted.

The shallowest depth at which wairakite is found is 877 m-MD (26 masl) in well A-104, where the downhole temperature is almost 260°C. Meanwhile, wairakite is noted in well AA-EXT-05 from 1,699 m-MD (-650 masl) to 2,653 m-MD (-1,466 masl) which is the deepest depth it is observed. Generally, wairakite in Sorik Marapi is observed in the productive reservoir west of the

main strand of the SFS where Pads A, AA, AA-EXT, and T are located (Figures 2, 3, and 12) and is largely absent in Pad C, D, and P wells.

The abundance of both wairakite and phyllic alteration at Sorik Marapi is consistent with an increasing aK+ and/or aH+ relative to aCa++ compared typical neutral-Cl waters producing propylitic alteration. However, diaspore or kaolinite/dickite, characteristic of advanced argillic alteration, are rarely observed at Sorik Marapi and produced fluids are benign. Wairakite is also observed as the latest vein filling mineral in phyllic altered zones in well A2 at about 710 m-MDRF at Muara Laboh (Baroek et al., 2018).

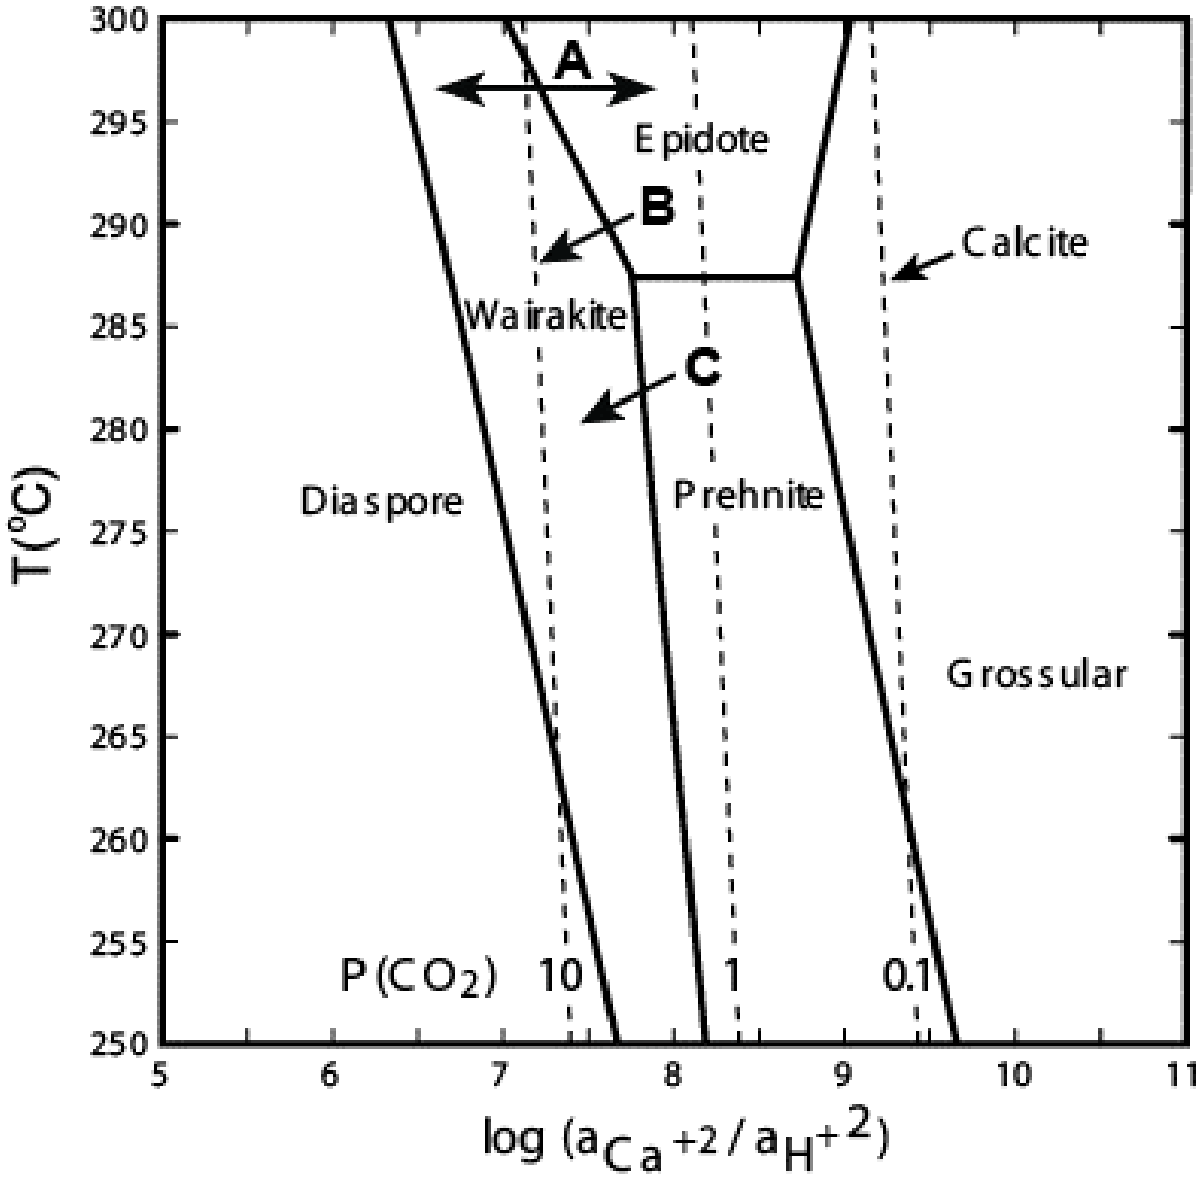

Figure 7. Phase relations between epidote, prehnite and wairakite for a fluid composition precipitating illite (from Moore et al., 2004). Arrows illustrate paths between epidote, prehnite, and wairakite: A) is a path for changing aCa++/aH+ at the same temperature, B) and C) are for concurrent cooling and decreasing aCa++/aH+ for epidote and prehnite to wairakite, respectively.

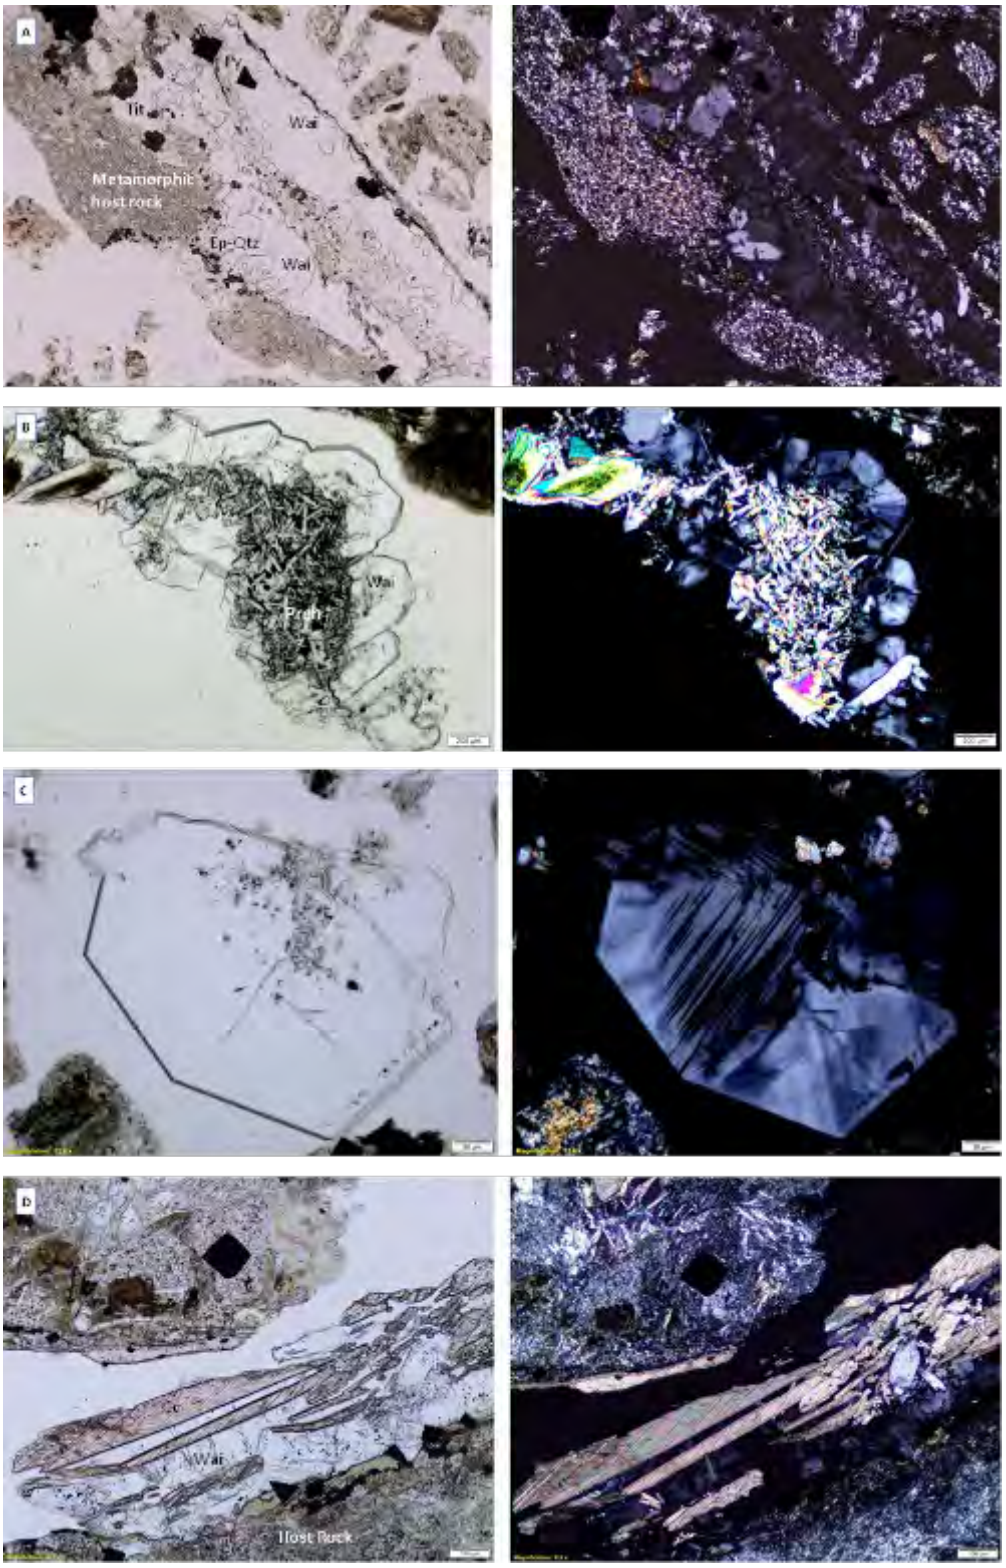

Figure 8. Wairakite at Sorik Marapi. A) Wairakite (Wai) infilling open veins with early quartz (Qtz). B) Wai encapsulating earlier prehnite (Prh). C) Euhedral Wai indicating growth in an open vein, possibly encapsulating minor calcite and epidote. D) Intergrown bladed calcite (Cc) and Wai suggesting boiling conditions.

3.2 Open Space Textures

Numerous petrographic studies of cuttings and core indicate that higher permeability is more likely when open space textures such as euhedral or subhedral intergrowths of common vein minerals are observed (e.g., Stimac, 2023). Conversely, filled vein samples may signal that system permeability has declined in that area. Commonly the onset of significant open space in veins corresponds with the top of the deep reservoir. Within the permeable Sorik Marapi reservoir veins with open space are commonly very abundant in the vicinity of major entries. This is evidenced by both open space textures such as euhedral crystals and a high abundance of vein fragments in cuttings samples (reaching 20-30%).

There is also evidence for hydrothermal and tectonic breccias with overgrowths of new vein minerals indicating that open space was created multiple times in some areas. For example, in well A-107 breccias consisting of both host rock and vein mineral fragments are overgrown by wairakite and wairakite-adularia (Figure 9). Wairakite, quartz (Figure 10), prehnite, and adularia are the most common minerals in these occurrences.

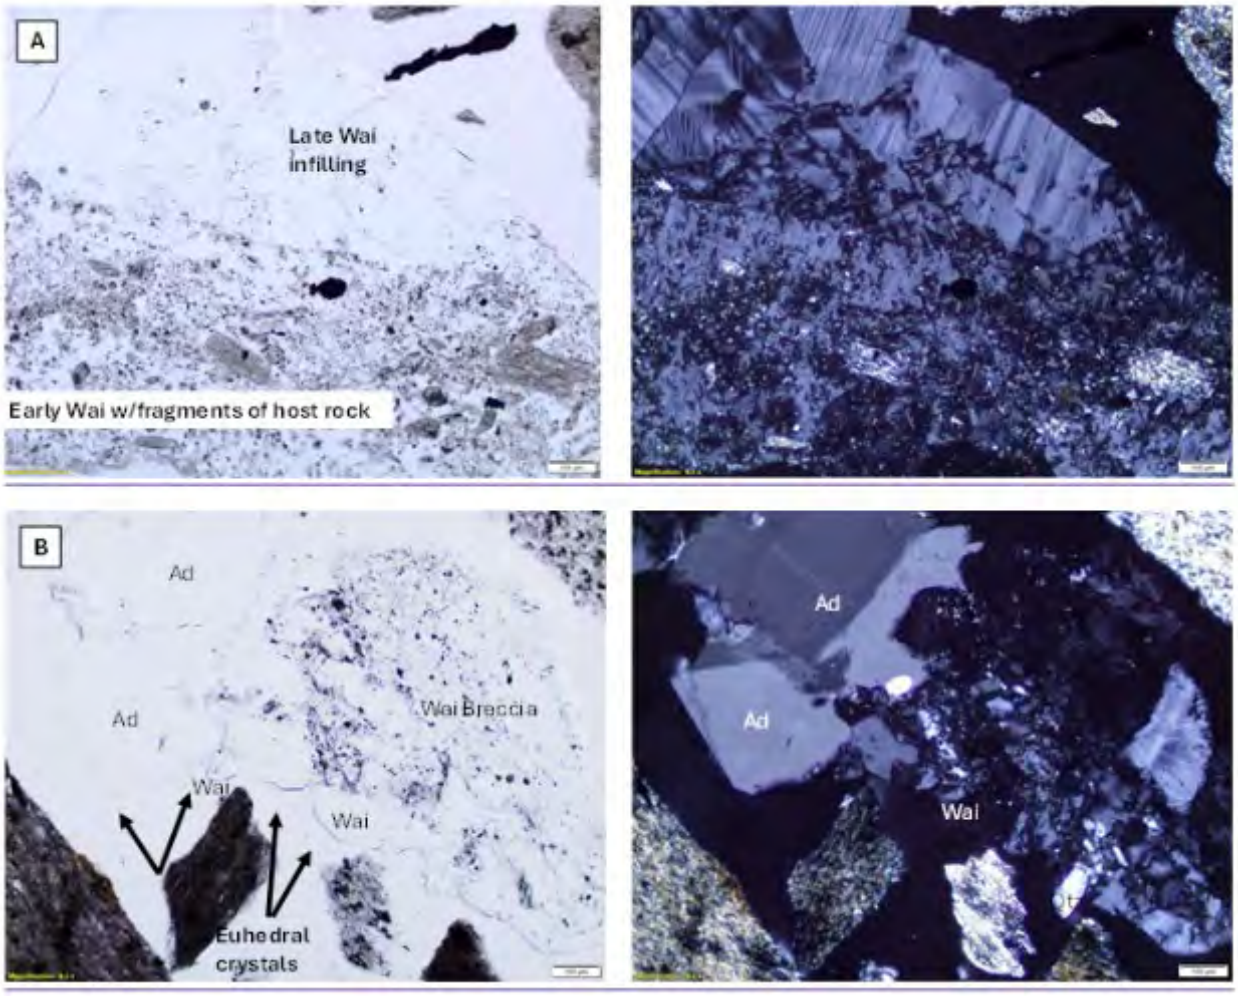

Figure 9. A) A-107 1393 m-MDRF – Multiple episodes of wairakite with clastic debris of host rock; B) A-107 1393 m-MDRF - Multiple episodes of wairakite with evidence of open space adularia-wairakite.

Figure 10. Open space mineral indicator, drusy quartz, from 1109 m-MDRF in well T-03. Drusy quartz grew with secondary silica as its platform.

4. WAIRAKITE DISTRIBUTION AND RESERVOIR PERMEABILITY

Across the productive Sorik Marapi reservoir, there is a correlation between the initial appearance of wairakite in wells and the top of the reservoir (Figures 4 and 5). The top of the reservoir has been determined by the top of isothermal intervals in stable static temperature logs and feedzones identified through analysis of PT(S) surveys taken after completion testing. Most feedzones in productive wells are in metamorphic rocks or intrusions, although a few feedzones have been observed in volcanics (e.g., A-101 and A-104). There are no clear permeability patterns at the margins of intrusions as have been observed at some other geothermal fields (e.g., The Geysers, USA). It is therefore likely that all the feedzones are associated with faults or major fractures. Wells A-101, C-113ST, T-01 and T-09 provide examples throughout the upflow and outflow zones of the relation between the appearance of wairakite, feedzones, and the top of the reservoir (Figure 11). Well T-09 is located near the >320°C upflow zone, well T-01 is in an easterly outflow, well A-101 resides in the shallowest part of the reservoir where a thin natural steam cap is inferred to exist prior to development, and C-113ST is in outflow to the south. The depths of the appearance of wairakite, feedzones, and isothermal intervals in these wells are presented in Table 1. While

wairakite can be distinguished under the binocular microscope when logging chips, it can be difficult to distinguish from other similarly colored minerals. The maximum vein abundance noted in thin sections from these wells varies widely from 6% in C-113ST to 100% in A-101. However, in the production section of each respective well vein abundance generally increases near the first observance of wairakite (Figure 11).

Table 1. Correlation between wairakite, feedzones, and isothermal intervals in select Sorik Marapi wells.

Well	Depth of Wairakite (m-MDRF; masl)	Feedzone Depth (m-MDRF)	Start of Isothermal Zone in Temperature Profile (m-MDRF)
A-101	870; 50	830	~870
C-113ST	1640; -700	1710	~1710
T-01	1010; -100	1440	~1010
T-09	1635; -750	1200 to 1840	~1170

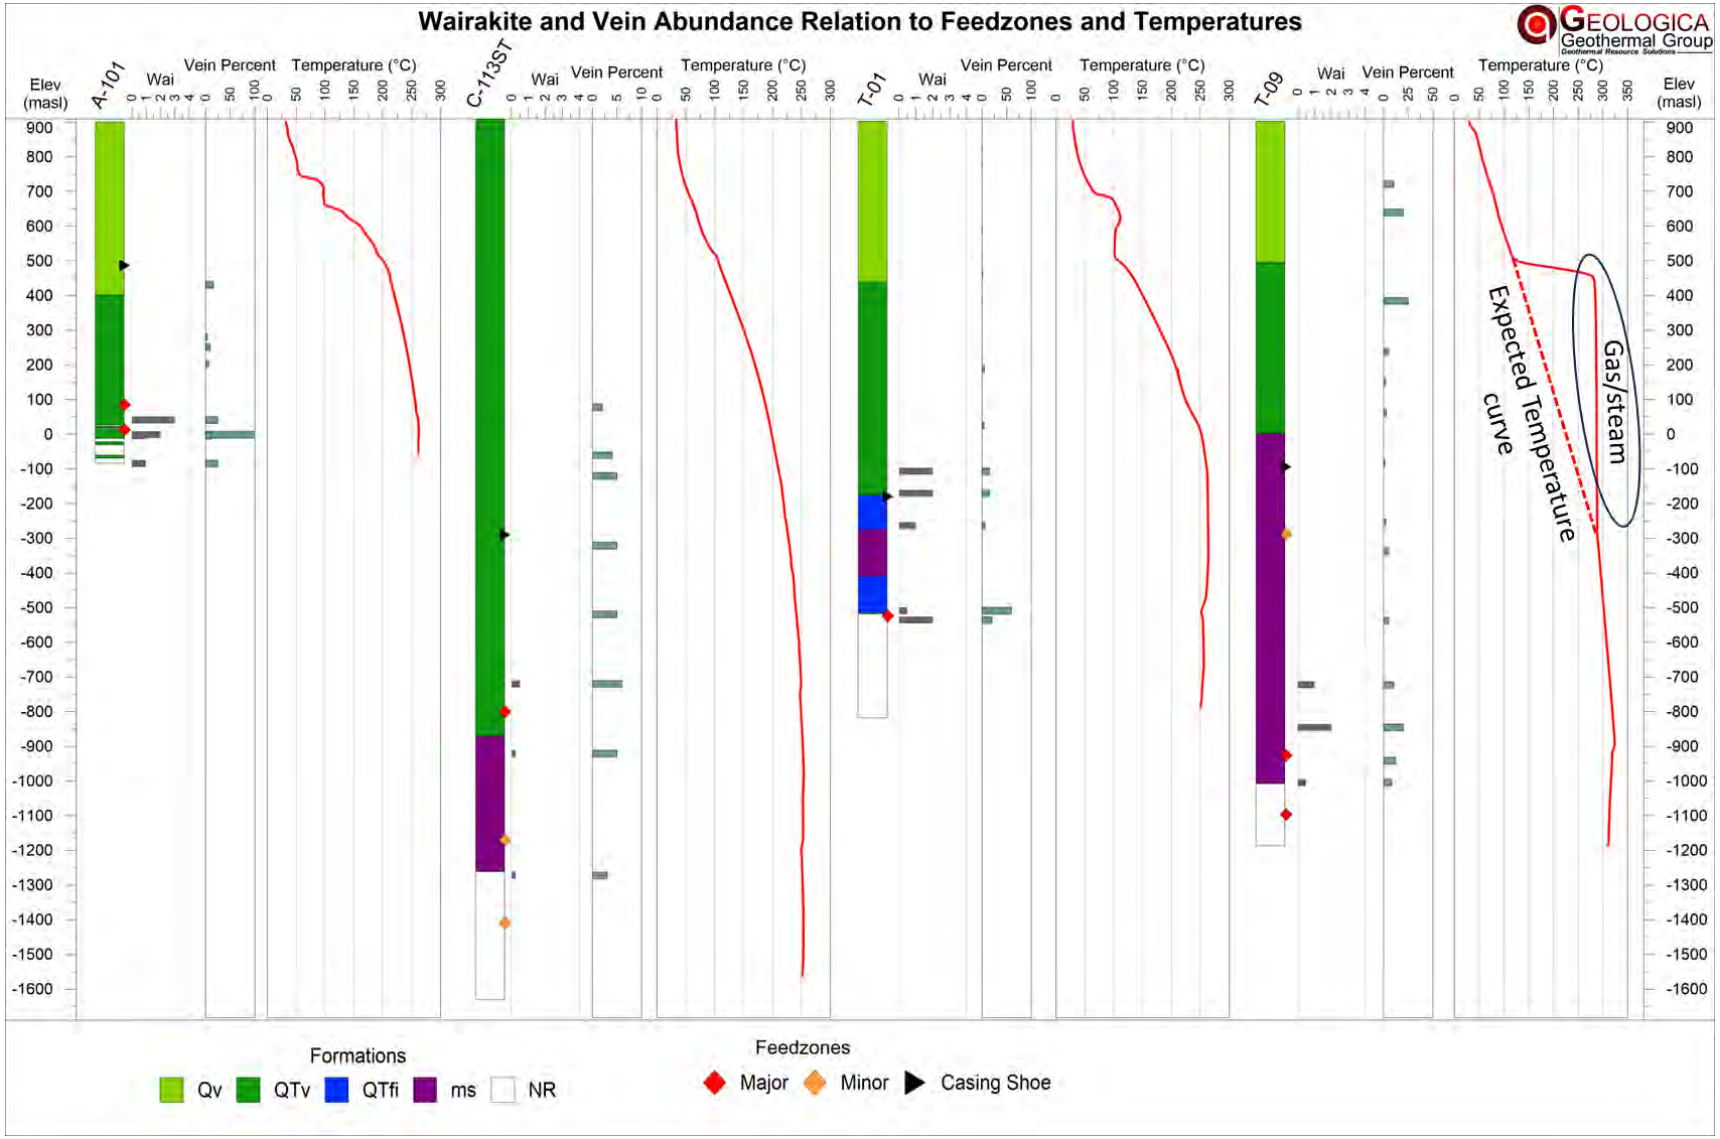

Figure 11. Select SMGP wells showing correlation of wairakite and vein abundance to reservoir permeability. Formations: Qv – Quaternary volcanics; QTv – Quaternary to Tertiary volcanics; ms - Paleozoic-Mesozoic metasediments; NR - no returns.

There is generally good spatial distribution of wairakite abundance (Figures 12 and 13) relative to permeability in the reservoir as defined by injectivity indices of feedzones. As shown in Figures 12 and 13, the highest qualitative abundance (see figures for key) of wairakite noted in thin sections is seen in wells near the upflow zone (near wells T-05 and T-09) and in Pad A wells where the top of the reservoir is shallowest (Figure 4). However, there are likely some high wairakite abundance areas within the reservoir that are aliased due to thin section sample selection (e.g., no thin section samples from A-105, V-02, and V-03), total lost circulation in productive wells (e.g., T-03L3 and T-10 have major feedzones below TLC intervals), and distribution of well tracks in 3D space. There is another area of higher wairakite abundance near well AA-EXT-05 that does not have a high injectivity index. This may represent an area that had higher permeability in the past but has not had fractures re-opened by fault activity in recent geologic time. Northeast of the main strand of the SFS, there are only two instances of wairakite in thin sections. This aligns well with the conceptual model which posits the main strand of the SFS is predominately a permeability barrier and a reservoir boundary. To the south of the productive reservoir, wairakite is only observed in the northernmost Pad C well, C-113ST.

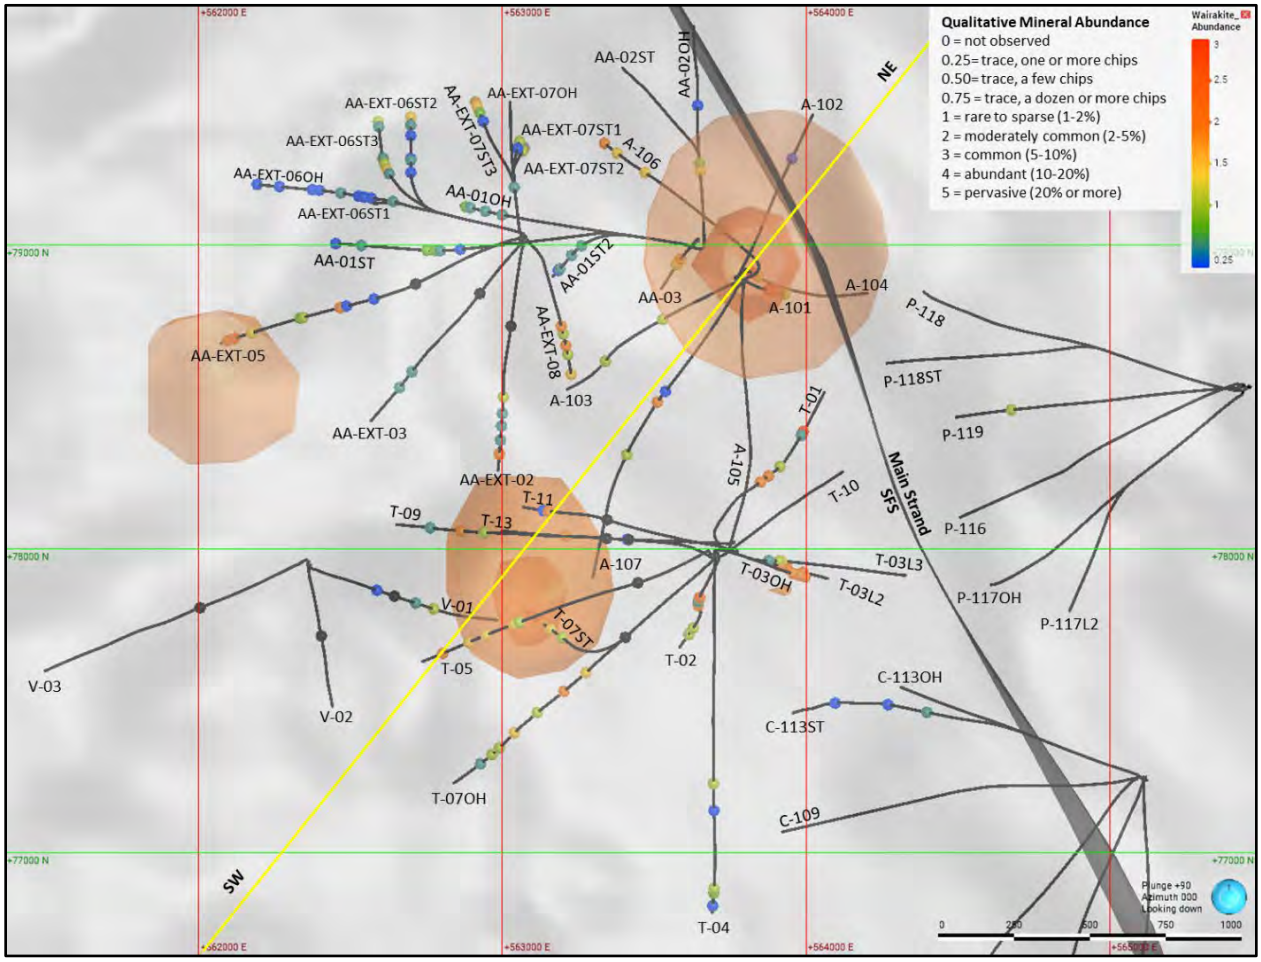

Figure 12. Plan view of drilled well tracks and wairakite qualitative abundance from thin sections (color-scaled spheres) with higher abundance areas emphasized (2.0 and 2.5 isosurfaces); black spheres are production casing shoes. Cross-section profile (SW-NE) used in Figure 13 is shown for reference.

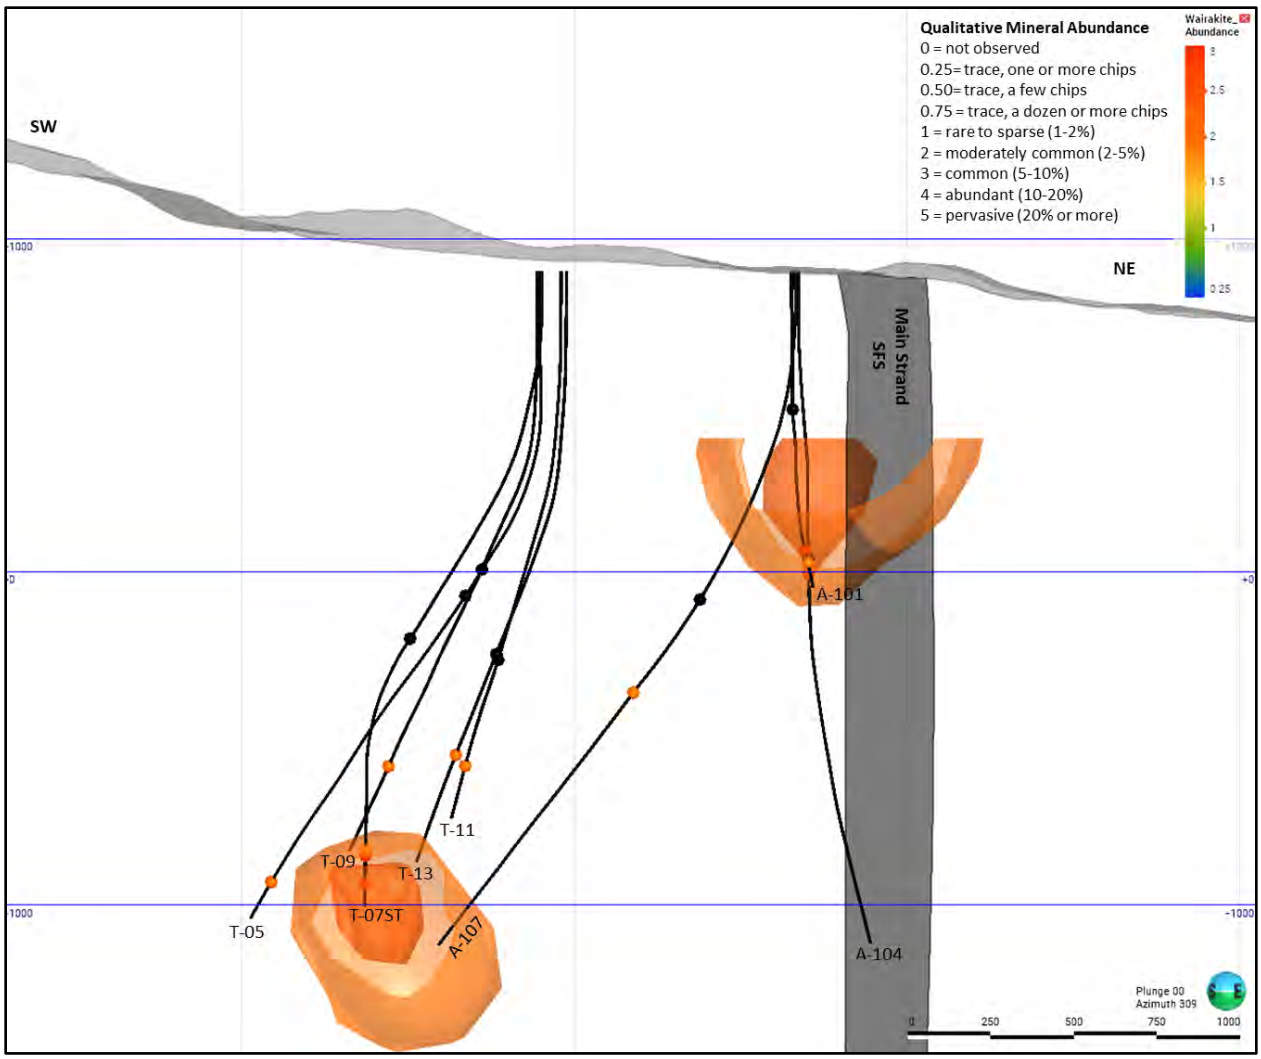

Figure 13. Section view showing wairakite qualitative abundance 2.0 and 2.5 spheres along well tracks and isosurfaces; black spheres are production casing shoes. These higher abundance zones are near deep upflow (e.g. near T-05, T-09) and the shallowest part of reservoir below Pad A (e.g. A-101, A-104).

5 CONCLUSIONS

There is a close correlation between the productive reservoir at Sorik Marapi and the presence of wairakite. Conversely, in wells outside of the productive reservoir, wairakite is generally not present. The top of the reservoir of the Sorik Marapi geothermal resource transects two major formations and includes metamorphic rocks in the deeper parts and volcanic rocks in the shallower parts. In the part of the cap that is made up of volcanic rocks, the alteration of the cap is argillic to mixed clay. In the part of the cap that is made up of metamorphic rock, the alteration in the cap is phyllic or phyllic-propylitic. In all areas across the field, independent of reservoir rock lithology or depth, the appearance of wairakite is most diagnostic of the top of the reservoir. This observation is based on vein paragenesis determined from thin section petrography illustrates where wairakite is observed, it is consistently the most recent vein filling mineral. This association with the top of

the reservoir and the recency of wairakite in vein paragenesis indicate it is the alteration mineral that is most closely linked with current reservoir conditions.

In general, wairakite is favored over epidote at lower pH and temperature. Over the past couple of decades, a pattern of later stage wairakite has continued to be recognized in several fields (e.g., Maura Laboh, Sumatra, Indonesia, Baroek et al., 2018; Rantau Dedap, Sumatra, Indonesia, Mussofan et al., 2021; outflow of Bacman, Philippines; Dimabayao and Rowe, 2020). Moore et al. (2004) made a case that late wairakite is typically related to mixing of steam condensate with reservoir fluid. At Sorik Marapi, the acidic or cooler conditions conducive to the formation of wairakite could be produced by alternating episodes of boiling and cooling, rupture, and down flux of condensed steam or steam mixed with peripheral waters. This work could benefit from selection of additional intervals of cuttings for thin section preparation and evaluation to farther refine the distribution of wairakite, and additional reservoir fluid sampling for geochemistry analysis to help determine the main mechanism responsible for forming wairakite at Sorik Marapi.

ABSTRACT

Since August 2022, an exploration campaign has been conducted in Northern Alsace, France, to enhance the understanding of the area and build 3D models integrating geological, geophysical, and geochemical data. These 3D models aim to mitigate the risks associated with future lithium extraction by modeling the effects of extraction on the subsurface. This comprehensive integrative approach will help lithium resource assessments and targeting future projects.

1. Introduction

Launched in 2020, Lithium de France's project aims to produce hot, lithium-rich fluid naturally circulating within a fracture network in the Upper Rhine Graben (URG). The primary target in their exploration license, named Les Sources, is the natural circulations within the fractured and faulted reservoir at the sediments-basement interface. Understanding and predicting these brine circulations inside the fault network are crucial for the success of geothermal projects.

Several geophysical acquisitions were implemented in Les Sources to build a 3D representation of the hydrothermal system. By integrating these geophysical surveys, this approach will aid selecting targets for future projects. Aware of the unresolved issues in subsurface exploration and the concerns of local populations, these 3D models are used to mitigate risks, prepare drilling operations, predict reservoir behavior during exploitation, and assess the lithium resource.

The preliminary forecasts for sustainable exploitation will help to facilitate the development of future projects. These models are designed to evolve with future drilling operations, well-data acquisition, and hydraulic tests.

2. Geophysical exploration

2.1 3D seismic campaigns

Two seismic surveys were conducted in 2022 and 2023 in Les Sources (Figure 1). Special attention was given to imaging deep-seated basement features, such as the top of the basement and the intricate network of faults and fractures within. In an onshore context with irregular surveys due to dense urban environments and high level of anthropogenic noise, several approaches were implemented to enhance the clarity of the deep-seated basement features and improve the interpretation workflow:

- A dense, irregular source configuration, with mid-size vibrators operating in high productivity mode using the simultaneous random sweep (SRS) configuration.
- An extra set of vibration points, using a single fleet of sparser, low-frequency sweeps emitted by three vibrators (Strobbia et al., 2024).

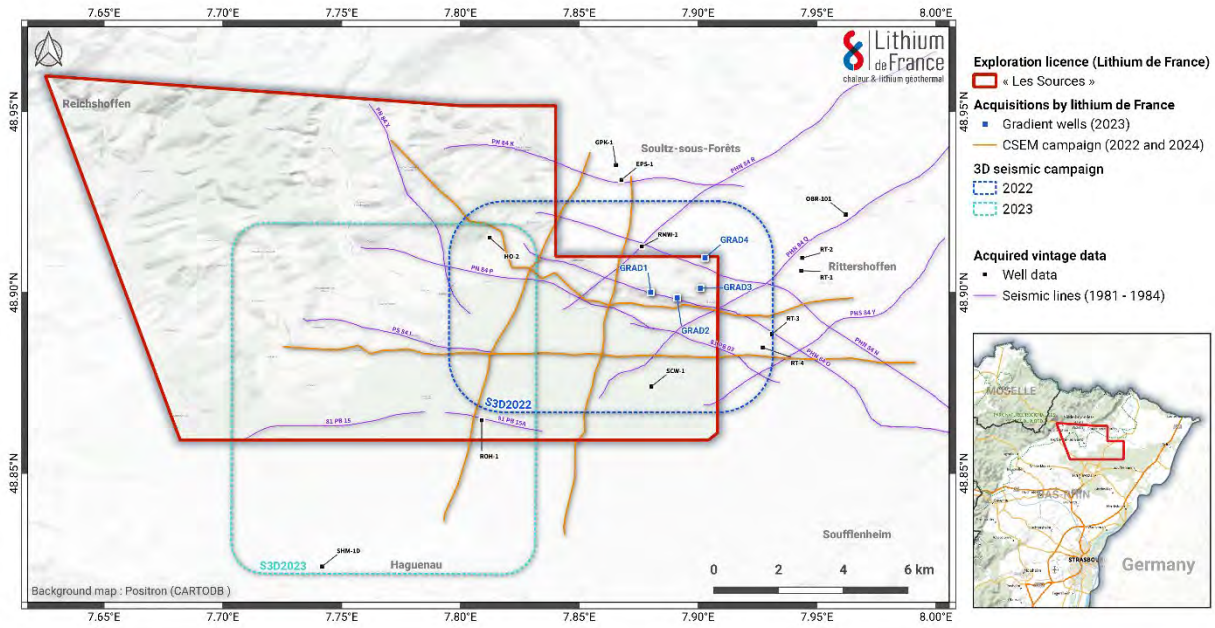

Figure 1: Exploration campaign; 3D seismic surveys, CSEM lines, and reprocessed 2D seismic lines conducted since 2022 in the Les Sources license area.

These two approaches enhance vertical resolution and signal penetration, benefiting the interpretation of geological structures (Figure 2a). Two main families of faults affecting the sediments-basement interface were observed:

- A major set striking in the Rhenish direction (N-S +/-20°) with large offsets, intersecting the entire sedimentary cover and rooting in the basement. These normal faults were well identified with 2D seismic lines, but their location and geometry were enhanced from the 3D survey.

- A minor set striking from the Rhenish to Hercynian (SE-NW to ESE-NWN) direction with moderate offsets, affecting the base of the sedimentary cover and rooting in the basement.

These faults were known at the well scale but poorly imaged on legacy 2D lines (Sausse et al., 2010).

Faults observed at the sediment-basement interface root several hundred meters into the basement. Improved fault connections through the 3D seismic survey reveal potential pathways for deep circulations and thus potential targets.

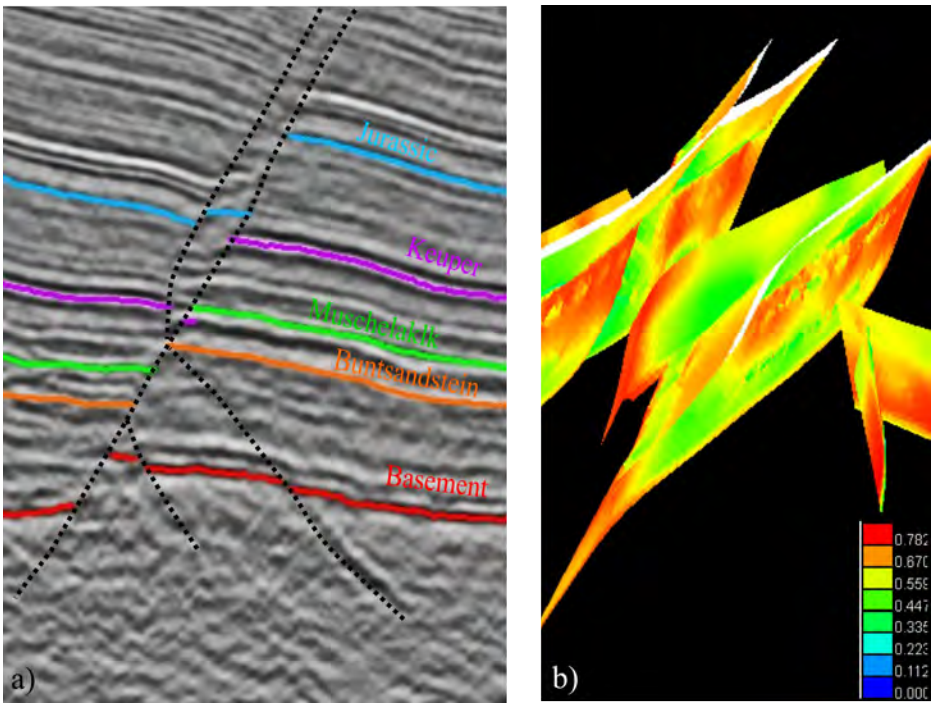

Figure 2: a) Interpreted crossline from the 3D seismic survey b) Slip tendency mapped along fault planes.

2.2 2D Controlled-source Electromagnetic surveying

Electromagnetic (EM) methods have proven effective for characterizing geothermal reservoir geometry in volcanic areas, hydrocarbon reservoir geometry in offshore sedimentary regions, and onshore mineral exploration (Constable, 2010; Coppo et al., 2016; Darnet et al., 2020; Hokstad and Kruber, 2023). Lithium de France, in collaboration with the French Geological Survey, developed this methodology to de-risk targets with high geothermal and lithium potential in deep fractured reservoirs, despite the high levels of anthropogenic noise (Darnet et al., 2023). Four Controlled-source Electromagnetic (CSEM) lines were acquired between 2022 and 2024 within the footprint of a 3D seismic acquisition (Figure 1).

The CSEM survey involved electric-field sensors distributed at nominal 500m intervals along 2D profiles. Along each profile, several grounded electric dipole transmitters, ranging from 1km to 3km in length, were deployed. To combat the anticipated high levels of EM noise, short boreholes (3 m deep) were drilled and equipped with metallic rods as injection electrodes. Additionally, multiple square wave signals with a wide range of fundamental frequencies (from 16 seconds to 512 Hz) were transmitted to maximize the signal-to-noise ratio at the receivers, regardless of the noise spectrum typology.

CSEM data were processed in the frequency domain using a robust processing approach (Smai and Wawrcyniak, 2020) and inverted using a 3D finite-difference scheme (CustEM, see Rochlitz et al., 2019). Frequencies with the best signal-to-noise ratios and the highest sensitivity to the target depth were selected, specifically 16s, 8s, 2s, 2Hz, 8Hz, 32Hz, and 128Hz.

The resulting resistivity model after inversion identified low resistivity anomalies following traces of faulted structures. These anomalies could be related to increased porosity within the fault zone and/or the presence of hotter and/or more saline hydrothermal fluids (Figure 3). These anomalies match with thermal anomalies known from past hydrocarbon exploration wells and provide new insights into permeable features of the reservoir that could not be detected based on seismic data alone.

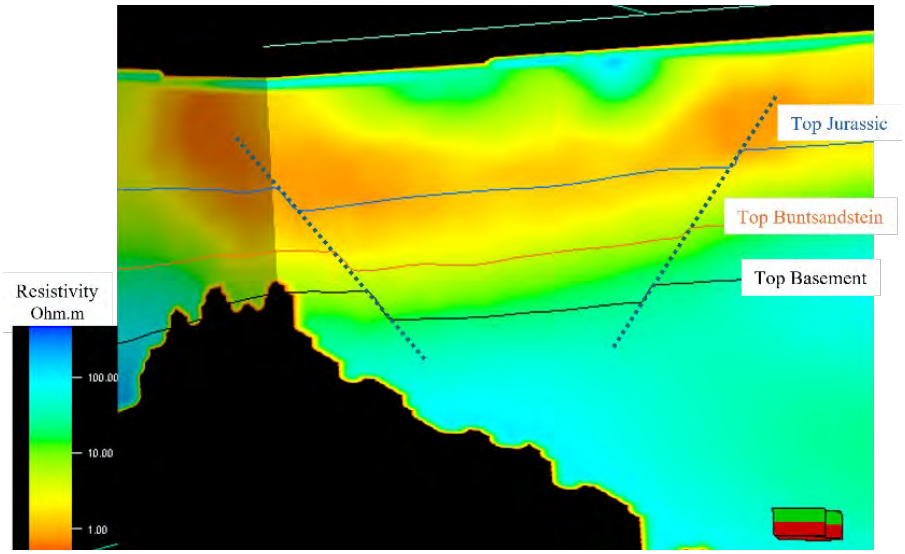

Figure 3: Random cross-sections from the 3D resistivity model derived from the inversion of CSEM data acquired in Les Sources license. Black dotted lines represent the faults identified on seismic data.

3. Geological 3D model

3.1 Building a static model

A 3D geological model was built using Leapfrog software (Seequent) to create a spatial representation of the project's geology based on results from the seismic survey interpretations. The stratigraphic contacts from the wells were used to calibrate the time-to-depth conversion of the seismic data and served as a control tool rather than an input for the geological model.

Five interpreted horizons were imported into Leapfrog as high-resolution point files, serving as the base for each of the five main lithological units and to model the faults present in the project area. Lithological surfaces were generated from these point files, with a threshold of 0.2 meters applied to remove points in zones of limited elevation change. This process allowed for the creation of simplified surfaces, reducing the processing time that would have been required if high-resolution point files were used. The newly created lithological surfaces were then utilized to create the fault surfaces by digitizing and connecting the visible fault offsets on each of the five surfaces (Figure 4a). This procedure was applied to both the main regional faults and other faults with limited vertical and lateral extents. It is important to note that the visible fault dip on each of the

lithological surfaces does not correspond to the actual fault dip; this is a normal artifact resulting from the seismic interpretation of fault zones rather than fault surfaces. This workflow is used to generate a fault surface passing through the center of the fault damage zone.

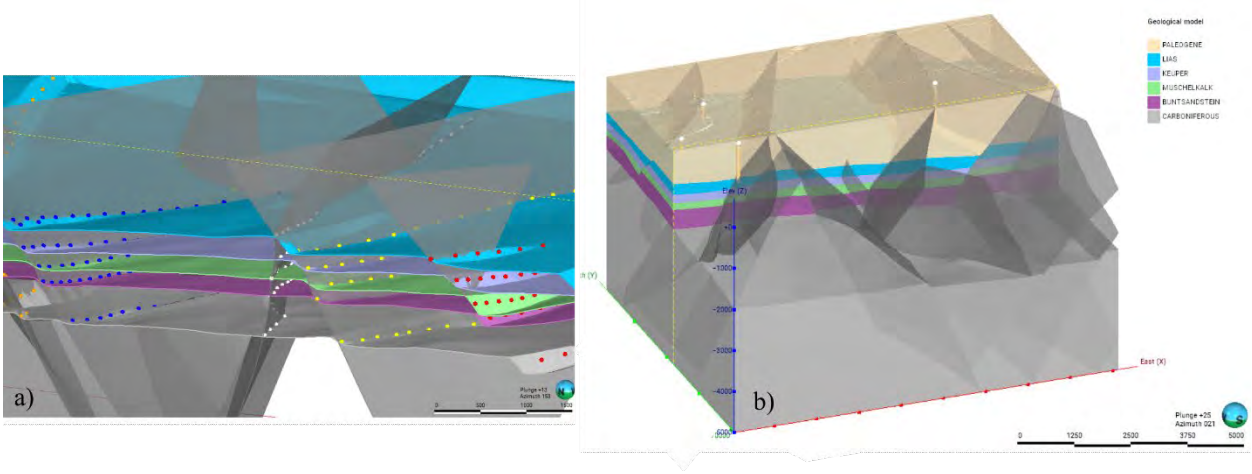

Figure 4: 3D geological model built with Leapfrog software (Seequent): a) fault construction b) lithological surfaces and fault planes used for geological modeling.

The triangulated points from the lithological surfaces were extracted and used in the Leapfrog geological modeling tool to build smooth surfaces between the main faults and generate the final geological model (Figure 4b). Using triangulated points rather than the lithological surfaces eliminates the fault offset artifact, as it creates separate contact surfaces in each block separated by the main faults. This 3D geological model is utilized for well planning and updating temperature modeling in the area.

3.2 Shallow temperature wells

In Les Sources license, the temperature model was poorly constrained by deep well measurements. In the northern area of the license, four shallow temperature wells were drilled down the first 200 m depth for geothermal gradient measurements (Figure 1). They are coherent to the highest geothermal gradient from hydrocarbon and geothermal wells existing in Northern Alsace. Based on the temperature profile of the deepest wells that reached the basement, the temperature of the deep reservoir was extrapolated, i.e. at 2 km depth in the license (Figure 5a).

With these additional data, the temperature model was updated using the Radial Basis Function (RBF) algorithm in Leapfrog (Figure 5b). This algorithm has the advantage of considering all available data in the model without limiting its interpolation between points based on a user-defined search radius, while giving more importance to the closest datapoints. The resulting model presents good coherence with known temperature anomalies from the literature and helps predict the upwelling of Li-rich hot fluids.

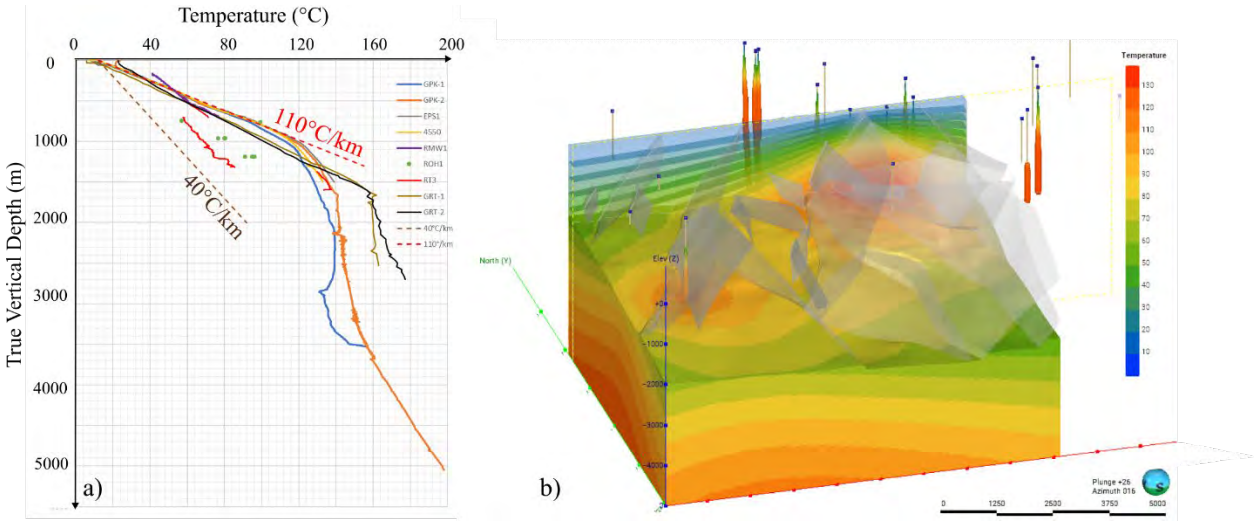

Figure 5: a) Temperature data from shallow temperature wells, legacy hydrocarbon, and geothermal wells in the area; dashed lines are geothermal gradient b) 3D temperature model from Leapfrog software (Seequent).

3.3 Mineralogical and geochemical observations

A comprehensive conceptual model was developed incorporating a large legacy database from hydrocarbon and geothermal observations. Mineralogical observations were conducted on deep existing wells that intersected the reservoir to identify alteration phases that could seal the fractures and faults but also delineate the thickness of damage zones and fault cores (Figure 6a & b) (Sy et al., 2023). A special focus was paid on clay minerals as they are known to affect the natural permeability of the reservoir but also as they are identified as Li-bearing source (Dugamin et al., 2024; Humphreys et al., 2023; Genter et al., 2024; Vidal et al., 2024). X-ray diffraction on clay fractions as well as Short Wave Infrared spectroscopy were conducted for a semi-quantitative approach in deep geothermal wells that reached Triassic and Permian sandstones and granitic basement. Inductively coupled plasma mass spectrometry (ICP-MS) measurements on deep cuttings samples provide Li distribution in the reservoir. Illite-rich facies are associated to low Li content (20-30 ppm) whereas zones dominated by ferromagnesians minerals reach 70 ppm. In parallel, geochemical data in fluids seems to be more homogeneous, between 166 and 210 ppm Li measured in deep wells from the Upper Rhine Graben (Figure 6c).

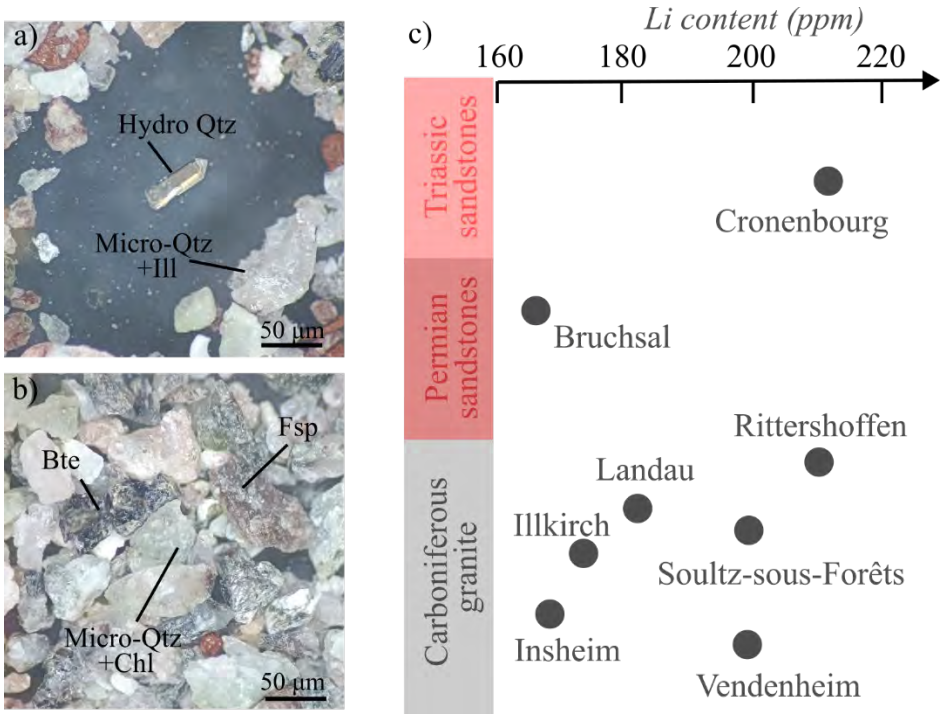

Figure 6: Mineralogical observation in granitic basement at (a) permeable level and (b) illitized zones. (c) Lithium content in ppm of deep geothermal fluids in the URG from Bosia et al. (2021), Pauwels et al. (1993) and Sanjuan et al. (2016). Qtz = quartz, Bte = biotite, Fsp = felspar, Chl = chlorite, Ill = illite.

4. Using modeling as prediction tool

4.1 Slip tendency

Following the Good Practice Guide for Induced Seismicity Mitigation co-published by the French Geological Survey in 2023, a slip-tendency study was conducted using 3DStress software (Southwest Research Institute). Utilizing a stress model based on Valley and Evans (2007), the slip tendency for fault structures in the 3D geological model was mapped (Figure 2b). Slip tendency of faults varies according to the dip and azimuth variations of fault planes, with higher values occurring in the strike of the horizontal stress. Information from the slip tendency map can be used with other geomechanical parameters to plan for the mitigation of seismicity.

It is important to note that slip tendency alone is not a criterion for seismicity, as many other geomechanical parameters can influence seismicity, such as fault friction and cohesion. Additional thermo-hydro-mechanical (THM) modeling is being conducted to further characterize potential induced seismicity (Wynants-Morel et al., 2024).

4.2 Thermo-Hydraulic modeling

A 3D TH model was developed using the OpenFlow suite (Beicip-Franlab) to evaluate exploitation scenarios. The natural state was calibrated based on historical data, including pseudo-hydrostatic profile, temperature gradients or petrophysical models, the traditional dual-porosity *Warren & Roots* approach, and previously presented acquisitions. The fracture model incorporated the two fault families discussed on section 2.1 3D seismic campaigns, featuring a damage zone of variable

thickness, as well as the hydrothermal alterations zones, discussed on the section 3.3 Mineralogical and geochemical observations (Figure 7).

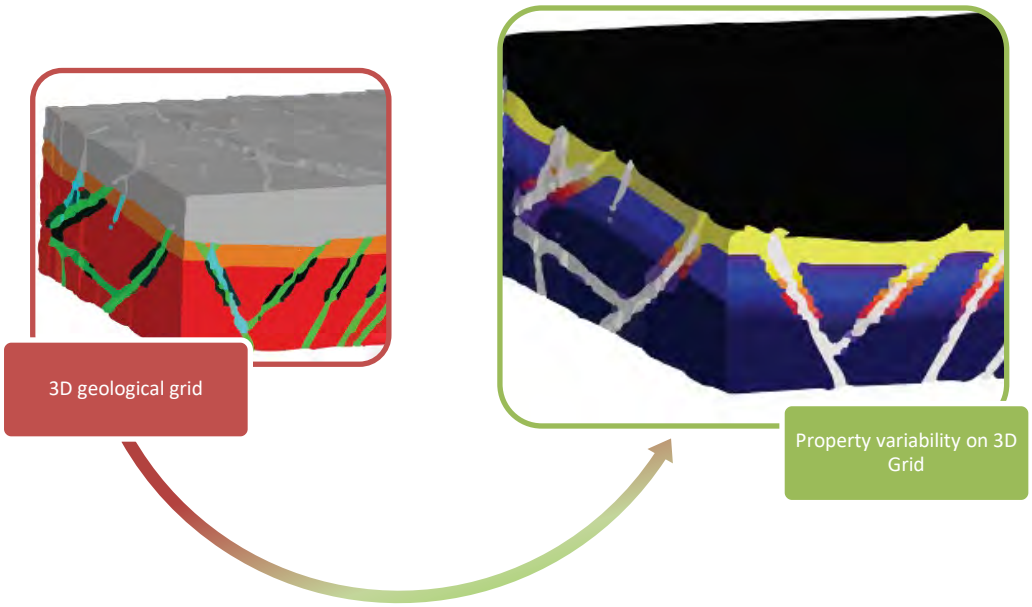

Figure 7: Schematic 3D Les Sources TH model.

Lithium was modelled as an inert tracer and its concentration and mass variability was investigated through time. Several scenarios were run to evaluate the impact of well locations, targeted structures, or the contribution of the damage zones, among others.

4.3 Lithium resource assessment

The sites proposed for the resource assessment were GRC, PUN, KON and KIL (Figure 8a):

- The GRC site had 2 J-wells spaced by 1km (GRC1-prod and GRC2-inj) and targeted a main fault affecting the porous and permeable sandstones with a variable production flowrate in order to consider the impact of flowrate on recovery.
- The PUN site had 2 vertical wells spaced 2.7km apart (GTPunA-prod and GTPunB-inj), targeting a minor fault zone in the sandstones layer for GTPunA and the damage zone of a major fault zone in the altered granitic basement for GTPunB.
- The KON site had two vertical wells GTKonA and GTKonB with 1km in between (GTKonA-prod and GTKonB-inj) targeting a major fault zone at the sandstones-granite interface for GTKonA and a damage zone of a major fault zone affecting the granite fo GTKonB.
- The KIL site had 2 vertical wells GTKilA and GTKilB, distanced apart by 2.7km (GTKilA-prod and GTKilB-inj) and targeting a minor fault zone affecting the sandstones for GTKilA and a major one affecting the sandstones fot GTKilB. Both faults targeted did not present associated damage zone.

All the scenarios were run with a mean flowrate of 3600 m3/d (42 L/s) except for one case of GRC. A conservative concentration of 180 mg/L was also used for the initialization of the lithium distribution on the 3D model (Figure 8).

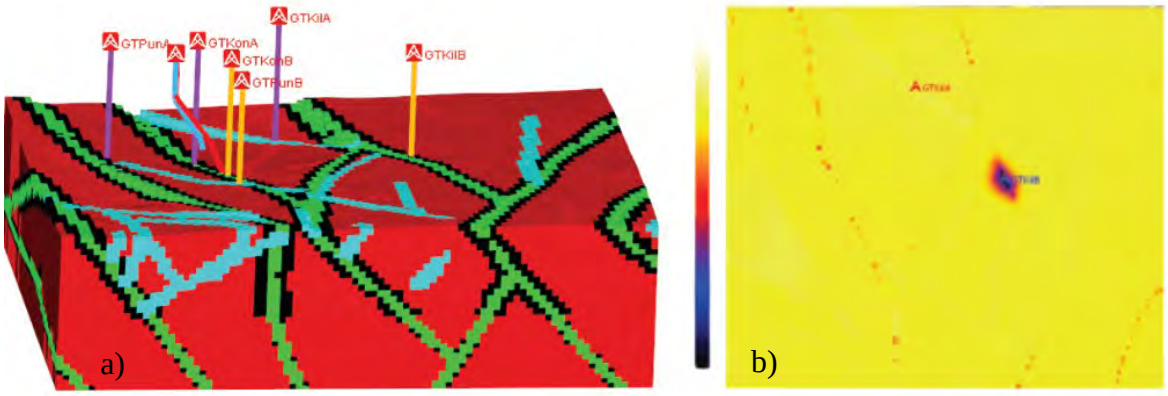

Figure 8: (a) Sites configuration for the lithium assessment. (b) Lithium depletion on the KIL site.

Between PUN, KON and KIL sites; the exploitation for KON showed the only receding trend for Li2CO3 or Lithium Carbonate Equivalent (LCE) over time with an annual mean decrease of 0.56% (Lithium concentration went from ~180 mg/L to ~155 mg/L over 25 years), see Figure 9. KIL and PUN sites had little changes on LCE with 0.03% mean annual decrease for both. The total LCE production was ~6000, ~6200 and ~6300ton for KON, KIL and PUN sites.

For the resource assessment on the GRC site, as mentioned, was decided to test a 3600 and a 3000 m3/D flowrate (42 and 35 L/s respectively). The reason behind this was to evaluate lithium recovery at different flowrates. The changes on lithium content were too small, having an annual mean decrease of 0.02% for the higher flowrate, and an annual mean increase of 0.01% for the latter. The total LCE produced for GRC1 was ~6200 and ~5200 ton over 25 years respectively.

When GTKilA and GTKonA are compared, differences between both fault families discussed on section 2.1 3D seismic campaigns are observed. The KON site intersecting a major fault produced about 3% less lithium than KIL site intersecting a minor one. Comparing GTKilA and GTPunA, reveals the production of GTPunA is more advantageous with 1% more of LCE produced over 25 years, than the GTKilA because the latter does not intersect the damage zone of the fault whereas GTPunA targets a large porous and permeable damage zone. This suggests that as long as the well is connected to the natural fractured reservoir, neither the fault family nor the damage zone thickness would have a significant impact on the lithium exploitation.

The availability of the lithium resource on the reservoir is quite important. At the exploitation of the KIL site (Figure 8b), no lithium depletion is taking place around the production well (GTKilA). The concentration is decreasing with the injection of depleted water on the reservoir, around the injection point (GTKilB).

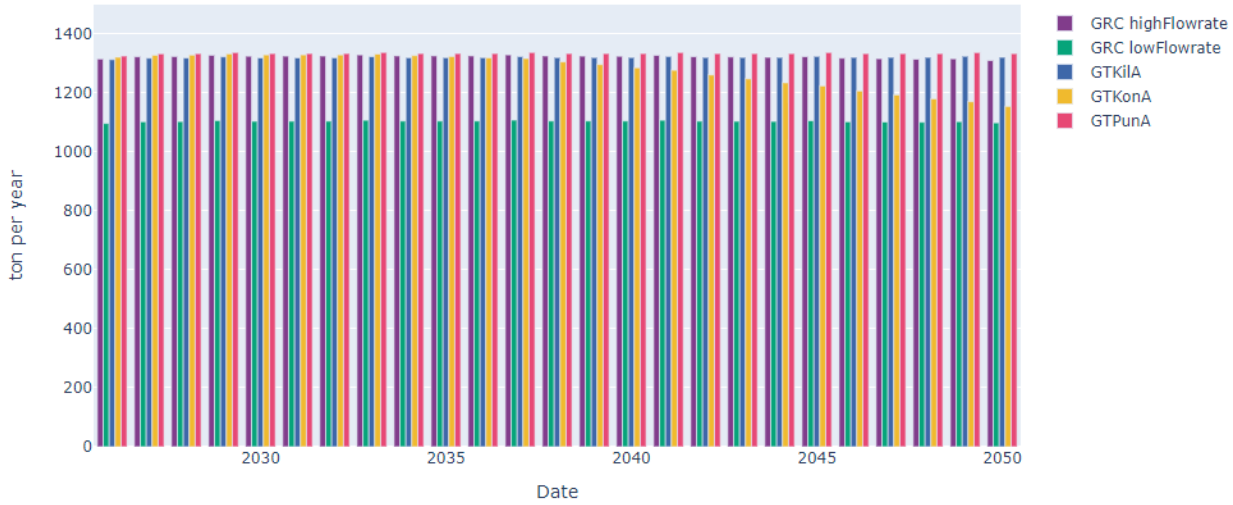

Figure 9: LCE production for the hypothetical exploitation of GRC, KIL, KON and PUN sites.

5. Concluding remarks and perspectives

The integrative approach for exploration campaign allows to identify the hydrothermal system architecture with cap rocks, reservoir rocks and source rocks as well as importance of fracture and faults contribution for circulations of hot Li-rich brine. It also underlines the importance of fault network with all striking, not only the major Renish one but also the deeper Hercynian one that enhance deep circulations for brine. Within our models, lithium concentration in the fluid is homogeneous on the reservoir, regardless of the lithology or the fault occurrences or the rock alteration degree. However, the distribution of the resource is uneven and heterogeneous because this is a function of the petrophysical parameters of the model. When the model is run in the exploitation, the lithium depletion is related directly to the injection of depleted water, pushing Li-rich brine on the fractured network towards the production well. This needs to be studied further, but it could mean that several different scenarios like the screening observed on the Enhanced Recovery Techniques for the O&G industry is necessary for lithium extraction.

ABSTRACT

Located at 4500m a.s.l in Andean cordillera (Northern Chile), Cerro Pabellón (CP) geothermal powerplant is the first commercial power plant in South America that exploits the Na-K-Cl fluid circulating in the fractured volcanic formations. This study focuses on hydrothermal alteration of the geothermal reservoir based on four production wells drilled on both sides of a graben structure and presenting unlike hydraulic properties. Cuttings were sampled and analyzed using X-ray diffraction (XRD) to observe the mineral distribution and variations of crystal-chemistry of clays (fraction <5 μm). Then, scanning electron microscopy coupled with energy dispersive spectroscopy (SEM-EDX) were used to perform chemical microanalysis of hydrothermal minerals. These results suggest a high heterogeneity of the reservoir in term of alteration: a pervasive alteration dominated by trioctahedral clays (saponite to chlorite sequence through corrensite and C-Crr mixed layers) was observed in all samples whereas a multi-event fracture-controlled alteration was only observed locally. A first event was observed at shallow depth in the active part of the reservoir composed of adularia + Ba-rich feldspar + feathery quartz + chalcedony + calcium arsenates + illite suggesting boiling processes. Another event dominated by dioctahedral clays (illite-smectite mixed layers with more than 90% of illite and illite) occurs in all permeable fracture zones intersected by wells. This multi-event alteration seems strongly controlled by the eastern graben fault and the wide fracture network connected to this structure.

1. Introduction

The geothermal system of Cerro Pabellón (CP) is located ~100 km northeast of Calama city (Antofagasta region, Northern Chile), near the Chile-Bolivia border, inside the Pabelloncito graben. Located at 4500 m a.s.l, this extensional structure affected by highly dipping and NW-striking faults hosts deep Na-K-Cl fluid circulations (>250°C). Since 2017, Geotérmica del Norte (GDN), a joint venture between Enel Green Power Chile and ENAP (Chilean National Oil Company), has exploited 13 wells for a power capacity of 83 MWe (Cappetti et al., 2021). These deep wells are unique witnesses of the reservoir, that remains hardly accessible in Andean geothermal system and could help to understand factors controlling deep hydrothermal circulations (Vásquez et al., 2014; Vidal et al., 2021). A total of 142 samples were examined in four deep wells: CP5A- (300-1000 m) and CP6A (400-1400 m), both located in the central part of the graben in the most active zone of the reservoir, CP2A (850-1550 m), located inside the graben but outside the core of the reservoir in term of productivity and CP4A (1500-2700 m), located in outside the graben. This study focuses on hydrothermal alteration of the reservoir and more specifically on clay minerals because they are very sensitive to temperature, rock and fluid chemistry, timing, fluid/rock (F/R) ratio, between other variables (Flexser, 1991; Inoue and Kitagawa, 1994; Patrier et al., 1996; Vásquez et al., 2016; Vidal et al., 2018). Thus, they are considered as good markers of past and present hydrothermal circulations. Spatial distribution and crystal-chemistry of clay minerals were investigated thanks to petrographic observations, X-Ray diffraction (XRD) conducted on the clay fraction (< 5 μm). Chemical microanalyses were performed with Scanning Electron Microscope coupled to Energy Dispersive Spectroscopy (SEM-EDX). Nature and the amount of hydrothermal parageneses associated to deep rocks would help to understand geodynamics of the deep system. Such a contribution may be of interest for other Andean geothermal systems with more limited geological information and may help in the further development of geothermal projects in the Chilean Andes and neighboring countries.

2. Area of study

The CP geothermal system belongs to the graben structure called the Pabelloncito graben (Figure 1). This depression of 20 km long and 3 km wide is framed between two main normal faults, N53°W to N60°W direction, and a secondary fault system in between with the same orientation affects the geological units (Rivera et al., 2021; Urzúa et al., 2002). The eastern border fault is divided in three strands North of the Pabellón dome. Exploration and deep wells drilled at CP confirmed deep circulations of geothermal fluid channelized into permeable fault and fracture zones (FZs) and sealed by a 300-m thick clay cap (Baccarin et al., 2021; Maza et al., 2018; Rivera et al., 2021; Vidal et al., 2022).

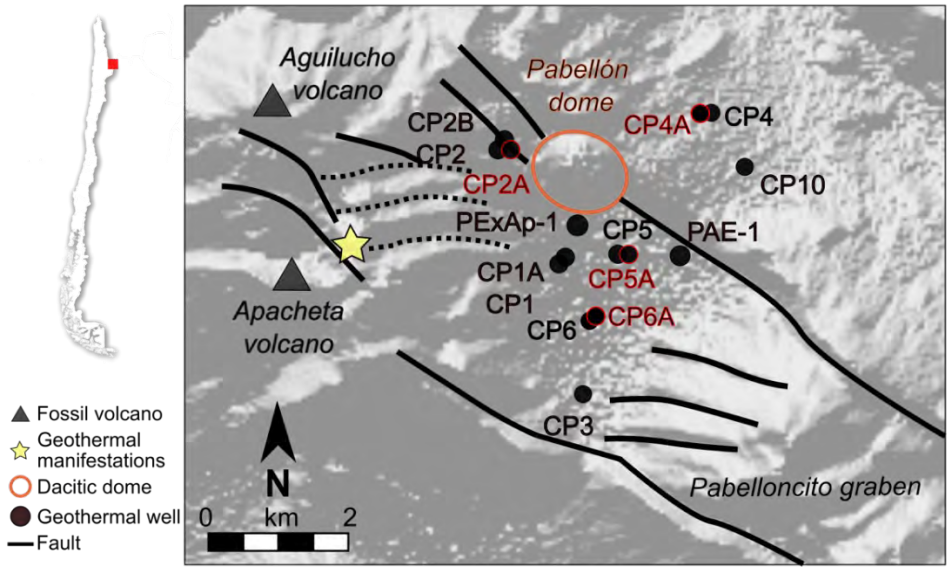

Figure 1: Map of Cerro Pabellón (CP) geothermal system with main normal faults of Pabelloncito graben and morphological lineaments in dashed lines. The studied production wells are represented in red.

The 3D thermal model of the CP reservoir shows a dome shape of the isotherms (Baccarin et al. 2021). The apex of the thermal dome marks the center of the upflow zone of the geothermal fluid in the eastern edge of Pabelloncito graben. This study is based on four wells intersecting andesitic lavas as well as lithic and dacitic tuffs.

- CP2A well is located in the northern margin of the thermal dome, with a temperature decreasing gradually. The well was drilled vertically above the median strand of the eastern fault. The temperature acquired ten months after drilling operations reached 245°C at 1800 m depth (Figure 2a). The main inflow of the well is observed at 1530 m depth, considered as the intersection of the northern strand of the fault, with an injectivity index of 10 m^3/h/bar (Rivera et al., 2018). However, partial mud losses were observed at 925 m depth in the andesitic lavas at the top of the convection. Production test of the well revealed a total fluid flow rate of 190 t/h with a wellhead pression of 8 bar and a title of vapor of 7% (Rivera et al., 2018).
- CP4A well is located outside the graben structure. The well was drilled down to 2700m MD and even if it is located in the peripheral limit of system, a good hydraulic connection to the main reservoir was discovered (Baccarin et al., 2021). The temperature acquired several months after drilling to reach 235°C at the bottom of the well (Figure 2b). A negative T anomaly from 2525 to 2650 depth matches a main permeable FZ which probably controls the hydraulic behavior of the well. The well presents a high injectivity with an absorption of 310 m^3/h without wellhead pressure (Rivera et al., 2018).
- CP5A well is located in the apex of the thermal dome. The well was drilled vertically until 1936 m depth above the eastern border fault of the graben. The temperature was acquired, one year after drilling operations, until 600 m where it reaches 220°C (Figure 2c). A permeable FZ was identified at 447 m depth, in andesitic lavas, with total mud losses during drilling and a negative temperature (T) anomaly in the T profile. However, the injectivity index of this FZ is low (Rivera et al., 2018). Partial mud losses were also observed at 525 m depth even thought the structural model of Baccarin et al (2021) does

not identify permeable FZ at this depth. A permeable FZ at 700 m depth is identified as the main structure responsible of the major injectivity (circa 7 m^3/h/bar) (Rivera et al., 2018). Total mud losses occurred at 1000 m depth making collection of cuttings impossible below this depth. The graben border fault was intersected at this depth according to the structural model of Rivera et al. (2021). Production test of the well revealed a total fluid flow rate of 305 t/h with a title of vapor of 18% (Rivera et al., 2018).

- CP6A well is also located in the *hot core* of the thermal dome. The well was drilled down to 2300m MD. The deep temperature reached 230°C few months after drilling operations (Figure 2d). A double T anomaly, positive one from 1210 to 1290m MD matches a first permeable FZ at 1240m MD and a negative one from 1290 to 1360m MD matches a second permeable FZ at 1320m MD from the structural 3D model. The structural model indicates at least 3 others deep FZs intersected by the well. The deepest one is interpreted as a local fault intersected at 2200m MD. CP6A well presents the highest injectivity index of the geothermal system with 20 m^3/h/bar (Rivera et al., 2018).

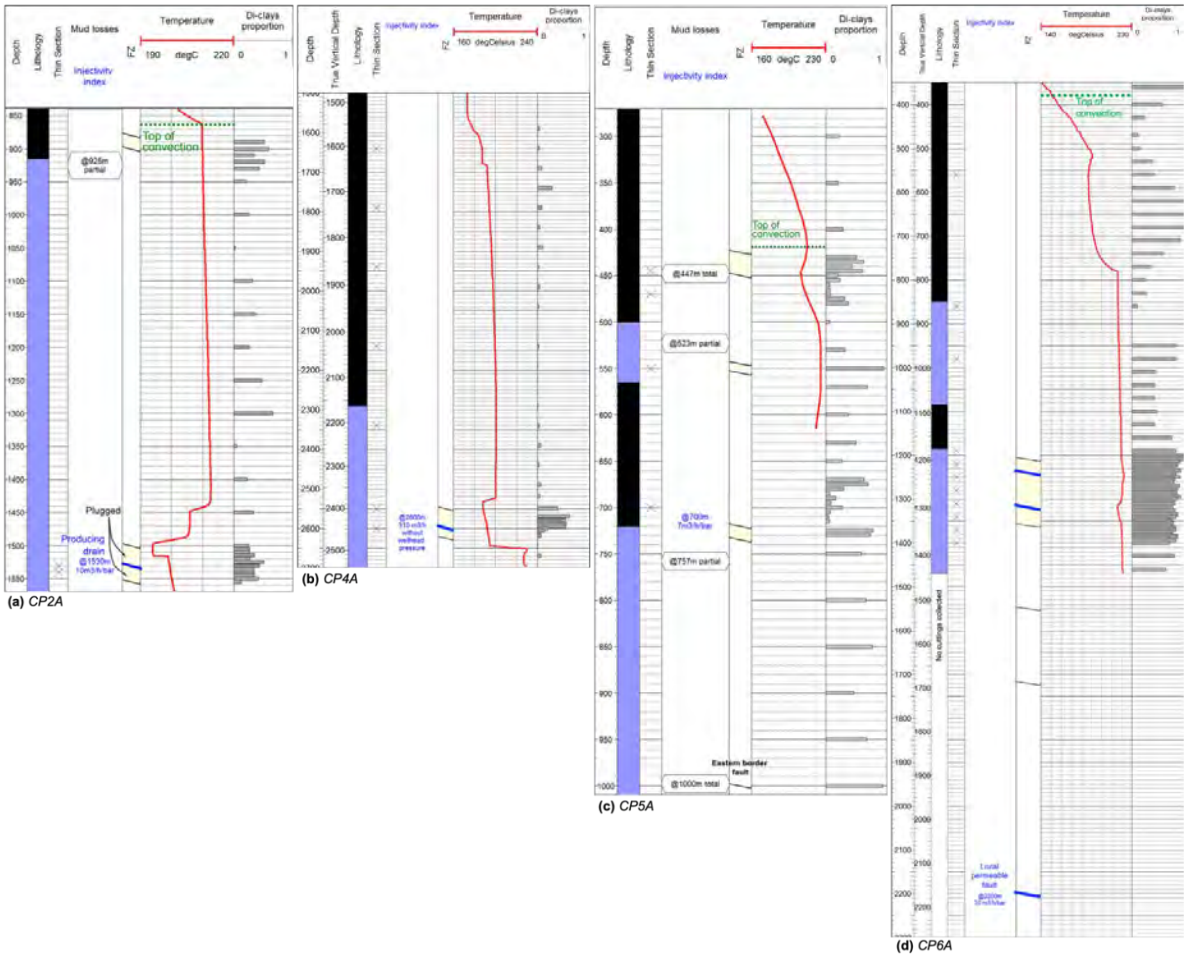

Figure 2: Lithology, mud losses, measured injectivity index, permeable fracture and fault zones (FZ), temperature profile and proportion of dioctahedral clays in a) CP2A well, b) CP4A well, c) CP5A well and d) CP6A well. The thickness and depth of the FZs are deduced from clay signature and thus, are constrained by the sampling.

In this study, special attention was paid to clay signature in order to evaluate factors controlling fluid flow and how tectonic control of the northern border fault influences the reservoir productivity.

3. Methodology

Petrographic investigations were carried out in thin sections of cuttings fixed in epoxy. As cutting samples present an average size between 0.5 and 2mm, spatial resolution is low and textural relations between minerals are hardly observed.

Identification of clays was conducted by XRD on the less than 5 µm fraction of 28 cutting samples in CP2A, 35 in CP4A 39 in CP5A and 72 in CP6A. Cutting samples were immersed in distilled water in absence of preliminary grinding, and then disaggregated by ultrasonic treatment to properly dispersed the clay particles in suspension. Oriented powders were prepared from sedimentation of the <5 µm grain size clay separate of the suspension on glass slides. Clay minerals were identified by X-Ray Diffraction (XRD) of air-dried and ethylene– glycol (EG)-saturated oriented powders carried out on a Bruker D8 Advance diffractometer (CuKα radiation, 40 kV, 40 mA). The analytical conditions were as follows: angular domain: 2.5–30° 2θ; step increment: 0.025 2θ; and counting time per step: 3s. Processing of the diffractometers was conducted using Match! Software (Crystal Impact). The clay minerals were identified according to Brindley and Brown (1980). All deconvolution processed are described in Vidal et al (2022). The proportion of dioctahedral clays was estimated from the peak areas according to the ratio: *(I-S area + Ill area Ill) / (I-S area + Ill area + Chl area + C-Crr area + Crr area).*

Chemical microanalyses of primary and secondary minerals were acquired on thin sections of CP5A and CP2A wells using a SEM JEOL JSM-IT500 SEM equipped with a BRUKER linxeye EDX associated with SPIRIT software at the IC2MP laboratory at the University of Poitiers. The analytical conditions were as follows: 15 kV; 1 nA; counting time: 50 s; and working distance: 11 mm. The analyzed elements were Si, Al, Fe, Mg, Mn, Ti, Ca, Na and K. The system was calibrated with a variety of synthetic oxide and natural silicate standards. The reproducibility of the standard analyses is approximately 1%, except for Na, which had a reproducibility of 1.5%.

Fluid-clay minerals equilibrium was simulated with PHREEQC software (USGS) based on the chemistry of geothermal fluid, gases and minerals. The software was used to calculate clay mineral saturation indices relative to chemical composition of geothermal fluid described by Giudetti and Tempesti (2021) and a recalculated pH of 5.7. Because water analyses lacking Al and Fe, concentrations of these both elements were estimated in order to force the water to be at equilibrium with Al-bearing mineral as suggested by Pang and Reed (1998).

4. Results

4.1 Alteration petrography

All samples collected in the four wells show evidence of hydrothermal alteration involving at least two alteration type: a pervasive one and a fracture-controlled one.

A pervasive alteration is observed in all samples with a moderate to intense stage. This alteration pattern is particularly well expressed away from permeable FZs. Pervasive alteration is characterized by the replacement of most of the original rock-forming mafic minerals (pyroxenes,

volcanic glass, biotite) and, at a lesser degree, of igneous feldspars by a great variety of trioctahedral clay species ranging from smectite to chlorite through corrensite and chlorite-corrensite mixed layers (Figure 3a & 2b). The fact that chloritic minerals may replace smectite in the altered pyroxenes or in the groundmass, suggests that the trioctahedral clay minerals may have occurred sequentially during the progress of the pervasive alteration (Figure 3i). Trioctahedral minerals are observed mostly in association with titanite, needle-shaped hematite and epidote (Figure 3b). In CP5A well, they are observed associated to numerous inclusions of arsenic minerals, calcite and quartz (Figure 3i). In CP4A and CP6A wells, Fe,K-rich minerals green clay minerals from the celadonite-glauconite group are observed in a lesser degree (Figure 3c).

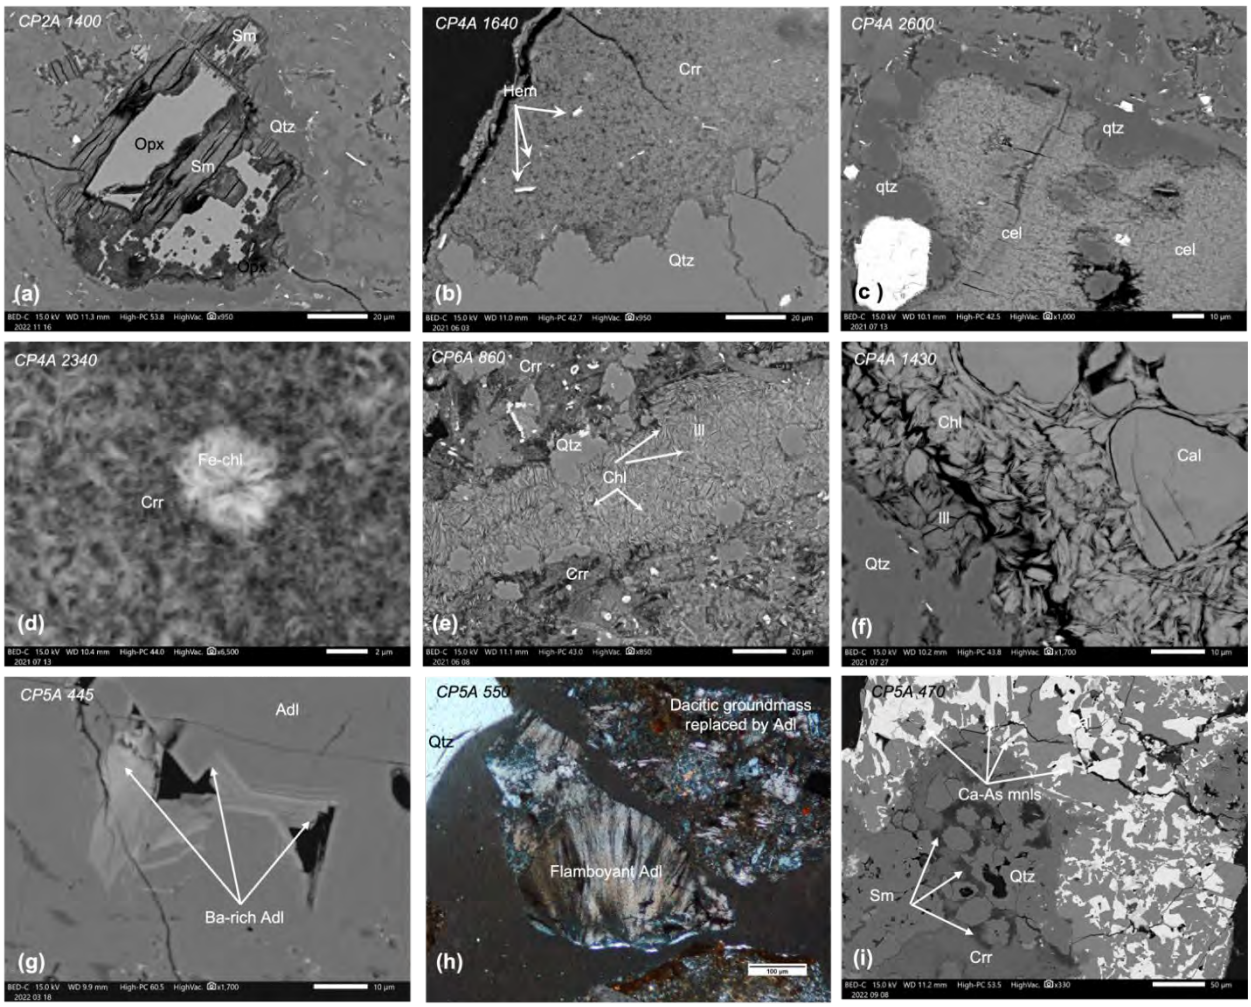

Figure 3: Mineral associations representative of pervasive alteration (a – c) and fracture-controlled alteration dominated by illitization processes (d – f) and boiling processes (g – i). Observations conducted by SEM in thin sections of cuttings fixed in expoxy in CP2A, CP4A, CP5A and CP6A wells. Adl = adularia, Cal = calcite, Chl = chlorite, Crr = corrensite + C-Crr mixed layers, Hem = hematite, Ill = illite, Opx = orthopyroxens, Qtz = quartz, Sm = smectite.

Close to permeable FZs, there has been highly destructive alteration characterized by destruction of the original texture of volcanic rocks, igneous minerals (excepting quartz in dacitic rocks) and minerals from pervasive alteration, as well as development of a vein network and cementation of open spaces (cracks and dissolution voids) (Figure 3d to 2i). This fracture-controlled alteration is characterized by illitic minerals that seem to precipitate together with chlorite +/- carbonates,

mainly calcite but also sometimes dolomite (Figure 3e & 2f). Co-precipitation of illite and chlorite suggests the occurrence of at least one other generation of chlorite than the one observed previously in association with epidote and titanite (Figure 3d). In shallow FZs of CP5A, an earlier fracture-controlled event is observed with a massive precipitation of adularia as microcrystalline aggregates in groundmass, and direct deposition from solutions into open spaces where it forms rhombic crystals (Figure 3g & 2h). Chemical zoning observed in rhombic crystals of adularia at the wall of open spaces is indicative of periodic increase in Ba for K substitution in the crystal lattice during their crystal growth (Figure 3g). Quartz and calcite are frequently associated with adularia. Specific texture of hydrothermal minerals in veins, such as flamboyant and feathery quartz, crustiform-collomorph bands including quartz or chalcedony and adularia and blade shape calcite are typical of precipitation from boiling fluids (Figure 3h).

4.2 Occurrences of clay minerals

From the XRD mineral identification, trioctahedral clays (i.e. smectite, corrensite, mixed chlorite-corrensite layers and chlorite) are present throughout in wells but appear strongly obliterate by dioctahedral clays in main permeable FZs (Figure 4). At the most one can note a rough trend to decreasing content of the highly expandable minerals (smectite, corrensite) in the total amount of trioctahedral clays with increasing depth. The proportion of dioctahedral clays in the bulk clay material is particularly high (higher than 50%) in the permeable FZ as well as in lithic tuffs. Dioctahedral clays consist uniquely in K-bearing minerals (i.e. I-S and discrete illite) (Figure 4). The I-S R1 (with smectite between 60% and 80%) are particularly abundant above the top of the fluid convective zone where temperature is lower than 200°C (Figure 4b). I-S R3 (with ill>90%) and illite are closely associated in depths where a very weak thermal gradient is observed traducing convective heat transfer. Locally, the percentage of illite in the I-S R3 increases slowly in the vicinity of both FZs with a maximum of illitic component at the depth of main permeable drains of FZs (Figure 4).

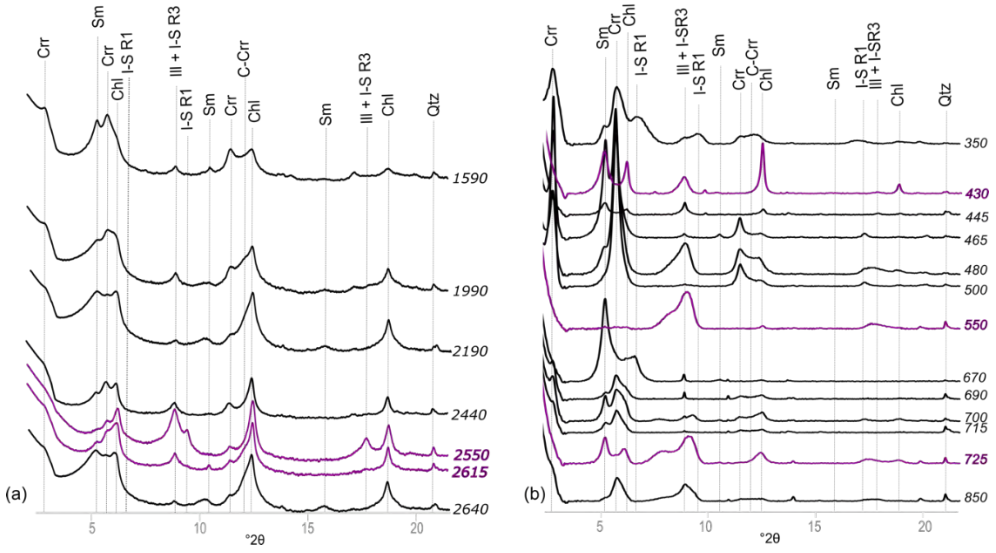

Figure 4: X-Ray diffractograms of EG-saturated oriented powder (<5 µm clay fraction) a) 1590, 1990, 2190, 2440, 2550, 2615 and 2640 in CP4A well b) samples 350, 430, 445, 465, 480, 500, 550, 600, 670, 690, 700, 715, 725 and 850 in CP5A well. Samples from permeable FZs are indicated in purple. Chl: chlorite, C-Crr: chlorite-corrensite mixed layers, Crr: corrensite, Ill: illite, I-S: illite-smectite mixed layers, Sm: smectite, Qtz: quartz.

4.3 Chemical compositions of clay minerals

Chemical analyses of trioctahedral clays reveal a wide compositional field that spread over clay species from saponite to chlorite through corrensite and C-Crr (Figure 5). From a crystallochemical point of view, all smectite are saponite presenting XFe ratios (Fe/(Fe+Mg)) between 0.2 to 0.5 probably relative to the chemistry of the mineral that they are replacing. Corrensite-to-chlorite transition is marked by a strong increase of the iron content at the expense of the magnesium content in the octahedral sheets; XFe increases from 0.1 to 0.47 from corrensite to chlorite. Two types of chlorite are distinguished based on XFe ratio. The Fe-Mg chlorite with 0.2<XFe<0.5 are observed in association with corrensite and C-Crr in replacement of all ferromagnesian magmatic minerals. These chloritic minerals are related to the pervasive alteration. The Fe-chlorite with 0.55<XFe<0.80 precipitate mainly with illitic minerals in veins. Sometimes, they are observed in replacement of Fe-Mg chlorite and corrensite from the pervasive alteration. This second generation of Fe-chlorite is related to the argillic alteration developed in FZ. When they co-precipitate with illitic minerals, the interlayer charge is slightly higher due to contamination. Some measurements of chlorite are in between both. Chemical analyses of dioctahedral clays (I-S R1, I-S R3 and ill) do not present major variations with depth and in both wells (Table S6). The interlayer charge is essentially satisfied by potassium and is between 0.70 and 0.90 for I-S and higher than 0.90 for pure illite. Detailed microanalyses of clay minerals are given in Vidal et al. (2022).

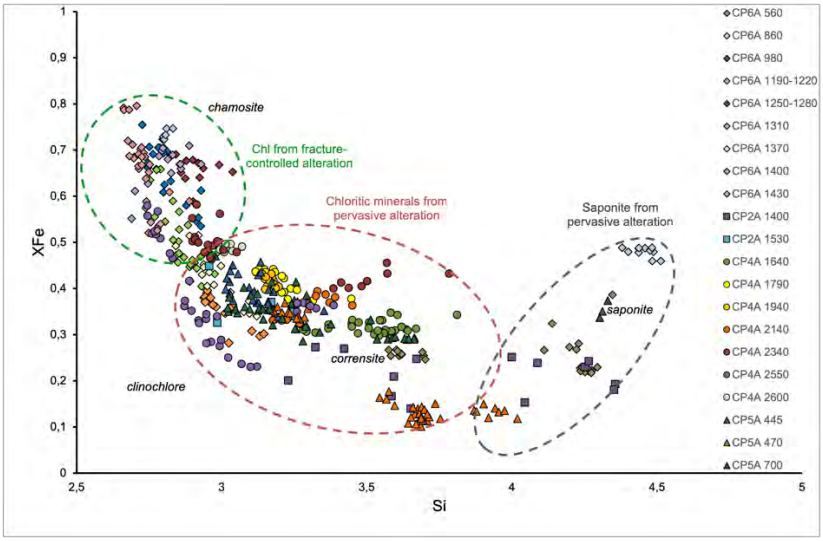

Figure 5: Plot of structural formulae of trioctahedral clays in a diagram of XFe versus Si for CP5A and CP2A wells (XFe = Fe/(Fe + Mg). All the samples are represented with a relative structure containing 14 oxygen atoms and assuming that the total iron content was composed of Fe2+. Theoretical compositions of chamosite, clinochlore, corrensite and saponite are provided for reference as black crosses.

4.4 Equilibrium of clay minerals

The state of fluid mineral equilibrium can be used to explain dissolution-precipitation of clay minerals. Figure 6 shows saturation index for clay minerals for a Na-K-Cl geothermal fluid (> 230 °C) with low gas content. Results from PHREEQC modeling are quite consistent with petrographic observations; negative saturation index for saponite and Fe-Mg chlorite suggesting an obliteration of clays from pervasive alteration by illite and Fe-chlorite from fracture-controlled alteration as

suggested by positive saturation index. The precipitation of Fe-chlorites directly from circulating geothermal fluid suggests reducing conditions of crystallization.

Regarding gases, CO_2 is the dominant species that is consistent with precipitation of carbonates' precipitation whereas H_2 and CH_4 are strongly depleted. However, the fluid sampling occurs in surface and fluid probably suffers degassing that led to an increase of solutes compared to the deep reservoir and these preliminary results of saturation index of clay minerals need to be improve with further fluid samples and geochemical studies.

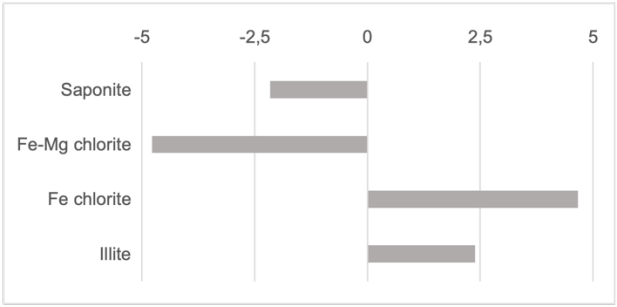

Figure 6: Modeling of saturation index for clay minerals with PHREEQC software

5. Discussion

The study of hydrothermal alteration in CP2A, CP4A, CP5A and CP6A wells demonstrated a great spatial and temporal heterogeneity of alteration within in the deep reservoir. At least two different styles of alteration were identified:

(1) A weak to moderate pervasive alteration style which is characterized by little change of the original textures and by the replacement of most of the original rock-forming minerals by trioctahedral clays (saponite, corrensite, chlorite-corrensite mixed layers (C-Crr) and Fe-Mg chlorite), calco-silicates (epidote, titanite, zeolites) and less frequently clays from celadonite-glauconite group. It is a propylitic alteration very common during cooling of magmatic intrusive bodies resulting from interactions between igneous minerals with stagnant fluids of diverse in pores or microcracks (Lowell and Guilbert, 1970; Thomasson and Kristmannsdottir, 1972). In the context of the andesitic volcanism, it is mainly dominated by trioctahedral clays and is representative of hydrothermal alteration in inactive flow regimes (Beaufort et al., 1990).

(2) A fracture-controlled alteration style which is characterized by a strong destruction of the original textures and in which both the original rock forming minerals and the minerals of the pervasive alteration have been dissolved and replaced. Two fracture controlled events were observed:

- A first mineral paragenesis characterized by *adularia + Ba-rich feldspar + silica polymorphs (quartz, chalcedony) + calcium arsenates + calcite + illite* was observed in shallow permeable FZs of CP5A well, that are possibly at a liquid/steam interface at about 4100m a.s.l., i.e 400 m depth (Baccarin et al., 2021). These hydrothermal parageneses are common in low-sulphidation epithermal deposits reported in the literature (Dong et al., 1995; Dong and Morrison, 1995; Patrier et al., 2013; Rowland and Simmons, 2012; Simmons and Browne, 2000). Adularia, blade shape calcite, quartz, chalcedony and their flamboyant, feathery and crustiform-collomorph textures suggest boiling processes that were already mentioned in PAE-

1 well (Urzúa et al., 2002). At the end of boiling processes, when pressure increases and pH decreases, illite with a very high interlayer charge (close to mica) can locally and temporarily precipitate until another boiling event occurs. The fact that these minerals assemblages are observed in CP5A well could be linked to the intersection of the graben border fault that allows unimpeded fluid upflow.

- A second mineral paragenesis characterized by *illite + illite-smectite mixed layers (I-S) + Fe-chlorite + carbonates (mainly calcite)* was observed in all permeable FZs in all wells of the CP geothermal system. Morphology of clays observed in permeable FZs suggest abrupt changes in the flow regime such as mixing of geothermal fluids that lead to explosive nucleation of small clay crystallites and promote occurrences of heterogeneous mineral assemblages, such as I-S (Beaufort et al., 1996; Mas et al., 2006).

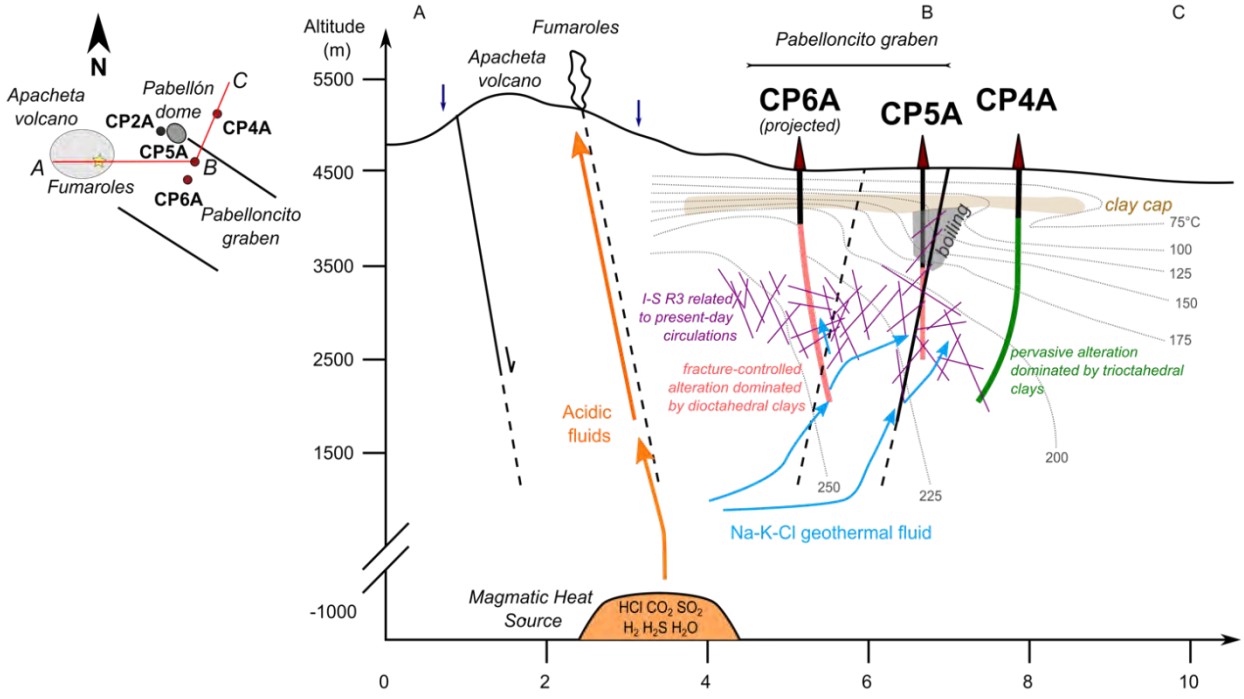

Figure 7: Conceptual model of the hydrothermal alteration occurring through the eastern border fault of the graben acting as a conduit and the wide permeable fracture network associated to it. Isotherms, structures and fluid circulations are schematically represented from Giudetti and Tempesti (2021), Maza et al. (2018), Urzúa et al. (2002) and updated with results of clay signature in CP2A, CP4A, CP5A and CP6A wells. The large-scale faults are from the structural model of Rivera et al. (2021) and the wide permeable fracture network developed in its vicinity follows the trace of the low resistive anomaly in the 3D magnetotelluric model from Baccarin et al. (2021). The depth of the magmatic heat source is from Gorini et al. (2018). I-S R3 refers to illite-smectite mixed layers with less than 10% of smectite.

These three alteration events can be spatially and temporally superimposed. The propylitic alteration probably started before but continues even if locally in the permeable levels, a multi-event fracture-controlled alteration occurred erratically. As an active system, dynamics of the fluid leads to a heterogeneous alteration; the dioctahedral sequence is mainly expressed in CP6A well, in the *hot core* inside the graben whereas the trioctahedral sequence is mainly expressed in CP4A, outside the graben (Figure 7). However, illitic minerals and more particularly I/S R3 ml (ill>90%) are observed as clay signature for FZs in all wells inside and outside the graben suggesting a unique source for the fluid circulating in the reservoir. Thus, the eastern border fault of the graben does

not act as an impermeable barrier and an interconnected fracture network is developed in the vicinity of the fault channelizing the geothermal fluid. The proximity of both wells to each other (circa 2 km between bottoms of the wells) and the injectivity index of CP4A confirms a good connection to the deep geothermal reservoir. However, the sudden decrease of the isotherms and the dominance of propylitic alteration in CP4A suggest limited fluid circulations outside the graben restricted to few FZs compared to the center of the graben. Intense paleo-circulations can lead to a sealing of the fracture network as suggested by the clay pattern in CP2A well where a significant amount of dioctahedral clays could seal the median strand of the eastern fault probably intersected by the well. In CP5A well, the eastern border fault acts as a preferential pathway for unimpeded fluid flow with evidence of boiling process at shallow depths (Figure 7). This eastern border fault is a complex structure in terms of fluid flow and circulations occur spatially and temporarily heterogeneously.

6. Conclusion

As the CP reservoir is an active system, it demonstrates high heterogeneity in terms of alteration mineralogy. Typical clay signatures observed along deep wells suggest a complex multi-event history of fluid circulations controlled by the eastern border fault of the Pabelloncito graben. The latter controls the narrow thermal plume promoting focused vertical fluid flow at the South of the Pabellón dome whereas the hydrothermal activity collapsed in response to intense illitization which plugged the fault zone at the North of the Pabellón dome. However, the eastern graben fault does not behave as barrier. The same clay signature is observed inside and outside the graben suggesting a wide permeable fracture network channelizing fluids in both side of the border fault. As exploitation of the geothermal system leans on well-connected fracture network providing sufficient permeability, the study of hydrothermal alteration and more specifically clay minerals is important for future geothermal development of CP system as well as other Andean geothermal systems. Moreover, recent results indicate that clays are the primary lithium-bearing minerals, and understanding their properties is crucial for advancing prospects of geothermal lithium co-extraction.

Keywords

Shallow temperature survey, 2m probe, Puchuldiza

ABSTRACT

Exploration drilling for geothermal resources is expensive and the risk of not discovering an economic resource with exploration drilling is high. Lower cost, shallower direct measurements of the subsurface have therefore been conducted as part of early-stage geothermal exploration since at least the late 1970s. These surveys prioritize low cost and rapid data gathering over a wide field area. Since the mid-2000s the technique has been further developed and data corrections have become more sophisticated. This paper compares three shallow temperature (2 m probe) systems used by public and private groups. Additionally, findings are described from a shallow temperature survey conducted in 2010 at Puchuldiza, Chile. The results indicate that shallow temperature surveys are an effective method for discovering and characterizing geothermal resources.

1. Introduction

Exploration drilling for geothermal resources is expensive with high risk of not discovering an economic resource with exploration drilling. A variety of geological, geochemical, and geophysical surveys are typically conducted to lower the risk of failure. One of these techniques is shallow temperature surveys, which have been conducted in the Basin and Range province of the United States since at least the 1970s. The goal of a shallow temperature survey is to locate a thermal anomaly quickly and at low cost so that further exploration surveys can focus on an area of interest.

2. Shallow vs deep drilling

Deep drilling (>1000 m) costing on the order of $1MM to $10MM is required to discover a geothermal resource (**Figure 1**). Consequently, explorationists trade lower cost for shallower and less representative information about temperature distribution. Slim wells to ~1000 m at a cost of ~$1MM are sometimes cost-effective, and handfuls of temperature gradient holes drilled from ~50 m to 150 m for $10k to $50k each are commonly used as well (e.g., Basin and Range, Salton Sea). Pushing this cost/depth relationship to its limit leads to shallow temperature surveys at depths of

~0.5 m to 2 m for a cost of <$500 per hole. A nominal depth of 2 m has become the standard in the industry for these types of surveys. A large number of these holes can be drilled for the same cost as a single temperature gradient (TG) hole and provide a much higher spatial density than a TG program. However, these shallow holes carry a higher risk of being impacted by surface effects and meteoric water than deeper TG holes.

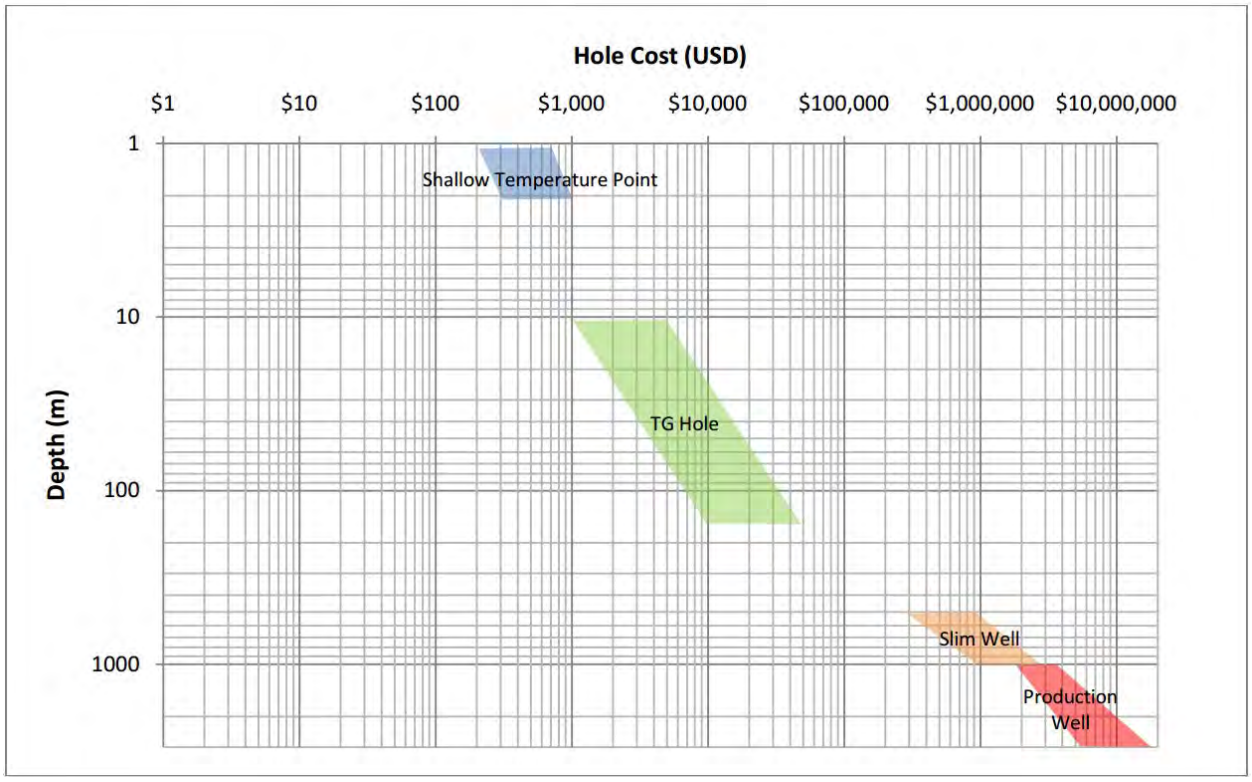

Figure 1. Hole cost vs depth relationship

The goal of a shallow temperature survey is to identify anomalously high shallow temperatures that may be associated with a geothermal reservoir at depth. Shallow temperatures on the order of 1 m depth are affected by many non-geothermal surface processes which can cause variations in temperature equal to or greater than the magnitude of the thermal anomaly above the background temperature. Wet or damp soil and shallow cold aquifers can mask a geothermal reservoir and so the method has only been used in arid regions like the Basin and Range. The diurnal temperature cycle is dampened sufficiently at depths as shallow as 0.5 m. The seasonal cycle is significant to a depth of 10 m or more, but changes slowly enough that it can be ignored during a short survey or compensated for with seasonal monitoring.

Since the temperature signal measured at 2 m from a geothermal reservoir can be <5°C above background, various corrections to the 2 m temperature data are usually required, including corrections for elevation, albedo, and slope aspect. These are discussed further below.

TG hole programs investigate even deeper. A shallow temperature survey does not replace a TG hole program. Rather it provides a low-cost data set on temperature distribution for the development of a conceptual model early in the exploration phase of a geothermal prospect. Together with other low-impact exploration techniques like fluid geochemistry, structural

mapping, and geophysical surveys such as MT and gravity, it can help target a TG hole program while environmental studies and drilling permits are obtained.

3. History of the technique

Shallow temperature surveys for geothermal exploration are first represented in the literature starting in the late 1970s and early 1980s. They were first used at depths of 1-2 m to investigate many known geothermal systems in the Basin and Range. The equipment used in these surveys is unknown but assumed to be a truck-mounted drill rig. A summary of the history of these studies is provided in Kraal et al (2024)

In the mid-2000s, the survey technique was revived by the Great Basin Center for Geothermal Energy (GBCGE) at the University of Nevada, Reno (UNR) to map a large number of greenfield geothermal projects and especially blind systems. GBCGE discovered at least seven previously unknown thermal anomalies in Nevada: Southern Gabbs Valley, Teels Marsh, Rhodes Marsh, Columbus Marsh, East Hawthorne, Emerson Pass, and Petrified Springs (Kraal et al, 2024). The GCBGE system utilized a side-by-side Utility Task Vehicle (UTV) with a hand-held electric hammer which pounds closed-bottom steel pipe (the probes) into the ground (**Figure 2**). This method of inserting the probes works well in soft sediment but is difficult or impossible in rocky soil. GBCGE has also used a 2-stroke gasoline rock drill with mixed success. This system is still in use at the time of this writing by GBCGE and graduate students at UNR.

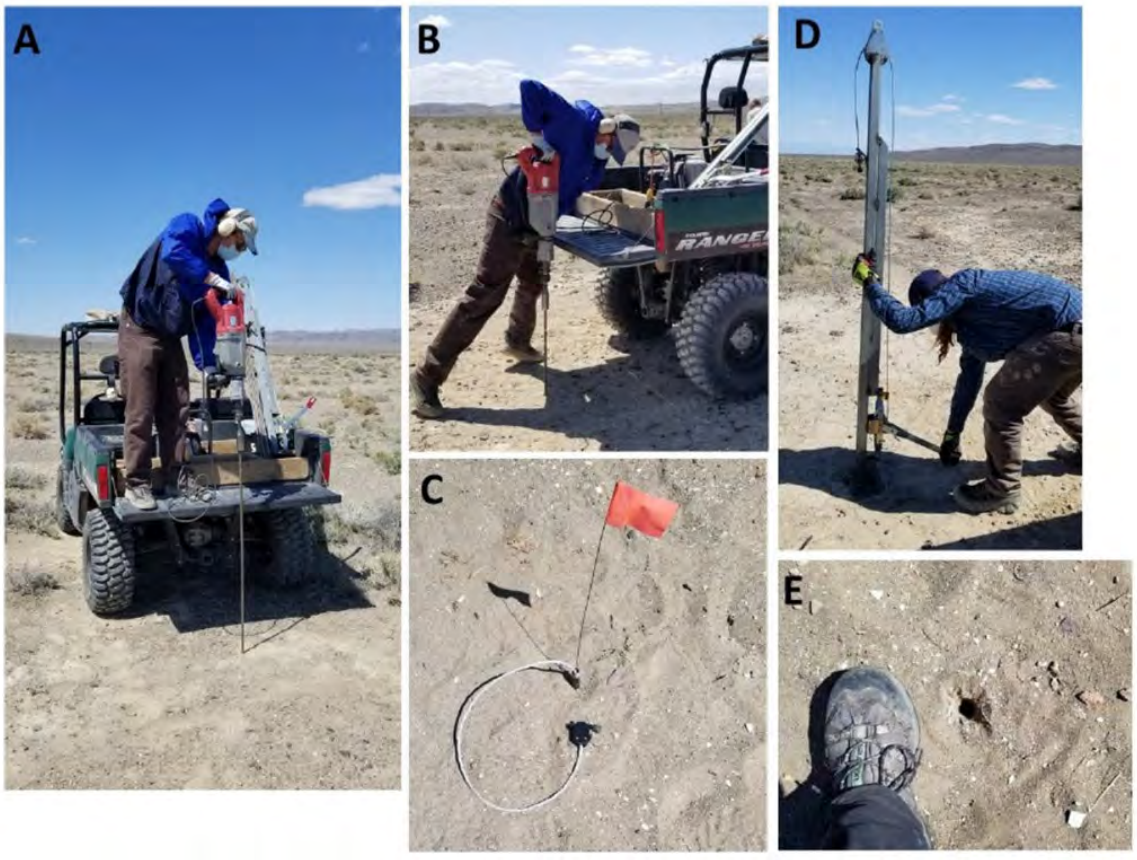

Figure 2. The GBCGE 2 m probe rig as described in Kraal et al (2024).

In 2009, a purpose-built rig mounted on a side-by-side and utilizing a custom mast-mounted electric rotohammer and ¾" concrete drill bits was built by Geoglobal Energy (GGE) for use in the Altiplano of Chile, where arid conditions similar to the Great Basin predominate (**Figure 3**). Details of this system and the data collected at the Puchuldiza project in Chile are discussed below. The fate of this rig is unknown but it is assumed to still be warehouse in northern Chile.

In 2010, an upgraded version of the GGE rig was used by Nevada Geothermal Power at Blue Mountain, Nevada. This rig was parted out and sold sometime in 2011-2012.

Figure 3. The GGE rig in use at Puchildiza, Chile.

In the early 2020s, at least one company in Nevada utilized a direct-push type drilling rig commonly used in the environmental and geotechnical industries. This type of system can work well, but is limited to fine-grained sediment and roads traversable by trucks.

In early 2024, a new 2 m probe purpose-built rig designed and built for Baseload Power U.S. (BPUS) by Double R Drilling of Reno, Nevada for use in the Basin and Range. The innovations of this rig include a tiltable mast-mounted rotohammer and custom-made 2 m fully-fluted concrete bits (**Figure 4**). This system is discussed in detail below.

Figure 4. The 2 m prove rig designed and built for BPUS by Double R drilling.

4. Methodology

The methodology of inserting the temperature probes is similar for all three systems discussed in this paper: 1) a side-by-side UTV is used to carry personnel and equipment to the field, 2) 2 m long probes are inserted into the ground, 3) after thermal equilibration temperature measurements are made down the hollow probe with a resistive temperature device (RTD) on a wire, and 4) the probe is removed from the ground and re-used.

The GBCGE system has generally used a handheld electric hammer to pound hollow steel rods (probes) into sediment. This works well in fine-grained sediments and rocky soils with clast size up to ~2-4 cm. The disadvantages of this system are that the electric hammer is hand-held which fatigues the crew, it is difficult or impossible to penetrate rocky soil, and the probes must be laboriously jacked out of the ground by hand to remove them.

By contrast, the GGE system employed a hinged mast and track system with a winch to mount a rotohammer. The mast allowed for remote operation with a tether and was significantly less laborious to operate. The rotohammer could be used to either pound probes in the ground, similar to the GBCGE system, or to drill holes using ¾” concrete bits available off-the-shelf. The holes could be blown clean with an on-board air compressor and a long, thin, tube attachment. The bits were 2 m long but the flights only continued ~1 m. This required repeated hole cleaning after 1 m depth which significantly increased the total drilling time.

The newest system created by BPUS and Double R used a pivoting mast built from unistrut with a track that allows the rotohammer to move up and down. The mast can be tilted back onto the rig while driving and redeployed to the vertical position at the next location. The winch in the mast can also be used to pull rods after the measurements are complete. Two people can operate the rig (**Figure 4**) comfortably. Upon reaching the desired depth, the hole can be blown clean with air and a hollow steel rod is dropped into the hole. A tap on the rod with a sledge hammer ensures good contact with the formation. An RTD (**Figure 5a**), is threaded on a wire down the rod (**Figure 5b**).

A small amount of water can be poured into the pipe to ensure good conductive thermal contact with the RTD.

Although the RTD only needs seconds to minutes to thermally equilibrate, the steel rod requires up to an hour or more to equilibrate with the formation. We prefer to leave the rods in overnight before making a measurement. To make a measurement the RTD is plugged into an electronic meter and the temperature is read off the display (**Figure 5c**).

Figure 5. RTD and meter (a); Threading the RTD down the probe (b); and reading the temperature (c).

5. Corrections

Various corrections must be made to the raw temperature data in order to correctly map the shallow temperature distribution. These corrections have been detailed in Sladek et al (2009) and Kraal et al (2024). In the Puchuldiza and BPUS surveys, the most useful corrections were found to be 1) seasonal drift, 2) elevation, and 3) albedo, in that order. Other attempted corrections included slope aspect and total solar insolation, but were not found to be significant. Examples of the Puchuldiza survey seasonal trend (**Figure 6**), and negative correlations with shallow temperature for elevation (**Figure 7**) and albedo (**Figure 8**) are shown below.

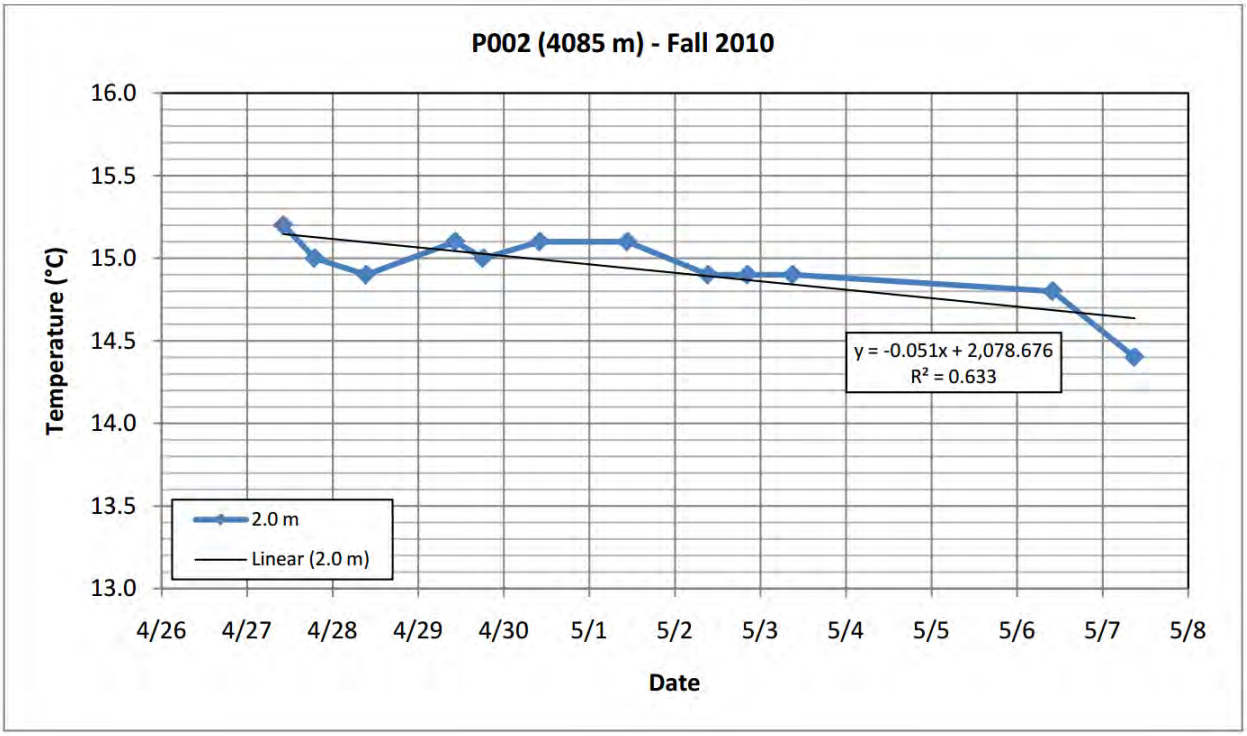

Figure 6. April/May monitoring of Puchuldiza base station P002. There was a small cooling trend at 2.0 m.

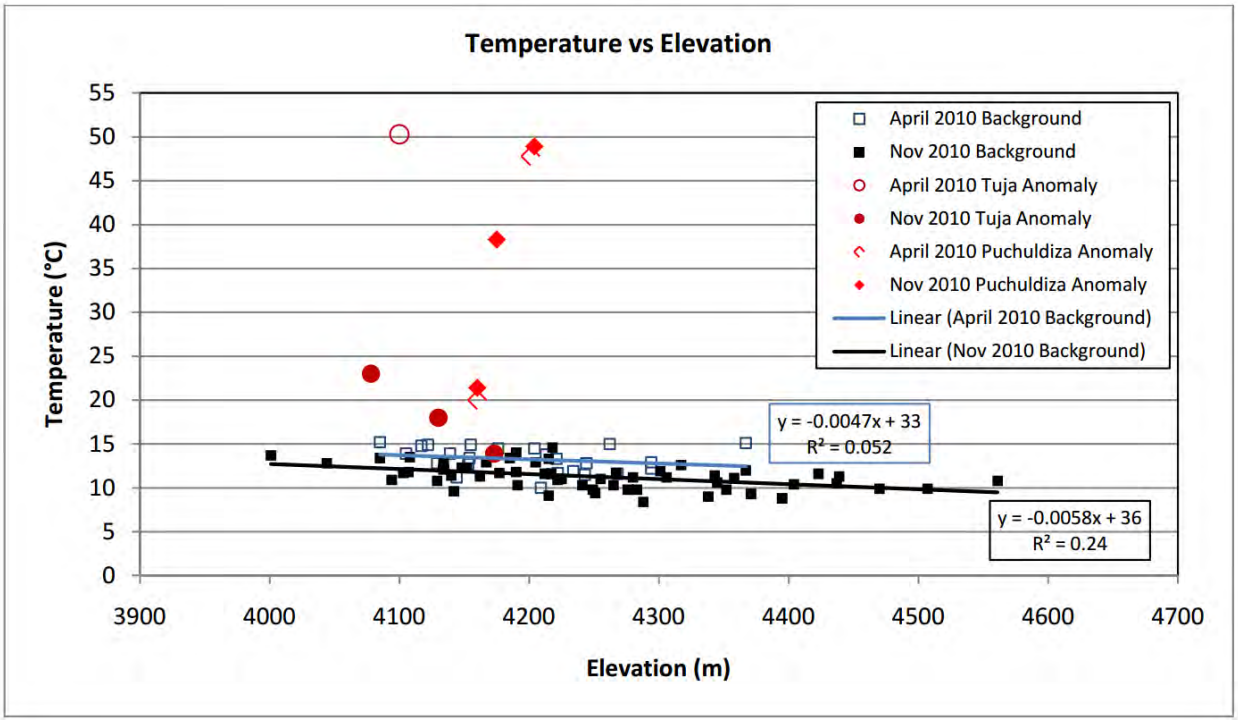

Figure 7. Puchuldiza uncorrected temperature vs elevation. There is a small negative correlation.

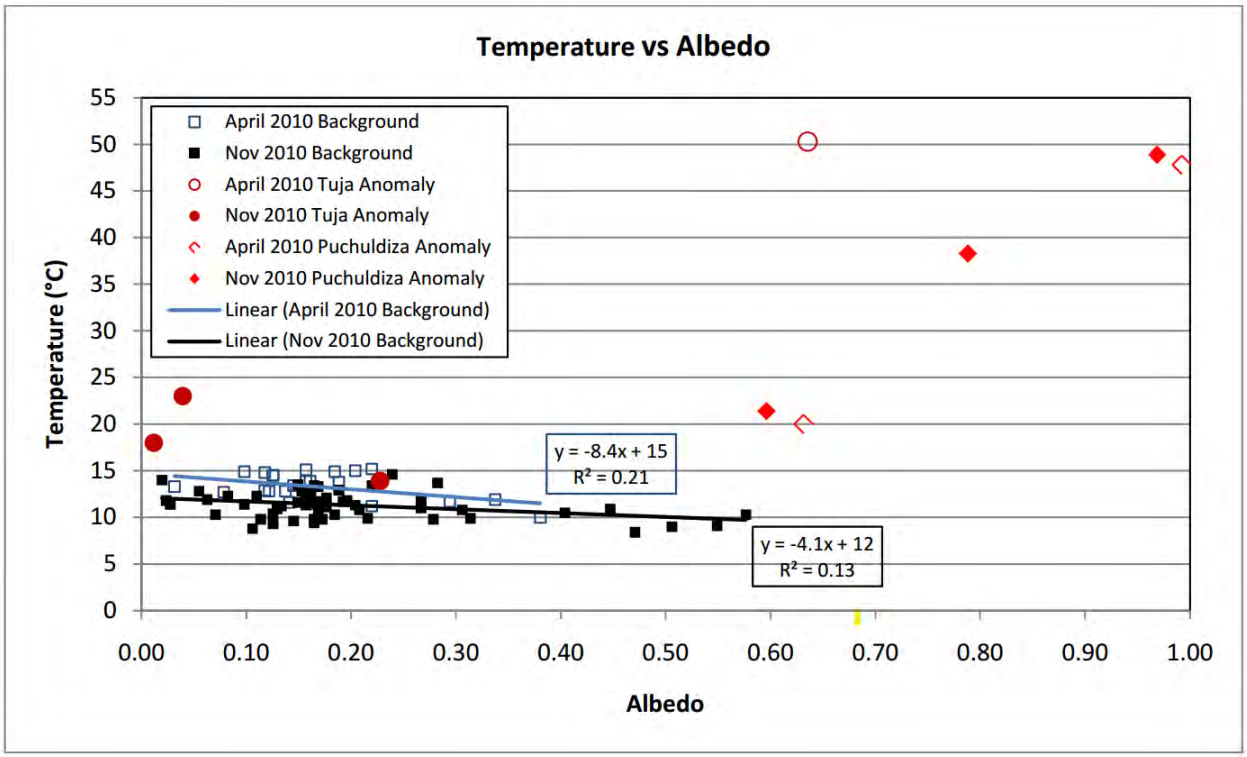

Figure 8. Puchuldiza uncorrected temperature vs albedo. There is a small negative correlation.

6. BPUS Standard Operating Procedures

The following Standard Operating Procedures have been developed by BPUS in concert with Geologica Geothermal Group. These SOPS build on the procedures used in the Puchuldiza surveys and borrow from the procedures of Kraal et al (2024).

6.1. Survey Operation

The essential aspects of 2 m surveying are 1) installing a 2-meter-long hollow rod (probe) into the ground, 2) waiting an appropriate period of time (typically at least two hours) for the probe to equilibrate with the ground temperatures, 4) recording the temperatures at 2 m depth, and 4) pulling the probe for later re-use.

6.2. Survey Design

The survey design consists of 1) at least two ‘base stations’ (label Base-1, Base-2, etc.) and 2) several dozen or more measurement locations (labelled 1, 2, etc.). It is critical that the field crew has a GPS-capable device (e.g. tablet or handheld GPS) that the survey design has been loaded onto prior to mobilization. This will ensure that data are collected in the correct locations.

6.3. Install Base Stations

On the first day of the survey, the first task is to install base stations. These probes are to remain in place for the entire duration of the survey. Locate each ‘Base’ location and install a probe.

Record the name of site (e.g., ‘Base-1’) and the time and date the probe was installed on the attached data sheet.

6.4. Installing Probes

To maximize time efficiency, it is recommended to install many (>10) probes, then return to measure the temperatures at each one and remove each one. The locations in the survey design are numbered (1, 2, 3…etc.), probes should be inserted in the same order as the numerical order of survey design. Locate and travel to location 1, install a probe. Record the name of site (e.g., ‘1’), the GPS coordinates, (Latitude and Longitude), and the time and date the probe was installed on the attached data sheet. Cap the probe with PVC cap (to keep out dust), and add flagging (so it can be easily found later, not accidental run over). Travel to 2 and repeat.

A typical survey might look like:

Day 1: Install two base stations
Install probes 1-15
Measure temperatures at both base stations
Measure temperatures and remove probes 1-15
Take a photo of data collection sheet and email it to office (if not using digital data input)

Day 2: Measure temperature at both base stations
Install probes 16-30
Measure temperatures and remove probes 16-30
Take a photo of data collection sheet and email it to office

Day 3: Measure temperature at both base stations
Install probes 31-50
Measure temperatures and remove probes 31-50
Measure temperature at both base stations, remove both base station probes
Take a photo of data collection sheet and email it to office

6.5. Making Temperature Measurements

Once many (>10) probes are installed, enough time (at least two hours) is likely to have elapsed, so the temperature of the probe is now in equilibrium with the temperature of the ground. Return to the first probe installed (e.g. 1). Insert the RTD, ensure that the RTD goes all the way to the bottom of the probe. Wait for the temperature readings to ‘settle’ on a single temperature. Typically, this takes less than 5 min. The RTD should be left at bottom for a minimum of 2 minutes. Record the time the measurement was taken, and the temperatures at 2m on the attached data sheet. Travel to the next probe, repeat.

6.6. Transmitting the Data

At the end of each day’s data collection take a photograph of the day’s data sheet and the base station data sheet and email it to the office. Depending on the day-to-day results, some adjustments to the survey design may be made. If adjustments are made, a new KMZ file will be emailed to

the field crew. On the final day of the survey measure temperatures at the base stations, pull the base station probes and send a photograph of the final day's data sheet and the base station data sheet to the office.

7. Quick Reference Guide for Standard Operating Procedure (SOP) at each survey location

The following Table (**Figure 9**) details the order of events that should occur at each survey location, including base stations.

ALWAYS WEAR PROPER PPE (Minimum: SAFETY GLASSES & WORK GLOVES)
2m probe survey: Probe installation
1) Locate and drive to the planned survey location. a. It is acceptable to deviate by up to 50 feet from the planned location to avoid areas that have obstacles (e.g. fence, debris, culvert, steep drainage channel, animal burrows etc.) b. Do not install a probe if there is standing or running water on the surface, relocate to the nearest dry area. Avoid drainage channels, even dry channels may have ground water just below the surface. 2) Install the probe to 2 meters (6 ft, 3 and 1/3 inches). a. In the event of a failed installation (less than 2 meters), re-locate by several feet and try again. 3) Record the survey point name (e.g., 1) and GPS location (latitude and longitude) in decimal degrees format with 6 digits in the decimal (e.g. 38.828714, -117.579906) even if it is identical to the plan, on the attached data sheet. 4) Save the location in a GPS or tablet as a point. 5) Record the time that the probe was inserted on the attached data sheet. 6) Record any site-specific information (e.g., had to move because of fence) on the attached data sheet. 7) Cap the probe with PVC cap. 8) Mark the probe with flagging or cone so it can be re-located easily and to prevent others from driving over it. 9) Travel to the next location.
2m probe survey: Temperature measurement
1) Relocate to the probe location. 2) Confirm that >2 hrs have passed since the probe was inserted. 3) Remove the PVC cap and insert the RTD. 4) Make sure the RTD goes all the way to the bottom of the probe (2m). 5) Wait at least 2 minutes for the RTD to equilibrate. 6) Record the time of the temperature measurement on the attached data sheet. 7) Record temperatures at 2m on the attached data sheet. 8) Photograph location, include station number (written on small white board or notepad) and meter with screen showing 2m temperature reading. 9) Pull the probe and move to the next station.

Figure 9. SOP Quick Reference Guide.

Conclusion

Shallow temperature surveys have been conducted as part of early stage geothermal exploration since at least the late 1970s. These surveys prioritize low cost and rapid data gathering over a wide field area. Since the mid 2000s the technique has been further developed and data corrections have become more sophisticated. So too has the custom equipment used in these surveys become more sophisticated. The 2 m probe survey methodology developed by the GBCGE, and private companies such as GGE and BPUS can be applied to a large area of the Basin and Range to explore for new geothermal systems, especially blind systems.

Acknowledgement

This work relied heavily on assistance from many people. The Puchuldiza survey was greatly assisted by the work of GGE team members Pedro Muñoz, Jim Stimac, Silke Lohmar, Domingo Maldonado, Sergio Iriarte and Andrea Gonzalez. Data analysis and report preparation benefitted from special contributions by Anna Colvin and Esther Mandeno, and from review by Glenn Melosh, Jim Stimac and David Sussman. The BPUS survey was heavily dependent on Chris Reede from Double R Drilling who designed and built the rig from BPUS specifications, and led the testing and data collection. Geologica staff contributed to the BPUS system design and testing including Peter Drakos, Matthew Folsom, and Leland Davis.

Fracture intensity, Structural features, Geological map, Geothermal conduits

ABSTRACT

In recent years, Taiwan has become actively to develop renewable energy sources and investigate geothermal resources. One area of interest is the Lushan region, known for its numerous hot spring outcrops. Preliminary surveys suggest that it holds potential for geothermal development. Successful geothermal energy development relies on the existence of an enough heat source and appropriate pathways for the heat to rise to shallow depths, and a detailed geological map is a must for effective and cost-efficient exploration.

This study bases on the previous geological map covering the western fringe at the middle part of the Central Mountain Range and zooming in the Lushan area with more detailed mapping. While the ongoing Quaternary orogeny in Taiwan has created a unique geological environment and the rapid uplift has brought in abundant heat sources, the compressed slate and meta-sandstone formations have resulted in complex subsurface structures, and the rugged mountain ranges and deep valleys also prevent a thorough geological field work. Finding additional and creative methods to build more precise geological map in such a challenging area for interpreting underground rock types and structures has become a pressing need.

Our approach is to gather data from field survey works, digital elevation model (DEM), and previous literatures for exploring various geological structure patterns, then fracture network analysis is executed to categorize those data for the fracture strength map. Five factors, including outcrop fracture density, rock porosity, outcrop fracture intensity, outcrop fracture connectivity, and surface lineament intensity, are determined for the analytical process. The normalized score from each factor is calculated and assigned into grid map for the final fracture strength index. The existence and trend of projected fault zones and other structural features are confirmed by comparison with the fracture strength index map in the Lushan area.

Our integrated results strongly indicate the important value of digital processing, which is not only capable of consistently describing outcrop information, but also effectively complements field

surveys in a remote area. Through the fracture strength index map, this study also implies the potential areas of the geothermal reservoir and hot fluid conduits, providing valuable information for geothermal exploration.

1. Introduction

In Taiwan, electricity generation primarily relies on thermal power, but the high dependence on imported coal leads to high generation costs and air pollution. In recent years, with increasing environmental awareness, clean energy sources have gained more attention, especially geothermal energy. As a base-load power source, geothermal energy poses no risks associated with nuclear power, making it one of the choices for energy development in Taiwan. (Song et al., 2015)

Taiwan's active Quaternary orogeny has created a unique geological environment with rapid crustal uplift providing extensive heat sources, making geothermal resource development favorable (Chen, 1975; Huang et al., 1997; ITRI, 1984; Lee et al., 1994; Song and Lu, 2018; Teng et al., 2013). However, the deeply buried and compressed metamorphic environment also results in complex underground structures. To effectively develop geothermal resources, more methods are needed to create more precise geological maps, interpret subsurface formations and structures, and subsequently construct a better geothermal model.

In geothermal development, when heat sources are sufficient, hydrothermal channels become a key investigation factor. When rocks fracture under stress, they form interconnected spaces that can serve as channels for hydrothermal fluids during power generation. Therefore, fault structures are a primary focus of the investigation. Fault activity generates fault damage zones around it, where new secondary fractures are formed in the rocks within the damage zone. These new fractures connect with existing ones, creating natural fracture networks (Faulds, 2014). Rock formation with higher fracture intensity is prone to have more porosity and/or permeability. Understanding areas with high fracture intensity can help determine the potential distribution of geothermal reservoir and hydrothermal conduits.

This study investigates the fractures in the Lushan area, applying topological network methods to calculate the fracture intensity and connectivity (Sanderson and Nixon, 2015; Hansberry et al., 2021). This is combined with surface lineament data interpreted from shaded relief maps, rock porosity, and joint density data. Each factor is normalized and scored to create a fracture strength index map, which aims to confirm the structure patterns in the geological map, and further identify the higher fracturing areas as potential geothermal development targets in the Lushan area.

This study concludes that our approach successfully employed a digital sampling method for efficient field sample handling, enhanced geological maps by incorporating supplementary DEM data for hard-to-reach remote areas, effectively utilized fracture strength analysis to verify structural patterns on the geological map, and most importantly, suggested the correlation between fracture intensity and the rock properties of porosity and permeability in metamorphic slate area.

2. Geological Background

Taiwan is situated at the boundary between the Eurasian Plate and the Philippine Sea Plate (Figure 1). The collision and compression of these two plates have produced complex geological structures

and a significant amount of thermal energy. During the Quaternary orogeny, rapid crustal uplift occurred, and the residual heat from this process has become the main source for geothermal development in Taiwan. (Lee et al., 2006; Wang et al., 2021)

Previous geothermal resource development and surveys in Taiwan have identified several hot spring outcrops in the Lushan area, located on the western flank of the Central Mountain Range in Nantou. The surface hot water temperatures in this area range from 54°C to 98°C, with substantial water flow rates, indicating a potential for geothermal development (Chang and Chiao, 1979). Identifying optimal locations for hydrothermal channels can facilitate further geothermal exploration.

The Lushan area comprises Tertiary meta-sedimentary rocks, specifically low-grade metamorphosed thick mudstone formations known as the Lushan Formation from the Miocene epoch (Hsiao et al., 1980). Based on lithological and stratigraphic variations, the Lushan Formation is subdivided into three members (Figure 1): the Chunyuan Member, the Yuanfeng Member, and the Kunyang Member, from bottom to top. The Chunyuan Member, the lowest layer, consists of slate interbedded with thin layers of fine-grained meta-sandstone. The Yuanfeng Member, the middle layer, consists of interbedded meta-sandstone and slate. The Kunyang Member, the uppermost layer, consists of slate interbedded with meta-sandstone (Lo and Yang, 2002).

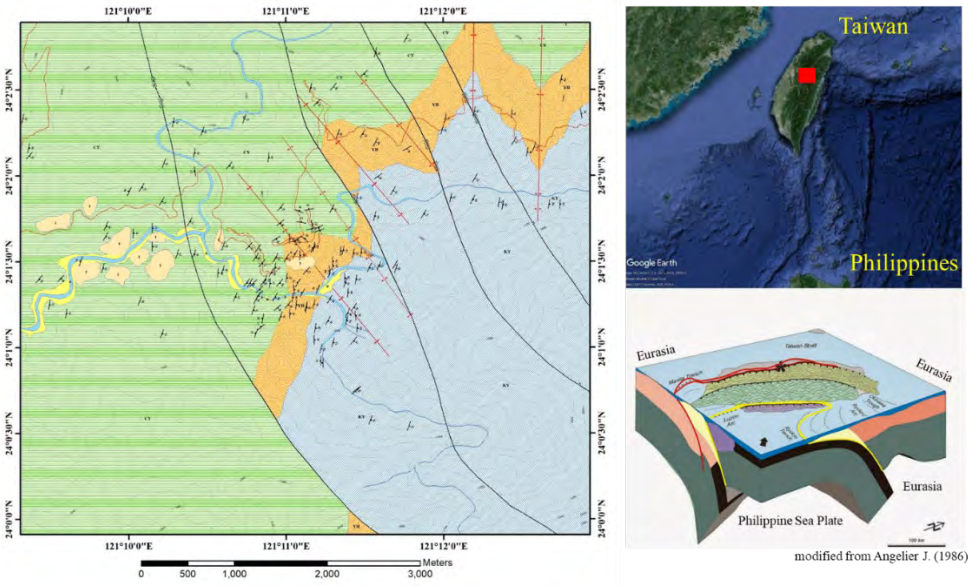

Figure 1: Geological map of the Lushan area, Taiwan. The green represents the Chunyang member, the orange represents the Yuanfeng member, and the blue represents the Kunyang member.

Although these metamorphic rocks have relatively low porosity, they are prone to fracturing due to the external forces during metamorphism. These fractures create void spaces that could serve as conduits for fluid flow, enhancing the reservoir properties. The well-developed cleavage in the slates from the Lushan area, coupled with the presence of four fault zones, should have generated extensive fracture zones, providing favorable conditions in geothermal exploration due to high porosity and permeability properties.

3. Data and Methods

3.1 Data elements

After a fault occurs, it generates a fault damage zone, which is usually accompanied by secondary faults and fractures (e.g., Bruhn et al., 1994; Billi et al., 2003; Odling et al., 2004; Berg and Skar, 2005; Faulkner et al., 2010; Choi et al., 2016), resulting in higher degree of fracturing in these areas compared to the wall rock. This study aims to identify areas influenced by fault damage zones through its characteristic features. We collect the following three types of data to investigate the degree of fracturing in the Lushan area:

(1) Outcrop scale fractures

Outcrops in the field directly reflect whether they have been affected by fault activity. If affected, more fractures or secondary fault structures can be observed on the outcrops. Therefore, it is necessary to conduct field surveys on the freshly exposed outcrops, measure the orientation data of fractures, and take photographs. In addition to the data obtained from field surveys, this study also references the results of the joint density survey of the Lushan area by Hsiao et al., 1980. In his survey, the number of joints present on outcrops was recorded every 100 meters, and the joint density was classified into six levels (Figure 2), showing the distribution of joint density at the outcrop locations.

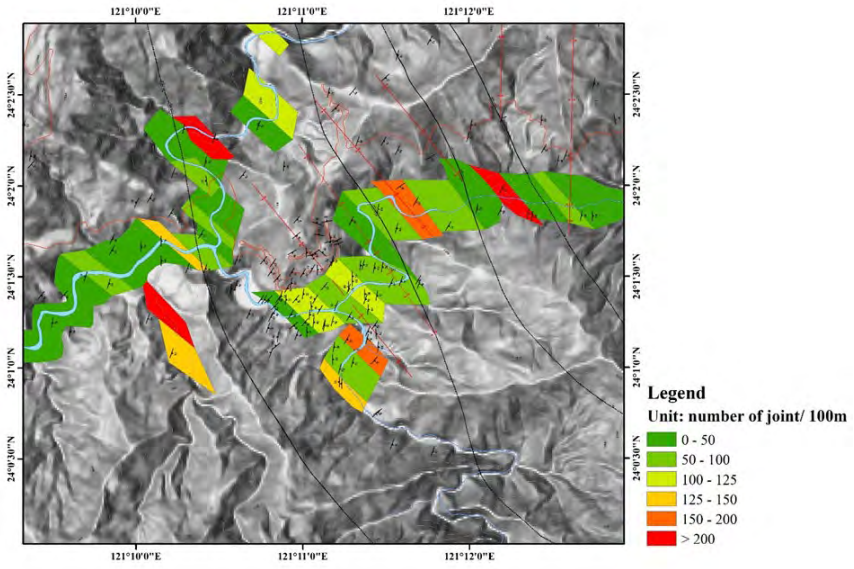

Figure 2. Fracture Density Distribution Map (revised from Hsiao et al., 1980)

(2) Remote sensing scale lineaments

During the field survey of outcrops, it was found that due to the steep terrain and high elevation of over 1,100 meters in the Lushan area, along with rapid river erosion, surveying outcrops in the river valleys is rather difficult. To obtain more comprehensive fracture data, this study uses a DEM to generate a shaded relief map, which effectively displays linear features on the surface, representing fracture patterns at that resolution (Henderson et al., 1996). This method compensates

the lack of surface information due to the difficulty of surveying certain areas in the Lushan region, and introduces substitutes through converted remote sensing data.

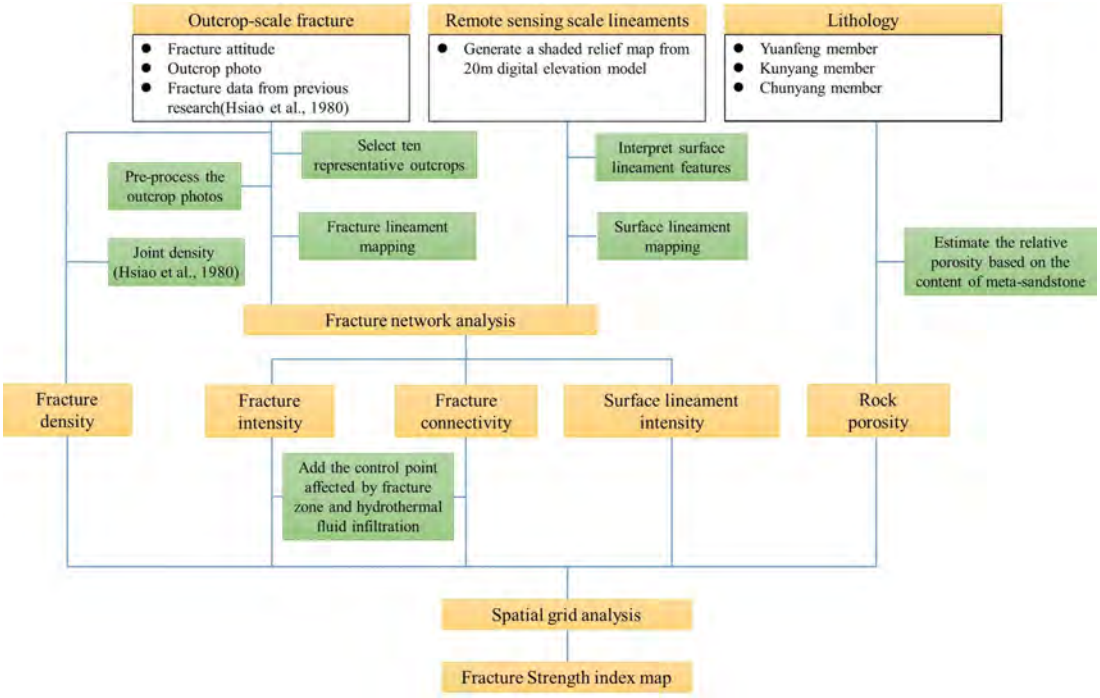
(3) Rock porosity

The quantity and morphology of fractures generated in different lithologies would look differently. For examples, lithologies with higher internal porosity tend to have lower compressive strength (Baud et al., 2014), making them more prone to fracturing under stress. The lithology of our study area mainly consists of slate and meta-sandstone. Based on the amount of meta-sandstone present in the three lithological units, the relative porosity content can be estimated. Thus, the meta-sandstone content in the three lithological units, from highest to lowest, is Yuenfeng Member, Kunyang Member, and Chunyang Member, corresponding to their relative porosity levels.

3.2 Processes and methods

Each dataset undergoes various processing steps before being classified into five factors for spatial grid analysis, culminating a fracture strength map (Table-1). Outcrop-scale fracture data are processed into two factors: fracture intensity and fracture connectivity. Remote sensing scale lineaments are processed into the surface lineament intensity factor. Plus the survey results on joint density in the Lushan area (Hsiao et al., 1980) represent the fracture density factor, while the relative porosity factor is demonstrated by the lithology. Five relevant factors are proposed by fracture intensity, fracture connectivity, surface lineament intensity, fracture density, and rock porosity. These are used for spatial grid analysis and produce a fracture strength map in the Lushan area.

Table-1: work flow



The processing methods for outcrop-scale fracture data and remote sensing scale lineaments are explained as follows:

3.2.1 Outcrop scale fracture lineament mapping

Before converting the surveyed outcrop data into parameters for fracture intensity and fracture connectivity, it is necessary to map the fracture lineaments on the outcrops. To improve analysis efficiency, reduce subjective bias, and shorten the time required for mapping fractures, this study adopts three steps to complete the fracture lineament mapping:

(1) Selection of Representative Outcrops

Based on the distribution of survey locations, the weathering condition, and fracture types, ten representative outcrops are selected from the field for efficiency purpose.

(2) Preprocessing and fracture recognition

To reduce subjective bias and maintain consistent fracture recognition rules, photographs of the representative outcrops were taken (Figure 3a). Adobe Photoshop was used to preprocess these photographs, removing areas that were not part of the outcrops and those with excessive vegetation. Next, the filter tool was used to convert the images into sketch effects, transforming the outcrop photographs into sketch lineament maps (Figure 3b), thereby completing the fracture lineament recognition.

(3) Lineament mapping

To shorten the time required for mapping lineaments, ArcGIS geographic information system software was used. With the ArcScan tool in ArcMap, the black parts of the sketch lineament maps were vectorized into line features, thus completing the fracture lineament mapping (Figure 3c).

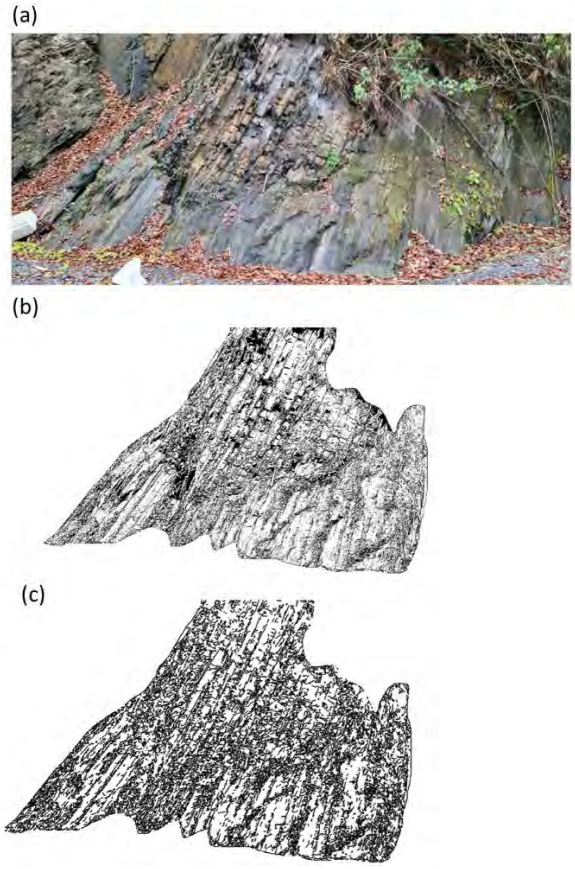


Figure 3. (a) Original outcrop photo before conversion to sketch effect; (b) Outcrop photo after conversion to sketch effect; (c) Conversion of sketch diagram to line features to complete fracture lineament mapping.

3.2.2 Outcrop fracture intensity and fracture connectivity

The fracture lineaments from the outcrops are converted into linear features to analyze fracture intensity and fracture connectivity. The parameters for fracture intensity and connectivity are analyzed based on the geometric and topological characteristics of the fracture network (Sanderson and Nixon, 2015). This analysis method involves calculating the types and quantities of nodes and branches based on the endpoints and intersection points of the fracture lineaments (Figure 4). Then, using formulas from Table-2, the two-dimensional fracture intensity (P_{21}) and average number of connections per branch (C_B) are determined, yielding the fracture intensity and connectivity values for each outcrop (Sanderson and Nixon, 2015; Sanderson and Nixon, 2018; Hansberry et al., 2021).

The P_{21} for fracture intensity is defined by the PXY system (Sanderson and Nixon, 2015). This system provides a specific definition for describing the degree of rock fracturing (Figure 5): P represents the parameter, X is the dimension of the sample, and Y is the dimension of the sampled feature. Thus, P_{21} represents the total fracture length per unit area. C_B, used for calculating fracture connectivity, is a dimensionless network connectivity indicator that measures the connectivity of the fracture network, with values ranging from 0 to 2. A value of 0 indicates no connectivity, 2 indicates full connectivity, and a C_B value of 1.5 suggests sufficient connectivity for fluid flow (Sanderson and Nixon, 2018). To quickly calculate these parameters, the study utilized the

Network Geometry and Topology toolbox developed by Nyberg et al. (2018). This tool provides an automated method for constructing the node topology of fracture networks, reducing the time and potential errors in manually identifying and calculating nodes and branches.

After calculating the fracture intensity and connectivity parameters for representative outcrops, these values are interpolated across the entire area using the Inverse Distance Weighted (IDW) method, with the representative outcrop locations as control points. This interpolation yields the fracture intensity and connectivity distribution in the Lushan area. During field surveys, those control points were observed that some outcrops had fault-induced fracture zones. When mapping fractures, the boundaries of these fracture zones are often marked, and due to extensive fracturing within the zones, the number of fractures may be lower. Some outcrops also have mineral deposits from thermal fluids (e.g., gypsum, sulfur, and calcite) covering the surface, which can affect the mapping of fractures and potentially introduce errors in the calculations of fracture intensity and connectivity. Although efforts are made to avoid selecting these affected areas when choosing representative outcrops, they still hold significance. Fault-induced fracture zones typically indicate the extent of fault damage, and the presence of thermal deposits is evidence of fluid outflow. Therefore, the fracture intensity and connectivity in these areas might be higher. To account for these factors in the analysis, the study includes outcrops with fracture zones and thermal deposits in the analysis, using the highest levels of fracture intensity and connectivity parameters as control points to minimize errors.

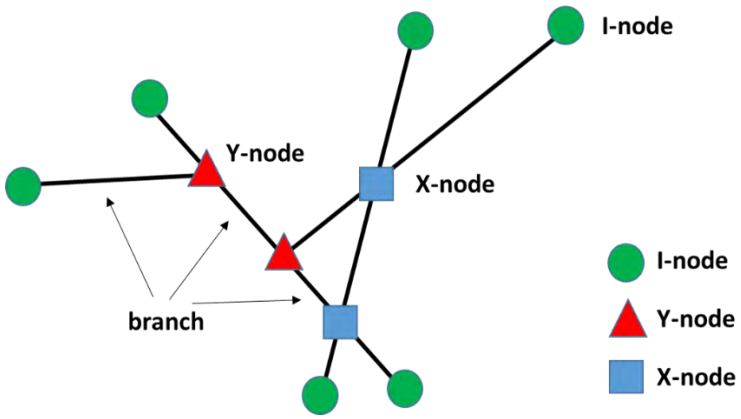

Figure 4. Example of nodes and branches presented by fracture lineaments (modified from Sanderson and Nixon, 2015)

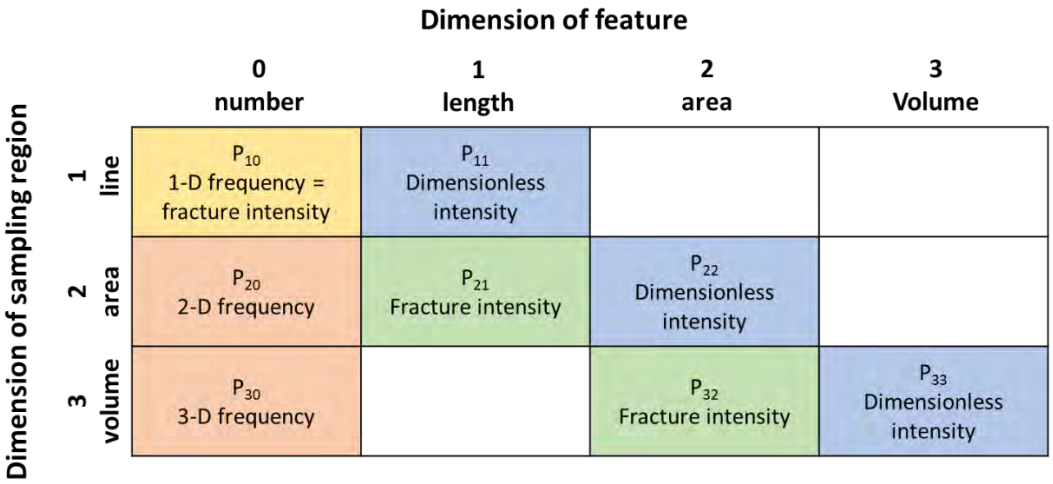

Figure 5. Dimensional significance of the PXY system according to the sampling area and recorded feature dimensions (modified from Hansberry et al., 2021)

Table-2. The topological parameters used in this study

parameter	Notation	Equation or description
Nodes	I,X,Y	Isolated, abutting, crossing
Number of Nodes	N_I, N_Y, N_X	
Number of Lines	N_L	N_L =(NI+NY)/2
Number of Branches	N_B	N_B =(NI+3NY+4NX)/2
Connections per branch	C_B	C_B =(3NY+4NX)/NB
Characteristic (ave.) length	L_C	Average length of lines
Intensity	P_{21}	P_{21} =$N_L L_C$/area

3.2.2 Surface Lineament Intensity

Surface lineament intensity is derived from the surface lineament features identified in the shaded relief map and is calculated using the P_{21} formula. The difference between fracture intensity and surface lineament intensity lies in the scale of analysis: fracture intensity is based on fracture lineaments interpreted from outcrops, while surface lineament intensity is derived DEM.

In this study, the shaded relief map was generated using a 20-meter resolution DEM. To calculate surface lineament intensity at different locations in the study area, the area was divided into 100-meter by 100-meter grids. The P_{21} parameter was calculated for each grid, illustrating the distribution trend of surface lineament intensity.

3.3 Integration of Correlation Factors

After calculating the values for the five relevant factors, it is necessary to integrate all factors to present the geothermal fluid channel scores for various locations in the Lushan area. Considering that the numeric scales of each factor differ, normalization must be performed before they can be

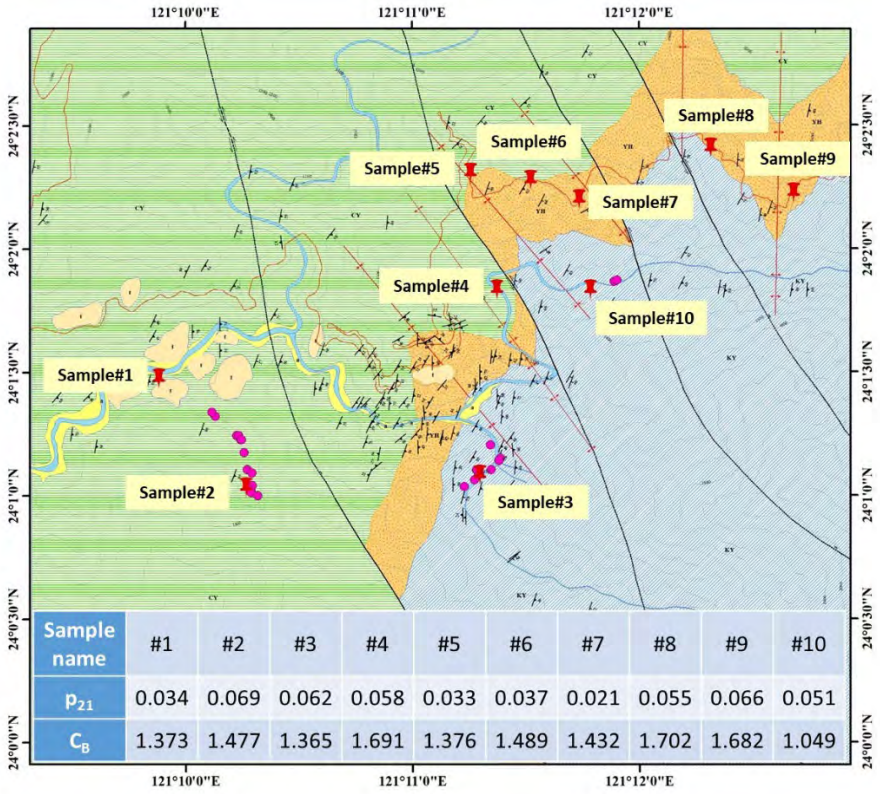
compared and combined. This study uses normalization based on the value ranges of each factor, employing the natural breaks method to categorize the data into five levels. Scores from 5 to 1 are assigned from high to low. Subsequently, the scores for each relevant factor at the same location are summed to determine the geothermal fluid channel score for that location.

4. Results

4.1 Field fracture intensity and fracture connectivity

The locations of the 10 selected representative outcrops and 27 control points are shown in Figure 6. The P_{21} and C_B values for fractures were calculated using the Network Geometry and Topology Toolbox, with the results presented in the table within Figure 6. The fracture intensity values in this area range from 0.021 to 0.069, with the highest at sample #2 and the lowest at sample #7; the branch connectivity values range from 1.049 to 1.702, with the highest at sample #8 and the lowest at sample #10.

Since these outcrop locations were selected as representative, the P_{21} and C_B values were interpolated to other locations using the Inverse Distance Weighted (IDW) method. The data were then categorized into 5 classes using the Natural Breaks (Jenks) method (Figure 7). Based on these classes, the highest classification levels were used to incorporate outcrops with fault-induced fracture zones and those with thermal mineral deposits into the analysis, resulting in the fracture intensity and connectivity factor distribution maps for the Lushan area (Figure 8). The high-intensity regions for fracture strength are mainly located in the southwest and northeast areas. The southwest area is situated along the first fault, suggesting that high fracture strength is due to the fault-induced fracture zone. Since there is no outcrop survey data in the northwest and southeast regions, the interpolated results in these areas remain unchanged, reflecting the same intensity levels, which is a less accurate aspect. The high-intensity regions for fracture connectivity are primarily found in the northeastern area and, to a lesser extent, around the first and second faults. However, when directly observed from the numerical values (Figure 7), there is generally no significant variation across the area.



Sample name	#1	#2	#3	#4	#5	#6	#7	#8	#9	#10
P_{21}	0.034	0.069	0.062	0.058	0.033	0.037	0.021	0.055	0.066	0.051
C_B	1.373	1.477	1.365	1.691	1.376	1.489	1.432	1.702	1.682	1.049

Figure 6. Locations of the representative outcrops (10 samples), control points (27 pink circles), and the calculated P_{21} and C_B parameters for each location.

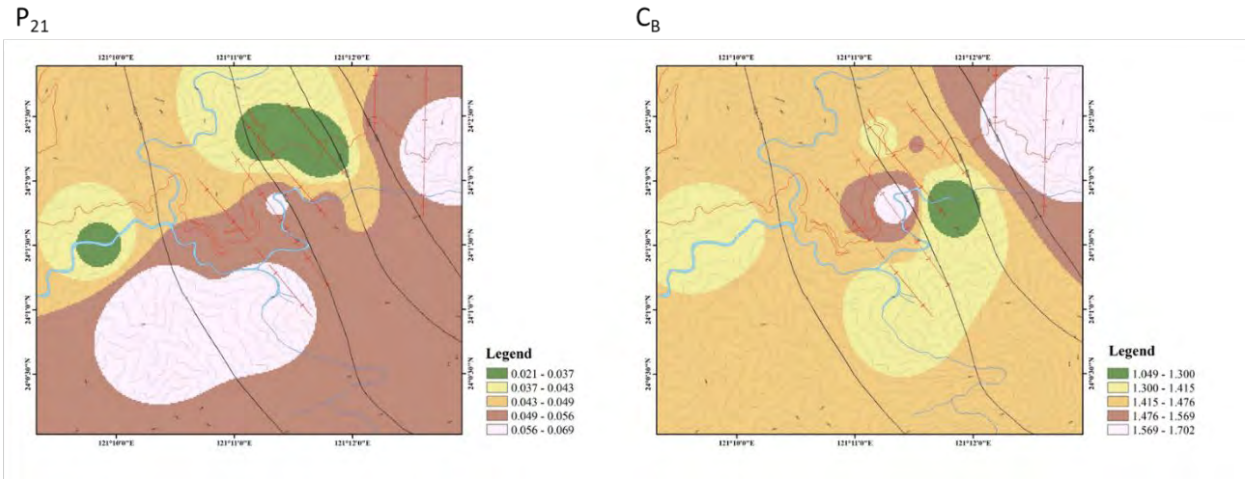


Figure 7. Distribution maps of fracture intensity factor (P_{21}) and fracture connectivity factor (C_B)

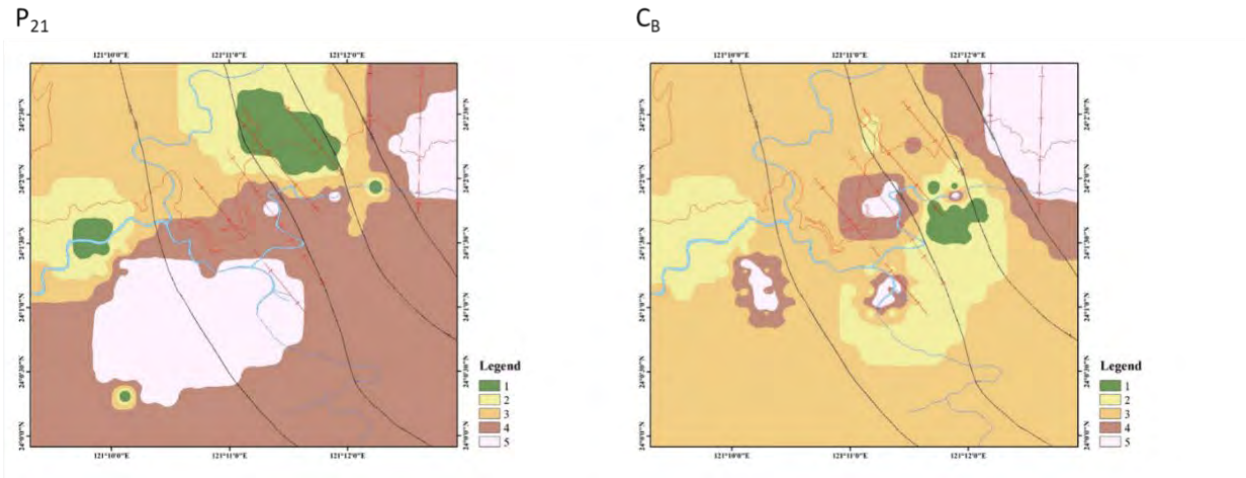

Figure 8. Distribution maps of fracture intensity factor(P_{21}) and fracture connectivity (C_B) factor grades.

4.2 Surface Lineament Analysis

Using a 20-meter resolution DEM, a hill-shade map was generated, and surface lineament features were mapped, as shown in Figure 9a. A total of 769 surface lineaments were mapped. These lineaments primarily display two dominant orientations (Figure 9b): N10°W-S10°E and N45°W-S45°E, with secondary orientations including N20°E-S20°W, N60°E-S60°W, and N85°E-S85°W. Given that the four left-lateral faults on the geological map extend in the N20°W direction, the related fractures generated due to these faults' displacements are shown in Figure 9c, where R-shear, R'-shear, and P-shear directions are N35°W, N85°E, and N10°W, respectively (Woodcock and Schubert, 1994). These directions are reflected in the surface lineaments, indicating that the lineaments are influenced by faulting and that the intensity of lineaments varies in specific areas.

The study area was divided into 100-meter by 100-meter grids to calculate the P_{21} values for each grid. The P_{21} values were then classified into 5 grades using the natural breaks method, resulting in the surface lineament intensity distribution map for the Lushan area (Figure 10). Except for the northeastern region, high-intensity lineament areas are mainly concentrated around fault zones. Comparison of these results with the fracture intensity factor grade distribution map (Figure 8) reveals similar results, except for some differences at the northern end of the third fault. However, due to the comprehensive nature of the surface lineament mapping, intensity trends are also observed in the northwest and southeast parts of the study area.

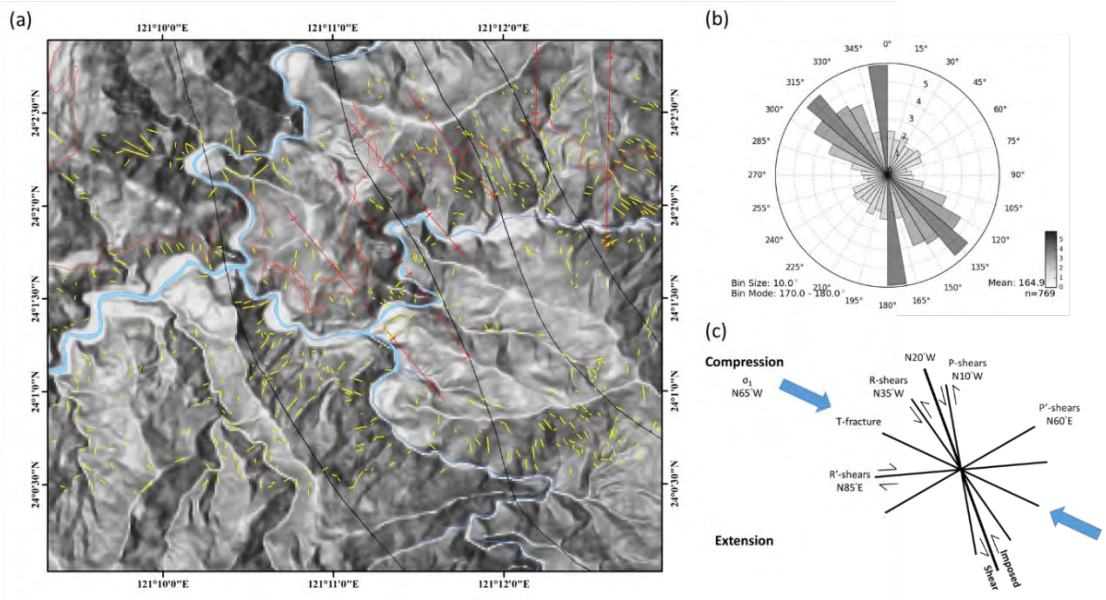

Figure 9. Surface lineament analysis. (a) Yellow lines represent the mapped surface lineament features. (b) Rose diagram of the directions derived from the surface lineament features. (c) Directions of fractures related to left-lateral faults in the Lushan area.

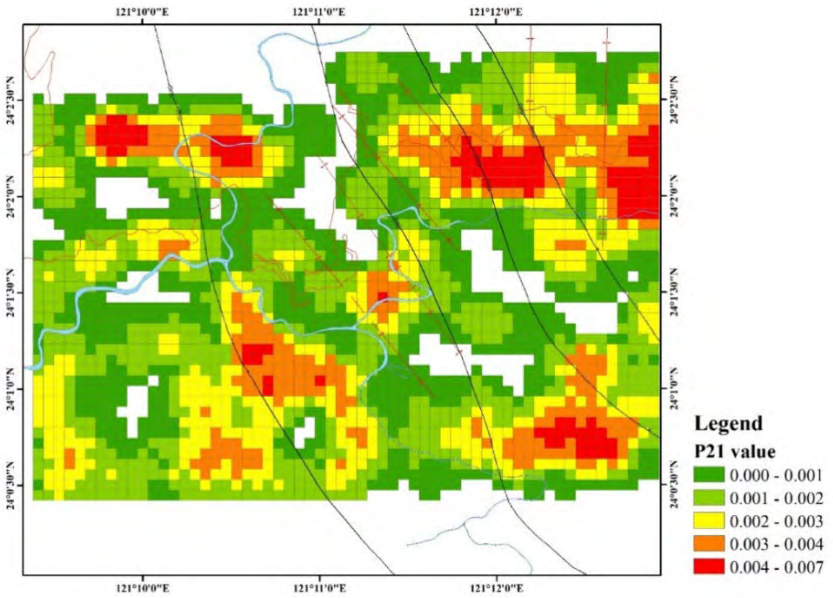

Figure 10. Distribution map of surface lineament intensity.

4.3 Fracture strength index map

Integration of surface lineament-related factors requires normalization before aggregation. To present the fracture strength distribution in the Lushan area, the study area was divided into grids

of 300 meters by 300 meters. Each grid's fracture index score was collected, and then Inverse Distance Weighted (IDW) interpolation was applied to display the fracture strength in five intensity levels (Figure 11).

According to our fracture strength index map, the highest scores are found in the northeastern region, followed by the central part of the study area, and lowest scores are around the western and northern parts. Such a result from this map is consistent with the locations of many geothermal manifestations.

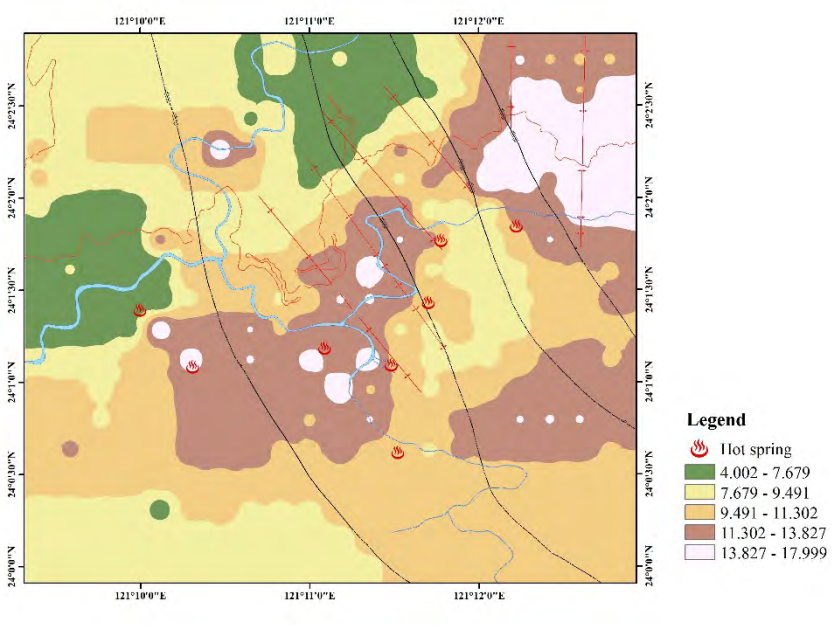

Figure 11. Fracture strength index map

5. Discussion

5.1 Advantages of using photo processing to record field fracture lineament data

Fracture analysis typically involves recognition and drawing fracture lineaments, which is often a time-consuming and labor-intensive task. Prolonged observation and analysis can lead to visual fatigue and decreased attention, making interpreters prone to missing details or making errors. Additionally, subjective factors such as the interpreter's expertise, experience, and personal biases can contribute to variability in fracture lineament interpretation (Bond, 2015). These subjective factors leading to inconsistent or inaccurate results should be eliminated or minimized through certain standard procedures and auxiliary techniques.

To mitigate such error-prone issues, this study employs a software tool in Photoshop for preprocessing into well recognizable fracture lineaments. The procedure starts with removing non-target areas in an outcrop photo, and then utilizes filters to convert the picture into simple black-

and-white line drawings. A digitized vector data can be imported to the ArcGIS platform for other processes.

However, such a conversion process using Photoshop may be failed to produce quality results and even worse than manual recognition. This could result from the complexity of the photo content, such as significant vegetation covers or severe weathering on the outcrop surface, where weathering crusts and other materials may be mistakenly interpreted as lines. These falsely recognized lines can impact the final fracture lineament drawing. Therefore, choosing high quality outcrop photos with a clean and fresh rock surface for the software processing is also a vital step.

5.2 Allocation of weight ratios for factors

In this study, the final fracture strength scores were calculated by summing the normalized scores of each five factors using equal weighting, implying that all factors are considered equally important. However, analysis results suggest that some data are more reliable, while some factors are deemed more relevant. By adjusting the weights according to the data accuracy, data precision, or the relevance of correlation, the result may be improved and closer to the reality.

For example, in this study, the orientation of surface lineaments is consistent with the fracture directions generated by fault movements, and it aligns with the fracture strength results at the outcrop scale. This consistency enhances the credibility of the surface lineament data, suggesting that its weight ratio should be increased. Conversely, the results for fracture connectivity show less variation, reducing the significance of this data and justifying a decrease in its weight ratio. For a better result, the weight ratios for each factor in Fracture Intensity, Fracture Connectivity, Surface Lineament Intensity, Rock Porosity, and Cleavage Density may be adjusted to 20%, 10%, 40%, 10%, and 20%, respectively.

5.3 The relationship between fracture patterns and fault distribution

The geological map drawn in this study (Figure 1) is based on the additional field investigations and references to previously published geological maps at this area (Chang and Chiao, 1979; Hsiao rt al., 1980; ITRI, 1984; Lo and Yang, 2002). While the general trends of the geological structures in those previous studies are similar, there were some specific faults and folds that have been interpreted differently, also regarding the location of fault structures and their impact on the Lushan area. To reconcile these geological maps and provide a clearer picture of the distribution and effects of fault structures in this region, this study investigates the characteristics of fractures formed by fault movement.

The fractures measured from the field survey were categorized into six area, labeled A to F, based on their proximity from West to East (Figure 12b). By organizing the fractures in each area, a total of six fracture sets were identified. The abundance of fractures in each area was categorized into three levels: high (red), medium (blue), and low (green), and presented in the table grid (Figure 12a).

Among these six fracture sets, all but the third set correspond to fractures generated by the left-movement faults (Figure 12c). In area B, C, and D, secondary faults or fault-induced fracture zones are commonly observed. These areas are primarily dominated by the fifth and sixth fracture sets, corresponding to the R-shear and T-fracture generated by faults (Figure 12c). Moving from area E towards area F, the number of R-shear fractures are fewer in area E than that in area F. Conversely, the number of T-fractures in area F drops to a medium level, with the dominant fracture set becoming the first set, R'-shear.

The variation in the number of R-shear and T-fractures suggests that area B, C, D, and E are within major deformation zones interacting with the three main faults from the central of our study area in the Lushan region, with similar changes in fracture sets and quantities. The right-most fault affects area F locating westerly in a separated deformation area, which is probably influenced by other factors at the northeast direction outside of our study area.

From above observations of trends and quantities in each fracture set, we may conclude that one major deformation area is at the center of our study area, including area B, C, and D, two faults, and along the Yuanfeng Member that containing relatively more meta-sandstone component; the other deformation area is located at northeastern corner of our study area, including area E and passing by one fault.

5.4 The implication between fracture intensity pattern and geothermal reservoirs and fluid pathways

Good targets of traditional geothermal reservoirs typically exist in rocks having higher porosity, permeability, and fracture networks such as basalts and sandstones. Geothermal development in

Taiwan faces unique challenges, as the primary geothermal targets are in metamorphic rocks with low porosity where the heat sources are associated with rapid crustal uplift and plate collision activities in the Central Mountain Range. Thus, relying solely on rock porosity is not effective for projecting potential reservoir and fluid pathway locations, and other critical factors must be considered.

Fracture patterns are an important consideration. Extensive fractures can act as conduits for fluid flow and/or as reservoirs confined by more compact rocks. Metamorphosed sandstones, which are structurally uniform and compressed, often have larger fracture spaces and relatively straightforward fracture networks; metamorphic sandstone and slate interlayers, often create a complex fracture network in slate than meta-sandstones are typically more suitable as reservoirs than slates. However, research in the Lushan area reveals that the P21 and CB values for meta-sandstones in the Yuanfeng Member (sample #5, #6, and #7 in Figure 6) are lower, while the data for the Chunyuan Member and Kunyang Member are higher (sample #2, #3, #4, and #10 in Figure 6).

This study hypothesizes that this may be due to the slates, after being affected by faults, forming stronger and more continuous fracture zones due to the interaction between fault-generated fractures and the dense cleavage developed in the slates. Based on the above assumption, we may speculate that the slate region within the Lushan area may offer a more favorable environment for potential geothermal reservoirs and hydrothermal conduits. However, additional research is necessary to substantiate this hypothesis.

5.5 Future attempts

The main factors analyzed in this study are based primarily on surface survey data. While this data can show the distribution of surface rupture severity and serve as a reference for subsurface fragmentation, it is hard to reflect actual subsurface conditions. If any subsurface data (e.g., MT data, optical imaging logging data from boreholes, etc.) were incorporated into the analysis, it would allow for a more comprehensive understanding of the three-dimensional fragmentation distribution in the Lushan area. Therefore, the future plan is to include subsurface data in the correlation factors and analyze them together to create a three-dimensional map of fragmentation intensity distribution for the Lushan area or any other potential targets.

Conclusion

- This study utilizes common image processing software to preprocess outcrop photos, simplifying the complexity of outcrop fracture recognition. By applying consistent criteria, this approach also enhances the accuracy of future fracture analysis.
- Representative outcrops are used as control points in this study, and interpolation methods are employed to extend the data across the entire area, together with the use of lineament features from DEM, addressing the issue of having few or difficult-to-reach outcrops.

- Combining the geological and fracture strength maps, slaty area tends to produce stronger fracture intensity than meta-sandstone area, affected by the trends of faulting and cleavage pattern.
- The fracture strength index map from this study may be relevant to the hydrothermal channel or geothermal reservoir in the Lushan area, offering important reference data for geothermal exploration in the region.

ABSTRACT

This study was conducted to investigate the potential for a hot sedimentary aquifer geothermal system within the NEOM area in the northwest of Saudi Arabia using regional geophysics and 2D seismic lines covering the main known basins along the Red Sea coast. The thickness of each basin was investigated to determine the maximum depth to basement within each basin. The Red Sea sedimentary basin deposition started as part of the Red Sea rift sequence and is mainly influenced by tectonic activity within each subregion of the early rift. The Red Sea rift began ~32 Ma and has created the basin that includes the modern-day Red Sea and the Gulf of Suez. The rift presents itself as a series of half grabens that extend from Bab Al-Mandab Strait in the south to the Mediterranean in the north. This tectonic arrangement was superimposed in the northern Red Sea by the strike-slip tectonics of the Gulf of Aqaba in which began movement ~12 Ma as part of the left-lateral Dead Sea Fault system.

This is the first attempt at geothermal exploration in these sedimentary basins, where currently no known systems exist. The basis for designing this exploration work is on the premise of conduction heat flow, with no impact of convection or magmatic processes that would diverge away from the background heat gradient. Using the known heat gradient in the area from oil and gas wells, the intent is to drill into a reservoir at a depth that delivers the necessary temperature for use as geothermal power, heating, and refrigeration. Using a greenfield exploration approach, the workflow has included the analysis of regional geology, heritage well data, published technical papers, geologic map data, 2D imagery, airborne magnetic and gravity data, along with the acquisition and interpretation of 180 km of 2D seismic. Of the mapping completed thus far, several targets were identified in the Midyan area where the investigation suggests deep basins which could host Hot Sedimentary Aquifer geothermal systems. The targets in the area lie in syn-rift sedimentary reservoir-seal pairs that are deeper than 3 km at present and are either within marine

turbidite sands, or early-rift continental sands capped by marine shales. The 2D seismic interpretation along with the assessment of other existing data will form the basis of discussion as to how the identified prospects were chosen.

1. Introduction

NEOM is the planned independent economic zone in the northwest of Saudi Arabia. It is born out of the ambition of Saudi Arabia's Vision 2030 to see the country develop into a pioneering and thriving model of excellence in various important areas of development. ENOWA is a 100% subsidiary of NEOM that is tasked with delivering NEOM's energy related vision to life. This vision is to become the world's most advanced renewable energy hub and the first at-scale fully renewable electrical system. NEOM aspires to have a high degree of electrification, which results in increased electricity requirements compared to traditional economies. To provide affordable renewable electricity, ENOWA aims to develop geothermal resources.

One of the main geothermal plays in development in the NEOM region is the hot sedimentary aquifer (HSA) geothermal system within the Midyan Basin. This is the first attempt at geothermal exploration in these sedimentary basins, where currently no known systems have been proven to exist, nor has geothermal infrastructure been established. This paper will discuss the exploration of the Midyan Basin's potential to host a hot sedimentary aquifer geothermal system from the standpoint of both existing and acquired geophysical data, and the identification of potential geothermal prospects that have resulted from the assessment.

2. Available Data

2.1 Published Regional Work

While there are not yet any published works about the NEOM development specifically, regional studies of the larger Red Sea and Midyan Basin areas have assisted in creating the framework and context of the depositional and structural history of the basin. Published geophysical studies of the area have also provided a baseline for the planning and expectations of further surface exploration.

2.1.1 Regional tectonic history

Bosworth (2015) provides a detailed description of the geological evolution of the Red Sea, along with Hughes & Johnson (2005), which in turn provides a detailed account of the lithostratigraphy of the Red Sea Region. These regional studies guide our understanding of the tectonic history of the Midyan Basin region and provide detailed information on the different lithological units that exist within the larger basin. The lithostratigraphy of the region is described in further detail in Section 3.3.

2.1.2 Regional magnetics and gravity

Regional gravity and magnetic data are available from SGS Saudi Arabia. This dataset was interpreted and used in choosing the locations of the 2D seismic lines for the seismic field study as described in sub-section 2.4. It is also used to de-risk the seismic interpretation by linking the newly acquired 2D seismic lines to the non-seismic surveys.

2.1.3 Published seismic profiles

In 2014, Tubbs et al., through one of the Saudi Aramco geologic field programs, acquired onshore 3-D, transition zone 2-D and offshore 2-D seismic data in the Midyan Basin to provide further insight into the geological history of the region. This study provides a detailed assessment of the structural interpretation of the Midyan Basin, along with a lithostratigraphic and seismic stratigraphic interpretation of the Midyan area.

2.2 Outcrop Geology

The surface geology of the NEOM area is based on a regional geological map of the NEOM area. Supporting surface geological interpretation includes satellite imagery maps and structural maps that have assisted in mapping structural faulting and observable lineaments.

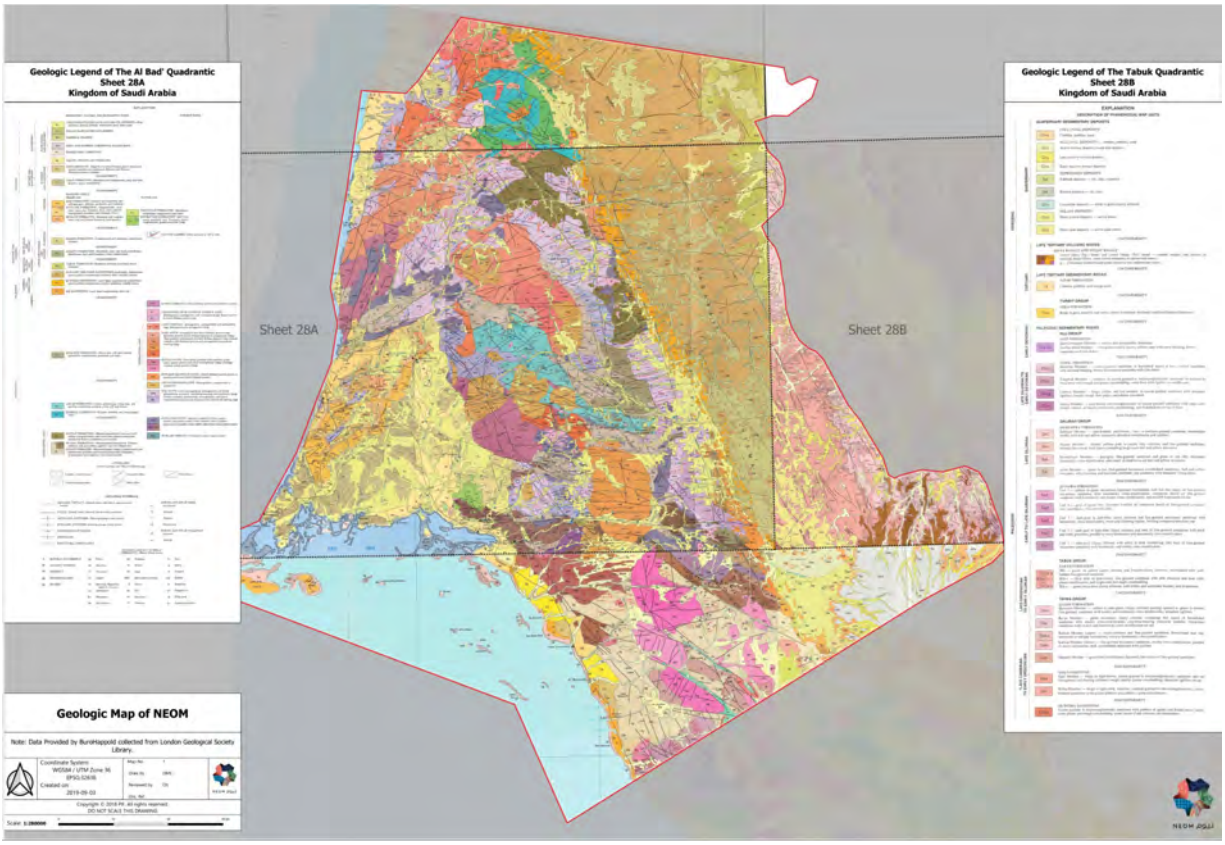

Figure 1. A regional surface geological map of the NEOM area. A more detailed regional context is provided in figures 5 and 6.

With these maps as a basis for field exploration, evidence of late Quaternary faulting was investigated during a field visit in August of 2022. From what was observed, it is thought that scarps found in the field were possibly associated with recent faulting and salt movement.

2.3 Legacy Well Data

Temperature surveys from 5 shallow (< 3000 m total depth) oil and gas wells drilled in the Midyan Basin were obtained. Measured temperatures in these wells reveal conductive geothermal gradients between 30-35 °C/km.

Limited information from shallow water wells that have been drilled in the area were also obtained, with majority of the wells drilled in the area of Tabuk, which is a town directly northeast of the border of the NEOM area. The wells that were drilled in Tabuk reach up to 600-1250 m in depth, and temperatures around 40 °C.

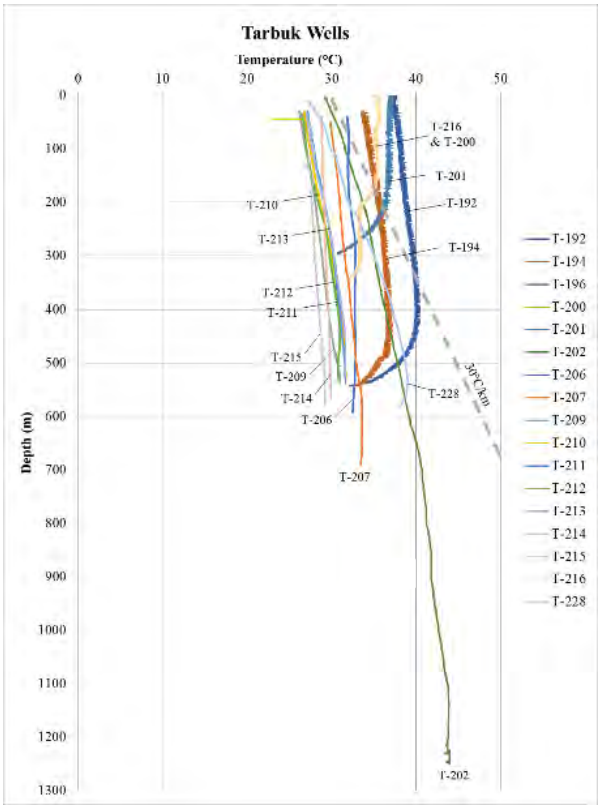

Figure 2. Temperature of water wells drilled NW of the town of Tabuk, directly NE of the NEOM area.

In addition, 1201 shallow geotechnical boreholes have been drilled along the western coast of Saudi Arabia and along the eastern shore of the Gulf of Aqaba. These wells do not surpass a depth of 60 m and present information of the shallowest formations in the area.

2.4 Newly Acquired 2D Reflection Seismic Data

As part of the study to identify areas of potential geothermal resources, 15 (fifteen) 2D onshore seismic lines were acquired in 2023 in the NEOM area to gather detailed subsurface information,

characterize the reservoir, identify structural features and reduce exploration risks. The seismic survey reached a total length of 180 km. The results of this seismic field survey helped identify the Midyan Basin as one of the main areas of interest for hot sediment aquifer exploration. The processing sequence follows a full production Pre-Stack Time Migration (PSTM) sequence to improve the overall structural imaging and resolution.

Figure 3. The locations of the seismic profiles in the Midyan area of the seismic survey of March 2023.

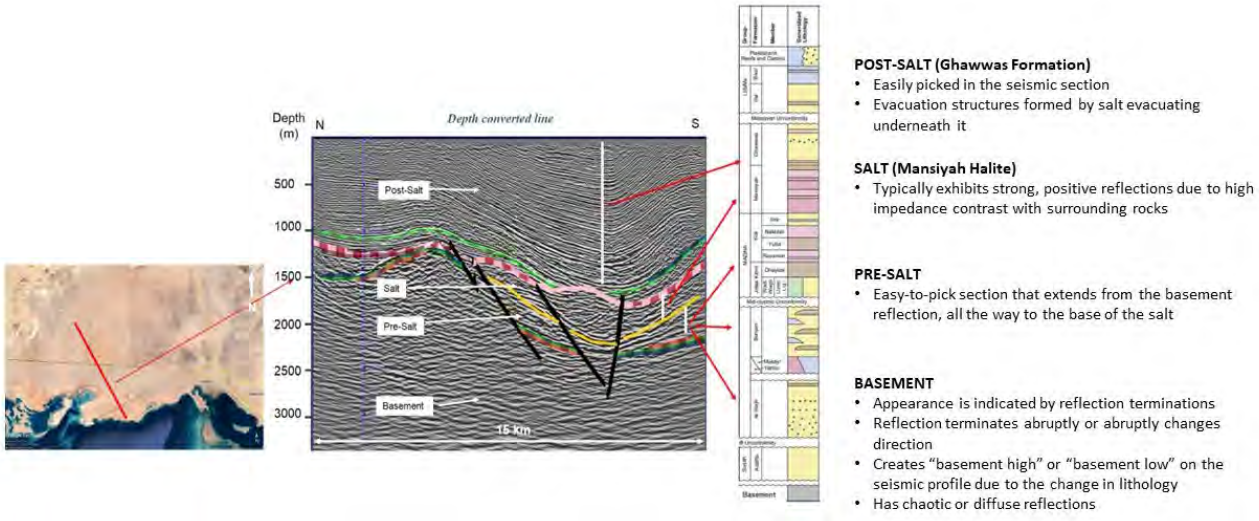

Figure 4. An example of a seismic line and interpretation from the 2023 seismic survey conducted in the NEOM area.

3. Regional Geology and Structural Style

3.1 Regional Geology

The regional area of interest is in the northwestern part of Saudi Arabia, directly northeast of the Red Sea Basin, which is a divergent plate margin. The Red Sea basin was formed by a continental rift that started 30-32 million years ago by initiation of the Afar Plume (Figure 6-a and -b) (Bosworth, 2015), and eventually developed into an oceanic rift that now hosts the Red Sea, and forms part of the boundary between the African and Arabian plates. The Red Sea basin started as an asymmetric rift that propagated from the south to the north in a series of deep half grabens all along the Red Sea. At the beginning of the rift, the Gulf of Suez was considered part of the Red Sea and shared the same history and structural trends. All along the Red Sea basin, there are several zones of half grabens that dip towards the Arabian plate, and others that dip towards the African plate with accommodation zones in between associated with oblique cross-basinal arches. These have been studied in detail in the Gulf of Suez and have also been demonstrated along the main Red Sea.

Pre-Miocene formations are considered to predate the development of the rift. Cretaceous formations are the oldest in the section, and are thickest within Gulf of Suez, and thin towards the south until they disappear offshore and in outcrop (on the Saudi Arabian side) within the northern areas of the Red Sea (Adaffa and Usfan Formations; Hughes, 2005). Some Cretaceous outcrops are preserved with down dropped basin grabens in outcrops within the NEOM area (e.g., Adaffa Sandstone Formation). There are some other Cretaceous outcrops preserved within grabens along the Saudi coast that extend to the south, nearly reaching the Yemen border.

The early stage of the rift resulted from rift-normal extension that is postulated to have opened the whole 2,200 km long Red Sea simultaneously (Figure 6-c) (Bosworth, 2015). At this stage, the Early Oligocene rift deposits were the continental sands of Al Wajh formation, which are present everywhere in the Red Sea as continental red beds and lacustrine deposits that reach up to 2200 m in thickness. This was followed by a marine incursion that deposited the deep marine turbidites of the Burqan formation where the rift was most active tectonically; in these areas the Burqan is the thickest formation.

A change in depositional environment is marked by outcrops revealing the intra-Burqan mid-clysmic unconformity (~17.5-18Mya) that ended the deposition of the Maqna group (Figure 8) (Tubbs et al, 2014). The Maqna group shows clear signs of low tectonic activity and of basin wide restriction where several regional anhydrite formations, interbedded with clastic and carbonate formations, were deposited. The basin restriction developed into a basin wide salinity crisis linked to the Mediterranean Messinian restriction, and the Red Sea that deposited the massive Mansiyah halite (Gargani, 2008).

Around 14-12 million years ago, the Gulf of Aden rift developed into an oceanic ridge with seafloor spreading and the Arabian and the Eurasian plates collided, rotating the Arabian plate around a north-African Euler pole counterclockwise and causing the Red Sea to switch to a rift-oblique extension (Figure 6-d) (Bosworth, 2015). The new shift in extensional direction caused reactivation of some faults, and strike-slip deformation as the faults moved to accommodate the differential extension.

The opening of the Gulf of Aqaba in the Late Miocene (5-12 million years ago) occurred after the Red Sea Rift had already stopped its initial rifting (~14 million years ago). Its opening helped accommodate the plate rotation, and the extension along the Gulf of Suez was abandoned, making it a dead rift. This also created late strike-slip deformation across the basin especially in the northern Red Sea and within the Midyan peninsula, creating pull-apart basins and further deepening the basin as a whole.

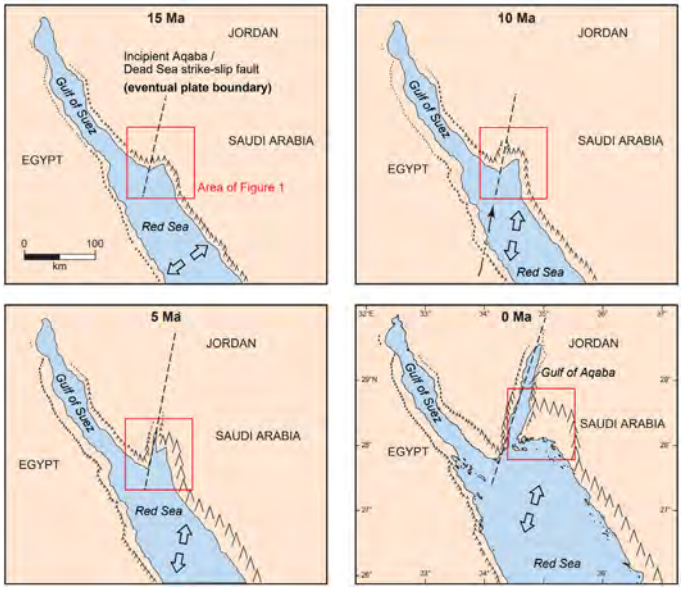

Figure 5. A schematic of the opening of the Gulf of Aqaba as illustrated by Tubs et al. (2014)

The Red Sea changed into a drift regime with the extension localized to the center of the Red Sea while the plate moved along the Aqaba strike-slip system to reach a total left-lateral displacement of 107 km (Quennell, 1959). The southern end of the Red Sea opened an extra 26 km due to the plate rotation. The combined displacement caused several pull-apart basins along transtensional bends to develop. The Gulf of Aqaba Sea is one large pull apart basin separating the Sinai Peninsula from the NEOM region.

Around 5 million years ago, seafloor spreading initiated in the southern Red Sea, and a ridge formed that transferred most of the deformation to the center of the sea (Figure 6-f). Continental rifting ceased in the south and only localized deformation continued offshore in the north.

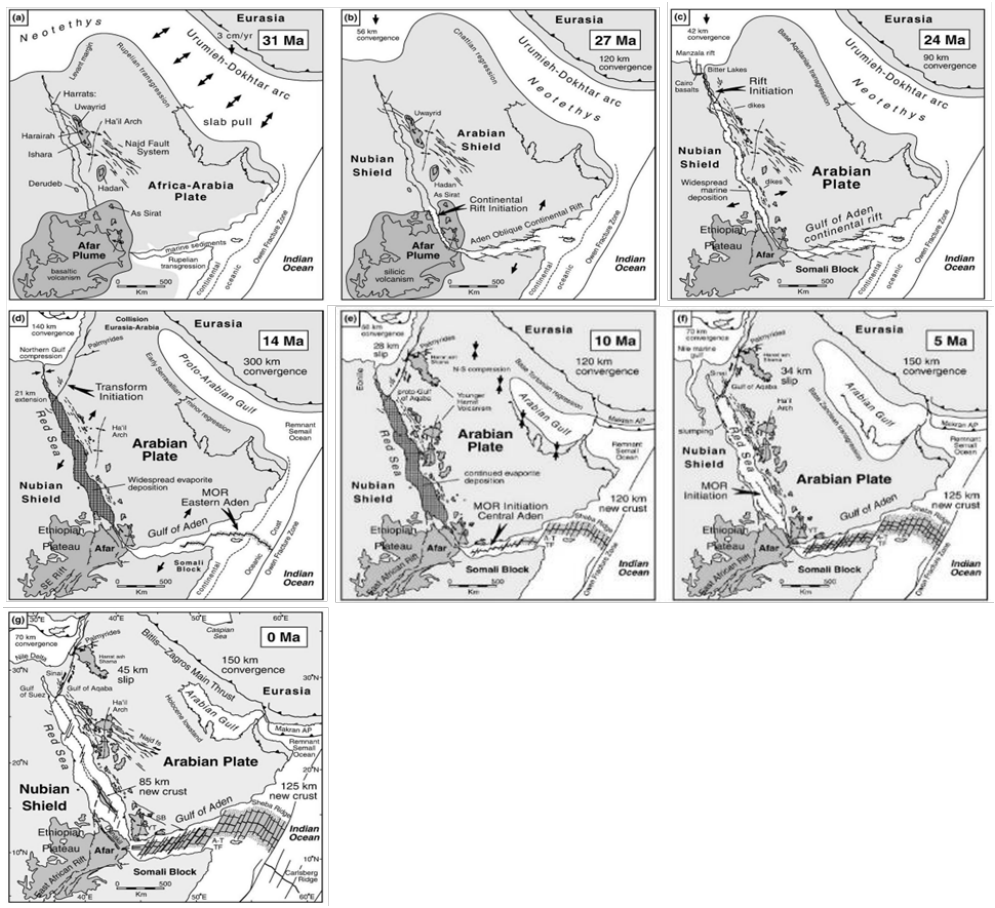

Figure 6. The evolution of the Red Sea rift from the initiation of the Afar plume, through the rift climax, strike slip initiation and rotation axis change, and to modern day system. (Bosworth, 2015)

3.2 Regional Structural Setting

The Red Sea developed as an asymmetric rift associated with oblique extension starting in the Oligocene through Late Miocene. A schematic of an asymmetric rift system can be seen in Figure 7-a. Under transtensional strain, a geometry of half grabens bounded by synthetic faults formed across the width of the basin (Figure 7-b). The dip polarity of the half grabens flips in several regions of the Red Sea and Gulf of Suez at several transfer zones from east- to west-dipping and west- to east-dipping. These transfer or accommodation zones link the displacement across regions of the sea and represent cross-basinal arches where dip directions rotate. The regional structural framework can help guide exploration by adding context to rift geometry at subregional scale.

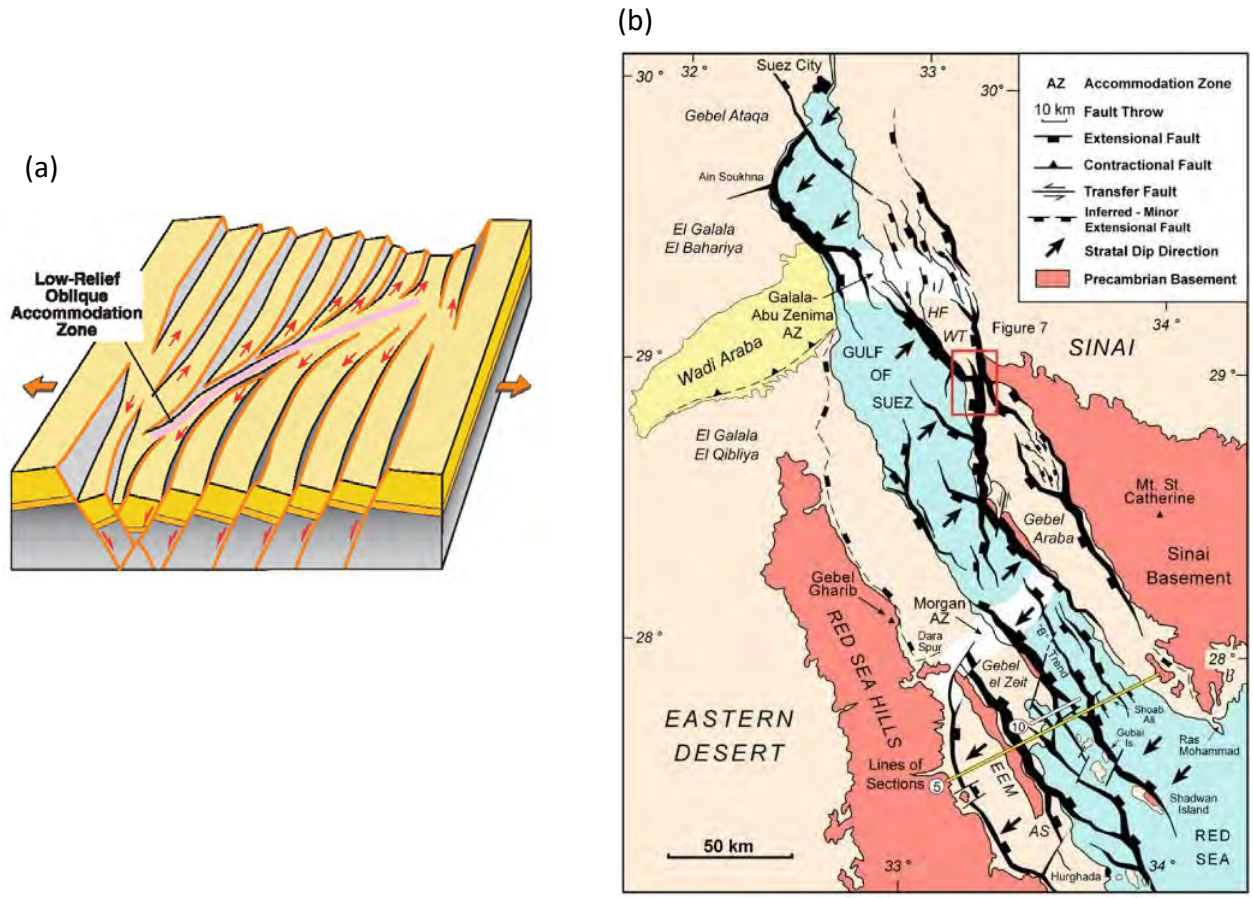

Figure 7. (a) Schematic of the transfer zone in asymmetric fault systems from a sandbox experiment. (McClay, 2002) (b) Faults in the Gulf of Suez with different transfer zones labelled. (Bosworth, 2005)

3.3 Stratigraphic Framework

The Red basin stratigraphic section is dominantly related to the tectonic history of the Red Sea rift. Overall, the pre-rift section is thin, and the rift sequence is often directly overlying crystalline basement. Therefore, a clear character to defining the stratigraphic section is in relation to the rift stage. This is especially useful because the kinematics of the rift itself are the largest influence on the depositional environment, as well as the basin shape and accommodation space. Hence, the section can be divided into a pre-rift, syn-rift, late rift, and post-rift. These must also be contextualized within the overall understanding of the space creation within the different zones of the Red Sea, the fact that the faults along the rift margin are no longer active, and the plate motion is accommodated by space creation offshore. There are several hypotheses related to the onset of the ocean crust formation, as well as hyper-extension of the offshore continental crust. The method in this report by which we define the rift formation relates to the rift fault kinematics onshore. The understanding of the onshore basin is calibrated by published literature on the onshore drilling results, and outcrop studies.

There are 6 formations that are a major part of the Red Sea Basins. From youngest to oldest, these formations include:

1. Ghawwas Formation (~12 to ~6 Ma)
   The Ghawwas formation is a post-salt formation dominated by sandstones with minor intercalated carbonates deposited within salt mini-basins controlled by accommodation space within the halite body.

2. Mansiyah salt formation (15.3 to ~12 Ma)
   The Mansiyah formation is a massive halite deposition formed during a basin wide salinity crisis that can be linked to the Mediterranean Messinian restriction. This formation acts as a regional marker in the area.

3. Maqna Group (17.5 to 15.3 Ma)
   The Maqna Group is a pre-salt formational group comprising interbedded fine to medium-grained clastics and carbonates that was formed during a period of low tectonic activity and basin-wide restriction.

4. Burqan Formation (20.5 to 18 Ma)
   The Burqan is a pre-salt deep marine turbidite that was deposited by a marine incursion.

5. Al Wajh Formation (33 to 21 Ma)
   The Al Wajh is a pre-salt high porosity sandstone formation that was deposited during the earliest stage of the rift.

6. Neoproterozoic Basement
   There is an unconformity present due to the transitional zone between the sedimentary units and the Neoproterozoic granitic basement. It is of note that the basement can also potentially host permeable faulting, below the sediments, however the nature of these faults has not yet been studied in depth.

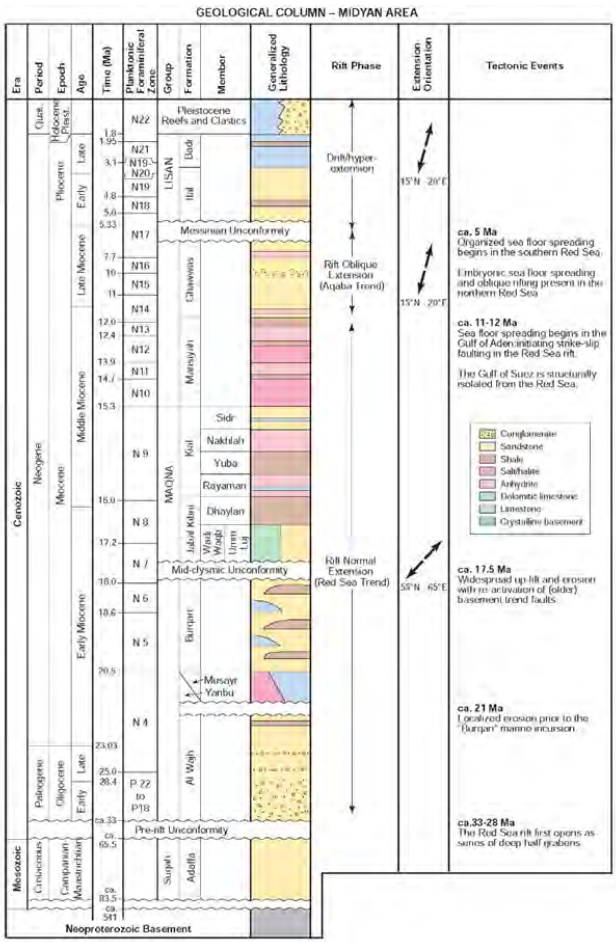

Figure 8. Generalized lithostratigraphy of the Midyan Basin.

4. Geothermal Workflow and Results

From the data presently available, the Midyan Basin has been assessed using a greenfield exploration approach, while under the assumptions associated with a hot sedimentary aquifer (HSA) play. In an HSA geothermal play, the reservoir is heated by conduction with no impact of convection or magmatic processes that would diverge the reservoir temperature away from the background heat gradient. The temperature that would need to be reached for geothermal commercial purposes would thus be a function of depth and background gradient. The permeability of the subsurface is below the convective threshold, but the conductive heat input to deep aquifers with local elevated permeability producing conditions suitable for a productive HSA that can be targeted by exploration. In an HSA play, there is a balance required in locating sufficient temperatures and permeability; temperature will increase with depth in a conductive temperature regime, however an increasing overburden with depth will also decrease the permeability of aquifer-hosting rocks. In the Midyan Basin, from oil and gas well temperature data, the geothermal gradient has been shown to be between 32-35 °C/km. To reach >100 °C it would be necessary to drill at least 3 km into the subsurface.

The exploration approach followed a typical greenfield exploration methodology. A desktop study was performed to assess the known information of the Midyan Basin from the standpoint of scientific literature and public data. This supported field visits directed at observing outcrops and verifying previously reported faulting.

The basin geometry was interpreted using potential field methods with the first interpretation based on the regional magnetics and gravity data from SGS Saudi Arabia, with supporting input from Tubbs et al. (2014). From the regional magnetic map below, there can be observed two magnetic lows, one in the south of the Midyan Basin close to the coast, and another low present in the back-basin, close to Al-Bada.

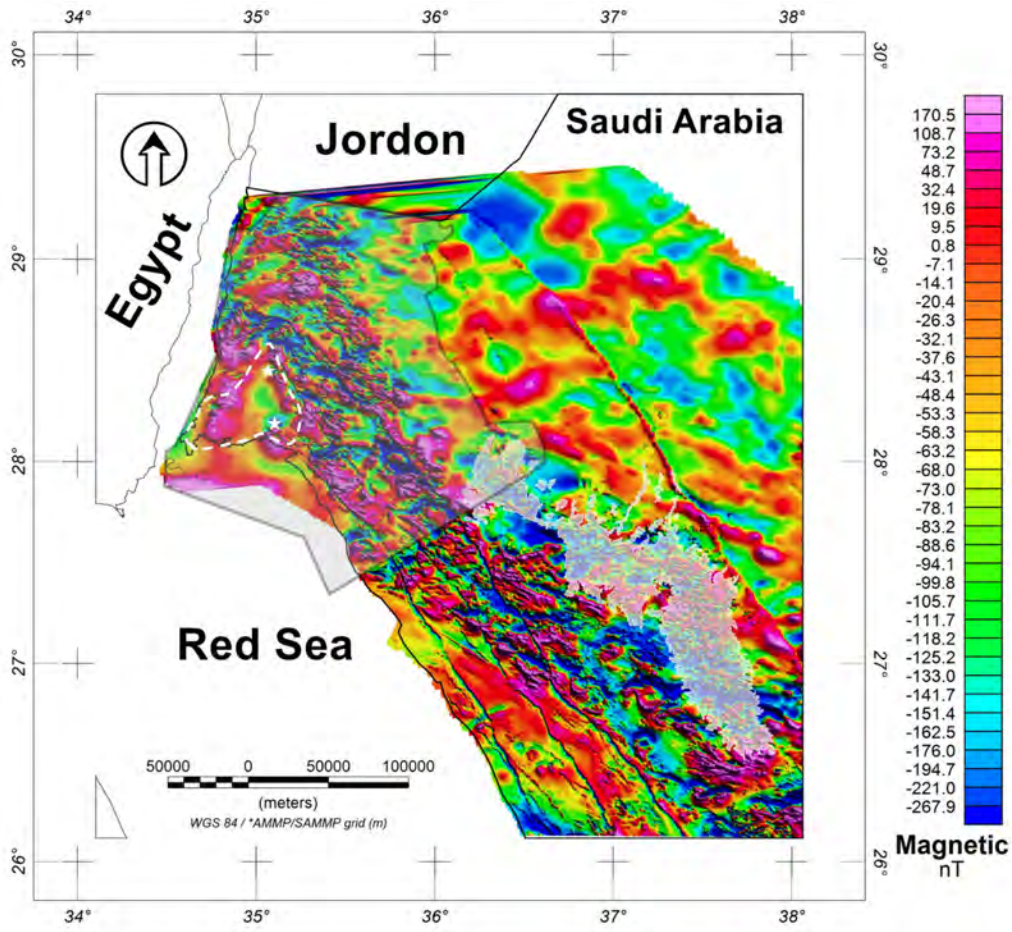

Figure 9. Regional magnetic map of Saudi Arabia. The NEOM area is outlined by the translucent polygon, while the Midyan Basin is outlined by the white dashed-line.

The observed magnetic lows were found to correspond to an interpreted low in the seismic lines presented by Tubbs et al. (2014). Comparing the seismic section in Figure 9 from Tubbs et al. (2014) to the magnetic anomaly map in Figure 10 , the location of the northernmost magnetic low in the Midyan Basin (shown as the northernmost white star in Figure 9) coincides with the deeper

basement depicted in the seismic section northward towards A'. Similarly, the basement also seems to be dipping southwest towards the coast as shown in the seismic section in Figure 10. This also corresponds with a magnetic low in the south, as seen in Figure 9.

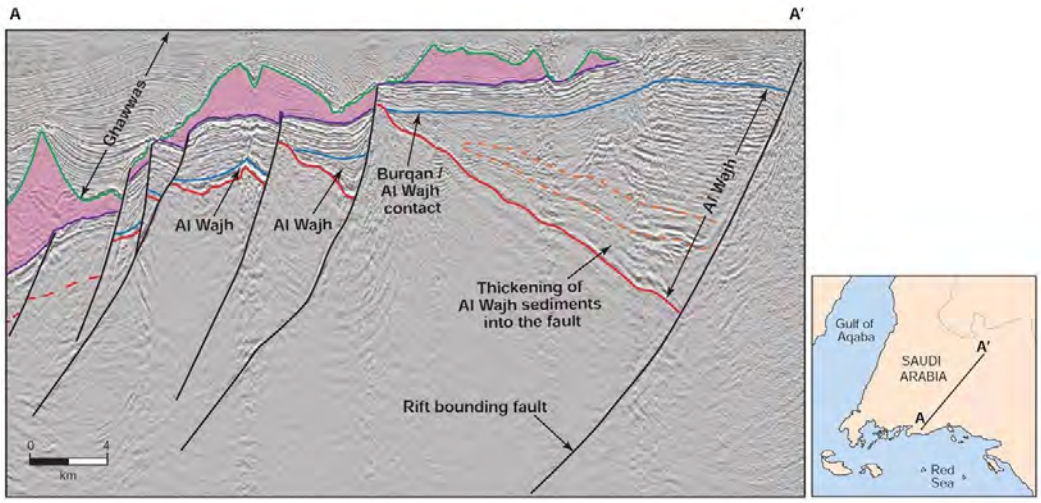

Figure 10. Interpreted pre-stack depth-migrated 3-D seismic section from Tubbs et al. (2014). Black lines = faults; green = top Mansiyah Formation; purple = top Maqna Group; cyan = top Al Wajh Formation, red = top basement. Highlighted in pink is the Mansiyah Formation. In this interpretation, the basement is deepening towards the northeast, towards A'.

The implied basin geometry derived from published regional magnetics and gravity along with the published seismic profiles from Tubbs et al. (2014) helped guide the location of seismic lines for a present day 2D seismic study which was performed to confirm the findings and further interpretation from already existing scientific literature. The resulting seismic profiles were used to map and confirm the depths to the granitic basement, map basin bounding faults and to define the sedimentary packages of the basin. Overall, the ideal geothermal targets in the Midyan Basin were determined to be found where the depth of the basement was the deepest, in that both a temperature of >100 °C and where permeable formations could be accessed. Numerous lithological units in the basin would make ideal reservoir targets, namely the Ghawwas, Maqna, Burqan and Al Wajh Formations. It will be required for any of these formations to be >3 km deep in order meet the target subsurface temperature of ≥100 °C.

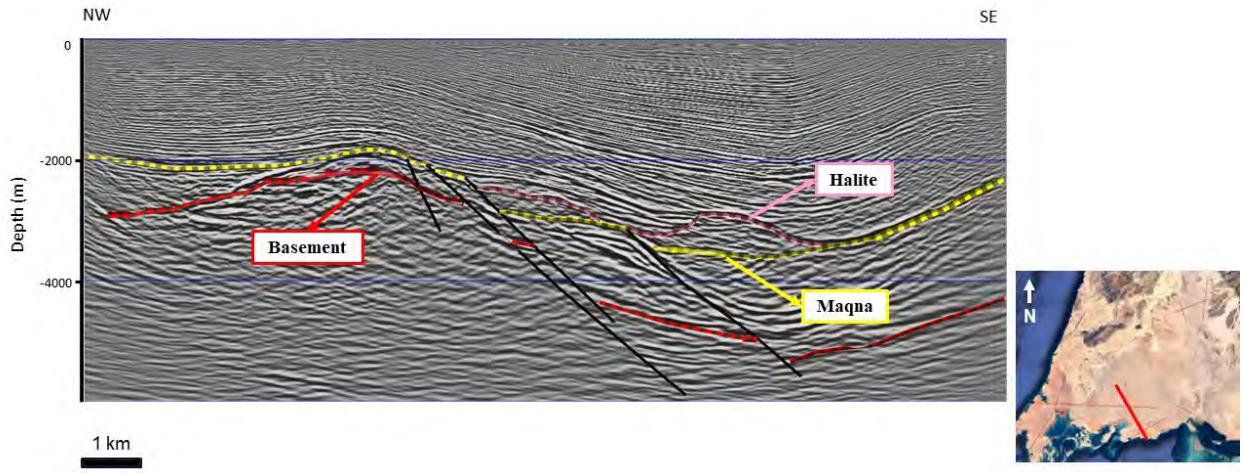

Figure 11 Newly acquired seismic showing the depth to basement exceeding 4 km on depth converted seismic sections. This makes the area attractive for geothermal development.

Based on the legacy data interpretation, the new seismic lines were acquired. Once processed, the 2D seismic sections revealed basin boundaries and depths. Detailed interpretations of the 2D data were performed and integrated with existing geologic information. Interpretation of the formation picks were divided into Basement, Pre-Salt (Maqna, Burqan and Al Wajh Formations), Salt (Mansiyah Halite), and Post-Salt segments (Ghawwas Formation). On the newly interpreted seismic lines, four (4) potential geothermal well locations were proposed in the Midyan Basin; three of the locations are closer to the coast in the northwest of Saudi Arabia, while the other is located more inland, farther north in the basin. It is in these locations where magnetic lows are encountered and where the basement is interpreted to be the deepest in the basin, thus increasing the likelihood of attaining both commercially viable temperature and permeability for geothermal utilization. These locations were either the center of the pull-apart basin from strike-slip displacement or the deepest points in the graben next to the basin bounding fault.

5. Conclusion

This study has demonstrated the potential of the Midyan Basin in the northwest of Saudi Arabia to host hot sedimentary aquifer (HSA) geothermal systems. Through a comprehensive exploration approach that included the analysis of regional geology, legacy well data, and newly acquired 2D seismic lines, several promising geothermal targets have been identified. These targets are located within deep syn-rift sedimentary reservoir-seal pairs that are deeper than 3 km and are predominantly found in marine turbidite sands or early-rift continental sands capped by marine shales.

The exploration work revealed that the Red Sea basin's tectonic history, characterized by stages of rifting and fault propagation, has significantly influenced the current structural configuration and sediment deposition. The depth to basement, a critical factor for geothermal exploration, was mapped using regional geophysics and seismic data. The deepest parts of the basin, where temperatures exceed 100 °C, were identified as the most viable for geothermal exploitation. These

areas correspond to magnetic lows observed in regional magnetic maps and seismic profiles, indicating significant sediment thickness and optimal conditions for geothermal reservoirs.

The Midyan Basin's geological setting, with its complex interplay of rift and strike-slip tectonics, provides a unique opportunity for geothermal development. The identification of key lithological units such as the Ghawwas, Maqna, Burqan, and Al Wajh formations as potential reservoirs further underscores the basin's suitability for geothermal projects. The successful exploration and eventual development of these geothermal resources can contribute significantly to NEOM's vision of becoming a leading renewable energy hub, providing sustainable power, heating, and cooling solutions.

In summary, the exploration efforts in the Midyan Basin have laid a strong foundation for future geothermal development. The current study highlights the potential of the Midyan Basin to support large-scale geothermal energy projects, aligning with Saudi Arabia's Vision 2030 and the ambitious goals of the NEOM project. Future work should focus on detailed reservoir characterization, drilling exploratory wells, and conducting feasibility studies to further de-risk the identified geothermal prospects and pave the way for commercial geothermal exploitation in the region.

ABSTRACT

Mammoth Lakes, California hosts a productive hydrothermal system within the seismically active south moat of Long Valley Caldera. Surficial evidence of the shallow hydrothermal system includes discrete zones of tree-kill dispersed between Shady Rest Park and the Casa Diablo Geothermal Power Plant (40 MW), as well as east of the power plant. The tree-kill areas are associated with elevated diffuse CO_2 emissions, heated ground, hydrothermal alteration, diffuse soil H_2S emissions, and gas vents. Previous mapping delineates prominent north and northwest trending structures within the south moat along the southwestern edge of the resurgent dome that may accommodate gas and fluid flow at the Shady Rest Park and Basalt Canyon tree kill areas (SRTKA and BCTKA, respectively). Both tree-kill areas are also located along contacts between resurgent rhyolite, mafic lavas, and surficial deposits which may provide additional pathways for gas and fluid migration in the shallow subsurface.

Characterizing structure and lithology using geophysical anomalies can help identify primary structural controls on the hydrothermal system and the extent of subsurface alteration at these sites. We conducted ground and airborne-based potential field geophysical surveys to map gravity and magnetic anomalies. These anomalies were then used to model subsurface geology, structure, and hydrothermal alteration. Here we present our preliminary geophysical mapping and modelling results at both tree-kill locations. Gravity and magnetic data suggest complex structural intersections are coincident with heated ground and gas emissions at the SRTKA and BCTKA. Hydrothermal systems are often observed or interpreted to exploit fault intersections which can serve as highly permeable pathways for hydrothermal fluid and gas discharge, enabling economic

geothermal energy production. Geophysical mapping and modelling are an effective means of investigating such structural complexity at Mammoth Lakes due to the presence of unidentified and concealed structures.

1. Introduction

The Long Valley Caldera (Figure 1) hosts an active hydrothermal system sustained by ongoing volcanic heat flux below the western moat of the caldera near Deer Mountain (Peacock et al., 2016; Sorey et al., 1991) and shallow permeable horizons arising from lithologic variations (Suemnicht et al., 2007) near Casa Diablo (Figures 1 and 2). Moderate hydrothermal fluid temperatures in and around Casa Diablo (150-170 °C; Bergfeld et al., 2006) enable geothermal productivity (40-Megawatt electric capacity; Suemnicht et al., 2007) adjacent to the town of Mammoth Lakes. Surface alteration, heated ground, gas vents, and areas of tree kill within the vicinity of Casa Diablo hot springs motivated a detailed geophysical study of this region to understand what structural controls contribute to the present state of subsurface hydrothermal activity and surface expression. Furthermore, the accessibility at Shady Rest Park has enabled continued experimentation with a variety of airborne-based tools to assess active surface processes (Zielinski et al., 2022). Small uncrewed aerial systems (sUAS) provide increased data coverage capabilities and cost effectiveness for small to moderately sized areas of interest. The roughly 5- by 3-km region of interest for geophysical mapping, extending from the Basalt Canyon tree-kill area (BCTKA) to the Shady Rest tree-kill area (SRTKA), is uniquely suited for sUAS (Figure 3). The current work focuses on presenting results from multi-year geophysical surveys that indicate the existence of magnetic lows coincident with known zones of tree-kill, soil and rock alteration, and gas emissions. Importantly, the shape of these zones of low magnetization has been refined better than previous regional magnetic surveys were capable of (Ponce, 2019). Gravity and magnetic anomaly mapping using data obtained from 2021 – 2024 provides a higher resolution look at anomalies within and surrounding areas of tree-kill.

Forward modelling of gravity anomalies provides a way to distinguish concealed structures that can be resolved by modelling variations in density that arise from faults and contacts. These inferred structures are non-unique in that the observed data can reflect faults, contacts, intra-unit density variations, or other structures that places rocks adjacent to each other with density differences great enough to yield a gradient. Forward modelling of magnetic data also results in non-unique solutions but provides information about differences in magnetic properties (induced and remanent magnetization) at the surface and at depth. Joint modelling of both gravity and magnetic data can strengthen model confidence because a good fit must match both observed gravity and magnetic data.

From 2021 to 2024, we collected gravity data in the vicinity of the SRTKA and BCTKA, as well as regionally within the south moat, to constrain gradients across potential concealed structures and construct preliminary potential-field models. We also collected aeromagnetic data across both tree-kill areas (Figure 3) to aid in mapping alteration zones, concealed structures, and young volcanic deposits. This joint method of forward modelling may be advantageous to identify and characterize concealed structures that lie beneath the south moat and may control the geothermal system.

White circles are locations of wells discussed in this work and used in modelling.

2. Geologic Setting

Long Valley Caldera (Figure 4) developed ~767 ka when a caldera-forming eruption released more than 650 km^3 of Bishop Tuff from a 5-km deep magmatic reservoir (Hildreth and Fierstein, 2016; Wallace et al., 1999). During eruption, a landslide of precaldera basement rock on the south wall broke loose and slid into the southern region of the caldera, reaching all the way to present-day Casa Diablo (Suemnicht et al., 2007). The subsequent 100 ka following caldera collapse sustained a series of intracaldera eruptions which emplaced rhyolitic flows, domes, and tuffs (Hildreth et al., 2017; Hildreth and Fierstein, 2016), herein referred to informally as early rhyolite (Bailey et al., 1976). This resurgent volcanism was followed by 400-500 meters of uplift from approximately 670 – 540 ka (Hildreth et al., 2017).

The hydrothermal system at Long Valley has experienced two major periods of activity. Th/U age samples collected from altered breccia zones, silicified veins, and calcite veins in the central and eastern caldera suggest a period of high hydrothermal flux between 300 – 200 ka (Sorey et al., 1991). Additional sampling at Casa Diablo, Hot Creek, and Layton Springs (Figure 1) reveals the latest period of hydrothermal activity initiated around 40 ka (Sorey et al., 1991). These ages indicate a primary period of hydrothermal activity centered in the central and eastern caldera, whereas the present system extends across the south moat as far west as Mammoth Mountain (Figures 1 and 2). The present-day hydrothermal system is sustained by a magmatic reservoir on the western margin of Long Valley, likely beneath the west moat and/or below Mammoth Mountain (Peacock et al., 2016; Sorey et al., 1991). Geothermal well logging indicates hydrothermal fluids upwell near Deer Mountain along deep basement faults and flow laterally southeast/east between the early rhyolite and Bishop Tuff toward Casa Diablo and then along the south moat before discharging at Hot Creek Gorge and other hot springs as far as the Owens River (Peacock et al., 2016; Sorey et al., 1991). The buried, syneruptive landslide block near Casa Diablo serves as a hydrologic barrier between cooler recharge waters within the Bishop Tuff and hotter hydrothermal waters within intracaldera fill (Suemnicht et al., 2007).

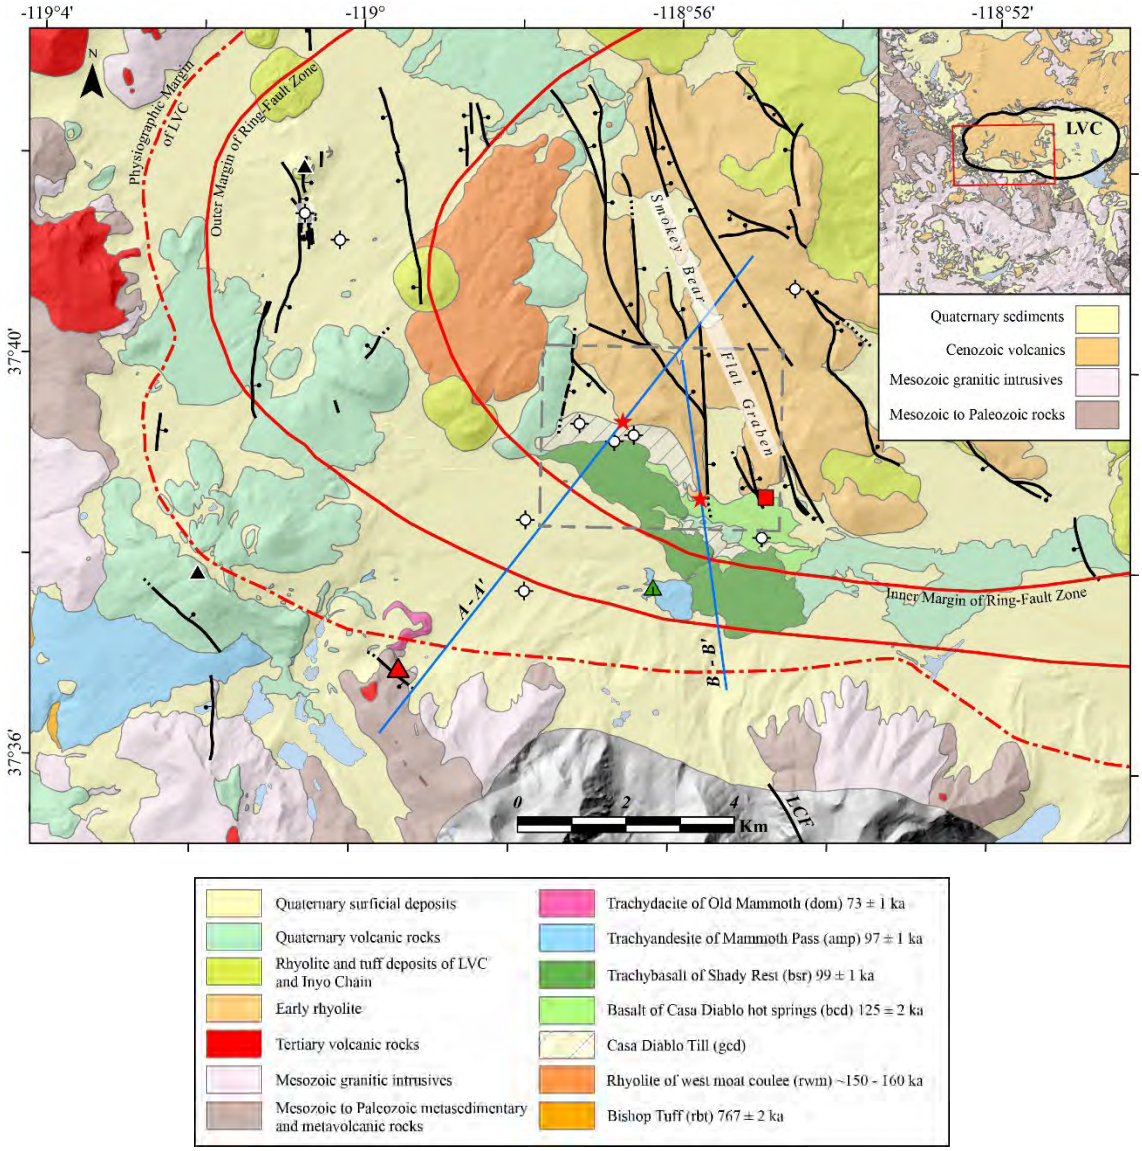

Figure 4: Digital Elevation Model (DEM) hillshade (USGS, 2024) overlain by geology of western Long Valley Caldera (LVC) adapted from Hildreth and Fierstein (2016). Top right inset shows DEM hillshade overlain by generalized geology adapted from Strand (1967) and red rectangle showing Figure extent. Ages of individual units from Hildreth and Fierstein (2016). Stars indicate locations of SRTKA and BCTKA. White circles are wells identified in Figures 2 and 3. See Figures 1 – 3 for regional feature identification.

3. Previous Geophysical Investigations

Long Valley has a long history of geophysical investigation, much of it centered on determining the extent and status of the Long Valley magma chamber. Geophysical and geological evidence indicate the chamber is moribund (Hildreth, 2017). However, seismic and geodetic data suggest active uplift beneath the early rhyolite is induced by “second boiling” fluid migration caused by progressive crystallization of the magma chamber. Recent tomographic models by Biondi et al.

(2023) of Long Valley Caldera (LVC) also support this second-boiling model to explain seismicity and uplift. The fluid migration is accompanied by earthquakes within the south moat seismic zone (SMSZ) (Hildreth, 2017; Shelly, 2016). Earthquake relocation indicates active seismicity at 3 – 9 km depths (Prejean et al., 2002) within the SMSZ. Although regionally active seismicity predominates in the extracaldera (Hildreth, 2017), the abundance of seismicity within the SMSZ and general absence within the rest of the caldera, as well as no evidence of elevated heat flow beneath the center of resurgent uplift indicate there are no active magmatic intrusions within the structural caldera. Surface expression of SMSZ faults and the ring fault system is lacking (Hildreth and Fierstein, 2016). However, active fumaroles, gas vents (Bergfeld, 2006), heated ground (Vaughan et al., 2018; Figure 3), and tree-kill (Figures 4 and 5) coincident with inferred zones of seismicity (Prejean et al., 2002) within the vicinity of Casa Diablo hot springs may indicate permeability is enhanced by SMSZ structures identified by Prejean et al. (2002).

A relatively thin zone of caldera fill in the south moat inferred from Kane et al. (1976), in addition to a WNW-ESE trending gravity gradient, and a complex magnetic low extending as a lobate tongue from the southern margin of the caldera to Casa Diablo may result from hydrothermal alteration and mineralization (Kane et al., 1976). Hydrothermal alteration may dissolve and remove magnetic material and mineralization can decrease porosity and locally increase observed gravity anomalies. However, the gravity gradient generally reflects the shape of the caldera, suggesting a conservative interpretation is warranted on inferences about caldera structure and lithology in the south moat. The tight gradient contouring the caldera boundary does broaden in the south moat but the coincidence of hydrothermal mineralization and Mammoth Mountain volcanic deposits in the south moat complicates a structural and lithologic interpretation of the gradient given the resolution of the survey presented by Kane et al. (1976). Similarly, the magnetic gradients from both the low- and high-level aeromagnetic surveys within the south moat align with ~NW SMSZ seismic inferences (Prejean et al., 2002) and fault interpretations (Hill and Montgomery-Brown, 2015; Riley et al., 2012) but Kane et al. (1976) posits the continuation of the magnetic low from Casa Diablo into the metamorphic basement rocks exposed along the south wall of Long Valley suggests the low may be explained in part by these rocks extending beneath the western caldera. The gravity and magnetic anomalies within the south moat suggest a variety of factors (hydrothermal activity, pre-caldera structure, active tectonics) are imposing these geophysical fabrics.

4. Data and Methods

Magnetic data were collected with a sUAS from 2021-2024 to supplement regional magnetic data collected at 400-m spacing and 150-m flight height (Ponce, 2019; Figure 6). The sUAS survey covers both the SRTKA and BCTKA (Figure 3). Aeromagnetic data were acquired using a Sensys MagDrone R3 fluxgate magnetometer flown at a height of 60 meters above ground with 60-meter line spacing at a speed of 10 m/s. sUAS calibration and compensation were conducted after Kaub et al. (2021) to remove flight heading effects. Aeromagnetic surveys were diurnally corrected using a Geometrics G-856 proton precession magnetometer with a base station located within the survey area. Flight lines were flown at a NE trend because of the strong NW orientation of mapped structure, contacts, and tree-kill at SRTKA (Figure 5). Tie lines were flown orthogonal (SE) to flight lines and used to level the surveys collected across all years (Figure 7). Flight lines and tie lines were used to grid the magnetic data at a grid cell size of 15 meters. Individual lines were minimally edited to reduce the presence of flight lines artifacts that place gradients along flight

lines. “Observed” magnetic anomalies in this work refer to values interpolated from the sUAS and regional aeromagnetic grids, used in the modelling.

More than 850 new gravity stations were collected within the Mammoth Lakes region between 2021-2024 using Scintrex CG-5 and CG-6 gravimeters. Gravity readings were processed by removing gravitational contributions from latitude according to the reference ellipsoid, earth-tide effects dependent on latitude and time, instrumental drift, the free-air effect arising from elevation above sea level, terrain effects within 167 km (complete Bouguer), and isostatic effects from topographic compensation at depth. Isostatic residual anomalies represent lateral variations of density in the middle and upper crust (Blakely, 1995) that provide insight into crustal structure. These data were subsequently merged with existing regional data from Langenheim et al. (2024), which were reprocessed for this study.

Tree-kill areas were outlined in 2016 by visual inspection of aerial imagery from 2014 and prior years (personal comm., Mads O’Brien 8/23/24). Geophysical mapping and modelling products and interpretations use gridded gravity data. “Observed” gravity anomalies in this work refer to interpolated values from a gravity grid. Profiles A – A’ and B – B’ fit data from 400-m cell size grids (Figures 9, 10), and profile C – C’ fit data from 100-m cell size grids (Figure 11) because of the dense station coverage in and around SRTKA.

Gravity and magnetic gradients yield insight into the location of possible structural boundaries (Blakely and Simpson, 1986). To aid our geophysical interpretations, we used pseudogravity (PSG) and reduced-to-pole (RTP) transformations to center anomalies over source bodies. The RTP transformation converts an observed anomaly to one where the magnetization and ambient field are vertically oriented whereas the PSG transformation involves replacing the distribution of magnetization with an equivalent density distribution to convert a magnetic anomaly into a representative gravity anomaly. Fundamentally, this transformation converts the observed magnetic field into a magnetic potential (Blakely, 1995). Using the resultant PSG anomalies, we calculated the horizontal gradient magnitude (HGM) points that indicate where the gradient is steepest. This derivative method is effective at producing lineations that lie along steep dipping structures, where rocks of differing density or magnetization are juxtaposed. Plotting the HGM maxima (maxspots) on top of the RTP anomaly grid simplifies geophysical interpretation. We connected these maxspots, representing ridges in a HGM grid, into continuous lines using an automated routine developed by Athens (2018). A HGM analysis was also carried out on gravity anomalies to identify structures arising from density contrasts.

We also collected rock samples of geologic units across the south moat to conduct density and magnetic property measurements to constrain the model parameters. Grain, saturated-bulk, and dry-bulk densities were calculated for collected samples by weighing samples in dry air, under saturated and submerged conditions, and saturated in air. Magnetic susceptibility measurements of hand samples were conducted using a ZH instruments SM30 meter with a resolution of $1x10^{-7}$ SI units. In addition, field-based outcrop susceptibility measurements were taken because these reflect unit properties more accurately compared to hand sample susceptibility measurements. Lastly, the well-documented geologic and tectonic history of this region (Hildreth and Fierstein, 2016; Bailey, 1976) and previous geophysical modelling work (Carle et al., 1988) provided constraints for assigning physical properties and delineating subsurface interpretations for the 2D geophysical models constructed in this work.

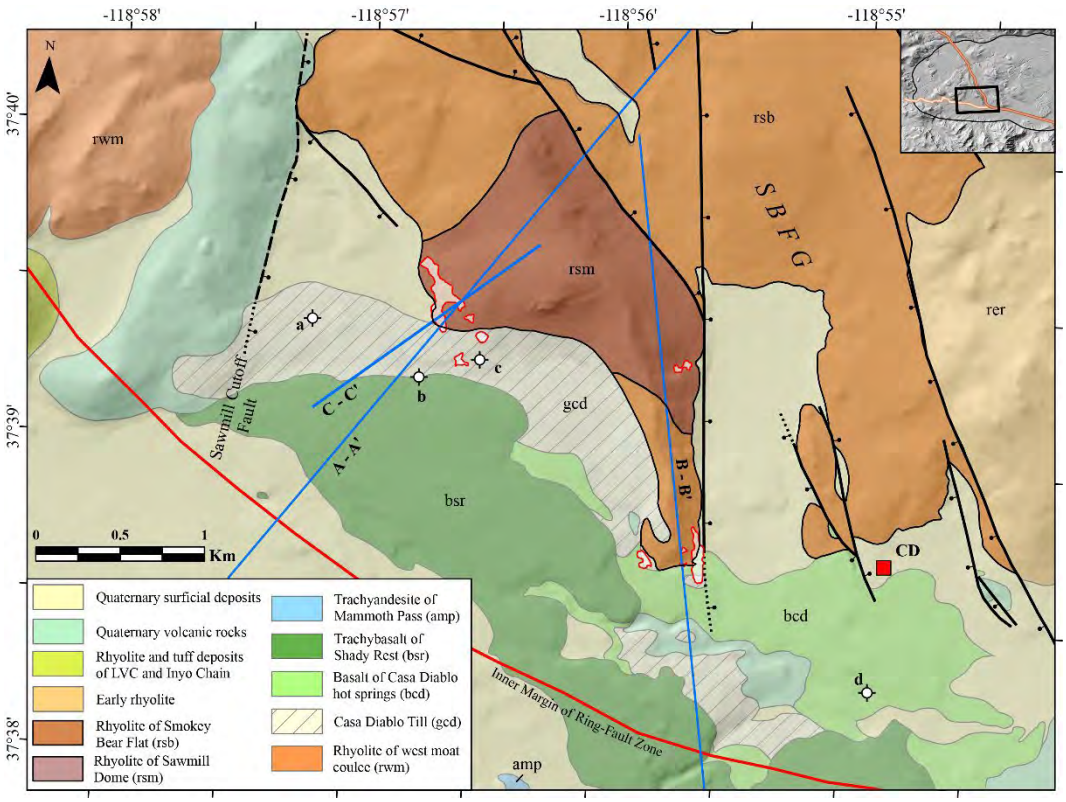

Figure 5: Digital Elevation Model (DEM) hillshade (USGS, 2024) overlain by geology in the south moat, adapted from Hildreth et al. (2017) and Hildreth and Fierstein (2016). Outline of early rhyolite subunits rsm and rsb were adapted from Figure 2 in Hildreth et al. (2017). Wells within this Figure: a, RDO-8; b, 57-25; c, 66-25; d, 38-32. CD, Casa Diablo Geothermal Plant and hot springs; SBFG, Smokey Bear Flat Graben. Top right inset shows DEM hillshade with thick black rectangle showing Figure extent, LVC physiographic margin in thin black outline, and major highways in orange.

5. Geophysical Mapping

Identifying structures at regional and local scales was conducted prior to the construction of 2D forward models. Geophysical mapping helps identify potential concealed structures that may be relevant to understanding the geothermal system. A particular interest was to investigate the concealed ring-fault zone of LVC (Figures 4 and 5) given its seismic activity and alignment with observed magnetic and gravity anomalies extending into zones of local interest (i.e., SRTKA & BCTKA; Figure 6). Regional scale magnetic and gravity mapping do not provide irrefutable geophysical evidence of ring faults, but anomalous bodies and major gradients in the south moat did inform 2D forward modelling.

5.1 Potential Fields

5.1.1 Regional Aeromagnetic Anomalies

Regional magnetic anomalies (Ponce, 2019) of interest are outlined in Figure 6. Boundaries were informed from (1) HGM maxspots on the PSG aeromagnetic grid and (2) significant anomalous bodies from the RTP grid. Bodies 1 (B1) and 8 (B8) are defined by HGM maxspots and correlate with exposures of Mesozoic plutons in the south wall of LVC (Figure 4). Body 4 (B4) is informed

by both HGM maxspots and RTP contours to emphasize the extensive magnetic low present at SRTKA and BCTKA. Body 5 (B5) is a north-trending magnetic high coincident with the mapped extent of unit rwm (Figure 4). The east side of B5 is well defined with HGM maxspots, and the western margin is informed by RTP contours. Bodies 6 and 7 (B6, B7) are well defined from HGM maxspots and correlate with mapped exposures of Mesozoic plutons (B7) and the Mammoth Mountain edifice (B6).

In addition to outlining bodies of interest, HGM maxspots delineated lineations that agreed well with mapped and inferred structure. Figure 6 shows line 1 (L1) parallel to the inferred inner margin of the ring-fault zone, traceable from well 38-32 (Figure 2) to the southwestern extent of B4. Lines 2 and 3 (L2, L3) align well with Smokey Bear Flat Graben (SBFG) faults north of SRTKA. Line 4 (L4) is well defined by HGM maxspots and may represent the concealed contact between Mesozoic plutonic rocks and Mammoth Mountain volcanic deposits.

Body 2 (B2) is a lobate magnetic high on the north side of Mammoth Rock (Figures 2, 6). The southeastern boundary of B2 is well defined by HGM maxspots, but the remainder of the outline is informed from RTP contours. Body 3 (B3) is a linear, east-west trending magnetic high defined by RTP contours. The magnetic high extends beyond Sherwin Creek Campground and appears to diminish where it intersects with the inferred inner margin of the ring fault zone. A minor saddle separates B2 and B3 northeast from Mammoth Rock. The coincidence of B2 and B3 with volcanic flows from Mammoth Mountain (Figure 4) and the inferred ring-fault zone motivate a further look at possible explanations of these features because profile A – A’ crosses over these anomalous bodies.

B2 correlates well with the mapped exposure of the informal trachydacite of Old Mammoth (Figure 4; unit dom, Hildreth and Fierstein, 2016). Between the western edge of B3 and Sherwin Creek Campground, the informal trachyandesite of Mammoth Pass (Figure 4; unit amp, Hildreth and Fierstein, 2016) is concealed by surficial deposits. Well 30M (Figure 2) encounters unit amp at ~40 meters depth and passes through ~120 meters of Mammoth Mountain volcanics down to a total depth of 195 meters (Hildreth and Fierstein, 2016, their Figure 6). Surface mapping and well logs support the hypothesis that B3 results from a buried source of high magnetization between outcropping unit dom and Sherwin Creek Campground.

Unit dom is only exposed at the foot of Mammoth Rock (Figures 2 and 4) and not encountered further east according to surface mapping and well logs (Hildreth and Fierstein, 2016). Unit amp is more widely exposed, outcropping west of Mammoth Mountain and as far east as Sherwin Creek Campground. Unit amp erupted prior to the construction of the Mammoth Mountain edifice (97 +/- 1 ka, Hildreth and Fierstein, 2016) and is older than unit dom by ~24 ka (Figure 4, legend). If B3 results from a buried flow, it is likely unit amp and/or older volcanic flows encountered in well 30M. Nevertheless, other reasonable alternatives should be considered. (1) This anomaly may arise from a buried ring dike. However, no such feature has been identified in the literature. (2) Faults on the north and south sides of B3 may account for the observed signal. The magnetic low on the south side of B3 attributable to metasedimentary units suggest a lithologic source instead. Nevertheless, the gradient on the north side of B3 may represent a ring fault structure.

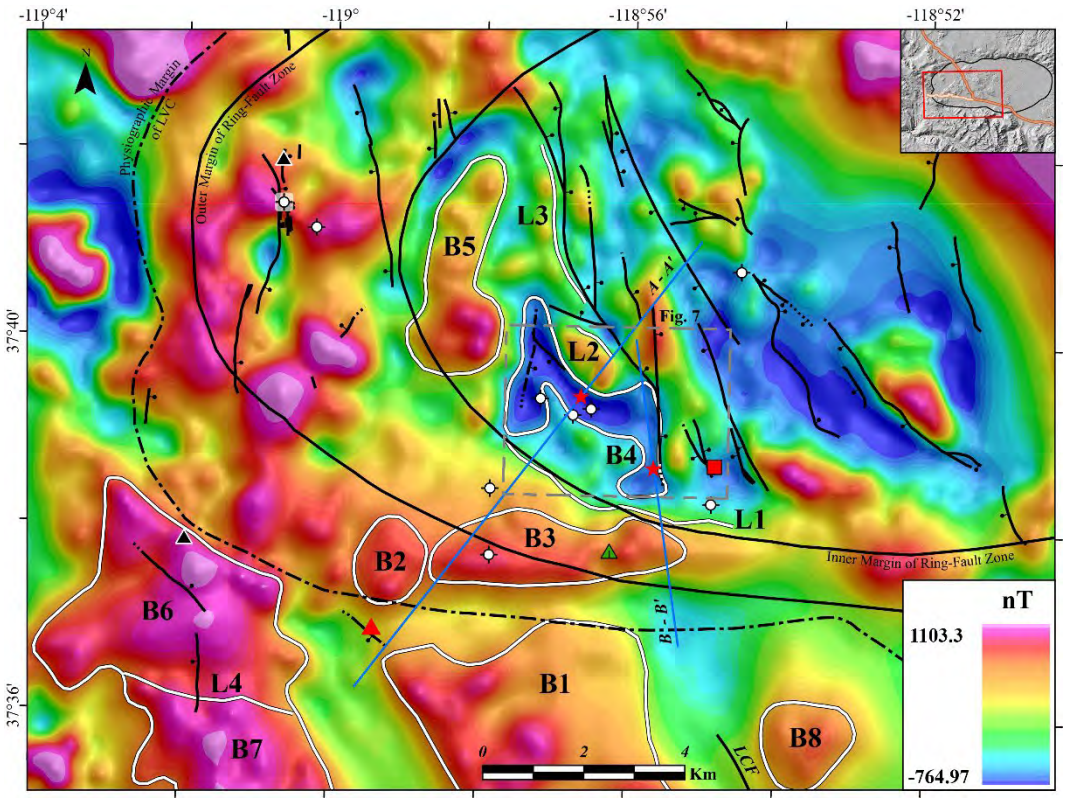

Figure 6: Regional aeromagnetic (reduced to pole) data from Ponce (2019). Faults are from Hildreth and Fierstein (2016). LCF, Laurel-Convict Fault from Strand (1967). White outlines delineate magnetic features discussed in text. Red stars mark tree-kill areas. Red box is Casa Diablo Geothermal Plant and hot springs. Black triangles are geographic features identified in Figure 1. Red triangle is Mammoth Rock (Figure 2). Green triangle is Sherwin Creek Campground. White circles are wells identified in Figures 2 and 3. A – A' and B – B' are model cross section lines shown in Figures 13 – 14. Top right inset shows DEM hillshade with red rectangle showing Figure extent, LVC physiographic margin in thin black outline, and major highways in orange.

Although more analysis is needed to definitively determine the source of the B3 anomaly, the presence of volcanic flows logged in wells from Hildreth and Fierstein (2016) presented irrefutable evidence that was used for 2D forward modelling in this work. Additionally, the inferred outer ring-fault margin from Hildreth (2017) was used to inform the placement of this major structure in the subsurface.

5.1.2 sUAS Magnetics

The magnetic anomalies observed with the sUAS (Figure 7) reveal greater resolution of regional features shown in Figure 6. Magnetic lows of note are northwest of SRTKA, within SRTKA, and at BCTKA. The dominant orientation of magnetic gradients (dotted black lines) is NW and shows good agreement with gravity HGM lineations (Figures 7 and 11). The NW-SE trending lineation northeast of SRTKA suggests a continuation of the fault that intersects the Sawmill Cutoff Fault. Additionally, cross-cutting lineations are indicated at the termini of SRTKA. An ENE striking magnetic low terminates at the northeastern extent of SRTKA, orthogonal to the main magnetic fabric. This feature is likely a contact between the informal rhyolite of Smokey Bear Flat and rhyolite of Sawmill Dome (Hildreth et al., 2017; Figures 7 and 5). At the southern extent of

SRTKA, an ENE striking magnetic lineation near well 57-25 (Figures 7 and 3) may indicate a potential cross-cutting structure.

A geophysically inferred structural intersection is also present at BCTKA. Magnetic lineations trend N-S along the west and eastern sides of BCTKA, paralleling the contact between the informal basalt of Casa Diablo hot springs (bcd) of Hildreth and Fierstein (2016), Casa Diablo Till (gcd), and early rhyolite (subunit rsb) (Figures 7 and 5). Also, an E-W magnetic lineation cuts directly through BCTKA coincident with faults mapped by Bergfeld et al. (2006) (Figure 3). Although the gravity lineations (white dotted lines) show good agreement with the N-S trending magnetic lineations, an E-W lineation is not present in the gravity HGM analysis. Magnetic data are more sensitive to shallow geologic heterogeneity and may be reflecting (1) shallow alteration present at BCTKA, (2) inherent differences between magnetic properties of unit rsb and unit bcd, and (3) terrain effects present across BCTKA.

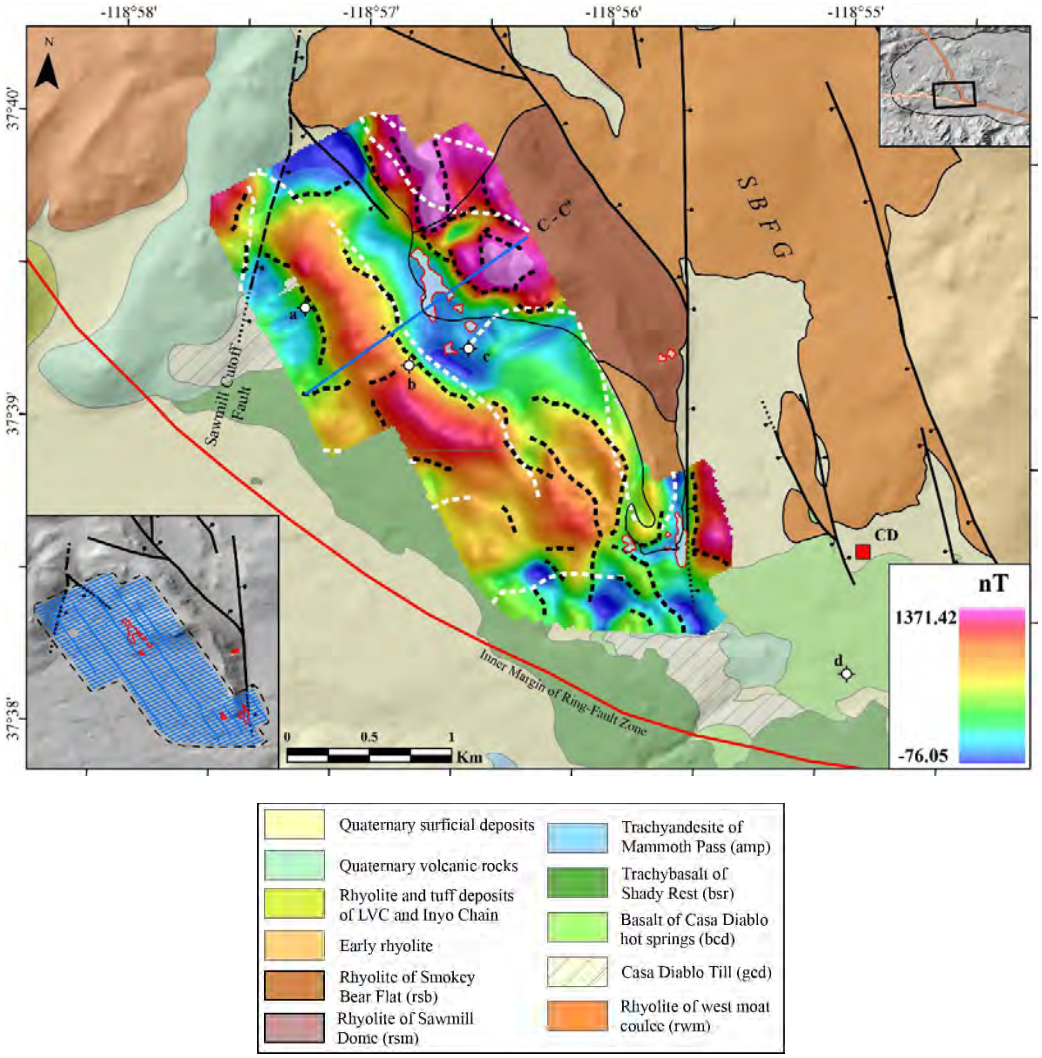

Figure 7: Reduced to pole magnetic anomaly map from sUAS acquisition. Black dotted lines are HGM lineations calculated from the pseudogravity magnetic grid. White dotted lines are HGM gravity lineations from Figure 11. Early rhyolite subunits rsm and rsb are included as thin black lines, see Figure 5 for geologic map. Red square is Casa Diablo Geothermal Plant and hot springs. Red outlines are tree-kill areas (see Figure 3). Wells symbols are identified in Figures 2 and 3. Bottom left inset shows sUAS

survey extent in dashed line, blue lines showing flight lines (NE oriented), and tie lines used to level the survey data (SE oriented). Wells within this Figure: a, RDO-8; b, 57-25; c, 66-25; d, 38-32. CD, Casa Diablo Geothermal Plant and hot springs; SBFG, Smokey Bear Flat Graben. Top right inset shows DEM hillshade with thick black rectangle showing Figure extent, LVC physiographic margin in thin black outline, and major highways in orange.

To assist the interpretation of observed magnetic anomalies, we computed magnetic topographic anomalies (Figure 8) across the survey extent using the method of Bouligand et al. (2016) with the assumption of a constant magnetization direction (equal to the direction of the ambient magnetic field) and intensity (1 A/m) in the subsurface. Correlated features in topographic and observed anomalies indicate topography contributes to the observed signal. However, the absence of a correlation suggests that the observed magnetic anomalies reflect magnetization variations at depth. A magnetic high over the early rhyolite (both subunits rsb and rsm), north and east of SRTKA, appears in both the observed anomaly and topographic anomaly, suggesting that this magnetic high can be explained by topography (Figures 7 and 8). The same applies for the early rhyolite outcropping near BCTKA.

The major NW trending magnetic high west of SRTKA (Figure 7) has a topographic contribution southeast from well 57-25 (Figure 8). This suggests that the magnetic high between BCTKA and well 57-25 has a topographic contribution to explain the observed signal. This region also is where mafic flows (units bsr and bcd) have been mapped on the surface by Hildreth and Fierstein (2016). However, northwest from well 57-25 (Figure 3), we see that the topographic effect is low compared to the observed signal. This suggests that this portion of the magnetic high results from a highly magnetized body concealed beneath surficial deposits.

The crossing structure at the northeastern end of SRTKA is coincident with a topographic anomaly, suggesting the magnetic low observed is in part due to topography. However, pre-existing structures (the contact between rsm and rsb) may predispose this zone to increased erosion due to a juxtaposition of physical properties, driving weathering, erosion, and topographic development. The correspondence between the subunit contact and magnetic anomaly should not be discarded as simply an artifact of topography. The crossing structure at the southern end of SRTKA does not show a significant topographic effect, indicating that the anomaly associated with this structure can be explained by subsurface magnetization variations that may result from a lithologic or structural contact between unit bsr and unit bcd.

The magnetic low at and around SRTKA is not associated with a magnetic low in the topographic anomalies, indicating that this area is characterized by lower magnetization. However, the magnetic low at BCTKA is partly observed in the topographic anomalies. This precludes the conclusion that this area is associated with a significant lower magnetization. Surficial alteration, heated ground, and gas vents are observed here, but less well developed and long-lived subsurface alteration at BCTKA (as compared to SRTKA) may account for this discrepancy.

The northwest trending HGM lineations on the west and eastern sides of SRTKA suggest some structure may be present on either side. The fault mapped north of SRTKA (intersecting the Sawmill Cutoff Fault just outside of the survey area) may extend into SRTKA if these lineations represent the continuation of this fault. These NW lineations intersect NE lineations at the northern and southern extents of SRTKA. These intersections may host enhanced permeability and control subsurface alteration. Notably, the northern end of SRTKA hosts a significant thermal anomaly (Figure 3) as outlined in Vaughan et al. (2018).

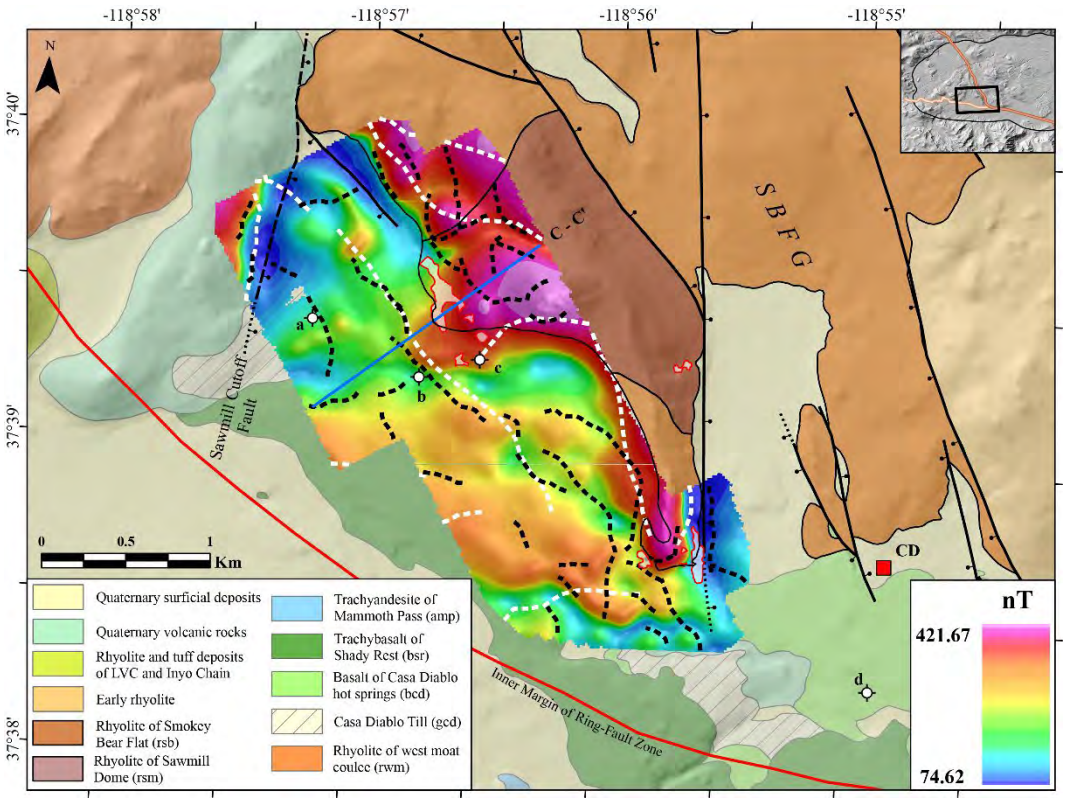

Figure 8: Magnetic anomalies resulting from topography. A constant magnetization of 1 A/m was assumed across the entire extent of the survey. Black dotted lines are HGM lineations calculated from the pseudogravity magnetic grid. White dotted lines are HGM gravity lineations from Figure 11. Early rhyolite subunits rsm and rsb are included as thin black lines. Red square is Casa Diablo geothermal plant and hot springs. Red outlines are tree-kill areas (see Figure 3). Wells within this Figure: a, RDO-8; b, 57-25; c, 66-25; d, 38-32. CD, Casa Diablo Geothermal Plant and hot springs; SBFG, Smokey Bear Flat Graben. Top right inset shows DEM hillshade with thick black rectangle showing Figure extent, LVC physiographic margin in thin black outline, and major highways in orange.

5.1.3 Regional Gravity

Gradients in gravity anomalies in the south moat (Figures 9 and 10) align with large-scale structures that have been inferred from seismicity (Prejean et al., 2002) and geologic studies (Hildreth, 2017; Hildreth and Fierstein, 2016). A major NW trend in the gravity gradient along the southern margin of LVC is subparallel to the inferred ring-fault zone (Figure 9). A closer look reveals a NW-trending gravity high extending from BCTKA to SRTKA (Figure 10). A minor saddle in the gravity high suggests a NE oriented structure may be present between BCTKA and the southern extent of SRTKA (Figure 10). A local gravity low, located where profile A – A' intersects the inferred inner margin of the ring-fault zone (Figure 10) suggests low density fill may be thicker. The agreement between regional gravity highs and lows with regional aeromagnetic anomalies near SRTKA and BCTKA (Figures 6, 9, 10) suggest that structure and/or alteration affect both density and magnetic properties of rocks in the subsurface.

Gradients near the BCTKA are predominately E-W and N-S trending (Figures 10 and 11). An oblate, E-W oriented gravity high south of BCTKA extends to Casa Diablo geothermal plant but appears to be cut off by the SBFG (Figure 11). Regional magnetic anomalies also indicate a strong E-W fabric in the gradients near BCTKA (Figure 6).

A N-S oriented gravity high along the eastern side of the SBFG is unexpected because one would expect a gravity low from thicker, low-density fill on the down-dropped (east) side of the fault. This likely reflects the low density of early rhyolite compared to mafic flows or a zone of mineralization because the regional aeromagnetic anomalies indicate a coincident magnetic high (Figure 6). The mineralized body would need to be highly magnetic to account for this observed anomaly, which suggests a mafic flow is more likely.

The regional gravity anomalies agree well with gradients from the regional aeromagnetic anomalies. Orthogonal fabrics at SRTKA (NW/NE) and BCTKA (N/E) suggest tree-kill areas are generally coincident with structural intersections, but a closer look at the gravity gradients in comparison with the sUAS survey will clarify the spatial correspondence with tree-kill areas using a HGM analysis.

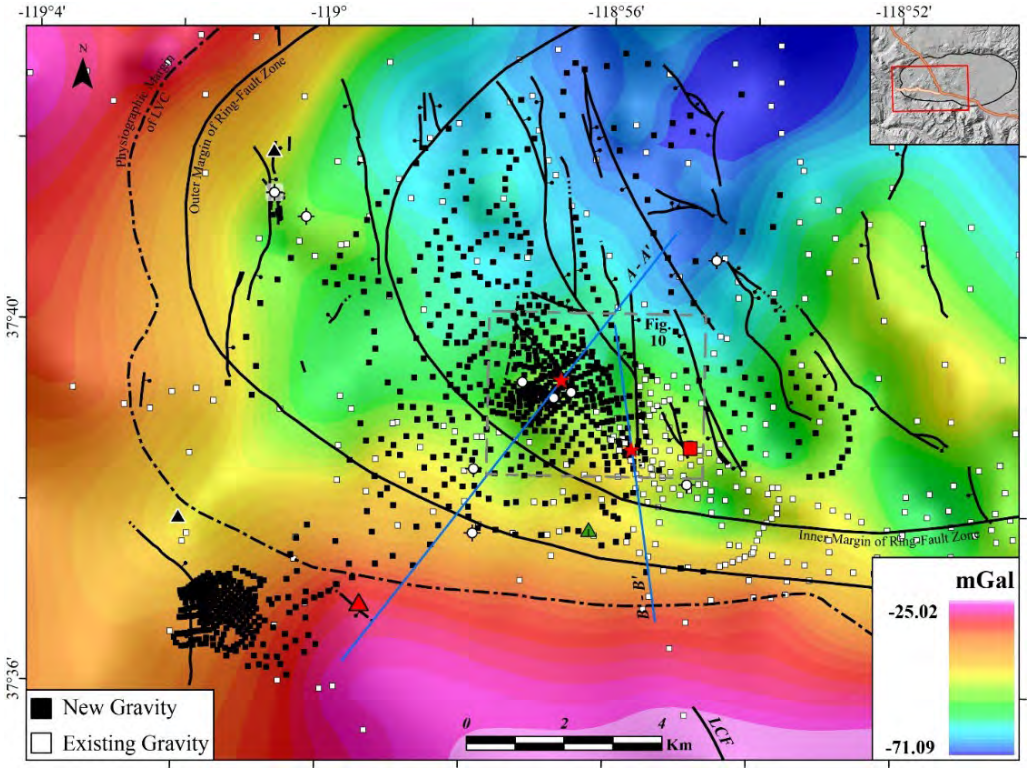

Figure 9: Isostatic gravity anomaly grid, 400-m cell size. Existing gravity coverage from Langenheim et al. (2024). Faults are from Hildreth and Fierstein (2016). Red stars are tree-kill areas, red square is Casa Diablo Geothermal Plant and hot springs. Other feature labels can be found in Figure 2. Top right inset shows DEM hillshade with red rectangle showing Figure extent, LVC physiographic margin in thin black outline, and major highways in orange.

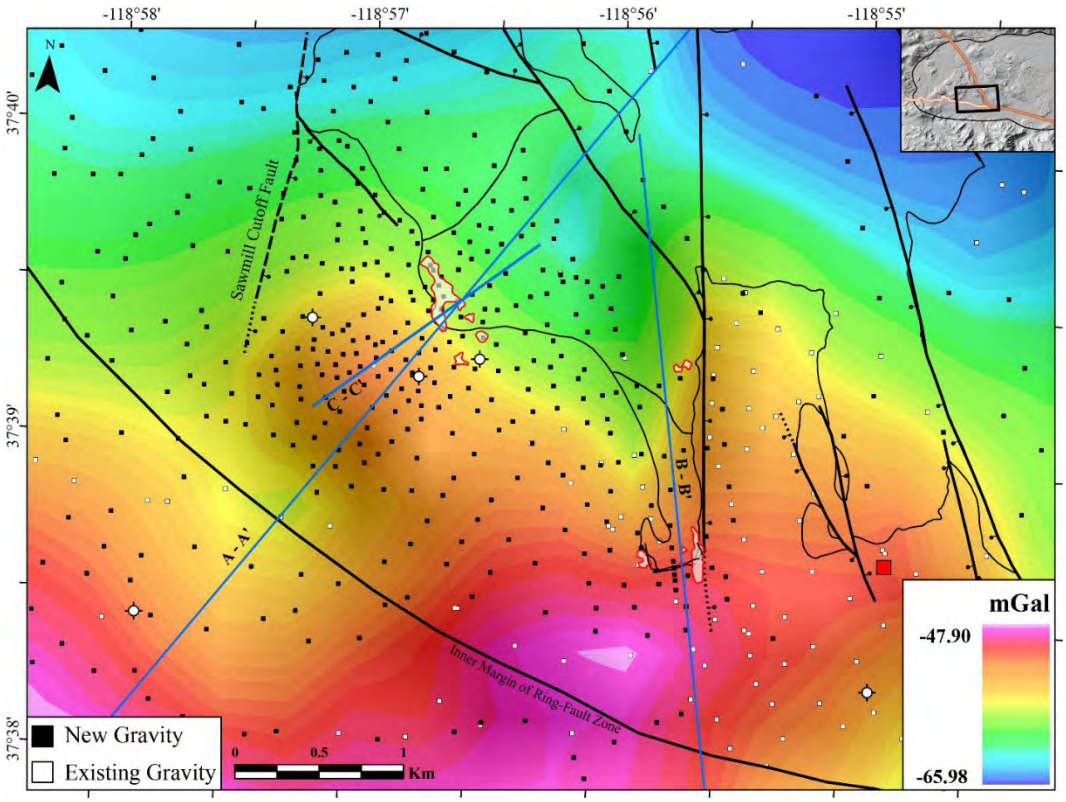

Figure 10: Isostatic gravity anomaly grid, 100-m cell size. Existing gravity coverage from Langenheim et al. (2024). Faults are from Hildreth and Fierstein (2016). Red outlines are tree-kill areas. Red square is Casa Diablo Geothermal Plant and hot springs. Top right inset shows DEM hillshade with thick black rectangle showing Figure extent, LVC physiographic margin in thin black outline, and major highways in orange.

5.1.4 Detailed Gravity

Gridding the gravity at 100-m cell size reveals finer details across the study area, but also agrees well with regional gradient orientations discussed in sections 5.1.1 and 5.1.3 with some differences. The NW fabric observed at SRTKA in regional aeromagnetic anomalies, sUAS magnetic anomalies, and regional gravity is present in the detailed gravity HGM lines (Figure 11, white dotted lines). However, the cross-cutting NE gradient inferred from a minor saddle in the regional gravity anomaly grid, postulated to be present somewhere between BCTKA and the southern extent of SRTKA, does not appear in the detailed gravity HGM analysis. However, a minor saddle is present at the southern extent of SRTKA.

The NE oriented HGM line near the southern extent of SRTKA is resulting from the juxtaposition of early rhyolite next to glacial deposits (Figure 5, unit gcd). This contact is interpreted as a glacial feature by Hildreth et al. (2017). No other NE trending HGM lineations are present near SRTKA, suggesting that any crossing structures here are shallow.

In addition, the gravity HGM lines do not coincide with the magnetic HGM lines paralleling the eastern side of SRTKA that suggest the continuation of a mapped fault. The lack of gravity HGM lines may indicate that this structure is shallow or that fault throw decreases to the southeast. The gravity HGM lines on the west side of SRTKA do agree well with the sUAS magnetic HGM lines,

supporting the hypothesis that some buried body of anomalous density and magnetization is present, juxtaposed against the western margin of SRTKA by a concealed structure (contact or fault).

Gravity lineations at BCTKA agree well with sUAS magnetic lineations along a NS trend on the western and eastern sides of BCTKA (Figure 11). In contrast, the EW gravity HGM line near BCTKA is offset toward the southwest. This lineation may represent the contact of mafic flows at their thickest here in the south moat. Although a definitive intersection is not found here at BCTKA between magnetic and gravity HGM lineations, the agreement with NS lineations supports the presence of structures that may regulate subsurface processes related to hydrothermal alteration, gas and fluid migration, and thermal diffusion. The discrepancy between gravity and magnetic HGM lineations suggest any structure or contact present here is shallow.

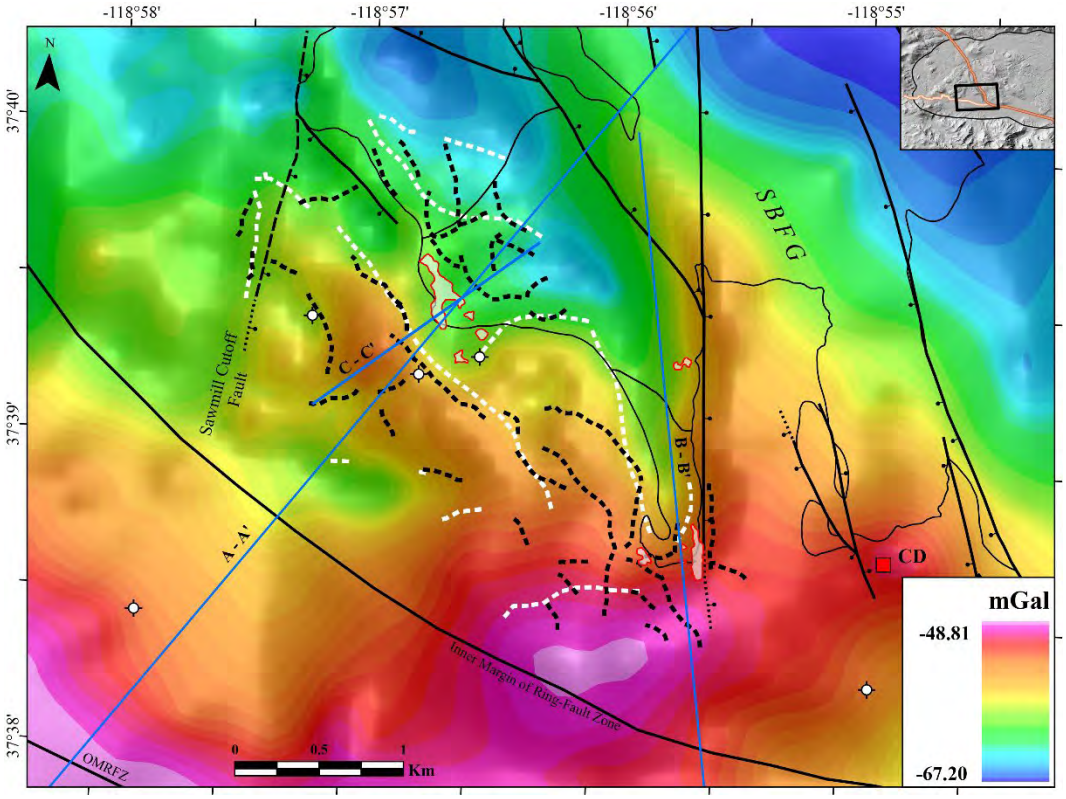

Figure 11: Isostatic gravity anomaly grid, cell size 100 m. Black dotted lines are HGM lineations on the magnetic grid. White dotted lines are HGM lineations on the isostatic gravity grid. Red outlines are tree-kill areas. Faults are from Hildreth and Fierstein (2016). OMRFZ, inferred outer margin of the ring-fault zone; SBFG, Smokey Bear Flat Graben, CD, Casa Diablo Geothermal Plant and hot springs.

6. Geophysical Modelling

6.1 Model Rock Properties

Rock density properties were determined by measuring collected samples for density and magnetic susceptibility, and supplemented from the literature (Ponce, 2021; Hildreth et al., 2014; Stevens and Greene, 1999; Palmer, 1996; Carle, 1988; Mankinen, 1986; Berkman, 1978; Williams, 1977;

Sheridan, 1970; Currie et al., 1953) when no samples were available to directly measure. Model properties for units included in the 2D profiles are in Figure 12.

6.1.1 Density

Saturated bulk densities (SBD) are used for all units on the assumption that the water table is relatively shallow compared to the depth of the model. Mafic flows, alteration zones, early rhyolite, sinter deposits, granitic rocks, and metasedimentary rock density values were determined from hand samples collected in the field and measured in a rock property laboratory. Metasedimentary densities are calculated from collected hand samples and data available from Ponce (2021). The lithology of the Morrison Block from Stevens & Greene (1999) was used to select rock types and calculate density from data from Ponce (2021). Welded and unwelded Bishop Tuff density values were computed by using grain density values from Carle (1988) and porosity estimates from Sheridan (1970). Pore space is assumed to be completely saturated with water. Welded Bishop Tuff SBD is determined to be 2,250 kg/m^3 with 5-10% porosity (Sheridan, 1970) for a grain density of 2,350 kg/m^3 (Carle, 1988). Unwelded Bishop Tuff is determined to be 1,630 kg/m^3 with 20-60% porosity (Sheridan, 1970) for a grain density of 2,050 kg/m^3 (Carle, 1988). The “high density and magnetic body” density value was adjusted to fit the gravity anomaly.

6.1.2 Magnetic Properties

Early rhyolite paleomagnetic directions are incorporated from Mankinen et al. (1986), using a Fisher mean to average between both subunits present in the study area (rhyolite of Sawmill Dome, Mankinens site 1; rhyolite of Smokey Bear Flat, Mankinens site 2). Magnetization values for early rhyolite are taken from Williams et al. (1977). Paleomagnetic directions from mafic flows were averaged (Fisher mean) using data from Hildreth et al. (2014) (their supplemental file 2). Magnetizations for the mafic flows are taken from Mankinen (1986) (his table 1, late basalts and trachyandesites). The paleomagnetic directions for the Bishop Tuff are taken from Palmer et al. (1996) and magnetization values are from Williams et al. (1977). Magnetization values for granitic rocks are taken from Currie et al. (1953). Magnetization values for metasedimentary rocks are taken from Berkman (1978). Paleomagnetic directions for both granitic and metasedimentary rocks are assumed to be a geocentric axial dipole (GAD) field at a latitude of 37.65 degrees given the typically poor ability for these rock types to retain a remnant magnetization. Susceptibility values from measured samples were used or informed by literature when not available. The paleomagnetic direction of the ”high density and magnetic body” was assumed to be the same as early rhyolite given its stratigraphic position. Its magnetization and susceptibility were adjusted to fit the observed magnetic anomaly.

	Unit	Density (kg/m^3)	Susc. (SI)	Mag. (A/m)	Inc. (°)	Dec. (°)
	Unconsolidated surficial deposits and till (0 - 200m)	2050	*	*	*	*
	Unconsolvidated surficial deposits and till (200 - 600m)	2150	*	*	*	*
	Mafic flows	2450 - 2500	0.01285	4 - 5	45.5	2.8
	High density and magnetic body	2600	0.0145	2.7	59.7	7.6
	Early rhyolite (high magnetization)	1960 - 2350	0.00413	2.5 - 5.6	59.7	7.6
	Early rhyolite (average magnetization)	1960 - 2280	0.00413	2.3	59.7	7.6
	Early rhyolite (below average magnetization)	2180 - 2350	0.00413	2	59.7	7.6
	Early rhyolite (low magnetization)	1960 - 2350	0.00134	0.5 - 1	59.7	7.6
	Sinter deposits	1940	*	*	*	*

Figure 12: Model rock properties. See text for sources of rock property data.

6.2 Profile Description

6.2.1 Profile A – A'

Profile A – A' crosses the south moat and directly through SRTKA. Joint forward modelling (Figure 13) suggests that the ring fault zone is not geophysically discernable with the available resolution of interpolated regional aeromagnetic data and regional isostatic gravity data. An early rhyolite (ER) body of low magnetization (0.5 – 1 A/m) relative to average values adjacent to SRTKA is necessary to fit observed gravity and magnetic values. However, an ER block of below average magnetization (2 A/m) within the low magnetization zone is needed to fit the magnetic high observed southwest adjacent to SRTKA. Welded Bishop Tuff is modelled as substantially thicker than unwelded Bishop Tuff to fit the observed gravity values. Low frequency magnetic anomalies between the basement exposures and SRTKA are fit by adjusting the thickness of buried mafic flows. This fit agrees with the conclusion that the E-W trending magnetic high along the southern caldera (feature B3 in Figure 6) wall can be explained from buried mafic flows. Thickening mafic flows toward the southern caldera wall are also consistent with the south moat being a local topographic low in relation to the uplifted early rhyolite (the resurgent dome, see Figure 1). Volcanic effusions from Mammoth Mountain periphery flow downhill along the south moat and pile up.

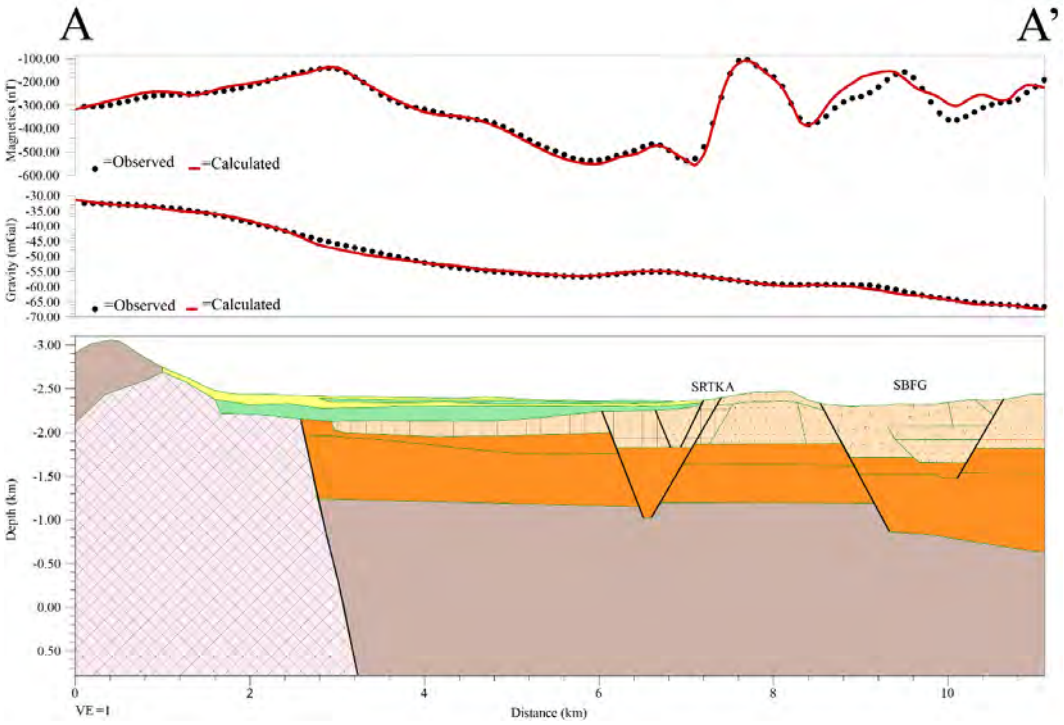

Figure 13: A – A' Preliminary forward model with Shady Rest tree-kill area (SRTKA) and Smokey Bear Flat Graben (SBFG) labeled. Magnetic anomalies modelled are from the total magnetic field (TMF) data from Ponce (2019). Gravity anomalies modelled are from 400-m gridded data (Figures 9 and 10). Thick black lines are major structures inferred by geophysics (ring fault at southern end, SRTKA structures discussed in geophysical mapping sections) or mapped (SBFG mapped by Hildreth and Fierstein (2016)). See Figures 2 and 4 for profile line locations.

6.2.2 Profile B – B'

Profile B – B' (Figure 14) extends from lower Laurel Canyon (Figure 2) across BCTKA and outcrops of early rhyolite. Similar to profile A – A' and conclusions in Carle (1988), welded Bishop Tuff is thicker than unwelded Bishop Tuff to fit the observed gravity anomalies (Figure 14). A large landslide block is modelled beneath early rhyolite but overlaying Bishop Tuff. This block agrees with findings by Suemnicht et al. (2007) that a syneruptive landslide block is extensive at depth in the Casa Diablo area.

The dominant magnetic high in the southern portion of the profile (at ~1-2 km profile distance) is fit by modelling early rhyolite of average magnetization overlain by undulatory mafic flows extending to BCTKA. Low magnetization of early rhyolite adjacent to BCTKA provides a good fit to the observed magnetic low. The low magnetization of early rhyolite upslope from BCTKA agrees well with observed alteration by this work's authors north from BCTKA and alteration mapped by Bailey (1976). A low magnetization block of early rhyolite beneath BCTKA agrees with the mapping that found BCTKA is better defined by magnetic anomalies than gravity anomalies (section 5.1.4). As in Profile A – A', observed magnetic and gravity data can be fit without incorporating multiple ring fault structures. This suggests that either (1) the resolution of the gravity and magnetic data used for these models do not permit delineation of this structure and/or (2) density and magnetic properties at depth are not sufficiently different to produce strong signals.

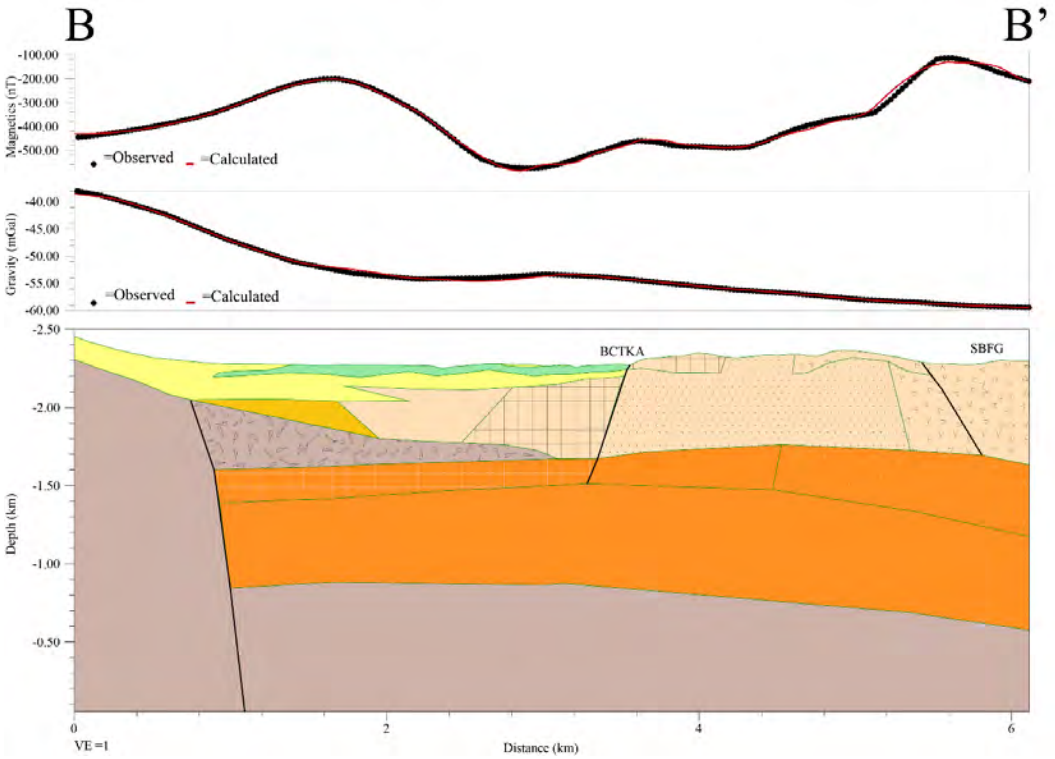

Figure 14: B – B' Preliminary forward model with Basalt Canyon tree-kill area (BCTKA) and Smokey Bear Flat Graben (SBFG) labeled. Magnetic anomalies modelled are from the total magnetic field (TMF) data from Ponce (2019). Gravity anomalies modelled are from 400-m gridded data (Figures 9 and 10). Thick black lines are major structures inferred by geophysics (ring fault at southern end) or mapped (fault mapped by Bergfeld et al. (2006), and SBFG mapped by Hildreth and Fierstein (2016)). See Figures 2 and 4 for profile line locations.

6.2.3 Profile C – C'

A short profile was modelled across SRTKA using sUAS magnetics data gridded as described in previous sections and gravity gridded values shown in Figure 11. As modelled in profiles A – A' and B – B', a thicker sequence of welded Bishop Tuff is needed to fit the observed gravity (Figure 15). Additionally, a zone of low magnetization early rhyolite is included beneath SRTKA to fit the magnetic low across the southern portion of the profile. Intra-unit gradational magnetization was incorporated within early rhyolite to fit the observed magnetic values at the NE end of the profile. Given the alteration needed at depth to fit the magnetic low, this model cannot conclusively determine whether a fault is merited as indicated by the geophysical mapping (Figure 7). An approximately 150-meter thick, 600-meter-wide zone of high density and magnetization is required to fit the observed gravity and magnetic values (the "high density and magnetic body"). This may represent a zone of hydrothermal mineralization, lithologic variation within early rhyolite or adjacent moat rhyolite units, or a buried mafic flow. Conducting an electrical resistivity tomography (ERT) or seismic reflection survey across this buried feature and SRTKA may elucidate subsurface electrical property variations and seismic velocity changes that could inform a robust interpretation concerning the source of the magnetic and gravity anomalies.

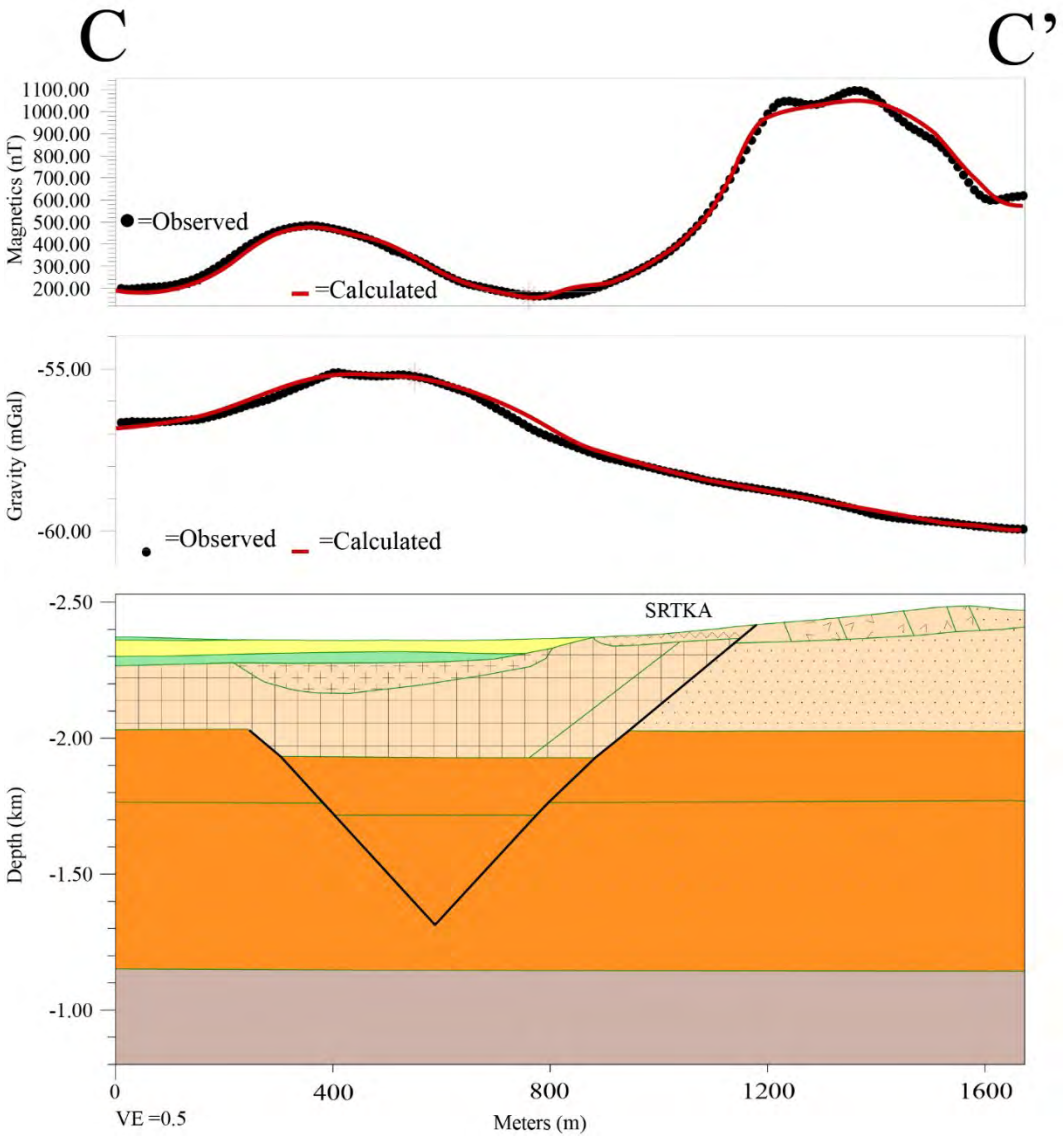

Figure 15: C – C' Preliminary forward model. Shady Rest tree-kill area (SRTKA) location is labeled. Magnetic anomalies modelled are from the total magnetic field (TMF) data from Ponce (2019). Gravity anomalies modelled are from 100-m gridded data (Figure 11). Thick black lines are major structures inferred by geophysics. See Figures 3 and 5 for profile line locations.

7. Conclusion

Geophysical data collected from 2021 – 2024 at Mammoth Lakes provide insight into the present state of surface and subsurface alteration and structure. Interpretation of potential field data provides new perspectives on the controls on localization of hydrothermal surface expression and subsurface alteration. Gravity and magnetic HGM mapping reflect previously known WNW structures along the SMSZ and suggest structural complexity may play a role in hydrothermal surface manifestations at SRTKA and partly at BCTKA. Although the preliminary 2D joint models proposed here cannot uniquely map these complex structures, they do reveal a subsurface architecture that requires significant density and magnetic juxtaposition to account for observed

anomalies. Continued work to characterize the subsurface rock property variability will enhance understanding and characterization of a structural model of the south moat.

Acknowledgements

Many thanks to Wes Hildreth and Judy Fierstein for providing valuable insight into the geologic history of Long Valley and pointing me toward useful resources. Thanks to Peter Kelly, Bill Evans, Deborah Bergfeld, Jennifer Lewicki, and Sara Peek for their cooperation and valuable insight into gas flux at Shady Rest and Basalt Canyon. Thanks to Greg Vaughan for assistance with thermal infrared interpretation and support in devising better TIR workflows. Base of Clay Cap Temperature Characterization in Sumatra Island, Study Case in PGE Fields

Muhammad Tajul Arifin[1], Aditya Abdurrahman Juanda[1], Mulyanto[1]

[1]PT Pertamina Geothermal Energy Tbk

Keywords

Cap, Conductor, Sumatra, Resistivity, Temperature

ABSTRACT

The formation of clay cap and its expected temperature are closely related to the geological setting of each geothermal field. In Sumatra Island, the overall geological setting is highly influenced by the interplay between a field's distance to the Great Sumatran Fault Zone and its pre-existing geological conditions. This interplay shapes both geological structures and hydrothermal fluid flow patterns, complicating the correlation of the base of clay cap with temperature.

To characterize the base of clay cap temperature in Sumatra Island, a comprehensive assessment was conducted of magnetotelluric (MT) data and borehole data such as the methylene blue (MeB) measurement of smectite clay in cuttings and temperature logs from five explored and developed geothermal fields of Pertamina Geothermal Energy (PGE). First, the consistency of the 3D resistivity model from MT surveys was evaluated by comparing it with the 1D model. Subsequently, the 1D model was refined using MeB data from wells to identify the base of the clay cap. We then examined the correlation between the base of the clay cap and temperature by analyzing nearby wells selected close to MT station locations.

The findings reveal a strong correlation between the base of the clay cap and the associated temperature. The details of this correlation vary depending on the geological setting of the geothermal system and especially the geothermal system evolution. This characterization offers a preliminary method for estimating the temperature of geothermal systems known or assumed to exist below the base of clay cap in Sumatra and, potentially, globally, tailored to specific geological settings and geothermal system evolution.

1. Introduction

The idealized model for a convective geothermal system has a cap that seals the hot fluids within the reservoir flowing upward to the surface. The sealing properties of the cap is derived from its main mineral composition, commonly consisting of hydrated smectite clay or mixed-layer clay. Due to the high cation exchange capacity and resulting high interface conduction that characterizes hydrated smectite clay, the geothermal reservoir cap typically has a low resistivity value of below

10 ohm-m (Ussher, 2000; Cumming, 2016). As temperature increases, the smectite clay of the argillic zone transitions to mixed-layer smectite-illite clay or to smectite-chlorite clay. A transition from smectite clay to a phyllic cap comprised of abundant illite is a special case also correlated with a moderate increase in resistivity. The transition to the more brittle illite or chlorite clay associated with the propylitic alteration characteristic of a high temperature reservoir would be correlated with an increase to much higher resistivity (Johnstone, et al., 1992; Cumming, 2016). The correlation of alteration and temperature data from wells with MT resistivity will better characterize the values of resistivity and temperature that correlate with these transitions in different geothermal settings.

Many of the earliest studies of the relationship between low resistivity and smectite clay and its importance in the exploration for geothermal resources have originated from Indonesia (e.g. Whittome and Salveson, 1990; Cumming and Matson, 2021). More recently, the importance of the base of clay cap and base of conductor in geothermal interpretation has been studied thoroughly at several geothermal fields in Sumatra such as Muara Laboh, Rantau Dedap, and Sorik Marapi (Dyaksa, et al., 2016; Ramadhan, et al., 2021; and Matson et al., 2021). The base of conductor found in these fields has resistivity ranging as low as 3 ohm-m up to 20 ohm-m. The higher "intermediate" resistivity cap corresponds to a mixed-layer clay cap. Both Rantau Dedap and Sorik Marapi have the base of conductor lying above and below the water table, depending on whether the underlying geothermal reservoir is boiling or not boiling, respectively. However, these publications tend to focus on the application of resistivity and smectite data to the assessment of reservoir geometry and well targets. The properties of the base of the low resistivity smectite cap have not been systematically studied and published for Indonesian geothermal fields, for example, in the manner that Ardid et al. (2019) compiled for the top and base of the smectite cap at Wairakei. Therefore, to support interpretations of geothermal fields, we have compiled and analyzed data on the properties of the base of the clay cap from five geothermal fields in Indonesia.

This study investigated and compiled data from the base of the smectite clay cap for five geothermal fields in Sumatra Island, namely: Kerinci, Bukit Daun, Hululais, Lumut Balai and Ulubelu. These field are located in the southern volcano-tectonic domain of the Sumatran Arc (Sutrisno, et al., 2020) (Figure 1). All of these fields are located close to the NW-SE dextral strike-slip segmented Sumatra Fault Zone, except for Lumut Balai where the shortest distance between the field to the closest Kumering segment of the Sumatra Fault Zone is 35 km. Ulubelu is located around 12 km from the splay of the Semangko Segment to the southwest, while Kerinci, Hululais and Bukit Daun are only 2 to 4 km from the nearest segment (Figure 1). All these fields are high enthalpy, volcano-hosted geothermal fields with benign hydrothermal fluids. They have a large range in likely capacity from 10s to 100s of MWe. At the surface, the five geothermal fields are covered by Quaternary volcanics, mainly derived from local volcanic eruption vents such as Bukit Gedang Hululais, Bukit Daun, Gunung Kunyit, Bukit Rindingan, Bukit Lumut and Bukit Balai (Gafoer et al., 1993; Gafoer et al., 1992; Amin et al., 1993; Kusnama, et al., 1992). Although fracture permeability is important to these fields, especially the upflows, matrix permeability of the Oligo-Miocene volcanics of the Hulusimpang Formation are responsible for much of reservoir permeability within the Kerinci, Bukit Daun, Ulubelu and Hululais reservoirs (Ikhwan, et al., 2023).

This study has utilized borehole logs and surface data. The borehole data includes temperature logs and MeB, x-ray diffraction (XRD) and petrography from cuttings. These are integrated with

the 3D and 1D resistivity models from magnetotelluric (MT) inversions to interpret the base of clay cap and infer its resistivity and temperature. Therefore, this study will improve the understanding of the temperature and resistivity distribution at the base of the clay cap in geothermal fields in Sumatra.

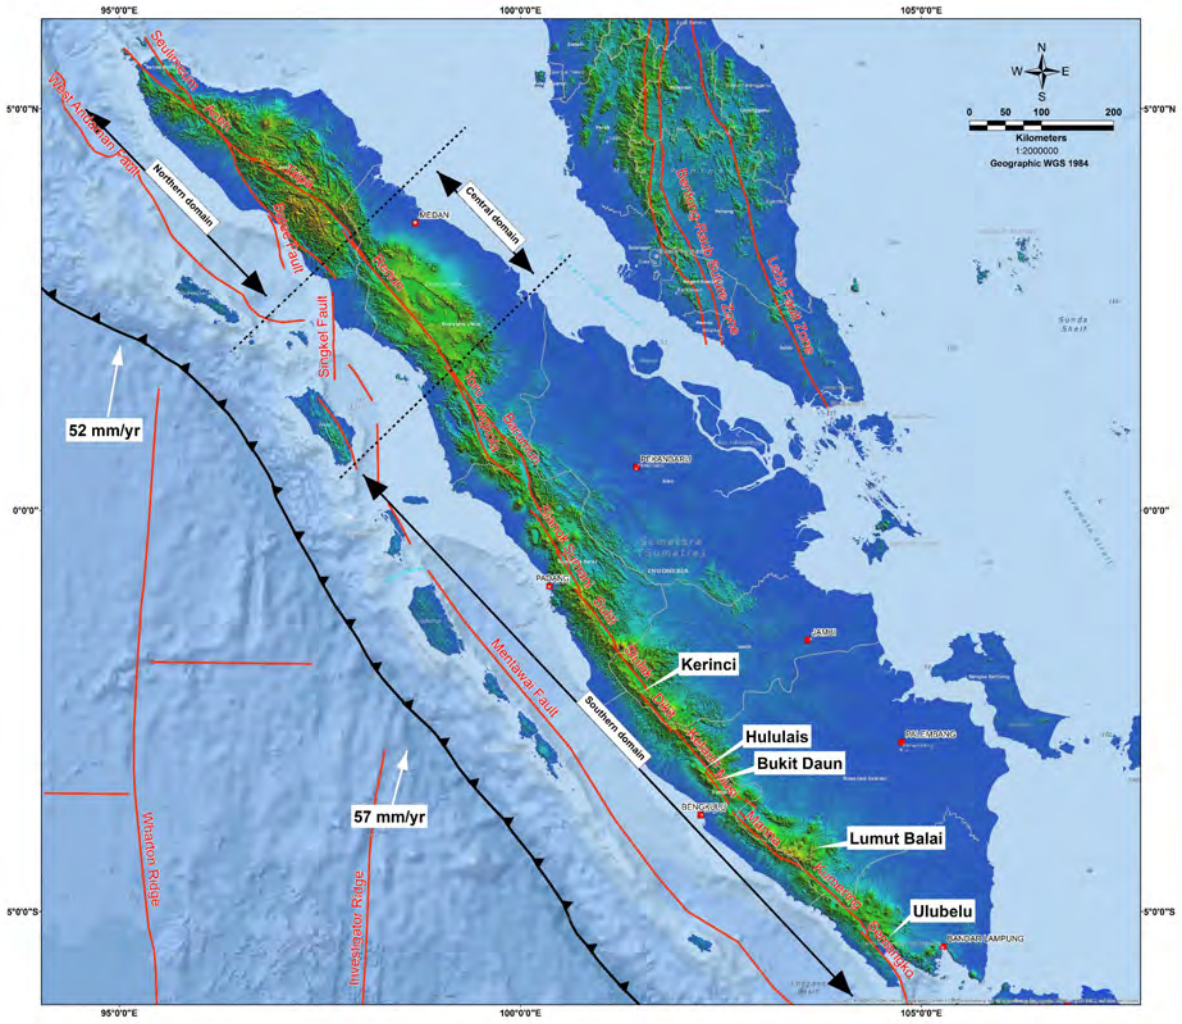

Figure 1. Location of reviewed geothermal fields overlain with DEMNAS, regional tectonic setting, Sumatran Faults, and related features (Sieh & Natawidjaja, 2001; Pour, et al., 2016), subdivision of geothermal system in Sumatra (Sutrisno, et.al., 2020)

2. BASE OF CLAY CAP IDENTIFICATION APPROACH

Before determining the base of clay cap, the consistency of the 3D MT resistivity model was qualitatively compared with 1D MT resistivity models. Resistivity values were obtained for the wells from the intersection of the wellbores with the model blocks from the 3D MT inversion, which are later used to obtain the resistivity distribution of the base of clay cap.

The base of the smectite clay cap in each well is identified by analyzing the general trend of methylene blue (MeB) index value, supported by X-Ray Diffraction (XRD) analyses. The MeB

test is commonly used during geothermal drilling to roughly quantify the smectite content in the rock (Gunderson, et al., 2000). The MeB index values are based on the procedure of Utomo, et al. (2022), using the equation as follows:

$$Methylene\ blue\ index\ (\%) = \frac{Volume\ of\ MeB\ (ml)}{Weight\ of\ the\ cuttings\ (gram)}\ x\ 3$$

The XRD results are derived from the interpretation of samples treated in three ways, air dried, glycolated and heated to 550°C. These helps differentiate the occurrence of different clay minerals. For example, a smectite response is expected from the glycolated samples but smectite should be absent from the samples heated to 550°C.

The clay transitions at the base of the clay cap determined from clay measurements is correlated with the temperature logs to derive the temperature distribution at the different clay transitions. The temperature log representative of the natural state temperature of the wells is identified based on the sequence heat-up temperature log measurements where several heat-up temperature profiles are close to each other, implying close to static temperature.

Therefore, this study integrated 3D/1D MT resistivity models, borehole geology data and temperature logs measured in five geothermal fields, Kerinci, Bukit Daun, Lumut Balai, Hululais and Ulubelu. Out of the 124 wells in these 5 geothermal fields, 92 have both temperature logs and MeB data. However, 7 wells lack temperature log measurements and are excluded from the assessment. For wells that only have temperature logs, the base of clay cap is identified using resistivity values from surrounding wells within the same well pad and supplemented by XRD measurements of cuttings or cores, if available.

3. RESULT AND DISCUSSION

3.1 Magnetotelluric (MT) Resistivity Results

MT resistivity data from all five fields involved in this study have been supplied by PT Pertamina Geothermal Energy. In general, the quality of field measurement data and the processing of MT data from each field has yielded acceptable results. The 3D MT resistivity model serves as a reference for determining the bottom of clay cap, which is the focus of this study. To check whether the smoothing applied to the 3D MT inversion might adversely affect the correlations with well data, the 3D results were compared to a simplified 1D inversion at each MT measurement (Figure 2). In the context of geothermal exploration, when we observe an area with low resistivity at a shallow depth, it is likely indicative of a high content of smectite clay (Cumming, 2016). This smectite clay alteration may cap a geothermal reservoir upflow or outflow or it may correspond to smectite clay unrelated to a geothermal field, an issue resolved by an integrated conceptual model interpretation. Where a low resistivity zone does cap a geothermal reservoir, this study characterizes the range of temperature and resistivity that may be correlated with the transition from the base of the smectite cap to the reservoir in different geothermal settings.

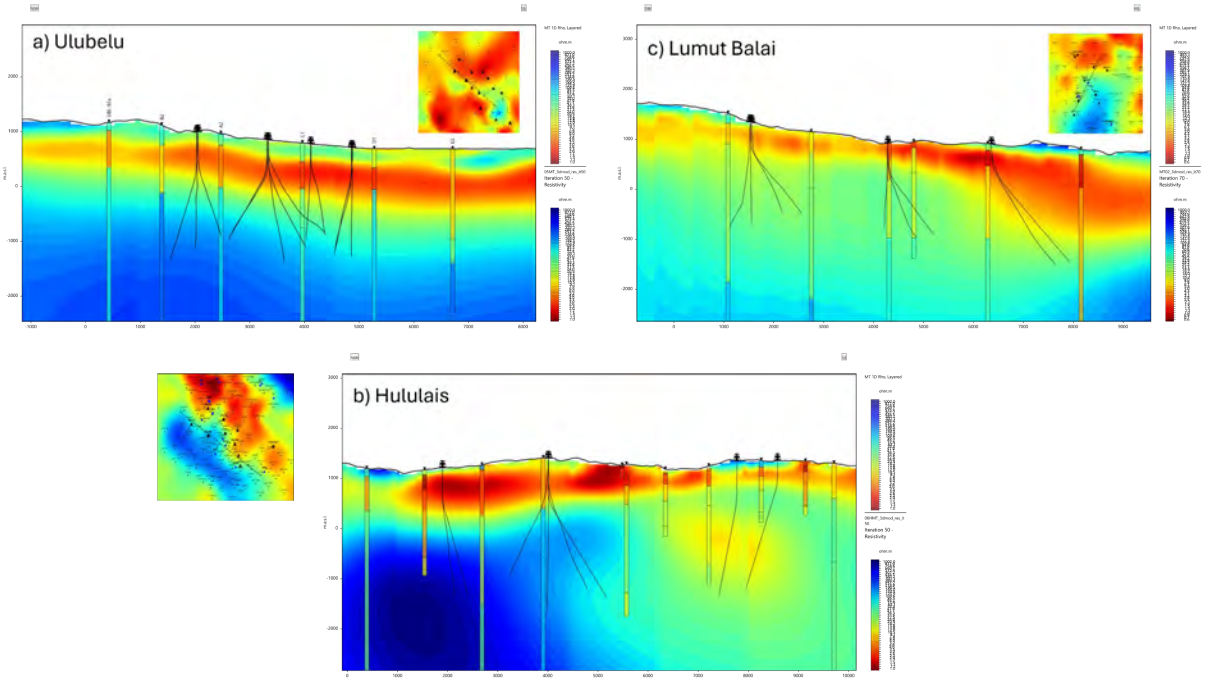

Figure 2. The 3D MT compared to 1D MT of Ulubelu, Lumut Balai and Hululais. In general, the 3D MT result is acceptable on resolving the low resistivity/conductor distribution.

3.2 Base of Clay cap Characterization

This study divided the base of clay cap into two categories, the base of smectite clay and the base of mixed/transitional clay. This grouping was based on borehole geology data, specifically the occurrence of temperature-sensitive clay minerals and the type of transition (Cumming, 2016; Matson, et al., 2021). The base of smectite clay cap was defined as the transition at the base of the argillic zone of mainly smectite clay (expected to be low resistivity) and at the top of a zone of transitional/mixed-layer clays (expected to be low to moderate resistivity). The base of mixed/transitional clay cap corresponds to transition at the base of the transitional/mixed-layer clay (expected to be low to moderate resistivity) and at the top of propylitic/phyllic alteration (expected to be much more resistive).

The base of smectite clay has been identified using the transition from values of the MeB index generally greater than 10 to values consistently below 10. At values greater than 10, the clay in the rock mainly consists of smecite clay, as confirmed by XRD. This situation also exists in the Muara Laboh and Rantau Dedap geothermal fields where an MeB index lower than 10 corresponds to a significant decrease in the content of smectite-clay (Dyaksa, et al., 2016). The base of mixed/transitional clay is identified by the transition of the relatively erratic values of the MeB index near values of 10 to more constant values below 3 to 6 of the MeB index. The base of mixed/transitional clay correlates with a transition derived from XRD where mixed-layer clay declines, and first epidote also transitions to the more crystalline form of continuous epidote as a marker of propylitic alteration (Figure 3).

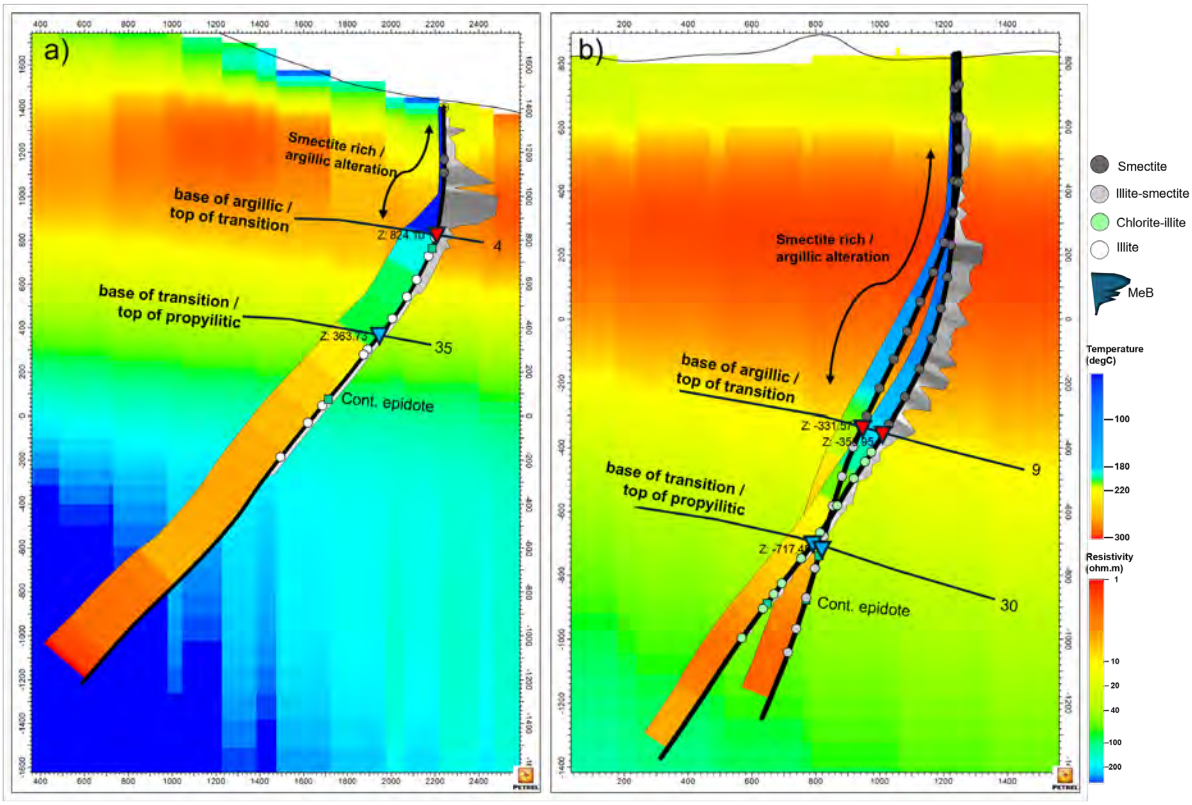

Figure 3. Base of argillic/top of transition and base of transition/top of propylitic are interpreted based on the MeB index value trend and the occurrence of clay mineral from XRD (a & b). When a well does not have MeB, besides the 3D resistivity MT the nearby well data is used to determine the base of clay cap (b).

The analyses and data compiled from the five geothermal fields investigated in this study reveal a consistent pattern of cap transitions and temperature in Figure 4a. The base of smectite clay category that corresponds to the base of the argillic/top of the transition, has a median temperature distribution of 152°C. Additionally, temperatures below 180°C account for 75% of the data, while those below 220°C comprise 93% of the P10 dataset (Figure 3). For the base of mixed/transitional clay category, equivalent to the base of transition/top of propylitic alteration zone, the temperature distribution is skewed to higher temperature in Figure 3, where the median temperature of the base of mixed/transitional clay is 207°C and 93% of the P90 dataset is below 250°C.

The correction of temperature with the petrological transitions at the base of clay cap in this study are consistent with those in the other fields in Sumatra. For instance, the base of conductor at Rantau Dedap bounds the isotherm below 180°C (Ramadhan, et al 2021). In a broader context for neutral/benign pH high enthalpy geothermal systems worldwide such as in the Philippines, this observed pattern is close to the range of smectite alteration zone of below 180°C and the transition alteration zone range from 180°C to 220°C (Reyes, 1990). Similarly, in New Zealand, the base of the conductor that overlies the reservoir unit in Wairakei-Tauhara has a median temperature of 198°C (Ardid et al., 2021), which is close to the median of the temperature at the base of mixed/transitional clay in this study at 207°C.

Shifting focus to resistivity, the value of resistivity at the base of argillic (or top of transition) zone for 80% and 90% of the data is less than 10 ohm-m and less than 15 ohm-m respectively, in Figure 4b. It is characterized by a strong skewness to lower resistivity and a median of 6 ohm-m. Meanwhile, the base of transition (or top of the propylitic) zone is more widely distributed to more intermediate and higher resistivity values, with a median value of 15 ohm-m and 90% of the data is under 42 ohm-m.

The median resistivity of 6 ohm-m at the base of argillic (top of transition) zone obtained from this study correlates with those in Sorik Marapi, Muara Laboh, and Rantau Dedap. At Sorik Marapi the intense smectite alteration of the argillic cap has a resistivity of 3 to 5 ohm-m but in some areas where reduced smectite content within the cap occurs, resistivity is 7 to15 ohm-m (Matson, et al., 2021). At both Muara Laboh and Rantau Dedap, the base of a 5 ohm-m zone corresponds to decreasing smectite content (MeB < 10) (Dyaksa, et al., 2016). This pattern also fits with the generalized geothermal system where both smectite and mixed layer caps are commonly found with resistivity values less than 10 omh-m (Johnstone, et al., 1982 and Cumming, 2016).

The base of the argillic (top of transition) zone in this study is located at a median elevation of about 150 mASL, while the base of the transition (top of propylitic) zone is at a median elevation of -84 mASL, implied a median separation of the zone of about 230 m. These numbers are given only to give a sense of the elevation distribution for the base of clay cap since the depth is significantly influenced by local topography in each field.

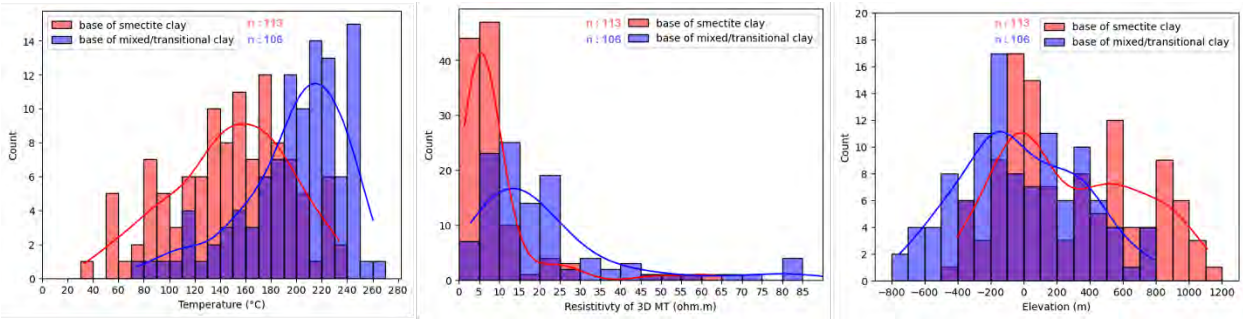

Figure 4. The histogram of temperature (left), resistivity (middle) and elevation (right) at the base of argillic (red) and base of transition (blue). The temperature distribution at the base of transition is skewed to the right to higher temperature, median 207°C. The resistivity at the base of argillic is heavily skewed to the left below 10 ohm-m, while at the base of transition is more widely distributed to intermediate resistivity value (median = 15 ohm-m). The elevation distribution at the base of argillic is more fluctuated compared to the base of transition elevation.

3.3 The Outliers

There are 6 wells in Lumut Bali that have higher than typical resistivity values for both the base of argillic (top of transition) zone (20-40 ohm-m) and base of the transition zone (60-80 ohm-m). In addition, 2 wells in Hululais have anomalous resistivity values at the base of transition (average 80 ohm-m).

In Hululais, the base of transition in those two wells sits on andesite breccia and andesite with medium to intense alteration intensity (20-50 alteration index) which consists of abundant calcite, common chlorite, illite, quartz, and illite-smectite, reflecting a mixed-layer clay or transition alteration zone (Figure 5a). These two wells have a maximum temperature of 215°C since they are

located on the northwestern margin of the field at the periphery of the northern trending outflow about 3 km north of the >300°C Hululais upflow (Figure 2b). The north-south hydrology of the outflow zone at Hululais follows the direction of north-south maximum horizontal stress, accommodating the open north-south structures (Nurseto, et al., 2020). Other wells that intersected the upflow and outflow have relatively higher alteration intensity, and higher injection index indicating higher permeability (Arifin, et al., 2020). Thus, the higher resistivity values in these two wells are interpreted as being associated with lower permeability and less intense alteration.

In the generally higher temperature southern and central parts of the Lumut Balai field, the conductor is thin, the base of conductor is shallower, and the conductor in this part of the field is generally more resistive than the conductive zone in the northern and northeastern parts of the field (Figure 2c). The MeB, XRD and petrographic analyses of the borehole cuttings from the southern and central wells show that the first epidote and continuous epidote found in cuttings are also associated with the occurrence of smectite and mixed-layer clay. The smectite clay is in equilibrium with the measured temperature, implying that the epidote is relict at those depths (Figure 5b). Garnet and veins of quartz-chlorite-epidote, indicating temperatures over 300°C, also occur with mixed-layer and transitional clay consistent with temperatures below 200°C. The maximum measured temperature in the Lumut Balai wells is 265°C. The retrograde alteration occurred at these depths, which the more resistive high temperature alteration is now relict and has been overprinted by more recent argillic clay. The cause for retrograde alteration in these wells is still debatable and needs further investigation.

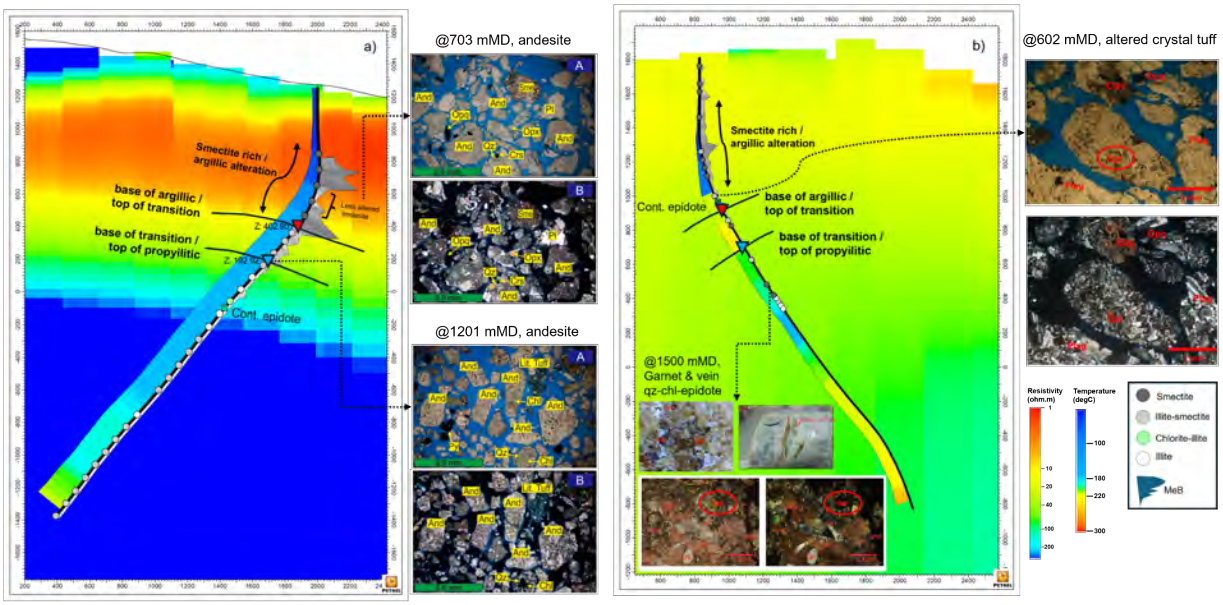

Figure 5. The outlier wells in Hululais field (a) and in Lumut Balai (b). Showing the high resistivity anomalies found in both wells and the geological findings in the cuttings.

4. CONCLUSIONS

Detailed correlations between MT resistivity and borehole cuttings, alteration and natural state temperature from 113 boreholes in five geothermal fields in Sumatra have characterized the range

of resistivity and temperature expected at the clay transitions at the base of the impermeable cap and top of the permeable reservoirs.

Although 3D inversion of MT data tends to smooth the resistivity model, the uncertainty of resistivity values can be evaluated by checking the consistency of the 3D resistivity model with respect to 1D Mt resistivity models.

Although a strong correlation is demonstrated between borehole temperature and the base of the clay cap determined from smectite and XRD measurements, the details vary based on the evolution of geothermal systems. Based on this study, the resistivity value of the base of argillic cap in Sumatra is typically below 10 ohm-m, whereas the base of transition zone or top of reservoir ranges from 10 to 25 ohm-m. The temperature range for the base of argillic zone varies from 120 to 200°C, whereas the temperature range for the base of the transition zone varies from 180 to 240°C.

Although the analyses used in the study have been limited to geothermal fields operated by PT PGE, Tbk. in Sumatra Island, similar results published for other geothermal fields indicate that the results have broader applicability for interpreting resistivity patterns and characterizing geothermal system temperatures.

In general, the temperature, resistivity and elevation at the base of clay cap presented in this study could be used as an analogue for other geothermal fields in Sumatra and elsewhere for at least two purposes. Firstly, within an area known to host a high temperature geothermal field, the results of this study can be used to interpret resistivity or estimate a likely range of temperature with respect to the base of argillic clay (top of transition) zone and the base of transition (top of propylitic) zone. Secondly, because the observations of the base of the clay cap are all in the cased and cemented section of the wells, the estimate of temperature and formation properties could support drilling engineering decisions regarding the borehole casing plan and cementing process. The specific correlations of resistivity, temperature and alteration transitions will vary depending on the conceptual model of a particular geothermal field, which requires the integration of the MT resistivity model with the geology, geochemistry and other geoscience data and, importantly, with the well data as it becomes available.

ABSTRACT

Geothermal energy development in Montserrat, West Indies, can help to improve energy security and reduce the island's heavy reliance on fossil fuels. A more detailed understanding of the spatial variation in physical properties across the lithologies which host the reservoir can greatly increase the ability to harness this renewable resource. Previous work was largely based on macro-scale characterization of the geothermal reservoir using geophysical techniques including seismic tomography. To enhance our understanding of the large-scale geophysical models we measured P- and S-wave velocities on three cores retrieved from the Montserrat's third geothermal well using a servo-controlled triaxial apparatus. Our results showed that P-wave velocity decreased by 9 % when temperature was increased to 150 Degrees Celsius. Our data also assessed the relationship between seismic properties and parameters such as porosity, lithology and alteration. These important relationships improve our ability to interpret geophysical data and target productive geothermal wells.

1. Introduction

Conceptual modelling contributes to reducing the risks associated with drilling geothermal wells in geologically complex volcanic regions. Exploration surveys consisting of geological, geochemical and geophysical studies contribute to building a conceptual model about the region of interest (Cumming 2009; Cumming 2016; Seyedrahimi-Niaraq et al. 2017). Amongst the aforementioned studies, geophysical surveys provide the best visual representation of the subsurface region at the exploration phase. For example, seismic tomography surveys of higher resolutions have been used to understand deeper areas in volcanic regions. As useful as these geophysical models are, geophysical inversions are non-unique and ill-conditioned.

Laboratory data provide the best opportunity to validate and improve on geophysical modelling. Several studies have utilized geophysical measurements on outcrop and borehole rocks to

develop a better understanding of the factors that influence variations in geophysical parameters (Heap et al. 2014; Siratovich et al. 2014; Siratovich et al. 2016; Heap et al. 2016; Mordensky et al. 2018; Kushnir et al. 2018; Goupil, Heap, and Baud 2022). Cores, a direct representation of the subsurface environment, offer the most realistic interpretation of the deep-seated geothermal environment.

Cores obtained in Montserrat, provide an avenue for investigating the meso-scale geophysical properties within the geothermal system. The island of Montserrat, located in the northern section of the Lesser Antilles arc (Figure 1a), comprises of four volcanic bodies: Silver Hills, Centre Hills, Soufrière Hills and South Soufrière Hills (Figure 1b). The north to south alignment of the four volcanic bodies reflect the geological history and migrating volcanism on the island (Harford et al. 2002; Hatter et al. 2018). Soufrière Hills is the only active volcano on the island. In 1995 began a series of phreatic explosions from the Soufrière Hills volcano which destroyed many of the existing thermal features on the island (Young et al. 1997; Wadge et al. 2014). The Hot water pond remains the only thermal manifestation on the island (Figure 1c). Andesitic composition is prevalent on all volcanic centres and topographic features on the island except for South Soufrière Hills. Basaltic to andesitic composition is characteristic at this centre (Harford et al. 2002; Hatter et al. 2018; Kiddle et al. 2010; Rea 1974).

The Montserrat geothermal field was mapped in the southern part of the island in the St. George's Hill – Garibaldi Hill – Richmond Hill (Figure 1c). Rea (1974) suggested that Garibaldi Hill and St. George's Hill were parasitic centres related to Centre Hills. Evidence of pumice fall deposits on the hills however led Harford et al. (2002) to propose that these areas were tectonically uplifted volcaniclastic deposits either from Centre Hills or Soufrière Hills. The tectonic setting of St. George's Hills is left lateral-transtensional where NW, WNW and NE structures abound and intersect to create rhombic fault patterns.

Using a joint interpretation approach, Ryan et al. (2013) found that a low velocity body, mapped in the south-west of the island from a seismic tomography survey (Shalev et al. 2010), was spatially aligned below a low resistivity region, mapped from a magnetotellurics survey (Ryan et al. 2009). The authors interpreted this as a fracture controlled geothermal system sitting below the conductive clay cap region in St. George's Hill. By integrating Ryan et al's study with geological and geochemical interpretations of the Montserrat geothermal system, two wells, MON-1 and MON-2, were drilled in this region to total depths of 2298 m and 2870 m respectively. In 2016, a third well, MON-3, was drilled to the north-east of the prior wells, also in the St. George's Hill region (Figure 1c). To further characterize the region, Ryan and Shalev (2014) utilized the high resolution seismic tomography data to model the temperature distribution within the geothermal system. Ryan and Shalev (2014) investigation of the one-dimensional velocity profile (Shalev et al. 2010) and the temperature profiles from MON-1 and MON-2 led the authors to hypothesize that the anomalous seismic velocities could be influenced by hydrothermal alteration. Temperature profiles of the wells are shown in Basant et al. (2022) and Ryan et al. (2014). The authors observed a decrease in anomalous velocities to 1750 mbsl followed by an increase in anomalous velocities. The authors suggested that at depths above 1750 mbsl the formation of phyllosilicate clays and in particular illite, acts to plasticize the rocks and reduce seismic velocities up to temperature of 200 ºC. Furthermore, the authors stated that below 1750 mbsl propylitic alteration, which involves the alteration of silicates such as epidote, quartz, and adularia, could be the cause for the velocity to increase.

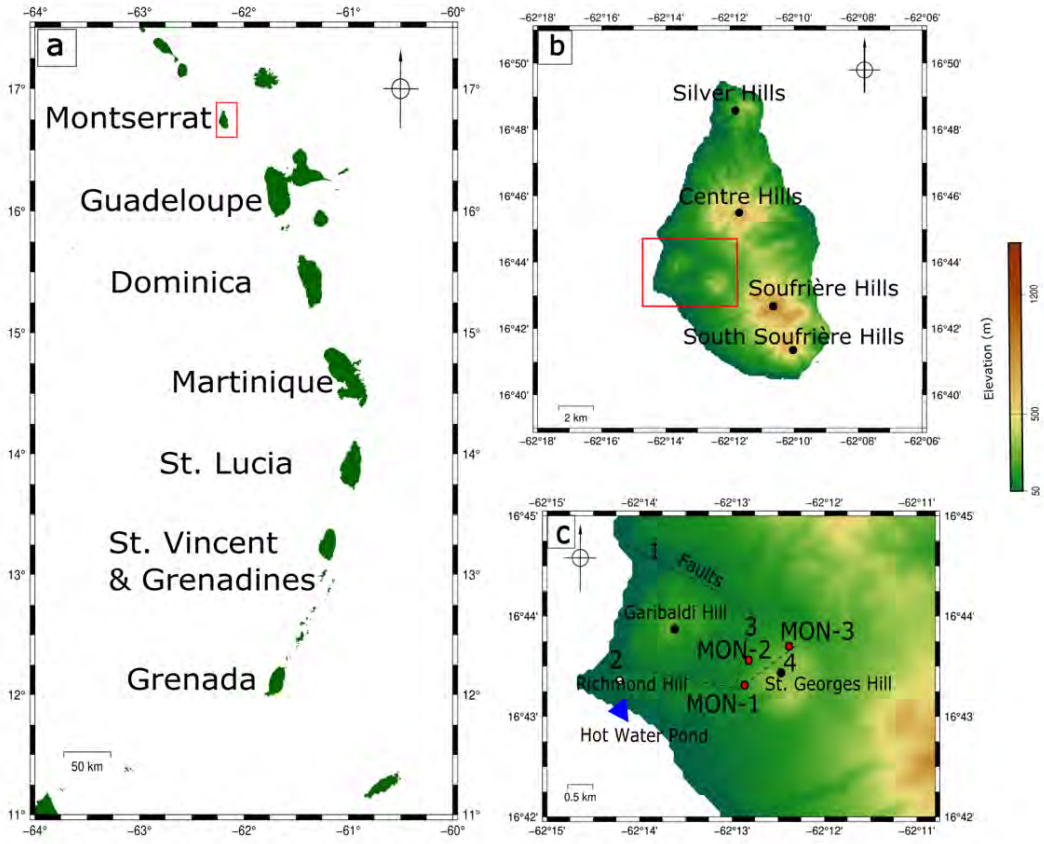

Figure 1:) Map of the Lesser Antilles arc b) Volcanic centres in Montserrat. Red square is the location of the Montserrat geothermal field c) Montserrat geothermal field showing the Hot water pond (blue triangle), faults (black dotted lines) and three wells, MON-1, MON-2 and MON-3 (red circles). Core samples were extracted from the MON-3 well (Basant et al., 2022)

In this study, laboratory geophysical studies on samples obtained from three cores are conducted to investigate and validate the seismic velocity variation in the Montserrat geothermal system, Montserrat, Lesser Antilles. With no prior work done on the core samples, we aim to understand the relations of P- and S- waves velocities with parameters such as porosity, lithology and degree of alteration. This advancement may help to guide future seismic exploration on the island.

2. Method

29 samples (~20 mm diameter) were plugged (both vertical and horizontal directions to the axis of the cores) from three 4 inch diameter cores (Core 1, Core 2 and Core 3). Core 1 and Core 2 are andesite lavas while Core 3 consists of various volcaniclastic sediments (siltstones, sandstones and mudstones) and limestones. XRD analysis on the cores showed that Core 1's alteration assemblage as smectite ± chlorite-smectite ± laumontite ± vermiculite ± calcite ± quartz. Core 2's alteration assemblage as chlorite-smectite ± prehnite ± calcite ± quartz ± laumontite ± anhydrite. Core 3's assemblages were classified as calcite ± quartz ± laumontite ± illite-smectite ± chlorite ± wairakite ± pyrite ± anhydrite ± chlorite-smectite ± rectorite.

The ends of the 20 mm samples were squared to a tolerance of ± 0.02 mm using a precision end

face grinder, were washed and then dried for a minimum of 24 hours at 50 °C. The samples were thermally equilibrated to ambient conditions before any measurements were taken. The dry bulk density was calculated using the measured weight and calculated volume of each sample. Porosity was measured using the PoroPerm equipment (porosimeter from Vinci Technologies, Inc). The PoroPerm measures grain and bulk volume. The Boyle-Mariotte's Law is used to determine grain and pore volume from the expansion of a known mass of nitrogen into a matrix cup of the PoroPerm apparatus. Porosity is calculated from the ratio of the pore volume (difference in bulk volume and grain volume) to the bulk volume.

Measurements of ultrasonic P- and S-waves were performed at the Geomechanics Laboratory, University of West Indies. A high-pressure-temperature servo-controlled triaxial deformation apparatus was used to measure the ultrasonic P- and S-wave velocities following the pulse transmission technique (Birch 1960, 1961). The apparatus consists of a hydrostatic pressure vessel with oil as the confining medium, a pulse generator and receiver, digital oscilloscope, and P- and S-wave piezoelectric transducers (fundamental frequency of 1.5 MHz) at the top and bottom to the core samples. More details on the apparatus are discussed in Iyare, Blake, and Ramsook (2021) and Blake et al. (2021). The apparatus can produce confining and pore pressures of up to 200 MPa and temperatures up to 200 ℃.

P- and S-wave travel times were measured on saturated samples. The samples were saturated by placing in a bath of deionized water under vacuum. The samples were next inserted into the triaxial apparatus where de-ionized water was pumped at a pressure of 10 MPa into both ends of the samples using the upstream and downstream pore pressure connections. Reservoir pore pressures, determined as the product of the density of water, sample depth and the gravitational constant (9.81 m/s), were next set. During this process, the confining pressure was always 5 - 10 MPa more than the pore pressure. Effective pressures were determined as the difference between the confining and pore pressures. The saturated samples were measured in a pressurization and depressurization cycle with effective pressures varying from 10 - 110 MPa. After measuring P- and S-wave travel times on saturated rocks, the temperature of the triaxial apparatus was set to 150 ℃ and the system was allowed to stabilize for 30 minutes. P- and S-wave travel times were measured on the samples at the set temperature.

The P- and S- wave velocities, $V_{p,s}$, were calculated by dividing the sample's length by the P- and S- wave travel times as shown in equation 1.

$$Vp,s = \frac{L}{trock} \tag{1}$$

where L is the length of the rock's plug and t_{rock} is the total one way travel time of the P- or S-wave though the core sample and the system i.e. $t_{rock} = t_{observed} - t_{system}$.

3. Results

We utilize the P- and S- wave velocities at the reservoir pressure for this analysis. The influence of temperature is first reported. An increase in temperature to 150 ℃ caused reductions in P-waves between 2 - 9 %. S-waves were not obtained at 150 ℃ as the waveforms were significantly

attenuated.

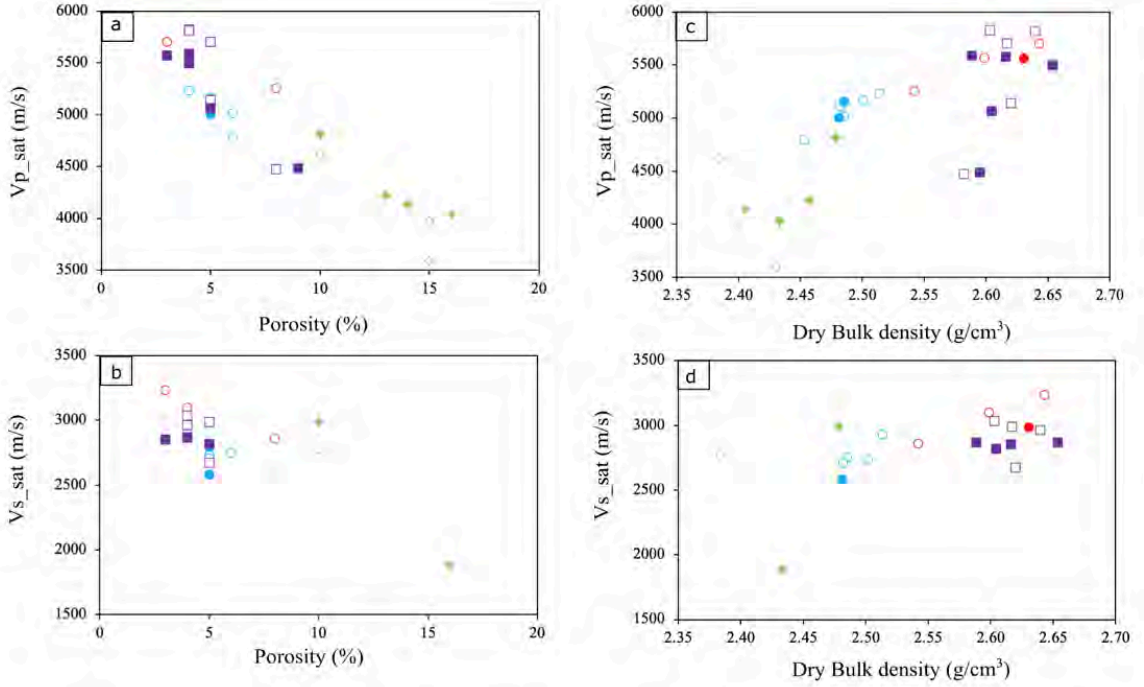

Figure 2: Variations in P- and S- wave velocities with porosity and bulk density under saturated conditions for core samples in Montserrat. Blue circles are Core 1 samples. Red circles are Core 2 samples. Green diamonds are Core 3 volcaniclastic sediment samples and purple squares are Core 3 limestones. The unfilled symbols represent vertical samples. The filled symbols represent horizontal samples.

The variations in lithology, porosity and dry bulk density with the saturated P- and S-wave velocities are shown in Figure 2. The volcaniclastic sediments of the highest porosities (10 – 16 %) and lowest densities (2.38 – 2.48 g/cm^3) measured the lowest P- and S-waves. Meanwhile, andesite lavas and limestones of relatively lower porosities (2 – 10 %) and higher dry bulk densities (2.43 – 2.65 g/cm^3) related to higher P- and S- waves. Differences in P- and S-waves were also observed between horizontal and vertical oriented samples (Figure 2). For the andesite lavas, variations in both P- and S- waves were no more than 100 m/s when comparing measurements on both horizontal and vertical samples. For the limestones, P- and S- waves on horizontal samples were lower (up to 639 and 172 m/s respectively) than the vertical samples. For the volcaniclastic sediments, the P-waves for the horizontal samples were higher (up to 443 m/s) compared the vertical samples. S-waves were highly attenuated at saturated conditions for this lithotype.

Taking into account only vertical samples, variations in seismic velocities are still observed in each lithology. For example, for the lavas, Core 2 samples have higher P- and S-waves (up to 1000 m/s) compared to Core 1 (Figure 2). Figure 2 shows that Core 2 samples were of higher bulk densities compared to Core 1. While porosity is relatively similar, both cores showed varying mineral assemblages. In particular, Core 1 contained smectite clays while Core 2 contained

chlorite-smectite. We expect the bulk and shear moduli for chlorite-smectite to be between the end member clays (i.e. higher than smectite), thus resulting in higher P- and S- wave velocities. For both the limestones and volcaniclastic sediments, the P-waves (for vertical samples only) varied up to 1500 m/s (Figure 2) within each lithology. Variations in porosity, alteration assemblages and textures observed amongst the samples may be reasons for this observation.

4. Discussion

We utilize our laboratory data to further investigate and validate the seismic velocity variation in the Montserrat geothermal system. Firstly, seismic velocities from the seismic tomography model at 1500 mbsl, 1700 mbsl and 2000 mbsl were 3.36 km/s, 3.63 km/s and 4.11 km/s respectively. The average velocities of Core 1, Core 2 and Core 3 were however greater than 4.8 km/s. The higher laboratory P-waves than the modelled P-waves may be due to the effects of temperature and scaling. A 9 % correction for temperature (150 ℃), based on our findings (maximum value), reduces the laboratory velocities. Jaya et al. (2010) and Janssen et al. (2021) observed similar reductions at this measured temperature. The authors however reported further reductions in P-waves between 10 – 40 % when temperature was increased from room temperature to 250 ℃ on rocks obtained from geothermal systems in the Krafla and Hengil geothermal fields, Iceland and Kızıldere geothermal system in Turkey respectively. With higher temperatures measured in the Montserrat geothermal system (Ryan et al., 2014), we expect a further reduction in the seismic velocities. To understand the effects of scaling, assuming a P- wave velocity of 5000 m/s, the corresponding wavelength is 500 m at 10 Hz (average seismic frequencies of the seismic tomography study), but only 3 mm at the ultrasonic frequency of 1.5 MHz (used in this study). The larger rock volumes sampled would include fractures, that may be up several meters long, again accounting for the differences in the field and laboratory velocities.

Despite the influence of scaling, the ultrasonic P-waves highlight important variations at the centimeter scale that can be used to help investigate and validate Ryan et al.'s (2014) previous hypothesis. Ryan et al. (2014) suggested that the anomalous seismic velocities in the Montserrat geothermal system could be influenced primarily by hydrothermal alteration. Ryan et al. (2014) investigated the influence of temperature, porosity and hydrothermal alteration based on logical reasoning supported by laboratory studies on volcanic rocks on geothermal systems (Kristinsdóttir et al. 2010; Boitnott 2003; Kiddle et al. 2010; Jaya et al. 2010). The potential influence of these factors is re-investigated using our new data with considerations for scaling.

Temperature logs obtained in the geothermal wells (MON-1, MON-2 and MON-3) showed increasing temperature in the Montserrat geothermal reservoir with bottomhole temperatures between 200 ℃ and 300 ℃ (Ryan et al. 2014). As mentioned earlier, increasing temperature is expected to cause further reductions in P-waves. Jaya et al. (2010) suggested reductions in P-waves were influenced by change of state in the fluid. At temperatures above 175 ℃ the formation of steam bubbles was interpreted to reduce the bulk moduli of the rock and thus, decrease the P-wave velocities. The influence of steam as a potential factor for lowering seismic velocities in the Montserrat geothermal system seems highly unlikely as reservoir geochemistry analysis conducted on the MON-1 and MON-2's producing fluid indicated that Montserrat's reservoir is likely to be a single-phase liquid system (EGS 2014).

Porosity is roughly the same from Core 1 (1478 mbsl) to Core 2 (1700 mbsl) which also do not support the lowest velocity perturbation observed at 1750 mbsl in the seismic tomography model. The effect of scaling, which considers potentially larger fractures, could however be a cause for

the anomalous velocities. The presence of a fault at ~1750 mbsl in the Montserrat geothermal system is again implausible as feeder zones were observed at ~1200 mbsl in the MON-1 and MON-2 wells (EGS 2014). While structural porosity may not a potential factor for the anomalous velocities modelled in the Montserrat geothermal system, stratigraphically related porosity could be a plausible explanation. Our dataset revealed that the volcaniclastic sediments are ~20 % slower than other lithotypes. Volcaniclastic sediments however appear both above and below 1750 mbsl in the Montserrat geothermal system (Basant et al. 2022) which again do not support the velocity perturbation depth profile.

Regarding the effects of hydrothermal alteration, our results showed the lowest velocities for the samples with the highest smectite content amongst the andesite lavas. The petrological findings from Core 1 depict that smectite is higher where the low velocity anomaly is observed (Basant et al. 2022). However, the smectite content is only consistent up to 1200 mbsl unlike the velocity anomaly. This is also supported by the lack of smectite in Core 2 and petrological findings reported in Basant et al. (2022). Ryan and Shalev (2014) proposed the particular influence of illite for anomalous velocities. Our analyses did not detect illite with the MON-3 samples which cannot validate this proposition. The XRD on the samples showed chlorite-smectite clay percentages increases to a maximum at 1700 mbsl and then decreases system (Basant et al. 2022). This variation supports the anomalous variation in seismic velocities. It is however important to note it is challenging to solely segregate the effects of chlorite smectite from other factors.

Overall, the petrological evidence shows that the spatial pattern in chlorite-smectite could be cause for the variations in the anomalous seismic velocities, however further work is needed to fully validate this statement. Also, Ryan et al. (2014) proposed the influence of propylitic alteration assemblages in particular episode below 1750 mbsl. None of our sample however contained epidote, an alteration mineral characteristic of propylitic alteration. Future work is thus proposed for investigating the effects of higher temperatures (> 200 ℃), particularly in the S-waves, increasing core samples that considers varying assemblages. Also, we propose a deeper investigating into the anisotropy of volcaniclastic and sedimentary rocks

5. Conclusion

We investigated the meso-scale properties in the geothermal system in Montserrat, West Indies using 20 mm core samples. Using the high precision triaxial apparatus at the University of the West Indies, we showed that P-wave velocity decreased by 9 % when temperature was increased to 150 Degrees Celsius. Our data show that variations in lithologies, porosity and hydrothermal alteration can cause changes in both P- and S- wave velocities. Using our meso-scale characterization, we hope to improve our ability to interpret geophysical data and target productive geothermal wells.

Acknowledgement

We thank the government of Montserrat for permission to use the geophysical data. We are also very grateful for FCDO for providing some funding. Moreover, we thank the University of the West Indies Campus Research and Publication for funding some of the materials used in the lab and for the X-ray diffraction analyses

Buffalo Valley, Temperature, Heat Flow, Geothermal, Exploration

ABSTRACT

Temperature measurements for thermal mapping are a primary indicator of potential thermal resources and location for a hydrothermal geothermal system. As such, various temperature measurements are often collected as part of geothermal exploration. In association with the INGENIOUS project, new heat flow values were calculated for the Buffalo Valley wells 72-23 and 31-26 and were interpreted for local context and exploration best practices. Heat flow values were calculated using the existing temperature logs and newly measured thermal conductivity values from the two wells. These new heat flow values are being utilized for geothermal concept model refinement and new well spotting. Additionally, existing temperature measurements of variable depth were examined in comparison to the deeper 72-23 and 31-26 wells, as well as virgin rock temperature calculations versus the existing temperature logs. Two primary observations were made that will be included in the INGENIOUS exploration workbook. First, virgin rock temperature is nominally higher than the temperature logs collected shortly after drilling. Bottom hole temperature in 72-23 increased by only 6% and 2% after 9 and 32 hours since drilling fluid circulation, respectively. This suggests that the calculation of virgin rock temperature may be unnecessary in some exploration circumstances and wait time between drilling and logging can be reduced without accuracy compromise for this specific location. Second, shallow nearby temperature measurements in the upper 175 m all have linear gradients, which would suggest regional heat flow; however, these gradients vary significantly from what is interpreted as background, increasing to what would be interpreted as near a geothermal system. This observation highlights the variation in quality and use of different temperature measurements and the necessary accompanying data when being used for exploration purposes.

1. Introduction

The INnovative Geothermal Exploration through Novel Investigations of Undiscovered Systems (INGENIOUS project) is a research project funded by the U.S. Department of Energy (DOE) Geothermal Technologies Office (GTO) to accelerate the discovery of new and commercially

viable hidden geothermal systems. Hidden geothermal systems do not exhibit surface manifestations like hot springs or steam vents, making them more challenging to locate and explore. The INGENIOUS project aims to develop and apply innovative techniques to identify and characterize these hidden geothermal systems, thereby expanding the tools to increase geothermal resource discovery and de-risk development of this clean energy resource. One key tool that will be produced is a geothermal exploration playbook, providing data types, collection methodologies, and other key parameters to de-risk exploration. Development of the exploration playbook is being supported by confirmation drilling that has taken place associated with INGENIOUS identified hidden geothermal systems. While this work is being performed within the Great Basin of the Western United States, the intention is that the exploration playbook will be useful and applicable for exploration in adjacent and analogous areas to the Great Basin.

One location being studied in detail as part of the INGENIOUS project in Buffalo Valley (Figure 1). The precursor and initial INGENIOUS play fairway analysis (PFA) maps identify this region as a potential geothermal target. Similarly, Buffalo Valley was previously identified as a potential geothermal resource area, partially due to the existing hot springs (Sass et al., 1976; Burgess and Faulds, 2024). This previous identification led to exploration activities, including a gravity survey, drilling of multiple shallow thermal gradient holes (~125 m) and drilling of 2 deep slim holes. Temperature logs were collected in the two slim holes. To date, no development has taken place in Buffalo Valley. Burgess and Faulds (2024) performed a more extensive assessment of the larger Buffalo Valley region to test and improve the INGENIOUS PFA methodology, including a 2-m temperature probe survey in Southern Buffalo Valley.

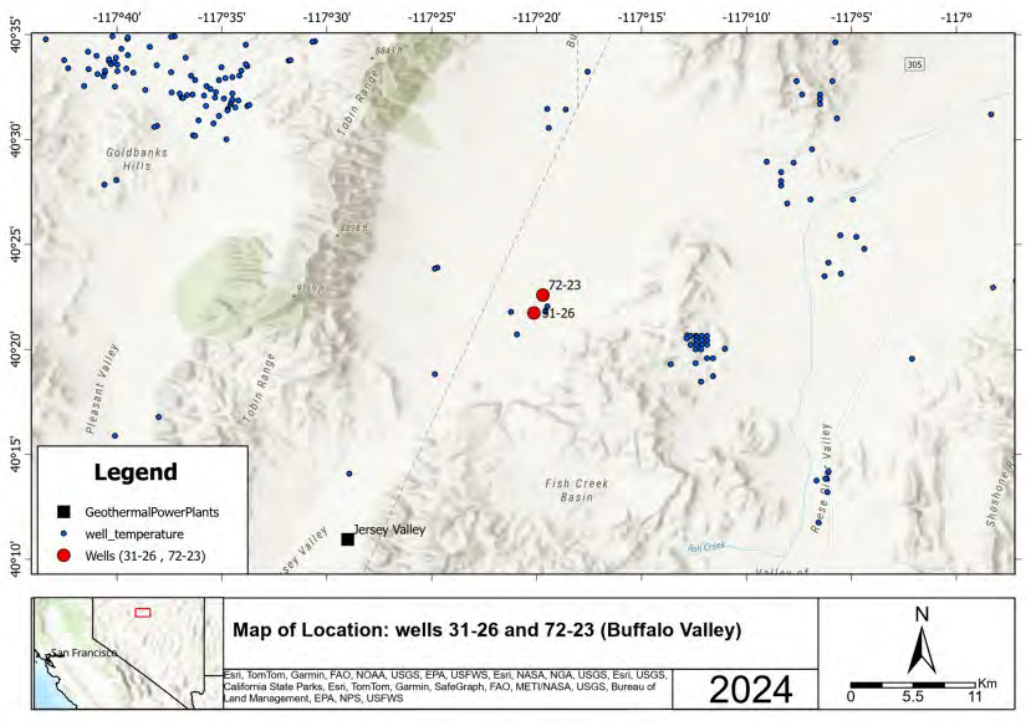

Figure 1. Map location wells BV 31-26 and BV 72-23.

To provide additional support for this PFA confirmation work, Teverra calculated and evaluated heat flow for the Buffalo Valley slim holes, using the temperature logs from the two wells, BV 31-

26 and BV 72-23, using traditional equilibrium temperature heat flow calculation methodologies (Beardsmore and Cull, 2001). As an additional test, the Virgin Rock Temperature (VRT) was calculated using the Horner plot method and compared to the supplied temperature logs. A sensitivity analysis was performed to determine heat flow uncertainty. Finally, temperature measurements from previous studies (Sass et al., 1976) were compared with the deep temperature logs for exploration insight and guidance development for the exploration workbook.

2. Methodology

Data available for this work included shallow (~125 m deep) temperature logs, 2 deeper (500 – 1000 m deep) slim holes, wells BV 31-26 and BV 72-23 with equilibrium temperature logs, and core samples for thermal conductivity measurements from the respective deeper slim holes. Given these data, equilibrium heat flow values were calculated for the deep slim holes and were used to establish regional thermal regime context. Equilibrium heat flow calculation was completed using the 1D heat conduction equation (Beardsmore and Cull, 2001). Detailed calculation methodology for the respective heat flow components is provided within each data section. Heat flow uncertainty was calculated based on the variability of geothermal gradient, thermal conductivity, and the variability of heat flow within the respective lithologies. Furthermore, applicability of deep versus shallow temperature data were examined, comparing the shallow temperature logs with the slim hole temperature logs.

2.1 Heat Flow Calculation

Heat flow is the rate at which heat is transferred from the Earth's interior to the surface (equation 1). Regional heat flow calculations are often simplified to 1D, utilizing multiple assumptions about the input data and the local subsurface conditions. Assumptions include: 1) conductive geothermal gradient, 2) constant heat flow within the near surface, 3) no thermal disturbance within the temperature data, 4) homogeneous thermal conductivity within individual lithologies. Utilizing these assumptions, heat flow can be calculated for individual lithologic sections, and variability between lithology sections show measurement uncertainty.

$$Q = dT/dz * k \quad (1)$$

Where:

Q = Heat Flow, mW/m^2

dT/dz = Geothermal Gradient, °C/km

k = Thermal Conductivity, W/m*k

2.2 Temperature Data

The primary temperature data used to calculate geothermal gradient for heat flow include temperature logs from the two exploration slim holes in Buffalo Valley, wells BV 31-26 and BV 72-23. These wells have multiple temperature – pressure surveys and lithology logs for stratigraphic correlation (Figure 2). The multiple temperature logs were collected at various times since drilling, which does show a re-equilibrating of the wellbore after drilling. The multiple temperature measurements enable thermal numerical modeling of the wellbore to estimate virgin rock temperature (VRT) following the Horner method (Ali et al., 2006; Beardsmore & Cull, 2001),

which is discussed later. Additionally, these temperature logs were examined for regionally representative geothermal gradient sections to use directly for heat flow calculations.

A geothermal gradient is considered regionally representative if it is deep enough to: 1) not be disturbed by climatic signals, 2) sufficiently separated from any known anomalous subsurface features such as hot springs 3) has no clear indicators of inter-borehole fluid flow and 4) contains a conductive gradient section, preferably 50 m in length (Richards et al., 2012). A regionally representative gradient is desired for heat flow calculations so that the heat flow represents the regional thermal regime and can then be compared to other regional data to comparatively rank potential thermal resource. A conductive geothermal gradient is identified within a temperature log as a temperature that is increasing linearly with depth. Both wells have large sections with conductive geothermal gradients, sufficient for heat flow calculation.

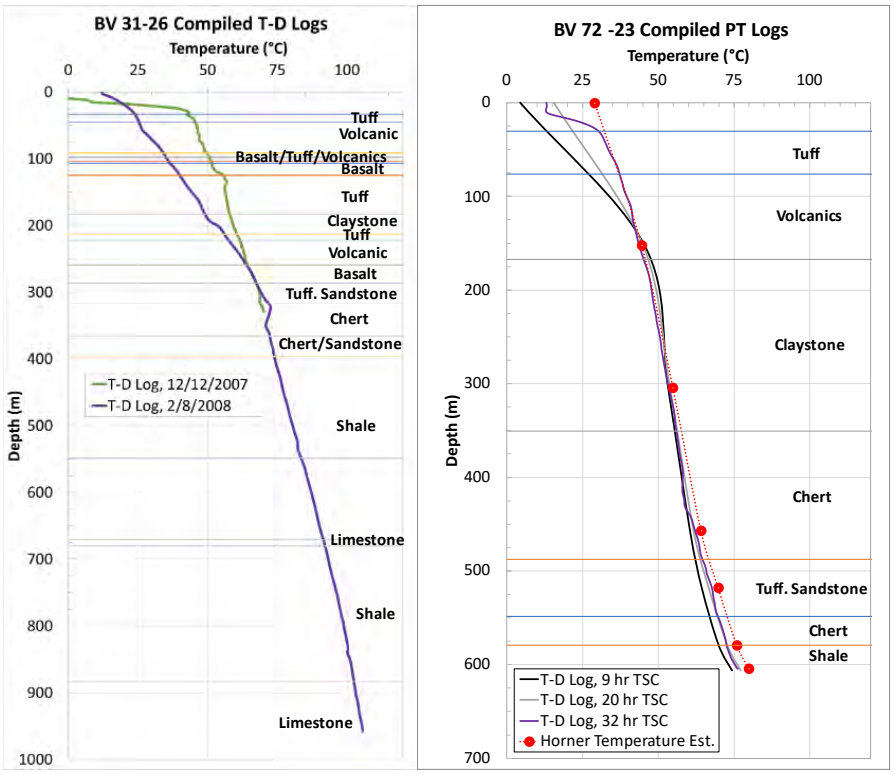

Figure 2. Temperature logs and associated lithologies for BV 31-26 (Left) and BV 72-23 (right).

Geothermal gradient is the change in temperature with depth within the Earth's subsurface. As stated previously, a conductive geothermal gradient is visualized in a temperature log as a linear increase in temperature with depth. Geothermal gradient, as the derivative of the temperature versus depth, will be a constant value with depth. Geothermal gradient is dependent on the thermal regime, specifically the heat flow and the thermal conductivity of the specific lithology. For both wells, the geothermal gradient starts high, above 100 °C/km and gradually decreases. In well BV 72-32, there is a section from ~100 – 350 m with relatively consistent thermal gradient, although more variation. In well BV 31-26, the thermal gradient between 300 and 1000 m is more consistent, showing variations correlated to lithology, with an average of 55 °C/km (Figure 3).

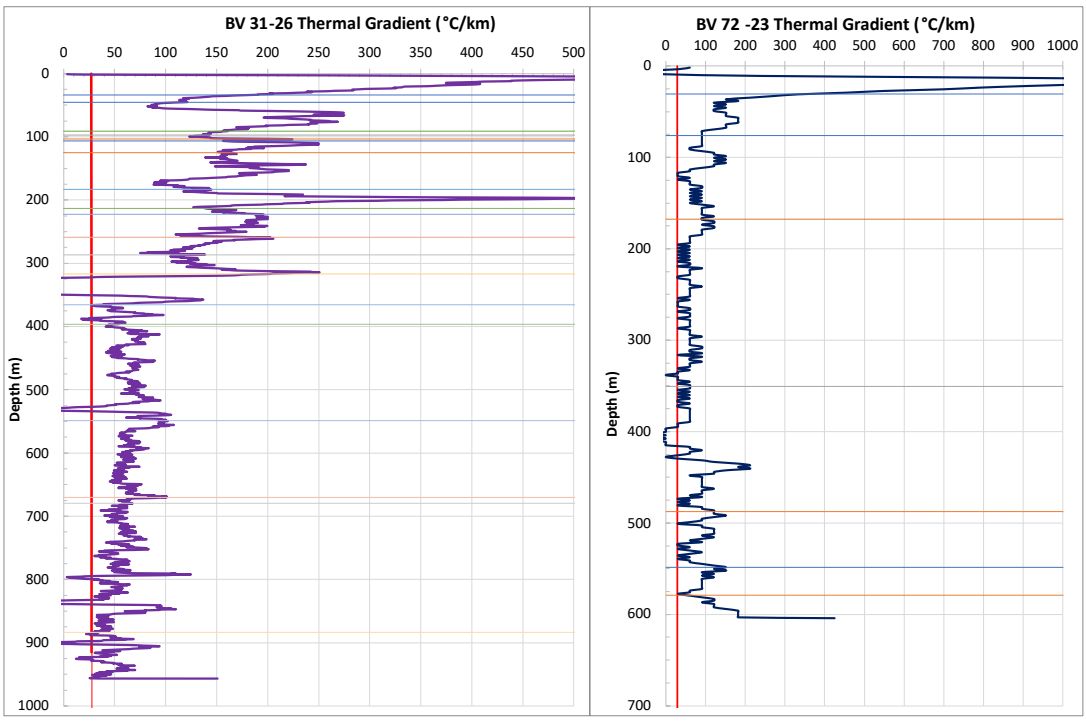

Figure 3. Thermal gradient BV 31-26 (left) and BV 72-23 (right). The red line represents a gradient of 27 °C/km.

2.3 Thermal Conductivity

Thermal conductivity is the rate at which heat is transferred through a material. For heat flow calculations, the material heat is traveling through are the respective lithologies encountered within the wellbore and documented on the lithology log. Thermal conductivity of rocks (and other materials) can be measured using multiple different methods and if often sample availability dependent. For rocks, thermal conductivity varies based on petrologic factors such as mineral composition, porosity, pore fluid, temperature, and pressure, which can vary significantly within a given rock type such as sandstone (Beardsmore and Cull, 2001). As such, measured thermal conductivity from rock samples within wellbores with temperature logs is the preferred method to increase accuracy of heat flow measurements. When rock samples aren't available, thermal conductivity is estimated based on previously measured values, introducing significant opportunity for uncertainty and heat flow calculation error.

For wells BV 31-26 and BV 72-23, both lithology logs and rock samples were available and were utilized for thermal conductivity measurement and heat flow calculation. Rock samples were collected from the major rock types and thermal conductivity was measured using the divided bar measurement device. Measurements were performed at the SMU Geothermal Laboratory, with samples being run a minimum of two times for repeatability and measurement uncertainty analysis (Richards, 2024). Where no rock samples were able to be acquired, generic rock type thermal conductivity estimates were used (Beardsmore and Cull, 2001). Lithology logs for wells BV 72-23 and BV 31-26 are presented in Table 1 and Table 2, respectively, and measured thermal conductivity for relevant rock types, Table 3. Note rock samples from specific lithologies were encountered in both wells. Uncertainty assessment was performed for lithologic groups from both wells to increase statistical significance and total number of thermal conductivity measurements

per lithology. Figure 4 shows the thermal conductivity values as a function of lithology and depth of the wells BV 72-23 and BV 31-26 that were utilized for heat flow calculations. As seen in Figure 4, thermal conductivity from the rock samples was propagated throughout the depth of the associated rock formation. Note that rock samples were not able to be collected from all lithologies.

Table 1: Lithology BV 72-23

From MD (m)	To MD (m)	Total Thickness (m)	Lithology	Short Description/Formation
30.5	76.2	45.7	Tuff	Fish Creek Mtn tuff
76.2	167.6	91.4	Volcanics	Ash/Volcanic breccia
167.6	350.5	182.9	Clay/Claystone

2.4 Horner Plot Analysis

The Horner plot method is a graphical technique used to determine the virgin rock temperature (VRT) in a borehole. VRT is the temperature of the undisturbed rock mass at the depth of the borehole in which temperature was measured. The method is based on the principle that the temperature of a borehole will approach the VRT as the borehole equilibrates with the surrounding rock mass (Ali et al., 2006; Beardsmore & Cull, 2001). Since originally discovered, several equations have been tested to calculate VRT (Lachenbruch and Brewer, 1959; Cao et al., 1988).

The Horner plot method involves plotting the bottom-hole temperature (BHT) of the borehole against the time elapsed since drilling or other activities that may have disturbed the temperature of the rock mass. The BHT is measured at several time intervals over days or weeks. The resulting plot will typically show an initial rapid increase in temperature followed by a gradual approach to a constant value. The VRT is estimated by extrapolating to “infinite” time since drilling.

The Horner plot method is a simple and effective way to estimate the VRT in a borehole. However, it is important to note that the method is only valid in boreholes with conductive thermal regimes (i.e., no significant fluid flow within the wellbore), and can only accurately be calculated with a minimal of 3 temperature versus time data points, preferably with more that show the logarithmic thermal warming (Deming, 1989).

Well 72-23 provided values of temperature logs at different times, which was sufficient to evaluate the virgin rock temperature (VRT). Table 4 shows the values of depth and temperature. Two methodologies of Horner style corrections were tested using the time-series of temperature logs within B 72-23, Cao et al. (1988) and Lachenbruch and Brewer (1959).

Table 4: Temperature logs at different times Lithology BV 72-23

3. Results

Utilizing the available data, heat flow was calculated for the wells BV 31-26 and B 72-23, including an estimation on measurement error. In addition to heat flow and measurement error, VRT calculations were made and analysis performed to examine shallow temperature data, deep temperature data, and VRT versus temperature logs.

3.1 Heat Flow

Geothermal gradient was calculated from the temperature logs provided for BV 31-26 and BV 72-23 and thermal conductivity was measurement for rock samples collected for the two wells. For both wells, the heat flow anomalously high in the upper section from approximately 0 to 400 m. In BV 31-26, there is a consistent heat flow of 89 ±36 mW/m² from 400 m to 900 m. In BV 72-23, there is a consistent section of heat flow of 125 ±41 mW/m² from 130 m to 350 m (Figure 5). Both wells show these sections of relatively consistent geothermal gradient and respective heat flow, although there is a high standard deviation associated with these sections. The high standard deviation is particularly high. Here, we attribute this high uncertainty value to the large spikes in geothermal gradient within the wellbore. These small spikes are likely minor zones of flow or

minor lithology changes that cause a drastic increase in gradient. These large fluctuation zones were not examined in detail since this region and this work was meant to build regional setting. Note that both wells increase in heat flow at the base of the wellbores. In BV 31-26, this could be an artifact of being at the base of the wellbore and logging procedure of sitting on the bottom of the well. For BV 72-23, there is a clear increase in calculated heat flow, which is variable. This could be an indication of recorded fluid flow, indicating that the base of BV 72-23 may not be in a conductive thermal regime.

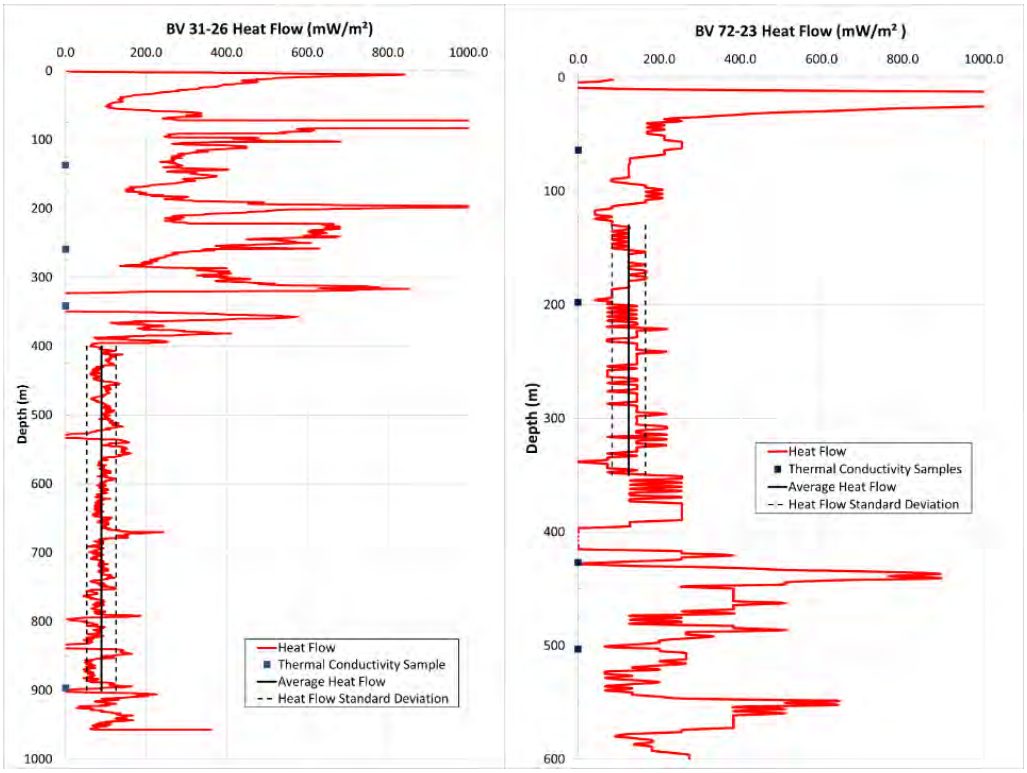

Figure 5. Calculated heat flow values for wells BV 31-26 (left) and BV 72-23 (right).

3.2 Virgin Rock Temperature Calculations

Figure 6 shows the virgin rock temperature results with the Hermanrud, Cao, and Lerche method. However, that method is also one of the least precise. The Horner method (Lachenbruch & Brewer, 1959) is considered more precise based on an observed similarity in the behavior of *in situ* temperature and pressure when disturbed by drilling. Figure 7 shows temperature plotted against Ln(1+(tc/dt)) to calculate the VRT. A straight line of best fit through all points from the same depth yields the VRT for that depth at the temperature axis intercept.

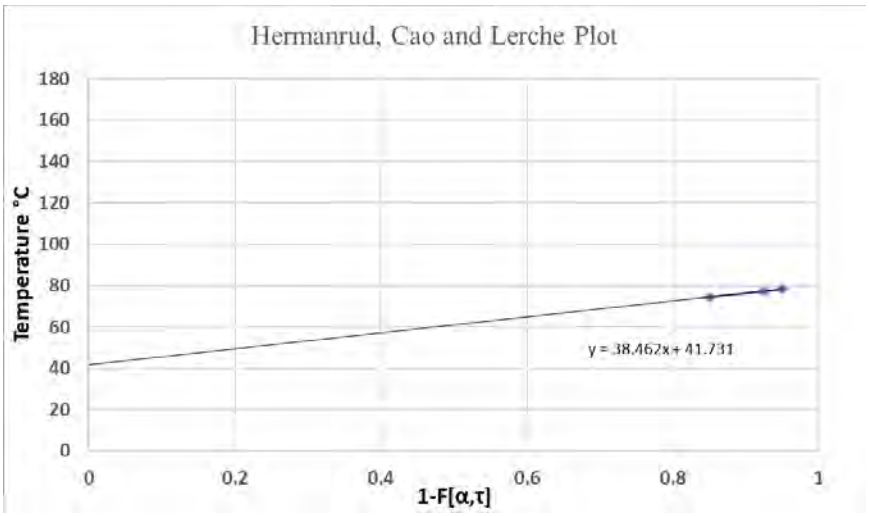

Figure 6. Hermanrud, Cao, and Lerche method BV 72-23.

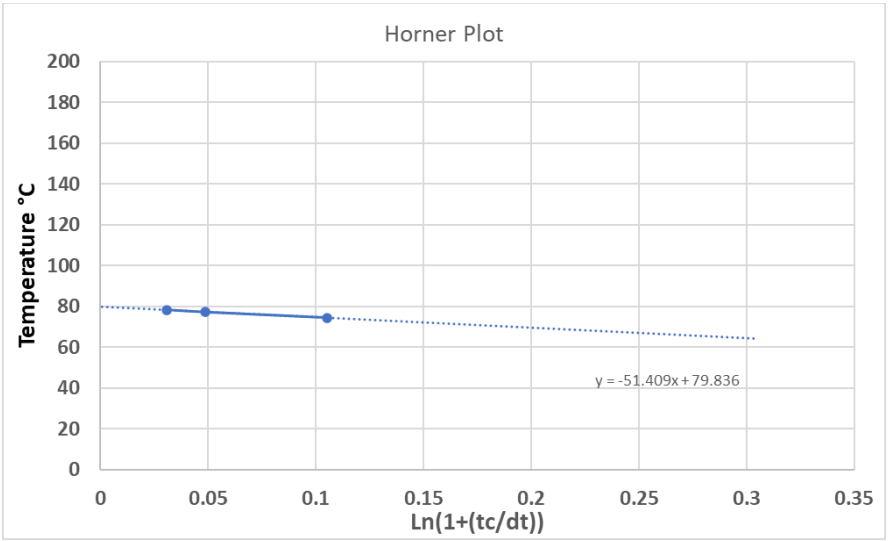

Figure 7. Horner Plot BV 72-23.

The temperature measurements of variable depth were compared to the deeper 72-23, as well as VRT calculations versus the existing temperature logs. Analysis shows a nominal increase in VRT compared to temperature logs collected shortly after drilling. VRT in BV 72-23 was greater than the measured bottom hole temperature by only 6% and 2% after 9 and 32 hours since drilling fluid circulation, respectively (Figure 2). In this specific location and exploration circumstance, wait time between drilling and logging could be reduced without accuracy compromise. This implies that the calculation of VRT may be unnecessary in some exploration scenarios.

4. Comparison of Deep and Shallow Temperature Measurements

Similar to VRT, existing shallow temperature data were compared to the two deeper wells in Buffalo Valley. These shallow nearby temperature measurements were in the upper 175 m and all have linear gradients, suggesting they are in a conductive thermal regime, and may represent regional heat flow. When compared with deep wells, though, the shallow gradients are

significantly higher than the interpreted background geothermal gradient (Figure 9). This is a similar result produced here where BV 31-26 shows a high heat flow anomaly in the shallow subsurface from 0 - 300 m depth. The key challenge identified here is how exploration activities can identify a regional thermal anomaly or a local geothermal system related thermal anomaly.

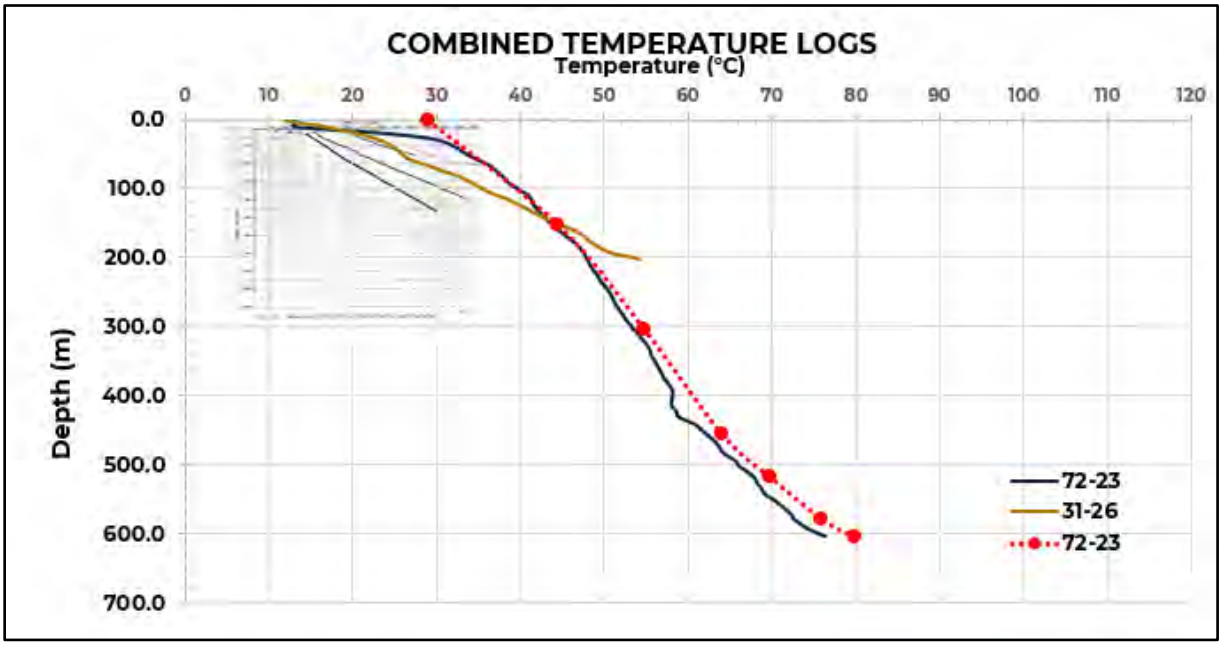

Figure 8. Combined temperature logs compared with Horner values (Well BV72-23).

CONCLUSIONS

This study calculated heat flow for two wells (BV 31-26 and BV 72-23) as part of the INGENIOUS project. Temperature logs and lithology were analyzed to determine geothermal gradient, measure thermal conductivity, and calculate heat flow values. As part of this work, comparison was made between the deep temperature logs discussed here with other existing, shallow temperature data within the Buffalo Valley region. This comparison was made to develop additional insights and recommendations for exploration procedures moving forward.

The temperature measurements of variable depth were compared to the deeper BV 72-23, as well as virgin rock temperature calculations versus the existing temperature logs. Two observations were made to be included in the INGENIOUS exploration workbook. First, virgin rock temperature is nominally higher than temperature logs collected shortly after drilling, increasing by only 6% and 2% after 9 and 32 hours since drilling fluid circulation, respectively. This infers that the calculation of virgin rock temperature may be unnecessary in some exploration circumstances and wait time between drilling and logging may be reduced without accuracy compromise. This should be further examined. Second, shallow nearby temperature measurements in the upper 175 m all have linear gradients, suggesting regional heat flow, but these gradients vary significantly from what is interpreted as background, which could erroneously highlight this area as an exploration target. Further analysis will be performed of this observation to determine how best to incorporate this comparison knowledge.

ACKNOWLEDGEMENTS

The INGENIOUS project is funded by the U.S. Department of Energy Geothermal Technologies Office under award DE-EE0009254 to the University of Nevada, Reno. Teverra performed this work as a subcontract on the INGENIOUS grant. Any use of trade, firm, or product names in this paper is for descriptive purposes only and does not imply endorsement by the U.S. Government. The authors thank Quentin Burgess, Maria Richards, Dr. Cary Lindsey and others on the INGENIOUS team for discussion that contributed to this work. Maria Richards performed the thermal conductivity measurements that were input for these heat flow calculations.

Microseismic, induced seismicity, fiber optic sensing, offset pressure monitoring

ABSTRACT

The Cape Modern project, a next-generation Enhanced Geothermal System (EGS) field, is being developed in Southwest Utah. The initial phase of the project involved the stimulation of three horizontal wells using a plug-and-perf hydraulic stimulation technique. To ensure comprehensive monitoring of induced seismic activity associated with EGS operations, an extensive microseismic network was deployed, comprising shallow borehole sensors, a surface nodal array, deep borehole fiber optic sensors, and 3-component (3C) passive sensors. A key observation from this setup was that the high-precision double-difference-based locations derived from the sparse regional shallow borehole array provided spatial resolution comparable to that of the deep borehole sensors, achieving accuracy down to a few hundred feet in real-time during injection operations. The high-resolution microseismic data from the deep borehole fiber optic-based Distributed Acoustic Sensing (DAS) revealed extensive linear features reactivated during the stimulation process. Interestingly, the orientation of these linear features was misaligned with the maximum horizontal stress (SHmax) orientation, suggesting the reactivation of preexisting natural fractures, faults, or lithological boundaries within the host rock and intrusive bodies. During the operations, a total of five seismic events with magnitudes greater than 2.0 were recorded, necessitating the activation of the Traffic Light System (TLS). Injection had to be paused three times out of the five, while the other two events occurred when there was no active injection. The largest event was measured at a local magnitude of 2.3, according to the USGS ComCat catalog. Importantly, ground motion levels near the nearest town remained low, well below the threshold likely to cause any noticeable effects or damage. Following each amber-level alert, seismicity levels returned to normal, indicating the effectiveness of the TLS in managing induced seismicity. This highlights the importance of real-time monitoring and responsive management in mitigating seismic risks during geothermal operations, ensuring minimal impact on surrounding communities.

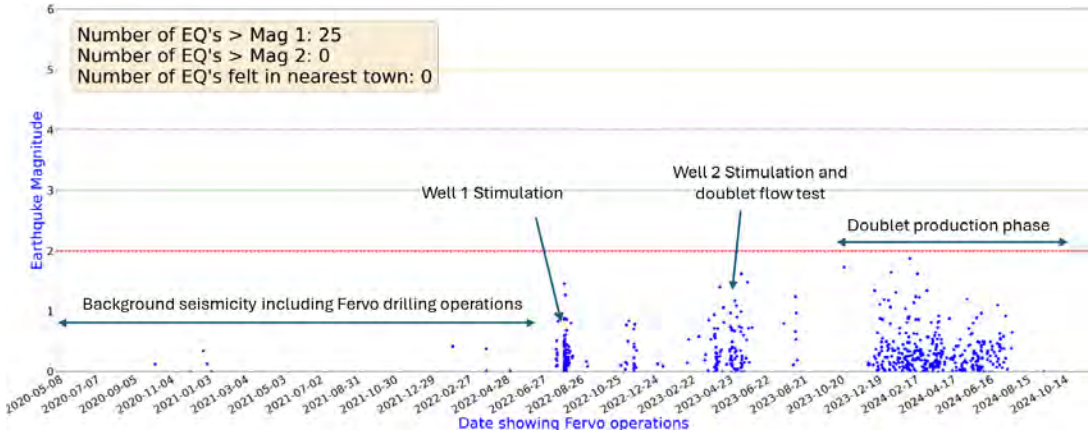
1. Introduction

A recent commercial liftoff report by the Department of Energy (DOE) estimated a substantial opportunity for next-generation geothermal energy, projecting a potential capacity of 2-5 GW by 2030 and up to 125 GW by 2050 (Blankenship. D., 2024). Realizing this potential will necessitate breakthrough innovations in drilling, stimulation techniques, resource identification and characterization, and risk mitigation. This paper focuses on seismic monitoring while optimizing Enhanced Geothermal Systems (EGS) in horizontal wells stimulated using plug-and-perf techniques—a method extensively tested and proven in the Unconventional Oil and Gas industry

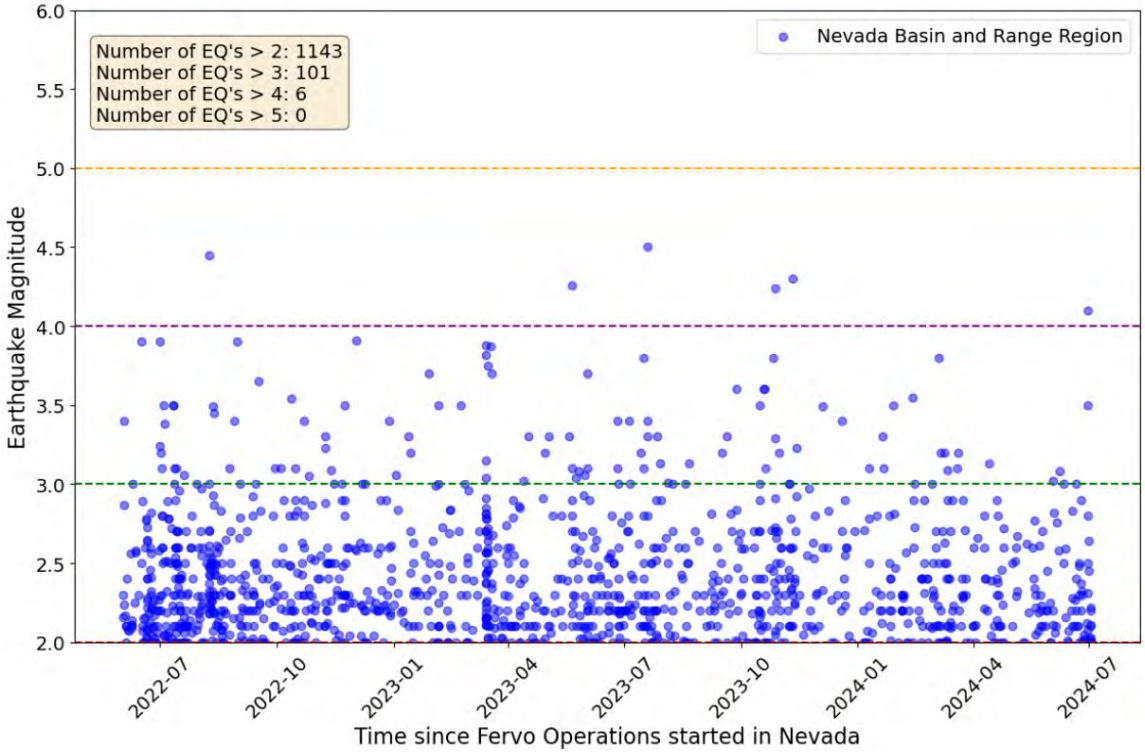
A crucial aspect of the monitoring program involves mitigating induced seismicity. The primary mechanisms identified to cause induced seismicity include direct pressure increases in faults, poroelastic stressing, and thermoelastic stress changes (Buijze et al., 2019). Direct pressure increases occur when fluid injection or production alters the pore fluid pressure within a fault. This pressure change reduces the effective normal stress on the fault, potentially bringing it closer to failure. The elevated pressure can diffuse away from the injection site over time, potentially inducing seismic events at the edge of the faults and even after the injection has stopped. This mechanism is particularly important in fractured rock masses, where fluid flow is dominated by fractures, leading to pressure diffusion and seismicity over larger areas (Deichmann et al., 2014). Poroelastic stressing refers to the stress changes within and around a pressurized rock volume due to changes in pore pressure (Segall & Fitzgerald, 1998, Mossop & Segall, 1997). This mechanism results in volumetric strain of the rock mass, which can either compress or expand the rock, depending on the location relative to the pressure source. This stress change can lead to fault reactivation, especially in areas where the initial stress state is near critical failure. Thermoelastic stress changes occur due to temperature differences between injected fluids and the surrounding rock, leading to thermal contraction or expansion of the rock mass. This thermal strain induces additional stress changes, which can contribute to fault instability. For example, the cooling of the rock around a reinjection well can reduce the total stress, making faults within and near the cooled volume more prone to seismic slip (Rutqvist et al., 2015).

The potential for induced seismicity is highly site-specific and depends on factors such as lithology, depth, and proximity to critically stressed faults. Norbeck and Latimer (2023) successfully demonstrated the feasibility of a commercial-scale, first-of-its-kind Enhanced Geothermal System (EGS) utilizing a horizontal doublet well design. The project, carried out by Fervo Energy in northern Nevada, involved drilling and stimulating horizontal wells within a high-temperature geothermal reservoir. The EGS development phases included drilling, stimulation, and a 37-day flow test, which confirmed the hydraulic connectivity between the wells. The seismic activity throughout the entire operation remained below magnitude two, indicating that the innovative approach to geothermal energy extraction can be achieved with minimal seismic risk (Norbeck & Latimer, 2023). Seismicity during the initial drilling, stimulation, and flow test phases was thoroughly examined by Dadi et al. (2024), where all recorded seismic events were found to be below magnitude 2. The seismicity continued to be monitored beyond the flow test phase, encompassing the production phase that began in October 2023 and extended through to July 2024. Throughout this period, all seismic events remained under magnitude 2, with the largest recorded event near the Fervo Doublet registering a local magnitude of 1.87 (Figure 1a). Significantly higher number of seismic events with magnitudes greater than 2, 3, and 4 are observed in the Nevada Basin and Range, which are attributed to natural processes and other anthropogenic activities such as mining, distinct from the EGS operations at the Fervo site (Figure 1b). This comparison

highlights the relatively low seismic impact of the Fervo Doublet operations in contrast to the broader regional seismicity.



(a)



(b)

Figure 1: (a) Seismicity recorded near the Fervo Doublet in northern Nevada from July 2022 to July 2024. The plot shows the number of earthquakes (EQs) with magnitudes greater than 2.0, 3.0, 4.0, and 5.0. Despite ongoing geothermal operations, including drilling, stimulation, and production phases, all recorded events remained below magnitude 2.0, indicating minimal induced seismicity associated with the Enhanced Geothermal System (EGS) activities. (b) Seismicity in the Nevada Basin and Range region over the same period, highlighting a higher frequency of seismic events with magnitudes exceeding 2.0, 3.0, and 4.0, which are primarily attributed to natural seismic processes and other anthropogenic activities like mining.

Microseismic monitoring also plays a crucial role in optimizing Enhanced Geothermal System (EGS) operations, particularly in refining completion designs that involve key parameters such as stage length, the number of clusters, perforation designs, fluid injection volumes per stage, and fluid types. To determine the most effective completion parameters, design of experiments methodologies is often employed alongside a tailored monitoring program. The EGS system design and deployment framework we seek to pioneer encompasses four critical phases: (1) resource identification and optimal planning and drilling of wells, (2) stimulation of wells to establish hydraulic connectivity, (3) injection and crossflow tests to validate system productivity, and (4) the production phase. Effective monitoring across all phases is essential to defining and optimizing the EGS system.

Advanced monitoring tools are increasingly being used to enhance EGS efficiency. These include pressure diagnostics such as Instantaneous Shut-In Pressure (ISIP), offset pressure monitoring, and sealed wellbore monitoring; fiber optic sensing for temperature and low-frequency strain measurements (Titov et al., 2024); and microseismic monitoring using multi-well Distributed Acoustic Sensing (DAS) (Dadi et al., 2024) and 3-component (3C) geophones. For instance, pressure measurements provide critical insights into the fracture gradient of the reservoir, the Volume to First Response (VFR) required to generate hydraulic fractures that propagate to offset wells, and fracture propagation velocity. Microseismic monitoring, on the other hand, is instrumental in characterizing the stimulated rock volume, fracture morphology, and out-of-zone injection, which could elevate the risk of induced seismicity.

In this paper, we present findings from microseismic monitoring of three horizontal wells, utilizing data from shallow borehole arrays, deep borehole fiber optics, and 3C geophones. The performance of the shallow borehole array, installed at 23 locations by the University of Utah and Fervo, is compared with results obtained from multi-well DAS-based microseismic data. Additionally, we discuss how real-time monitoring, in conjunction with a predefined Traffic Light System (TLS) and effective communication with the operations team, successfully mitigated induced seismicity during the stimulation of the three horizontal wells. The stimulated wells underwent successful flow testing in July and August 2024; however, the detailed flow results and seismicity data from this period are beyond the scope of the present paper. These findings will be comprehensively reported in a subsequent publication.

2. Geologic setting

Cape Modern is located adjacent to the Utah FORGE site in Milford Valley, Utah. The reservoir comprises granitic basement rocks, including granite, granodiorite, diorite, and Precambrian gneiss. Figure 2 displays a fault map of the area near Cape Station, highlighting three main fault structures: the Opal Mound Fault, the Mag Lee Fault, and the Mineral Mountains West Fault System. The Mineral Mountains West Fault System has a surface expression visible on LiDAR and terminates south of the area of interest (Fercho et al., 2024).

The drilling campaign at Cape Modern included a deep vertical monitoring well (Delano 1-OB) and four deep horizontal wells (Frisco 1-I, 2-P, 3-I, 4-T), as shown in Figure 3. The Frisco 1-I and 3-I wells serve as horizontal injectors, while the Frisco 2-P and 4-T wells function as producers. The injector wells are deeper than the producer wells. The vertical monitoring well is drilled deeper than both the injectors and producers and is equipped with a permanent fiber optic cable behind

the casing and a pressure gauge outside the casing at the reservoir depth. This vertical well extends further down to record microseismic data significantly deeper than the horizontal wells.

The project utilized three-dimensional geologic and temperature models derived from existing data from the nearby Blundell and FORGE wellfields, which were iteratively updated with new drilling results. The orientations of the horizontal wells were guided by the maximum horizontal stress (SHmax) indicators from adjacent wells, indicating a consistent SHmax of 10°-15° (NNE) across the field (Figure 4). SHmax refers to the direction of the maximum horizontal compressive stress in the Earth's crust. Understanding SHmax is crucial because it influences the orientation and propagation of induced fractures during hydraulic stimulation. By aligning wells approximately perpendicular to SHmax, we maximize the effectiveness of the fracturing process, as fractures tend to open and propagate perpendicular to the minimum principal stress direction. This approach enhances the connectivity of the fracture network, which is essential for efficient geothermal energy extraction. In our case, the wells were oriented at angles of 75°–80° relative to SHmax, which is close to perpendicular. This slight deviation from the ideal 90° was due to operational constraints and geological considerations, but it still effectively enhances fracture development. The stratigraphy at Cape ranges from Miocene basin-fill deposits to granitic basement rocks. A comprehensive 3D geologic model was developed and refined using well logs, gravity profiles, and cuttings analyses, providing critical insights for well targeting and improving model accuracy with each drilled well (Figure 3).

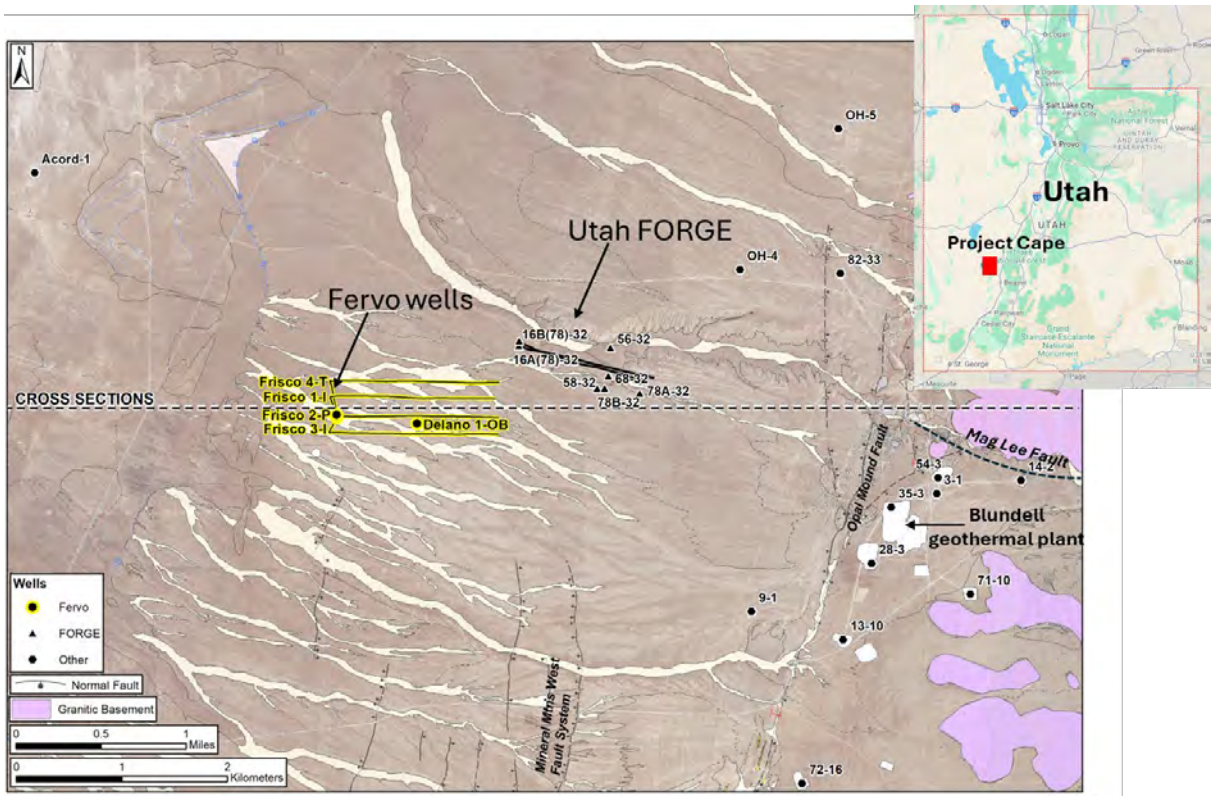


Figure 2: Map view of the Frisco wells, Delano 1-OB vertical observation well, Utah FORGE wells and the Blundell geothermal plant wells. The wells of interest in this paper are the Frisco 1-I, Frisco 2-P and the Frisco 3-I wells. In the figure, the Frisco and Delano wells are highlighted in yellow. The Utah FORGE wells are represented by solid triangles, while the Blundell wells are depicted as solid circles

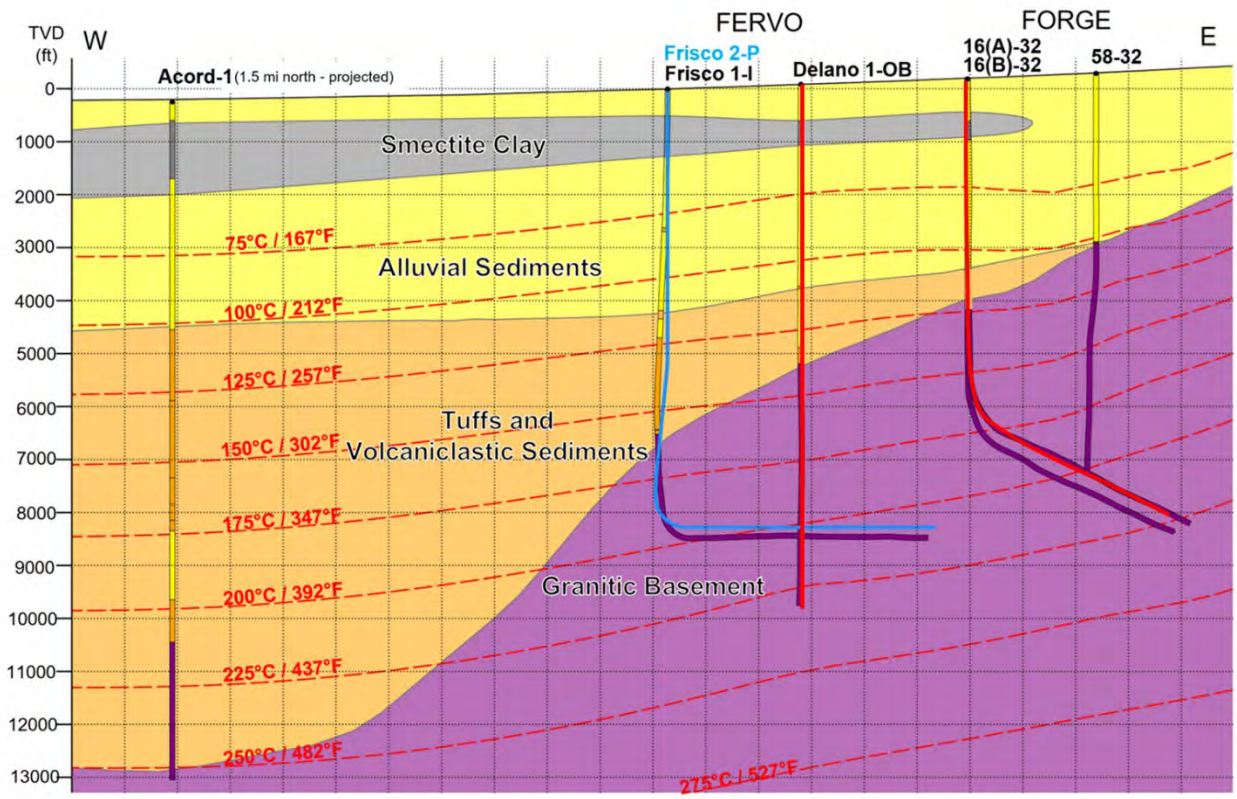

Figure 3: Cross section view of the Frisco wells, Delano 1-OB well and the FORGE wells. The red lines show the fiber optic cables permanently installed behind casing on the Delano 1-OB and the 16B well. Data from both the fiber optic cables along with a 3C sensor in 56-32 are used for microseismic monitoring.

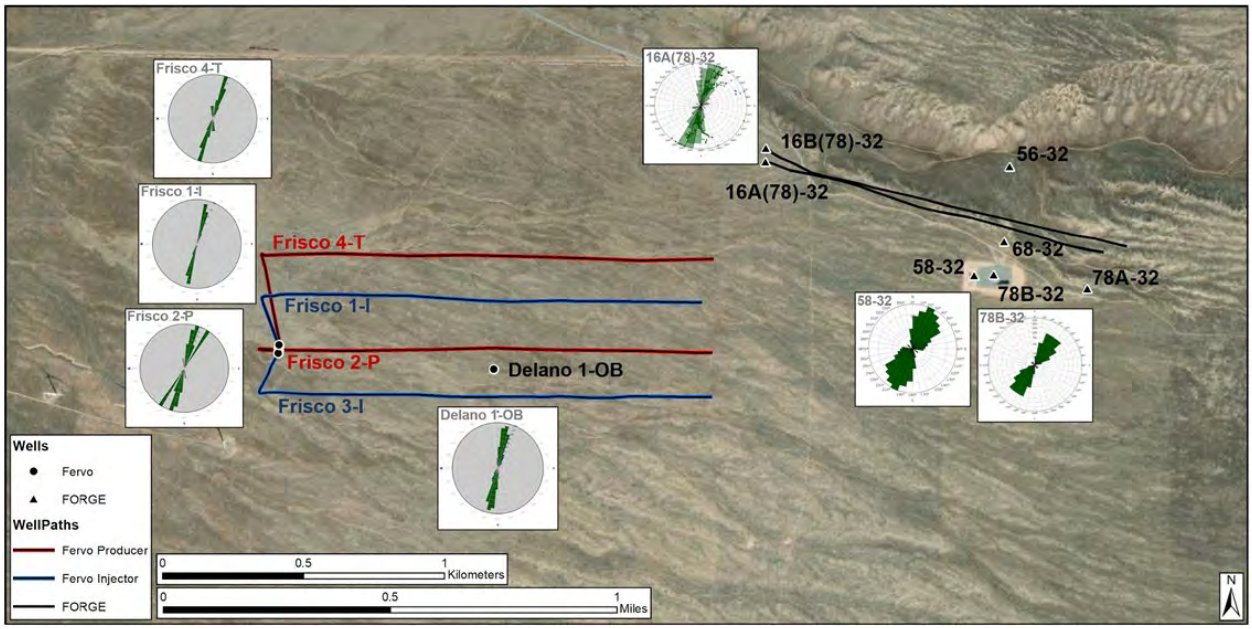

Figure 4: Orientation of the drilling induced fractures in Fervo and Utah FORGE wells showing NNE-SSW orientation representative of the SHmax.

3. Monitoring Acquisition summary

3.1 Shallow borehole array:

A local seismic monitoring network was installed at Cape Station as part of the Utah FORGE project in December 2016 and has been operational since. The network comprises a total of seventeen stations installed by the University of Utah Seismograph Stations (UUSS) and six additional stations installed by Fervo Energy and Berkeley National Lab. The seventeen UUSS stations monitor the Utah FORGE project, while the six additional stations infill the UUSS network and serve as backups in case the UUSS FORGE network fails during critical operations conducted by Fervo.

The seismic monitoring network includes a variety of sensors: fourteen broadband sensors, seven strong motion sensors, and two short-period sensors. These sensors are distributed as shown in Figure 5, spaced approximately 2 km, 8 km, and 12 km from Cape Station. Additionally, there are strong motion accelerometers at the Blundell geothermal plant and Milford High School to measure ground motion both for background levels and during stimulation activities. This comprehensive seismic monitoring network ensures robust data collection and enhances the ability to monitor and mitigate induced seismicity in the area.

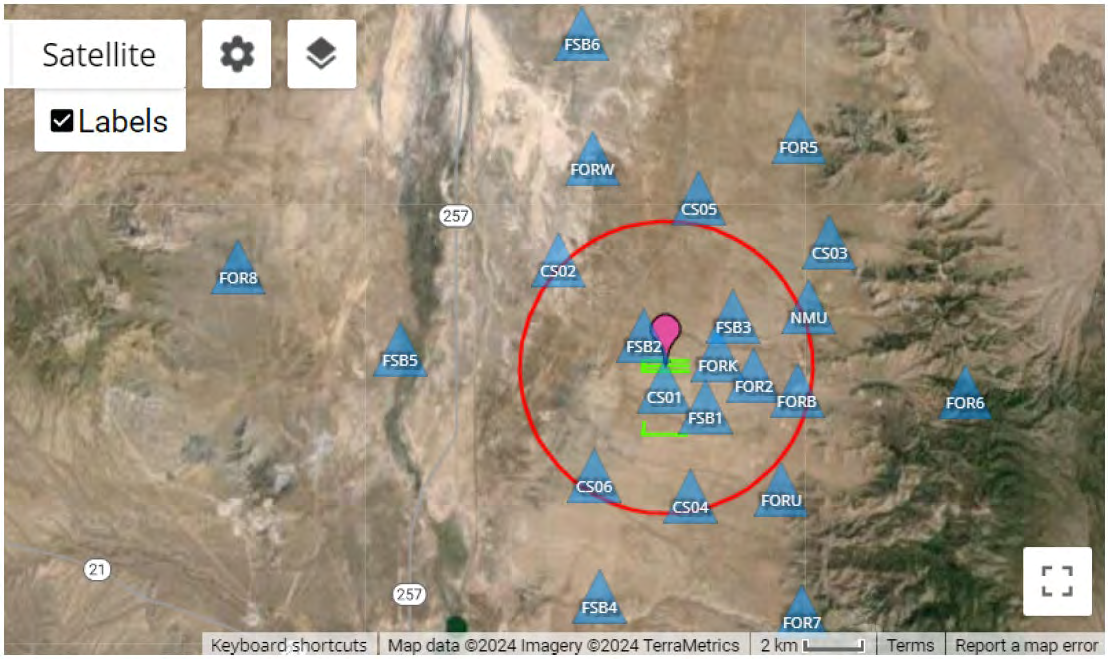

Figure 5: Location of the Shallow Borehole array around the Cape Modern area. The green lines are the drilled Fervo horizontal wells. The red circle shows the 5 km buffer area where the Traffic Light System is active.

3.2 Deep Borehole Fiber Optic DAS and 3C geophones

Two permanent fiber optic cables, installed behind the casing in the Delano 1-OB and 16B wells (shown in red in Figure 3), are used to detect microseismic events. Additionally, a passive 3C

sensor is located in the 56-32 FORGE well (not shown here). During the stimulation of Frisco 1-I, a temporary wireline fiber was deployed in the horizontal Frisco 2-P well. Similarly, a temporary disposable fiber was deployed in the Frisco 3-I well. However, the deployment in Frisco 3-I achieved only partial success because the bare disposable fiber was not rated for the high temperatures encountered in the well.

4. Operations summary

Out of the four wells drilled at the Frisco site, three—Frisco 1-I, Frisco 2-P, and Frisco 3-I—were stimulated. Each well was stimulated with 27 stages, except for Frisco 2-P, which was stimulated with 28 stages using a plug-and-perf technique. The stimulation was conducted in two phases. The first phase, carried out in February/March 2024, involved the stimulation of all 27 stages of Frisco 1-I, all 27 stages of Frisco 3-I, and 2 stages of Frisco 2-P. Due to operational issues beyond the scope of this paper, the remaining 26 stages of Frisco 2-P were stimulated in June 2024. Notably, stages 10 and 11 of Frisco 3-I and stages 2 and 3 of Frisco 2-P were stimulated using a zipper frac style.

In addition to the stimulations at the Frisco well pad, the Utah FORGE project conducted additional stimulation activities in March/April 2024. The shallow borehole array used for monitoring the regional area was able to detect the microseismic events corresponding to the Utah FORGE stimulations, providing a comprehensive view of the seismic activity in the region.

5. Observations

5.1 Seismic monitoring

5.1.1 UUSS/USGS monitoring:

The Shallow Borehole Network includes stations from both the University of Utah Seismograph Stations (UUSS) and those installed by Fervo/LBNL. UUSS oversees seismic monitoring at the FORGE site and given that Fervo's operations are within a 3 km buffer radius of FORGE, they also monitor seismic activity related to Fervo's operations. All raw waveforms from both UUSS stations and the Fervo/LBNL stations (designated with the 6K* station code) are accessible for download from the IRIS Data Management Center (DMC). UUSS event locations are archived and searchable through the USGS ComCat. Fervo conducts its own real-time seismic monitoring, utilizing both UUSS stations and six additional stations that enhance the UUSS network.
Figure 6 provides a comparison of seismic activity with magnitudes greater than 2 near the Cape Station against seismicity across the Lower 48 states since the beginning of 2024, while Figure 7 presents a similar comparison focused on the state of Utah. All events in this figure were located by UUSS. There have been ten events with magnitudes greater than 2 recorded at the Cape Station in the USGS catalog, with the largest event registering a local magnitude of 2.3. For context, between the start of 2024 and August 26th, when this paper was submitted, there have been 4,952 earthquakes with magnitudes greater than 2 across the Lower 48 states.
Out of all the events shown, UUSS/USGS generated one ShakeMap, as illustrated in Figure 8. The peak ground acceleration (PGA) value for this event in Milford, Utah, was approximately 0.05% g, which is below the commonly accepted lower limit felt threshold of 0.1% g (Richter, 1958).

Fervo proactively engaged with the communities in Milford and Beaver during and after the stimulation activities, and no felt reports were received from these towns.

(b) Magnitude versus time plot for these earthquakes, with red dots representing earthquakes near the Cape Station and blue dots indicating earthquakes in Utah. The duration of the extracted catalog is from the beginning of 2024 to August 26th, 2024.

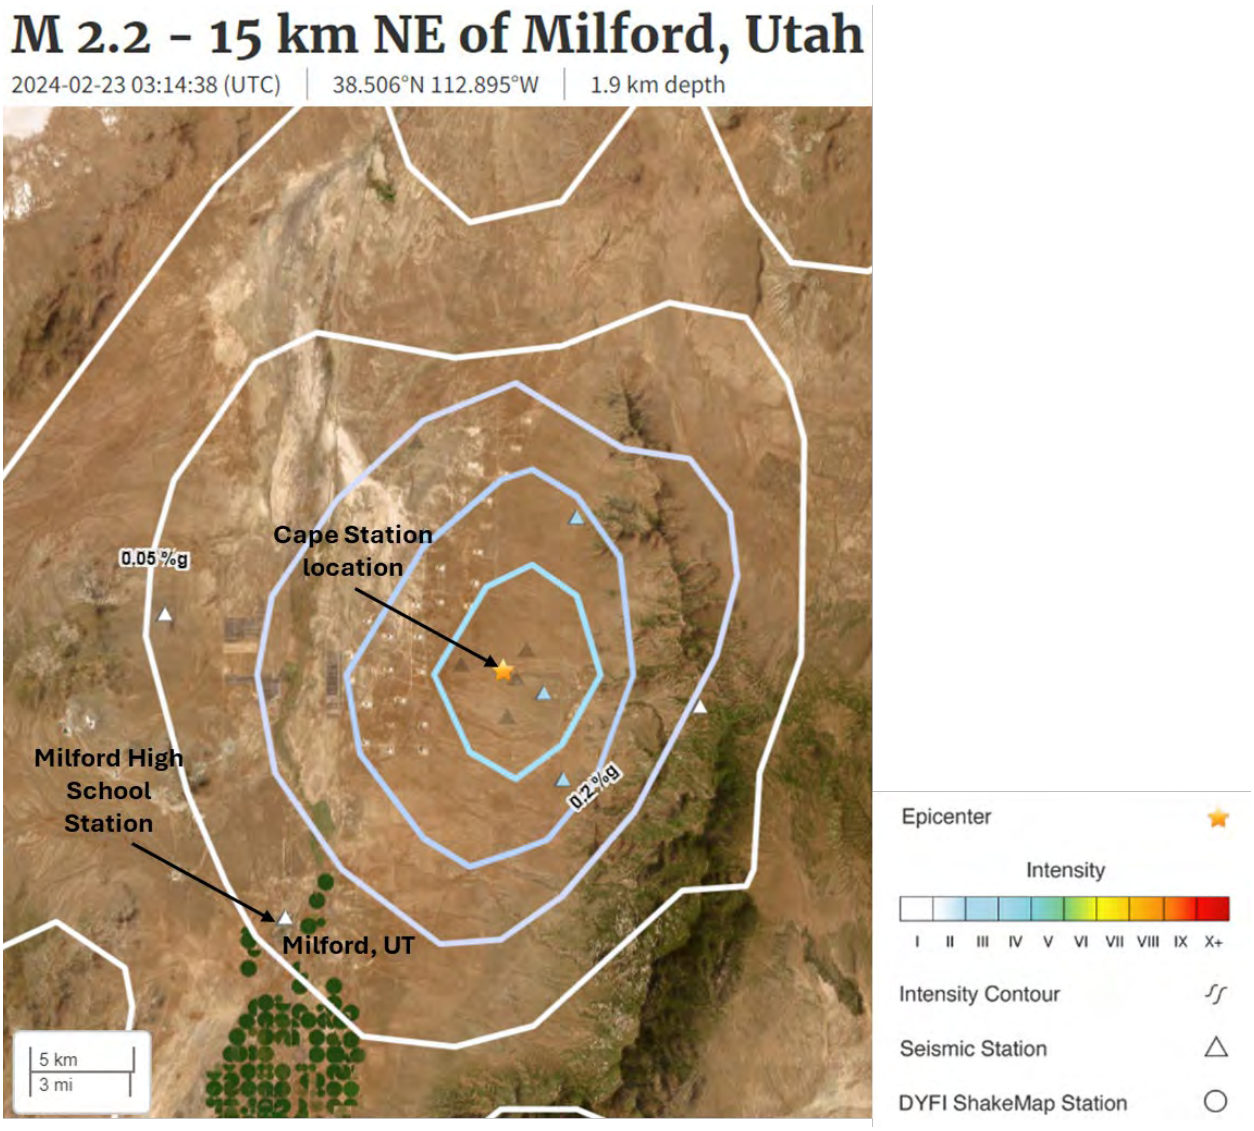

Figure 8: Map showing the location and intensity contours of a magnitude 2.2 earthquake that occurred 15 km northeast of Milford, Utah, on February 23, 2024, at 03:14:38 UTC. The earthquake's epicenter is marked by a star, with surrounding intensity contours illustrating varying levels of ground shaking. The Cape Station and Milford High School seismic stations are indicated on the map, with intensity values recorded at different distances from the epicenter (USGS event ID uu80046841).

5.1.2 Fervo seismic monitoring

Fervo's real-time seismic monitoring is conducted with the assistance of a vendor, resulting in differences in the number of detected events and their estimated magnitudes compared to UUSS monitoring. Fervo's detection thresholds are intentionally set lower to capture smaller magnitude events during drilling activities. For the purposes of this paper, it is important to note that Fervo's magnitude estimates are calculated using slightly different parameters, leading to variations in reported magnitudes. It is well understood that magnitudes of smaller earthquakes can vary depending on the method used for estimation. Through personal communication with UUSS

personnel and a comparison of the methodologies used in the UUSS and Fervo catalogs, several key differences were identified:

1. **Magnitude Estimation Method:** UUSS estimates duration-based magnitudes (Md) for smaller events, typically those below magnitude 1, and uses local magnitudes (Ml) for events greater than magnitude 1. In contrast, Fervo consistently reports local magnitudes for all events.

2. **Calculation Differences:** UUSS calculates local magnitudes following the methodology detailed in Pechmann et al. (2007, BSSA, 97, 557-574), whereas Fervo uses the equation from Hutton and Boore (1987, BSSA, 77, 2074-2094).

3. **Instrument Response Differences:** Differences in the damping constant and static magnification (gain) in the Wood-Anderson frequency response also contribute to variations in magnitude estimates between the two catalogs.

These points highlight some of the reasons for the observed differences, though this is not an exhaustive list. Since the beginning of 2024, the Fervo catalog has recorded seven earthquakes with magnitudes greater than two near the Cape Station area. Of these, five coincided with Fervo's stimulation and injection activities, while two occurred during FORGE injection operations. The two largest events in the Fervo catalog were recorded with local magnitudes of 2.67 and 2.51. Table. 1 shows the PGV and PGA values for the five greater than 2 magnitude earthquakes during Fervo operations. Based on the PGA/PGV thresholds established in the literature, none of the events with magnitudes ranging from 2.09 to 2.65 recorded at the UU.MHS2 station would be felt at the nearest town, Milford, UT. The peak ground accelerations (PGA) are well below the 0.3% g threshold, and the peak ground velocities (PGV) are significantly lower than the 0.1 cm/s felt threshold. Consequently, these events are unlikely to have been perceptible to people in the vicinity (Richter, 1958; Siskind et al., 1980; Worden et al., 2012).

Table 1: Ground motion parameters for seismic events with magnitude greater than two during Fervo operations recorded near the Cape Station. Each table presents peak ground acceleration (PGA) and peak ground velocity (PGV) values across three channels (ENE, ENN, and ENZ) from UUSS station UU.MHS2. The MHS2 station is located at Milford High School in the nearest town to Cape Station.

M_L = 2.65

Channel	Intensity	PGA (cm/s²)	PGV (cm/s)

UU.MHS2.01.ENZ	I	0.2791	0.0024

Fervo employs a predefined Traffic Light System (TLS) to manage induced seismicity, with a green threshold set at magnitude 2 and a red threshold at magnitude 3. This detailed TLS protocol is designed to ensure prompt and effective response to seismic events and a detailed description of

the TLS is included here. Among the five events with magnitudes greater than 2, three occurred during active injection, triggering the TLS and resulting in immediate operational adjustments to mitigate seismic risks. The remaining two events occurred after injection activities had ceased, leading to a suspension of operations in accordance with the TLS guidelines until the required pause period was satisfied. This approach underscores Fervo's commitment to proactive and adaptive management of induced seismicity.

5.2 Seismicity rate analysis with pressure and injection volumes

Prior to the stimulation at the Frisco Pad, the seismicity in the area primarily concentrated near the Blundell Geothermal plant bounded by the Opal Mound fault to the east and the Mag Lee fault to the north. From 2020, there seem to be periods of high- and low-density seismicity which could be due to the occurrence of natural seismicity in the area or some of the stations are occasionally dysfunctional. Based on the seismicity identified on the surface/borehole stations there is no elevated seismicity during the three stage stimulation at 16A(78)-32 in April 2022.

The stimulation of the Frisco 1-I produced significant microseismic activity above the background seismicity level clearly demonstrating the microseismic is due to the stimulation operations (Figure 9). During the stimulation when there is pause in operations as shown by the constant cumulative injection rate (black curve in Figure 10a) there is steep decline in seismicity in a few hours. The pressure gauge at the reservoir level measured reservoir pressure during the stimulation. There is spike in the pressure when the stimulation in Frisco 1-I is nearest to the Delano 1-OB well and the pressure decreases as the stimulation progressed to the heel stages (as shown in the green curve in Figure 10a). A similar but larger spike is observed during the stimulation of the Frisco 3-I stimulation. The larger spike is due to the proximity of the Delano 1-OB observation well to Frisco 3-I well compared to the Frisco 1-I well. The total injected volume and the cumulative seismic moment is correlated very well during the Frisco 1-I and 3-I stimulation. The seismicity rate dropped significantly as soon the stimulation was complete as seen by the flat cumulative seismic moment after the stimulation.

A similar increase in seismicity level was noticed during the Frisco 2-P stimulation during June 2024. During the interval between the two stimulation phases, seismicity levels returned to background levels, except during the FORGE stimulation and an injection test in the Frisco 1-I well. The pressure gauge in the Delano 1-OB well generally shows similar behavior as the Frisco 1-I and 3-I stimulation as there is a spike in pressure when the stimulation is closer to the observation well (Figure 11a). However, the pressure started increasing from the beginning of the stimulation of Frisco 2-P. This suggests a high connectivity of the hydraulic network during the Frisco 2-P stimulation. The cumulative seismic moment during the Frisco 2-P stimulation is also well correlated to the injection volumes (Figure 11b). There is a continued increase in cumulative seismic moment after the Frisco 2-P stimulation due to continued pumping operations as soon as the stimulation is complete. The injection rates are not available at the time of submission of this article to include in the cumulative injection curve (pink curve in Figure 11b).

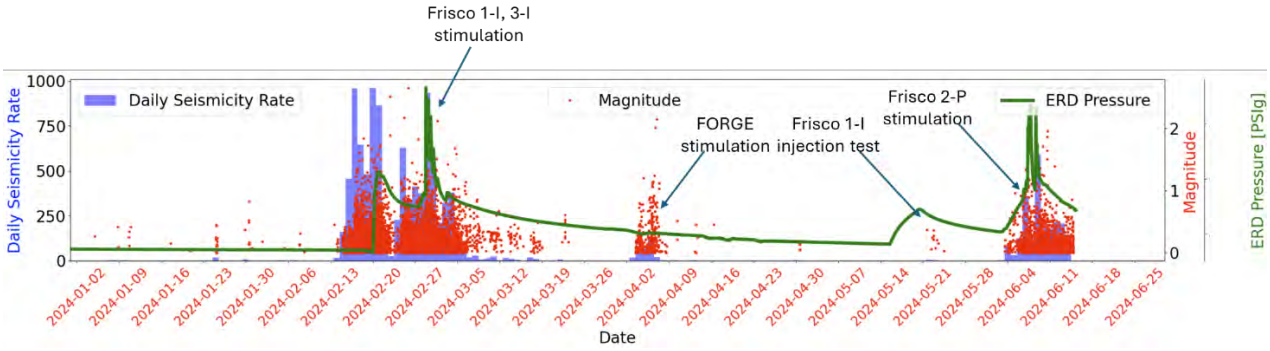

Figure 9: The figure illustrates the seismicity rate as a blue histogram, spanning from the beginning of January until June 15th, 2024. It highlights the time periods during which the Frisco stimulations occurred. The green curve represents the downholegauge pressure at the reservoir level outside the casing on the Delano 1-OB well. For confidentiality reasons, the actual pressure values have been masked. This visualization aims to correlate seismic activity with reservoir pressure changes and stimulation events over the specified timeframe.

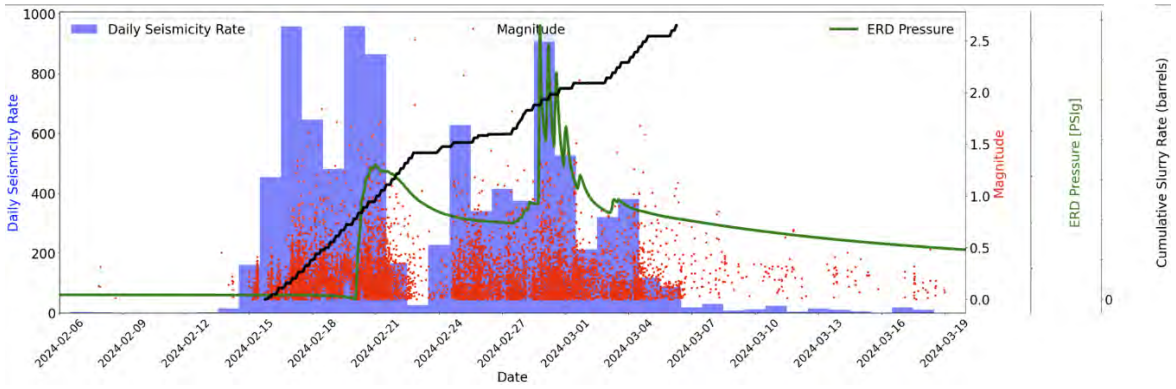
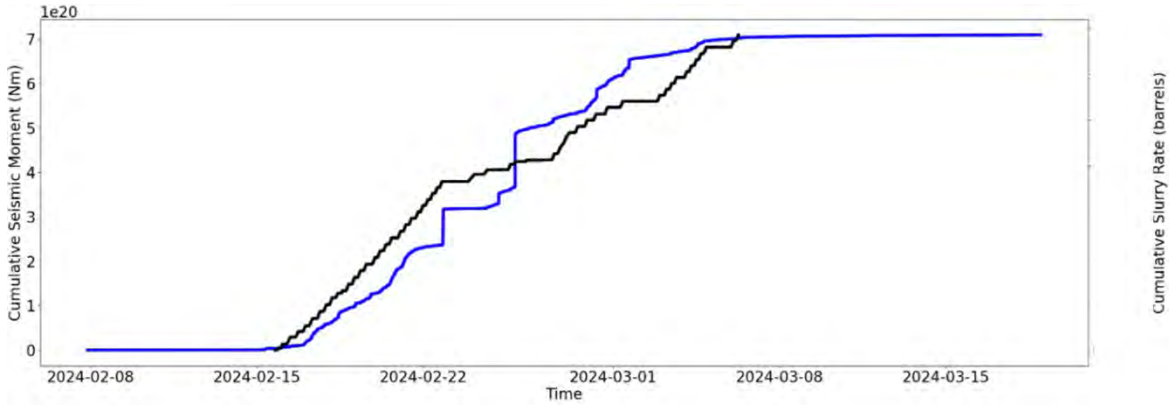


(a)



(b)

Figure 10: (a) Figure displays the seismicity rate and downhole pressure data, along with the magnitudes of the seismic events during the stimulation of Frisco 1-I and Frisco 3-I wells. The black curve represents the cumulative injection rate. This detailed view allows for a closer examination of the relationship between seismicity, reservoir pressure, and injection activities during the stimulation periods. (b) This plot shows the cumulative injection rate against the cumulative seismic moment released from all seismic events during the stimulation of Frisco 1-I and Frisco 3-I wells.

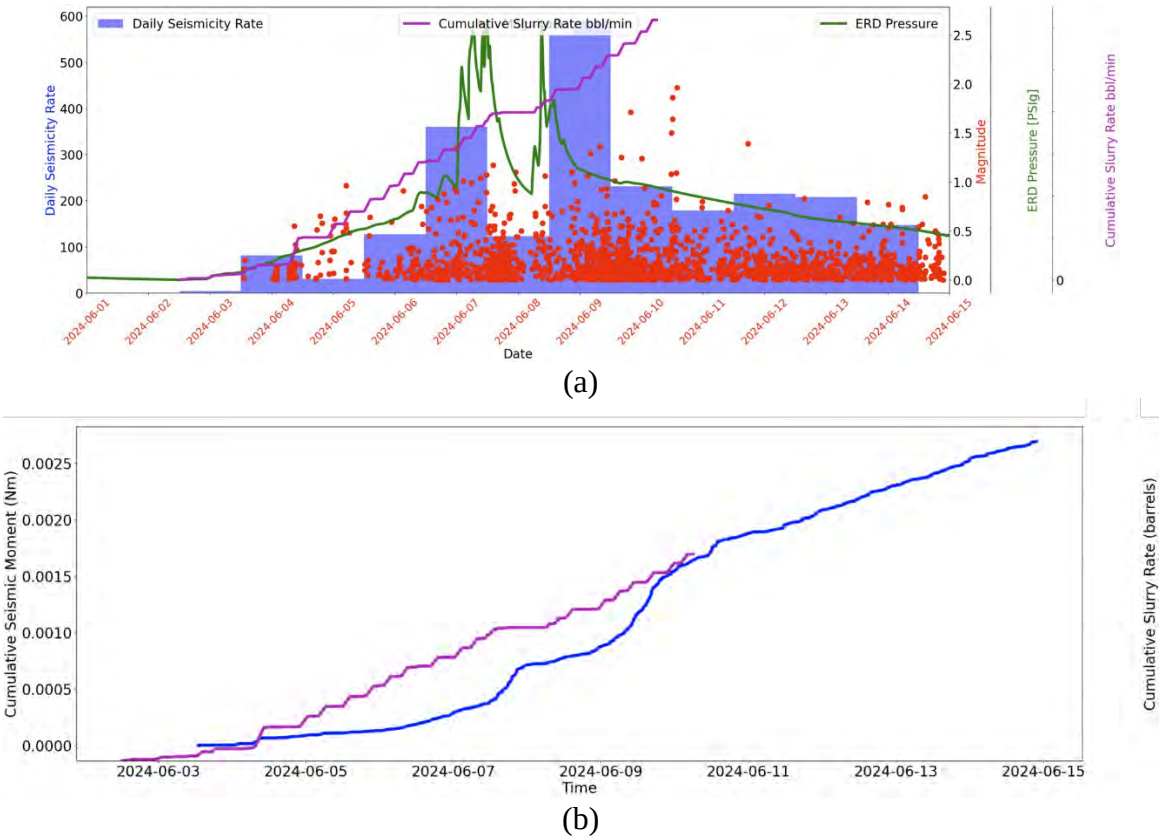


Figure 11: (a) Figure displays the seismicity rate and downhole pressure data, along with the magnitudes of the seismic events during the stimulation of Frisco 2-P. The black curve represents the cumulative injection rate. This detailed view allows for a closer examination of the relationship between seismicity, reservoir pressure, and injection activities during the stimulation periods. (b) This plot shows the cumulative injection rate against the cumulative seismic moment released from all seismic events during the stimulation of Frisco 2-P.

The seismic analysis of the Frisco 1-I and 3-I stimulation phases shows a higher number of events with magnitudes greater than one and two compared to the Frisco 2-P stimulation and post-stimulation phases, with 125 and 26 events exceeding magnitude 1, respectively (Table 2). The magnitude-frequency distributions reveal a b-value of 1.509 for Frisco 1-I and 3-I, indicating a relatively higher frequency of smaller events, while the b-value for Frisco 2-P and post-stimulation is slightly higher at 1.787, suggesting a steeper decay in event frequency (Figure 12). The **b-value** is a parameter from the Gutenberg-Richter law, which describes the relationship between earthquake frequency and magnitude in a given region. A higher b-value indicates that smaller magnitude events are relatively more frequent than larger ones, while a lower b-value suggests a flatter distribution with a higher proportion of larger events. Both b-values during the two stimulation phases are higher than the typical tectonic b-value of 1, indicating that induced seismicity from the stimulation phases results in a greater proportion of smaller earthquakes. These findings imply that the stimulation activities are associated with seismicity characterized by a higher occurrence of smaller events compared to natural tectonic processes.

Table 2: Seismic activity summary for the Frisco 1-I and 3-I stimulation phases compared to the Frisco 2-P stimulation and post-stimulation phases.

	Frisco 1-I and 3-I stim	Frisco 2-P stim and Post Stim
No of Events with Mag > 1	125	26
No of Events with Mag > 2	5	None
No of Events with Mag > 3	None	None
No of Events felt in nearest towns	None	None
Total No of Events	29967	19579
Mc	-0.162	-0.3
b-value	1.509	1.7
Mmax	2.67	1.88

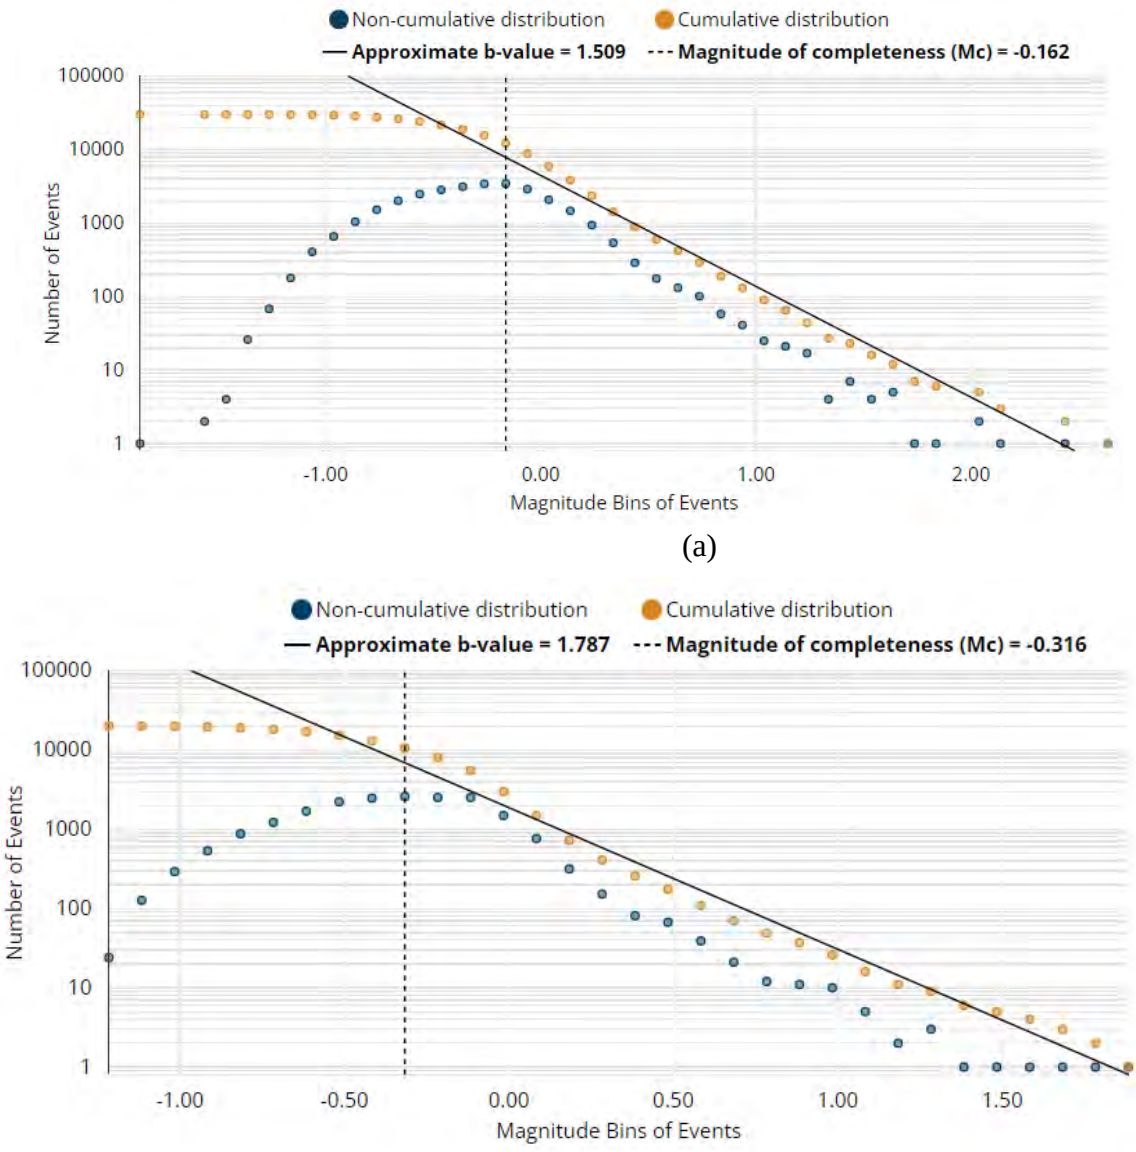

Figure 12: (a) Magnitude-frequency distribution for seismic events during the Frisco 1-I and 3-I stimulation phases, showing both non-cumulative (blue dots) and cumulative (orange dots) distributions. (b) Magnitude-frequency distribution for seismic events during the Frisco 2-P stimulation and post-stimulation phases, also showing both non-cumulative and cumulative distributions.

5.3 Microseismic catalogs

A 3D velocity model was constructed using all available Sonic logs from Utah FORGE wells and Fervo wells, including Delano 1-OB, Frisco 1-I, along with the top of the basement from 3D seismic and gravity data (Figure 13). A constant basement velocity of 5649.1 m/sec was estimated based on the hypocentral distance versus travel time (pick time minus event origin time) plot shown in Figure 14.

Figure 15 compares the microseismic activity during the stimulation of all three Frisco wells using data from the shallow borehole array and deep borehole DAS and 3C geophone data. Both datasets reveal linear features oriented either N-S or 10°-15° NNW-SSE, which is not aligned with the SHmax orientation shown in Figure 4. The likely reason for this is that the linear features represent existing natural fractures and faults, which are reactivated because they are optimally oriented for failure under the SHmax orientation, as determined from the image logs. While the number of detected events is significantly larger with the deep borehole array-based locations, the general geometry and extent of the features are similar in both datasets.

To better understand the hydraulic behavior of one of the fault features (Figure 15b), the microseismic cloud associated with that specific fault was isolated, and a microseismic diffusion analysis was conducted. The hydraulic diffusivity was estimated by modeling the migration of the triggering front of microseismic events (MEQ) using a diffusion model. The relationship $r=\sqrt{4\pi D\Delta t}$, where r is the distance from the wellbore, D is the hydraulic diffusivity, and Δt is the time since fluid injection, was applied to the data. Different values of D were fitted to the observed microseismic event data to capture the best-fit diffusivity, with the resulting curves compared against the actual event distribution to estimate the hydraulic properties of the fault zone. The data points and the model curves were plotted to visualize how varying diffusivity values influence the spread of seismicity over time. The estimated hydraulic diffusivity for the fault feature in this study of 0.1 - 0.15 m^2/s (Figure 16) is significantly higher than values reported from other experiments, such as the EGS Collab, where a diffusivity of D=0.008 m^2/s was fitted across different stimulation episodes (Yu et al., 2024). In contrast, the hydraulic diffusivity estimated during the third stage of the FORGE stimulation in April 2022 ranges between D = 0.15 - 0.2 m^2/s, suggesting a much more permeable fault zone at the FORGE site (Yu et al., 2024). This indicates that the hydraulic properties at the FORGE site and at Cape Station are more conducive to fluid flow, likely leading to a more rapid propagation of the seismic triggering front compared to the EGS Collab site.

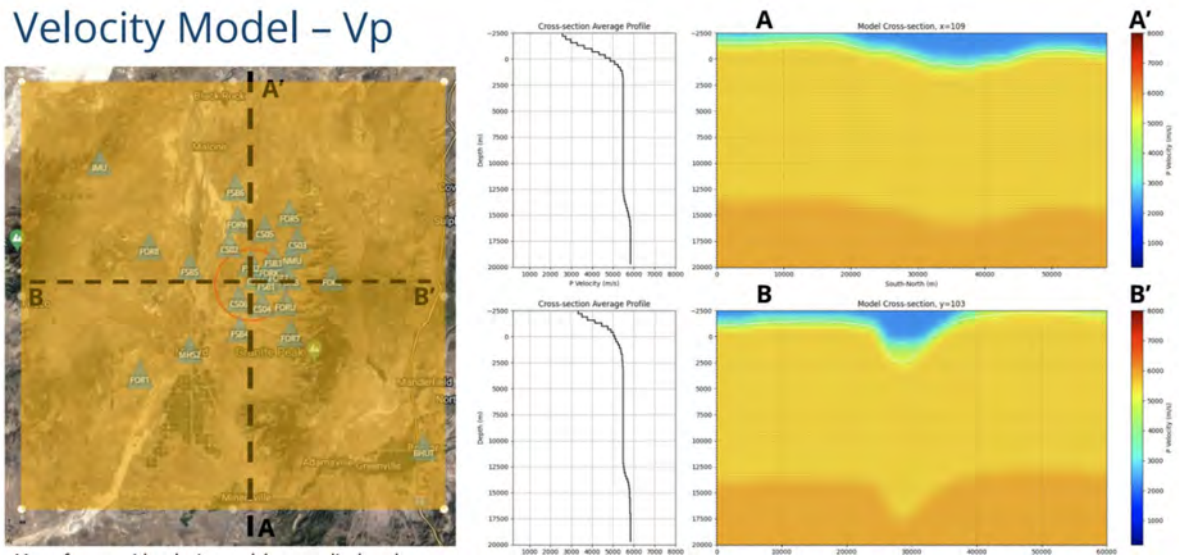

Figure 13: (a) Map of array with velocity model extent displayed as orange box. Cross-sections shown to the right are highlighted as black dashed line. (b) Vp cross-sections: Right image shows velocity variation across the section, left plot displays cross-section average profile.

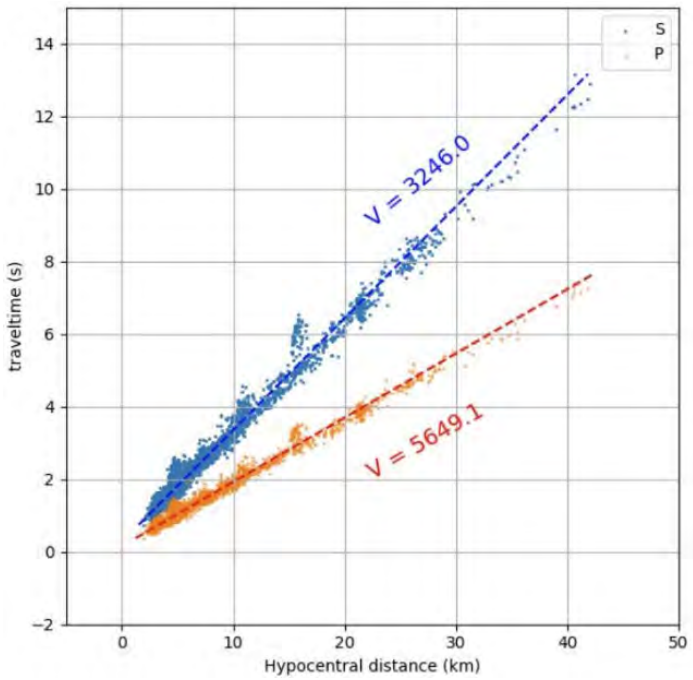

Figure 14: Plot for traveltime (pick time minus event origin time) vs hypocentral distance per phase per event per station, dashed lines are the fitted lines with estimated Vp and Vs velocity values.

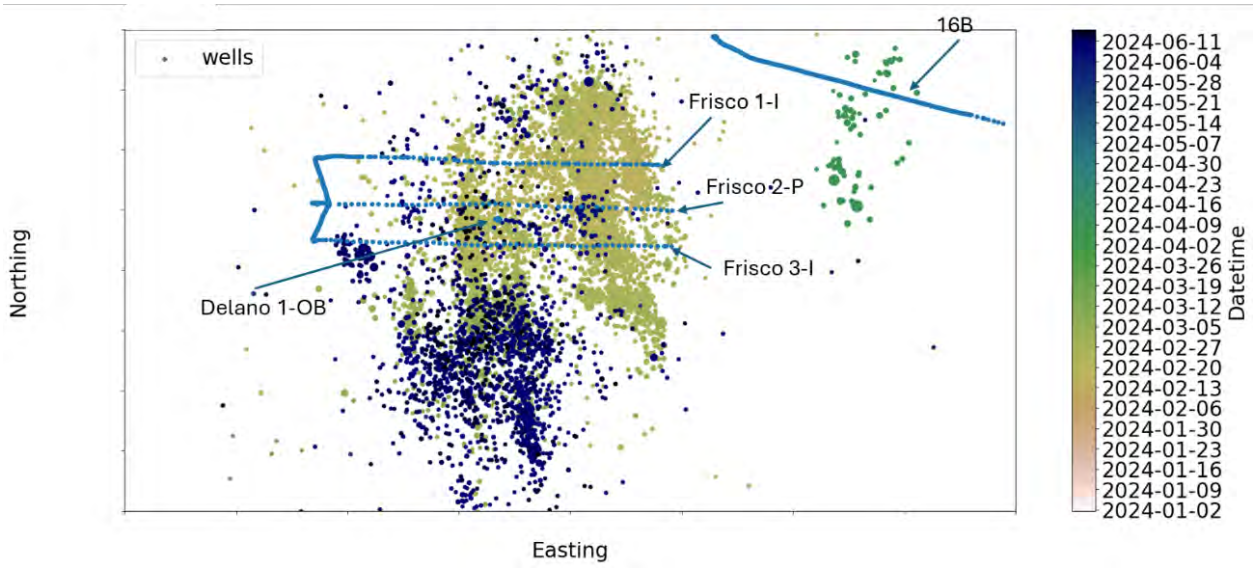
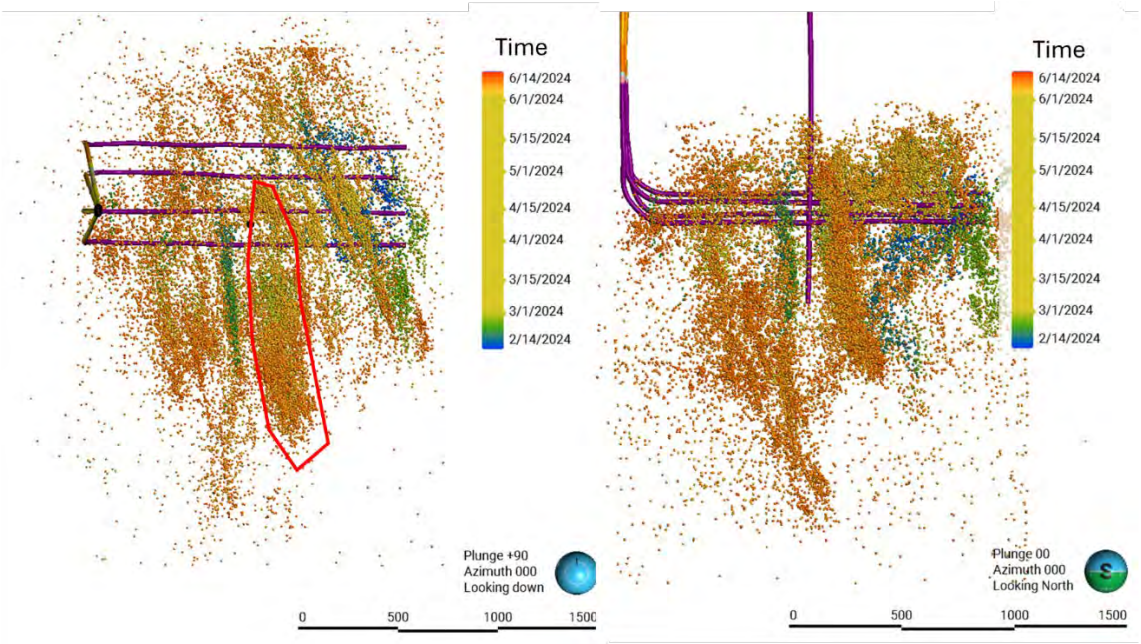


(a)



(b)

Figure 15: (a) Microseismic catalog during the Frisco 1-I, 2-P and 3-I stimulation based on the Shallow Borehole array data. (b) Microseismic catalog during the Frisco 1-I, 2-P and 3-I stimulation based on the deep borehole fiber optic DAS and 3C sensors in the 56-32 well. The figure on the left is the map view and the figure to the right is the cross-section depth view of the microseismic. The red polygon in Figure YY indicates the reactivated fault feature where the hydraulic diffusivity is estimated during Frisco 1-I ad 3-I stimulation.

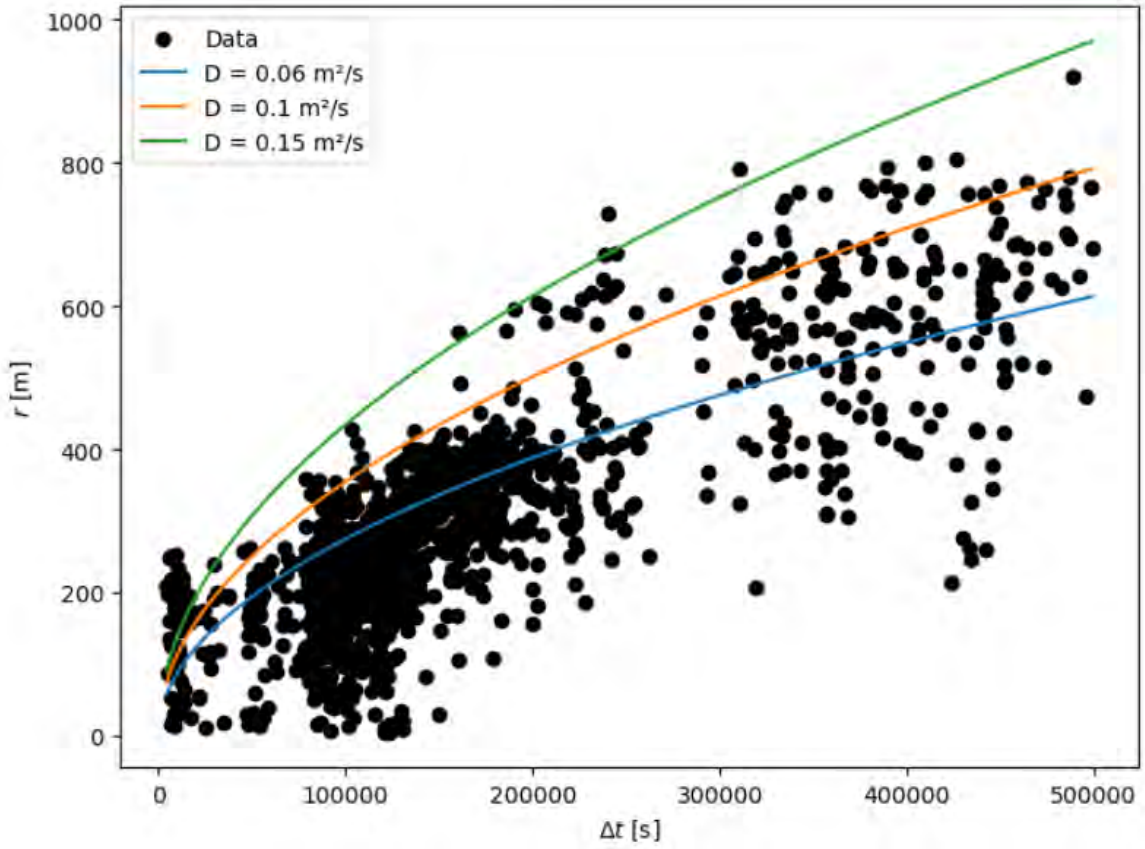


Figure 16: Plot showing the relationship between the distance r in meters of microseismic events from the wellbore and the time elapsed since the initiation of fluid injection (Δt) near the fault of interest. The red polygon in Figure 10 indicates the reactivated fault feature where the hydraulic diffusivity is estimated. The black dots represent the observed microseismic event data. The colored curves represent the modeled distances for different values of hydraulic diffusivity D within the fault: D=0.06 m^2/s (blue), D=0.1 m^2/s (orange), and D=0.15 m^2/s (green). The plot illustrates how different diffusivity values influence the spread of seismicity over time, aiding in the estimation of hydraulic properties of the fault zone.

5.4 Focal mechanism analysis

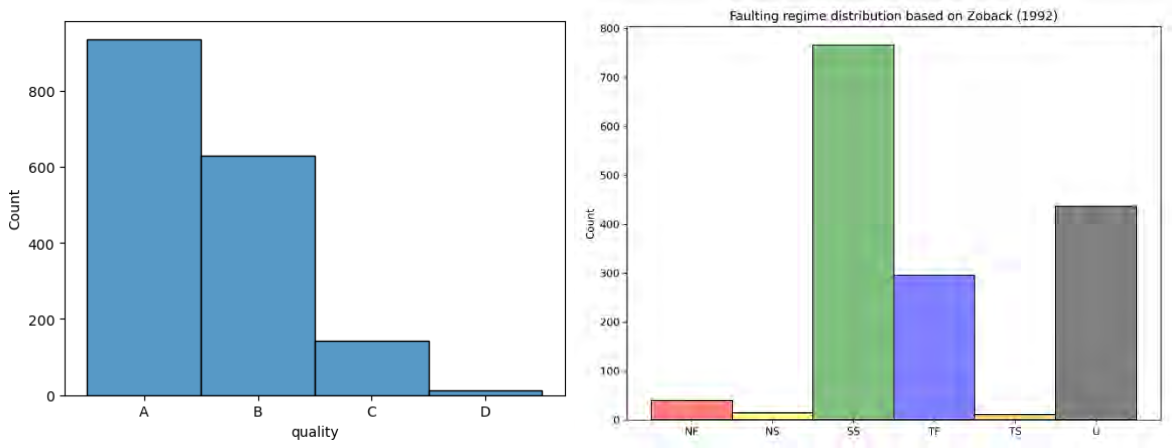
In addition to the shallow borehole network and deep borehole measurements, a surface nodal array has been deployed around the Frisco Pad area, actively recording data since February 2024. Further details on the nodal array's geometry and acquisition setup can be found in Nori et al., 2024.

This paper includes the focal mechanisms of seismic events from the Frisco 1-I and 3-I stimulation phases in February and March 2024. To predict P and S wave arrival times and phase polarity, we utilized the EQNet model (https://github.com/AI4EPS/EQNet), an advanced version of PhasNet (Zhu and Beroza., 2019). In our analysis, we selected only those picks where the P phase score was 0.8 or higher to ensure the reliability of our focal mechanism estimations. To improve the accuracy of S-wave amplitude estimation, we rotated the three-component signals—originally in the vertical, north, and east directions—into vertical, radial, and transverse components based on

the event-station azimuth. We then estimated the P-wave amplitude on the vertical (Z) component and the S-wave amplitude on the transverse (T) component. Following these processing steps, we generated a refined database of 1,719 events.

For the focal mechanism inversion, we employed the SKHASH Python package (Skoumal., 2024), a modernized version of the widely used HASH package originally developed in Fortran over two decades ago. SKHASH leverages recent advancements to better constrain focal mechanisms for small-magnitude or poorly recorded earthquakes. In our workflow, we varied the 3D earthquake locations and velocity models to identify acceptable solutions. As input for the focal mechanism solutions, we used P-wave first-motion polarity and enhanced the constraints by incorporating S/P wave amplitude ratios. Additionally, we included horizontal and vertical location uncertainties in the inversion process to minimize errors related to event location.

Using the aforementioned technique, focal mechanism solutions were successfully derived for 1,719 events, with 1,564 of these classified as A and B quality, indicating solutions with low uncertainty (Figure 17a). To classify the faulting regimes and determine the maximum horizontal stress (Shmax) for each event, the methodology described by Zoback (1992) was applied. This approach enabled the events to be categorized into distinct faulting regimes, including strike-slip (SS), normal faulting (NF), and thrust faulting (TF) (Figures 17b, 18 and 19). Additionally, hybrid regimes were identified, such as transtension (NS), which combines features of NF and SS, and transpression (TS), which combines features of TF and SS, consistent with the classifications proposed by Zoback (1992). The dominant faulting mechanism for the study area is strike-slip with more reverse faulting patterns in the East and North sections, which can be normal faults that reactivate as reverse faults.



(a) (b)

Figure 17: (a) Distribution of the SKHASH focal mechanism solutions by quality, with classifications ranging from A to D, indicating varying levels of uncertainty. (b) Faulting regime distribution based on the criteria outlined by Zoback (1992), categorizing events into normal faulting (NF), strike-slip (SS), thrust faulting (TF), transtension (NS), transpression (TS), and undefined (U) regimes.

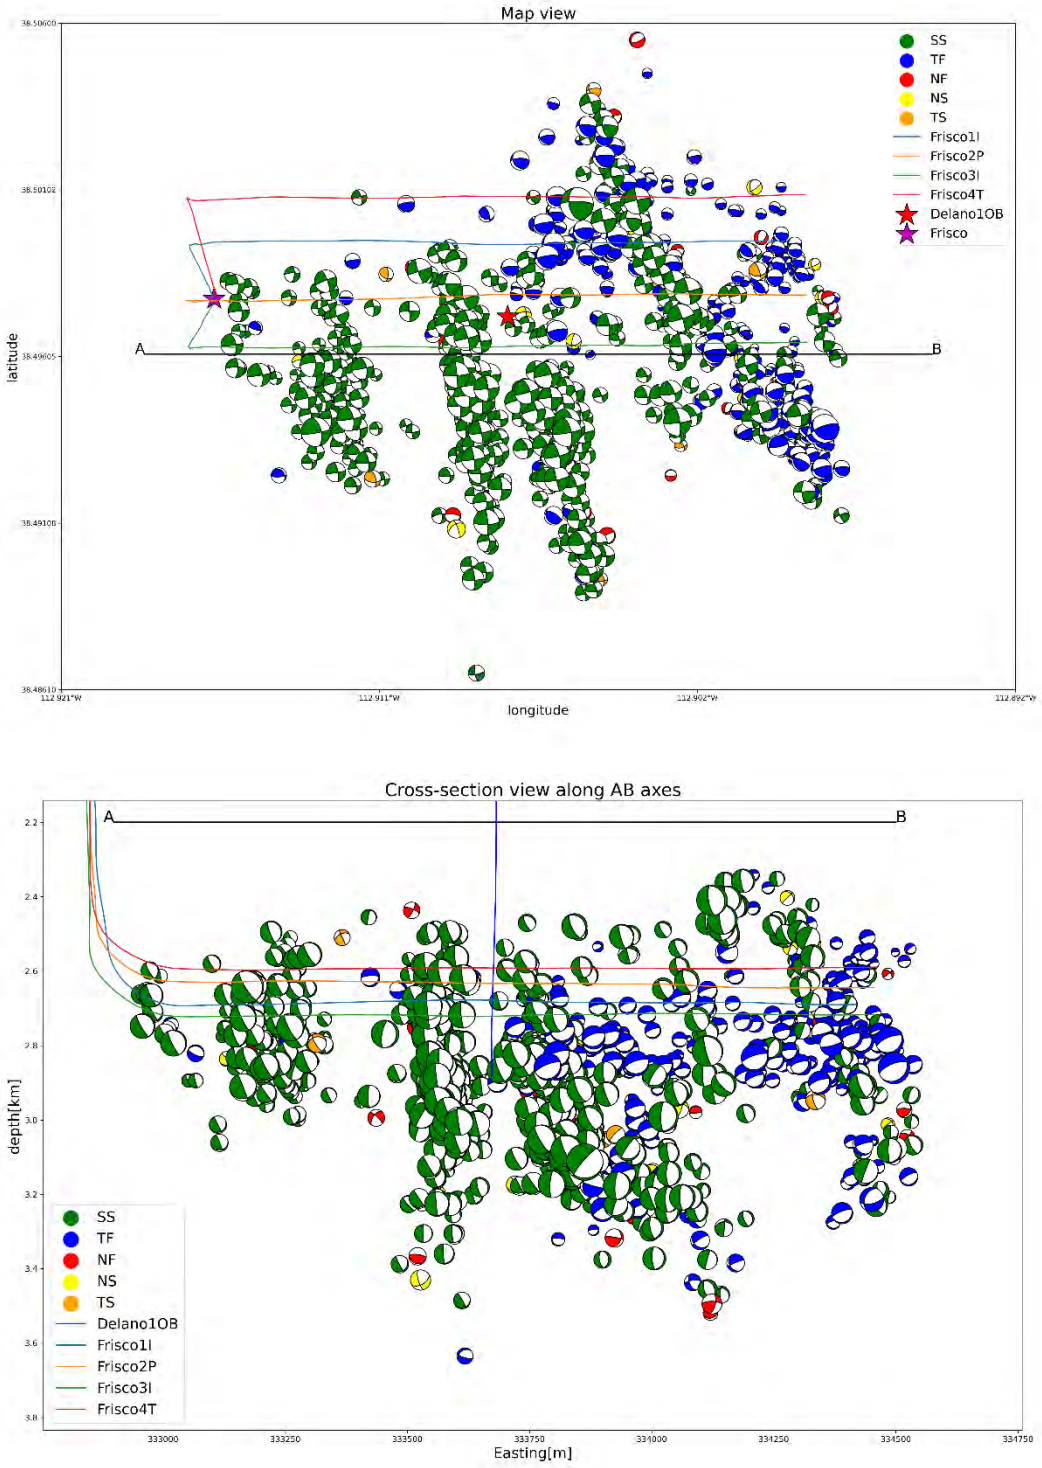


Figure 18: Top view (above) and cross-section view along the AB axes (below) of the study area, showing the distribution of focal mechanisms for the seismic events categorized by faulting regimes, including strike-slip (SS), thrust faulting (TF), normal faulting (NF), transtension (NS), and transpression (TS). The map also highlights the location of various wells, including Frisco 1-I, Frisco 2-P, Frisco 3-I, and Frisco 4-T, as well as the Delano 1-OB well.

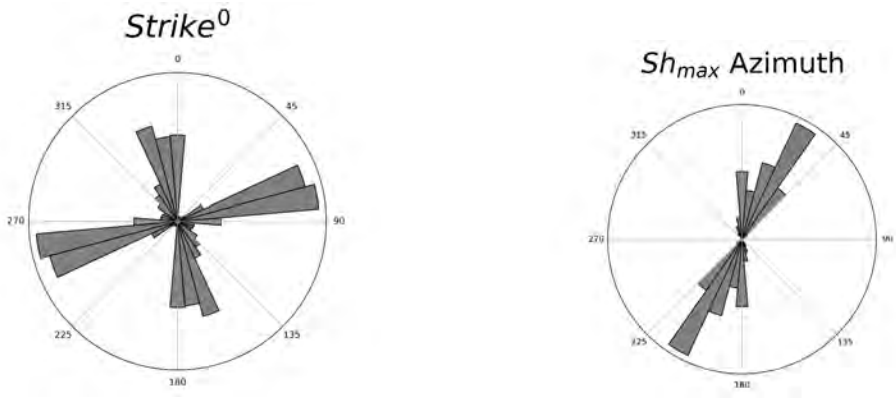

(a) (b)

Figure 19: (a) Rose diagrams showing the distribution of nodal plane strike angles (top) and (b) the orientation of maximum horizontal stress (Shmax) azimuths (bottom) for the seismic events analyzed. These diagrams provide insights into the dominant faulting directions and the stress field orientation within the study area.

6. Conclusion

The Cape Modern project represents a significant advancement in the development of Enhanced Geothermal Systems (EGS), particularly in the application of comprehensive microseismic monitoring and real-time management strategies. The project involved the stimulation of three horizontal wells using a plug-and-perf completion design, a technique adapted from the unconventional oil and gas industry, which proved effective in creating hydraulic connectivity within the reservoir. The microseismic data revealed a trend of increasing seismicity correlating with the volume of fluid injected during stimulation. The real-time monitoring system provided reliable updates that were instrumental in making timely operational adjustments. When seismic events with magnitudes of 2.0 or greater were detected, these real-time data allowed for immediate activation of the Traffic Light System (TLS), leading to pauses in injection and other mitigation strategies to control seismicity. Additionally, the downhole pressure gauge installed in the monitoring well played a crucial role in managing induced seismicity. A clear relationship between downhole pressure and seismicity was observed, suggesting that pressure monitoring can be effectively used to anticipate and control seismic events. This proactive approach ensured that even as seismicity increased with fluid injection, the safety of operations was maintained, with the largest event recorded at a local magnitude of 2.3, resulting in ground motion levels lower than “felt” threshold near the nearest town. Active community engagement was a key component of the project’s success. Fervo Energy actively engaged with the local community before, during, and after the injection activities, providing clear communication about the induced seismicity protocols in place. This included holding informational sessions and sharing a seismicity education blog that detailed Fervo’s approach to managing induced seismicity. This proactive engagement helped build trust and understanding within the community, ensuring that residents were informed and reassured about the safety measures implemented throughout the project. The successful integration of real-time seismic monitoring, pressure monitoring, adaptive operational strategies, and active community engagement underscores the importance of a holistic approach to managing geothermal operations.

ABSTRACT

The northeastern portion of the Reese River basin in north-central Nevada is the focus of detailed geophysical and geological studies as part of the INGENIOUS project, which aims to identify new, commercially viable hidden geothermal systems in the Great Basin region of the western U.S. This location, herein referred to as Argenta Rise, occupies a broad (~15km wide) left-step between major range-front fault systems along the northwestern edge of the Shoshone Range and Argenta Rim, with numerous ENE-striking intra-basin faults presumably accommodating sinistral-normal oblique slip across the step-over. Four discrete regions have been identified within the study area that have favorable structural settings for hosting a blind hydrothermal system. However, with no definitive or extensive surface manifestations of an active hydrothermal system (e.g., geysers, steam vents, sinter, etc.), detailed geophysical studies are necessary to resolve subsurface geology and structure, and identify zones of enhanced structural complexity that may promote hydrothermal fluid flow. Hence, we collected high-resolution gravity, MT, and rock property data (density, magnetic susceptibility), and analyzed the recently acquired GeoDAWN aeromagnetic data to characterize potential geothermal resources in this region. Using the new geophysical datasets, we jointly modeled gravity and magnetic data along a series of intersecting 2D profiles that integrated information from recent, local-scale fault mapping. Rock property measurements performed on outcrops and hand samples throughout the study area constrained the models. The MT data were used to construct a 3D resistivity model that highlights the location of inferred alteration and fluids in the subsurface. Combined MT and potential field results reveal which structures may be most important for controlling hydrothermal fluid migration, as well as which geologic units may host hydrothermal fluids. Our gravity derived depth to basement surface

coincides well with the base of shallow conductive anomalies, suggesting hydrothermal fluids may be confined to basin fill sediments and volcanics. This work supports our development of 3D geophysical and geologic models that are focused along the western flank of the northern Shoshone Range and aids the process of selecting sites for temperature gradient drilling.

1. Introduction

The northeastern Reese River basin was initially identified for having high geothermal resource potential in the Nevada Play Fairway Analysis (PFA; DeAngelo, 2019; Faulds et al., 2019). Subsequently, this area was chosen for detailed geological and geophysical investigations as part of the Innovative Geothermal Exploration through Novel Investigations Of Undiscovered Systems (INGENIOUS) project (Ayling et al., 2022; Earney et al., 2022; Williams et al., 2022; Earney et al., 2023). Argenta Rise is located approximately 15 km southeast of Battle Mountain, NV, along the western flank of the northern Shoshone Range within the north-central Basin and Range Province (Figure 1). The Beowawe Geysers, an active geothermal area with numerous geysers and sinter deposits is ~15 km further east of Argenta Rise at the southern end of Whirlwind Valley. The Beowawe flash powerplant was established in 1985, and produced 16.7 MW from a roughly 200°C resource (Benoit and Stock, 1993). Although the geothermal resource at this location has degraded over time (Benoit and Stock, 1993), presumably due to recharge of cold meteoric water, the powerplant generated 13.7 MW of electricity in 2018 (Ayling, 2020). Argenta Rise lacks definitive surface manifestations of active thermal features, such as those observed at the Beowawe Geysers; however, it occupies a favorable structural setting thought to be conducive to hydrothermal up-flow (Faulds et al., 2011; Faulds and Hinz, 2015; Faulds et al., 2024). Faulds et al. (2024) identified two discrete regions with potentially elevated shallow temperatures proximal to the range-front fault zone on the western side of the northern Shoshone Range (Figure 1, inset map). To further refine areas favorable for geothermal activity at Argenta Rise, we conducted high-resolution gravity, magnetotelluric (MT), and physical property surveys, and analyzed Geoscience Data Acquisition for Western Nevada (GeoDAWN; Glen and Earney, 2023, 2024) aeromagnetic data to map and model subsurface geology and structure. Model parameters are constrained by physical property measurements (density, magnetic susceptibility) collected from hand samples and outcrops of the relevant geologic units throughout the northern Reese River basin and adjacent ranges. Our results support ongoing efforts to develop three-dimensional (3D) geologic and structural models, and identify specific sites for temperature gradient drilling.

2. Geologic Framework

Argenta Rise occupies a nearly 15 km wide left-step between major ENE-trending range-front fault systems along the northwestern edge of the Shoshone Range and at Argenta Rim (Figure 1). Numerous ENE-striking intra-basin faults presumably accommodate sinistral-normal oblique slip across the step-over. Beyond the favorable structural setting, there are two large-scale crustal features that make this region particularly favorable for geothermal resource investigations: 1) the Northern Nevada Rift (NNR); and 2) regionally high background conductive heat flow (Figure 1, index map). The NNR is a series of several narrow, arcuate, NNW-trending features that extend for at least 500 km from southern Nevada to the Nevada-Oregon border (McKee and Noble, 1986; Blakely and Jachens, 1991). The eastern segment of the NNR (Stewart et al., 1975; Zoback, 1979; Glen and Ponce, 2002) passes just east of the study area. Studies have proposed that the NNR was caused by a highly magnetic, mafic dike swarm that intruded the upper crust through deep-seated

crustal fractures that were reactivated in the middle Miocene during the passing of the Yellowstone hotspot along the Oregon-Idaho border (Zoback and Thompson, 1978; Glen and Ponce, 2002). The stresses induced by magma emplacement, and the contrast in physical properties between NNR-related intrusions and the surrounding country rock likely make the boundaries of the NNR structurally weak, and prone to faulting and fracturing. In regions with high strain rates, such as the Basin and Range (Zeng, 2022), these structures can frequently be reactivated, maintaining permeable pathways for deep circulating hydrothermal fluids. Thus, characterizing faults and fractures associated with the NNR will play an important role in understanding and identifying potential geothermal resources at Argenta Rise. This area also has anomalously high background conductive heat flow, largely as a result of regional extension within the Basin and Range. The study area sits on the eastern edge of the Battle Mountain High, a lobe of high heat flow in north-central Nevada with average surface heat flow estimates of 100+ mW/m^2 (Sass et al., 1971). Based on new maps of conductive heat flow within the Basin and Range (DeAngelo et al., 2022), estimated surface heat flow values at Argenta Rise are ~97.6 mW/m^2, and across the entire Basin and Range heat flow values are on average ~78.6 mW/m^2. These data suggest, at least regionally, that there is a higher potential of encountering geothermal resources at economically feasible depths in the north-central Basin and Range.

At Argenta Rise, the stratigraphy pertinent to our modeling efforts consists of highly deformed and thrusted Paleozoic siliciclastic and carbonate rocks that are overlain by minor deposits of Mesozoic sediments and intruded by Mesozoic and Tertiary granitoids (Crafford, 2007). Overlying these units are locally voluminous packages of Cenozoic volcanics and basin fill sediments (Crafford, 2007). The Paleozoic units, exposed along the northern Shoshone Range, at Battle Mountain, and in small outcrops at the southern end of the Sheep Creek Range, are presumed to be the primary basement lithologies throughout the northern Reese River basin. Although discrete intrusive bodies (i.e., dikes) related to the NNR are mapped at the surface in the northern Shoshone Range (Ramelli et al., 2001; John and Wrucke, 2003; Ramelli et al., 2017), the bulk of these rocks occur at depth along a NNW-trend through the northern Shoshone Range and Sheep Creek Range on the east side of the study area (Watt et al., 2007). For the purposes of two-dimensional (2D) and 3D modeling in this project, we generalize the Nevada state geological map (Crafford, 2007) within the region surrounding the study area by grouping together units that would be expected to have similar physical properties (density, magnetic susceptibility, magnetic remanence; Figure 1).

The two predominant fault orientations observed at Argenta Rise trend NNW and ENE, recording the transition from NNR-related ENE-WSW directed extension in the middle Miocene to the NW-SE directed extension characteristic of the modern-day Basin and Range, respectively (Zoback et al., 1994). Complex interactions between these opposing fault sets create numerous structurally favorable zones for promoting hydrothermal fluid flow within the study area (Faulds et al., 2011; Williams et al., 2022; Faulds et al., 2024). The geophysical data presented herein delineate concealed intra-basinal faults, and resolve subsurface fault interactions, providing a more complete view of subsurface fault complexity.

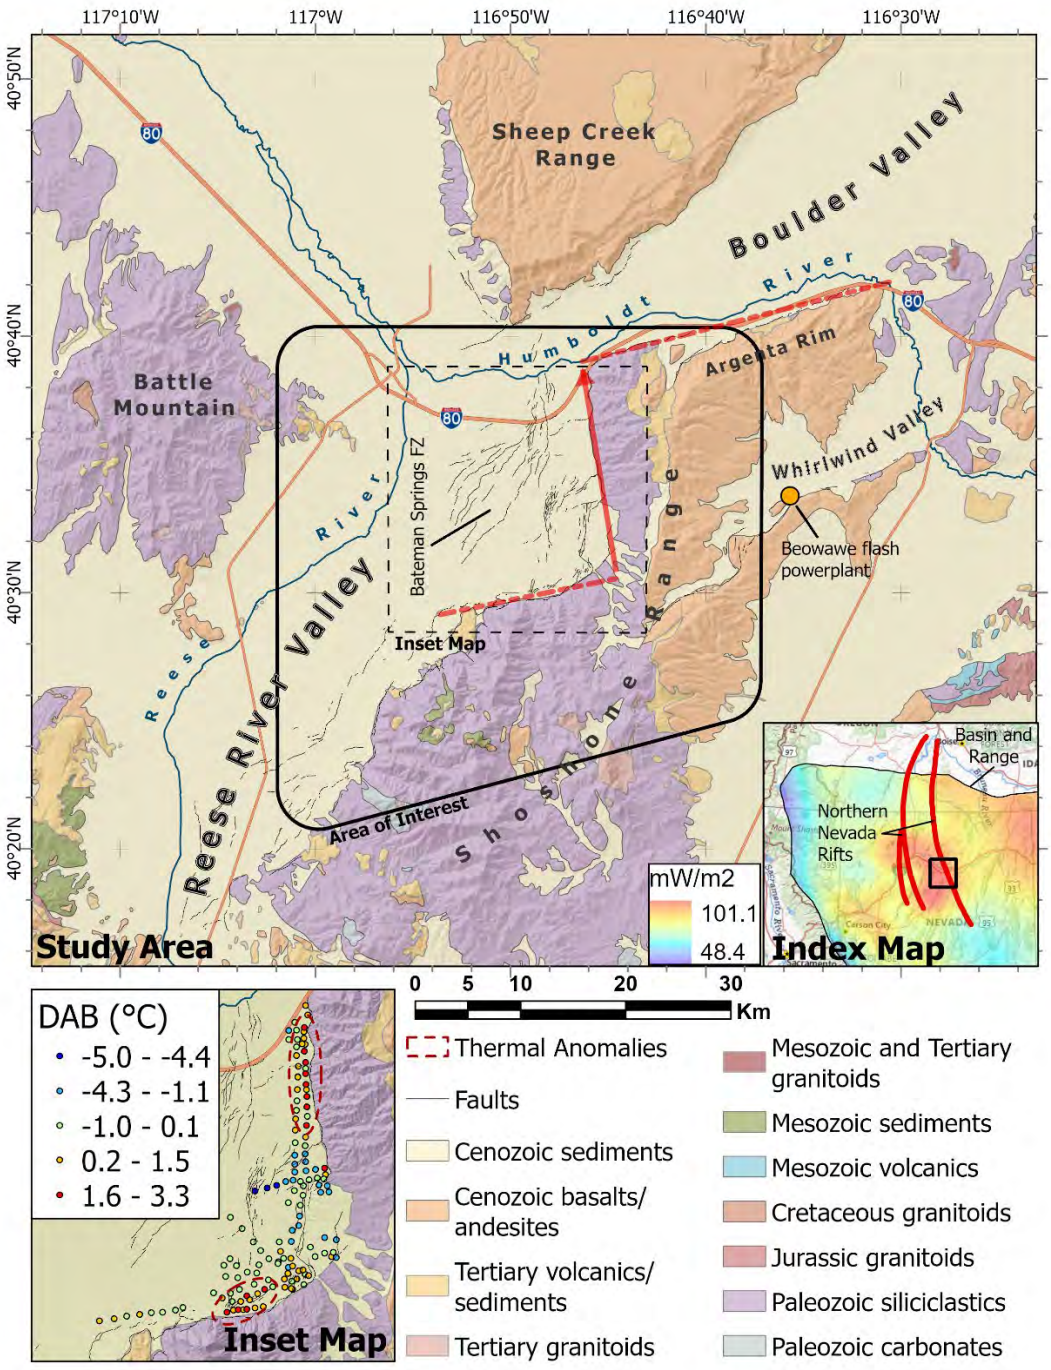

Figure 1: Study Area – Digital elevation model (DEM) hillshade (U.S Geological Survey, 2021a) overlain by simplified geologic map (adapted from Crafford, 2007). Faults are a compilation of existing (USGS, 2021a), and newly identified faults mapped by the University of Nevada, Reno (UNR) using lidar (U.S. Geological Survey, 2021b). The dashed red lines and red arrow indicate the left-step between range-front fault zones along the northwestern edge of the Shoshone Range (southern dashed red line) and Argenta Rim (northern dashed red line). Inset Map – 2-meter temperature survey conducted by UNR in July and November 2021 measured in degrees above background (DAB; Faulds et al., 2024). Index Map – Regional location map showing the location of the study area, the boundary of the Basin and Range, traces of the NNR (Glen and Ponce, 2002), and background conductive heat flow (DeAngelo et al., 2023).

3. Geophysical Data

Geophysical methods are valuable tools for investigating geothermal systems because they facilitate mapping of subsurface structures which may inhibit or host fluid flow and can be used to help resolve basin depths and geometries. Natural variations in gravity, magnetic, and electrical fields arise due to lateral and vertical contrasts in physical properties (e.g., density, magnetic susceptibility/remanence, and conductivity, respectively), which can reflect facies changes, presence of hydrothermal fluids, alteration products of hydrothermal fluids, offset across faults, and/or geological contacts. At Argenta Rise, the geology is quite varied, consisting of mafic igneous rocks, siliciclastic and carbonate rocks, granitoid intrusives, and tuffaceous and sedimentary rocks. The strong contrast in physical properties between these geologic units leads to distinct gravity, magnetic, and conductivity anomalies. We present new gravity, magnetic, and magnetotelluric data collected across the northern Reese River basin. We use various derivative, filtering, and modeling methods to characterize concealed geology and structures.

3.1 Gravity

A total of 1,207 new gravity measurements were collected in 2021 and 2022, encompassing ~2,000 km^2 of the northern Reese River basin and adjacent ranges. These data augmented an existing network of 3,899 gravity measurements from the surrounding region (Ponce, 1997; Hildenbrand et al., 2002 [PACES]; PACES database was made available from University of Texas, El Paso on 5/29/2018 [Ben Drenth, U.S. Geological Survey, written comm., March 2021]), improving regional coverage in areas of sparse control and providing detailed coverage (200 to 300 m station spacing) across range front and intra-basin structures. Isostatic anomaly values were calculated using standard gravity reduction methods (Blakely, 1995), assuming an average crustal density of 2,670 kg/m^3, a density contrast of 400 kg/m^3 at the crust-mantle boundary, and a sea level crustal thickness of 25 km. The isostatic anomalies were gridded using a minimum curvature routine with a cell size of 400 m. A residual isostatic anomaly map was subsequently generated (Figure 2) to facilitate structural mapping and interpretation of subtle anomalies produced by shallow crustal features that might otherwise be difficult to recognize in the presence of regional fields.

3.2 Magnetics

Magnetic data reveal subtle fluctuations in the magnetic field that reflect variations in the magnetization of rocks in the subsurface, and are particularly useful in regions where bedrock may be concealed by young basin fill sediments. In the northern Reese River basin, the strong contrast in magnetic properties (magnetic susceptibility and remanent magnetization) between the predominant lithologies (young sedimentary deposits [low magnetic properties], Cenozoic volcanics [high magnetic properties], and Paleozoic basement rocks [low magnetic properties]) results in distinct magnetic anomalies. These anomalies delineate structures such as faults and contacts that may provide natural permeable pathways for hydrothermal fluids.

The recently acquired GeoDAWN survey included a high-resolution aeromagnetic survey over northern and western Nevada and eastern California (Glen and Earney, 2024), and spans our study area at Argenta Rise. The survey was flown with a nominal flight height of 150 m above terrain over areas with low topographic relief and 200 m above terrain over mountain ranges. Flight lines were flown along an azimuth of 90 degrees and spaced 400 m apart, while tie lines were flown along an azimuth of 180 degrees and spaced 4,000 m apart. Magnetic data were recorded at 10 Hz.

The total field (TF) magnetic anomaly was gridded using a cell size of 100 m. We applied a number of derivative and filtering methods to this grid to simplify anomalies and aid interpretations of structural features. The reduced-to-pole (RTP) transformation (Blakely, 1995) was applied to the TF magnetic anomaly map to effectively center magnetic anomalies over their sources (Figure 3A). Additionally, several residual grids were created to highlight very subtle, shallow anomalies associated with young intra-basinal Quaternary faults (Figure 3B). To produce the residual grids, we upward continued the TF map a distance of 50 m and subtracted the result from the original TF map, then recalculated the RTP anomaly.

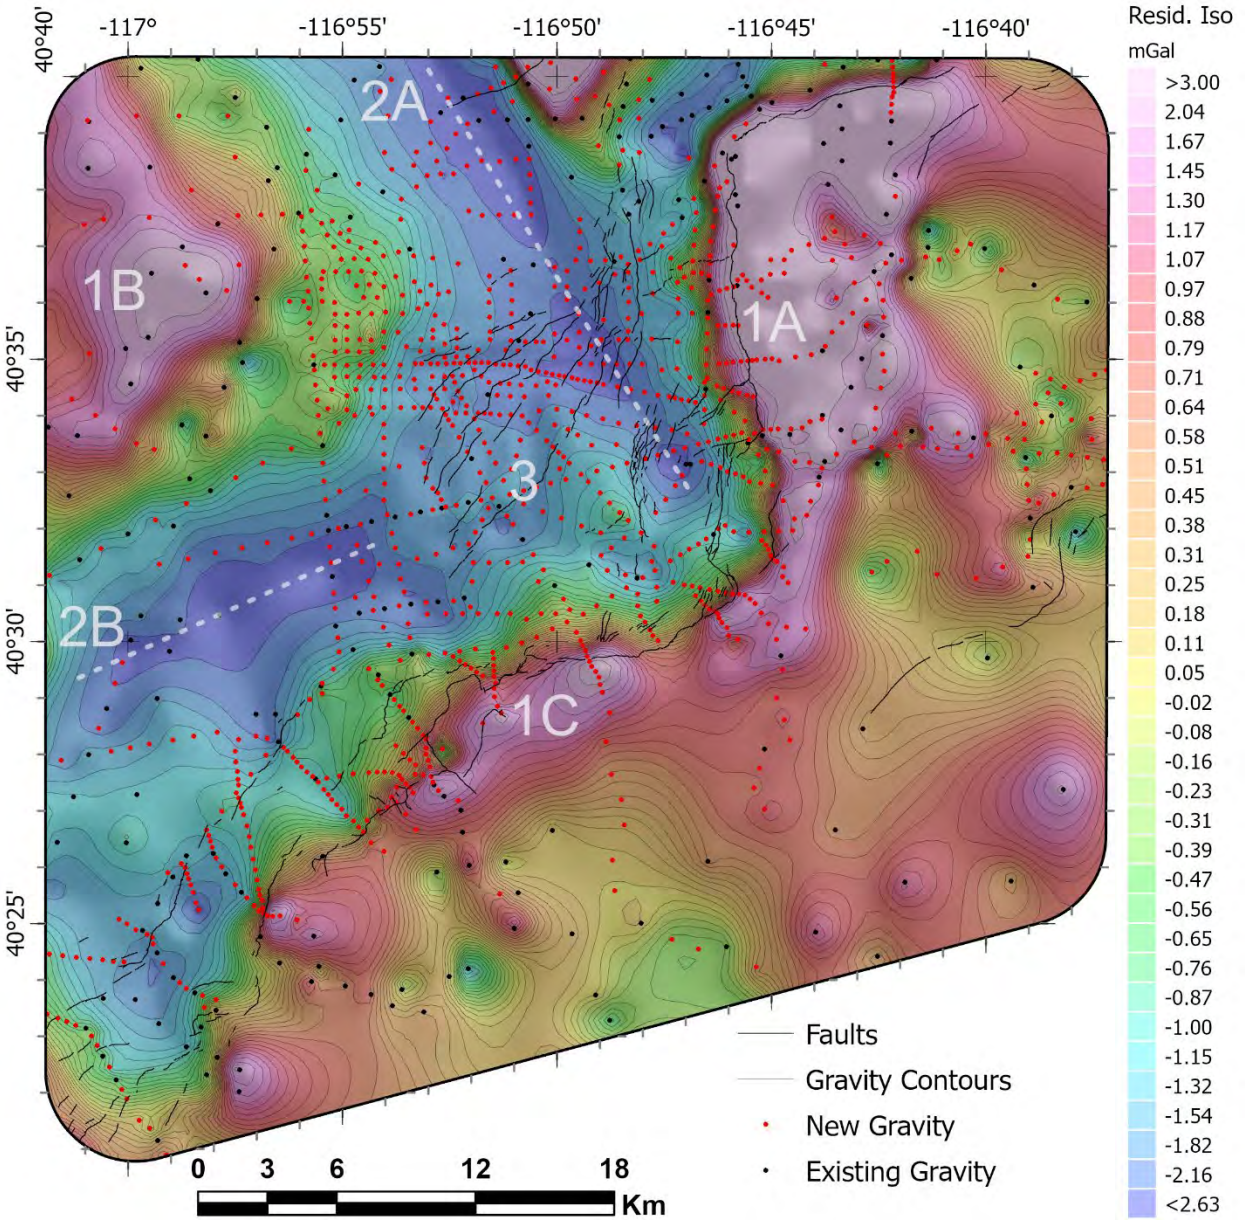

Figure 2: Residual isostatic anomaly map overlain by faults (dark black lines), gravity contours (light black lines; contour interval corresponds to bins in the 'Resid Iso' color bar), new gravity stations (red dots), and existing gravity stations. Labeled features are described in the Discussion section of this manuscript.

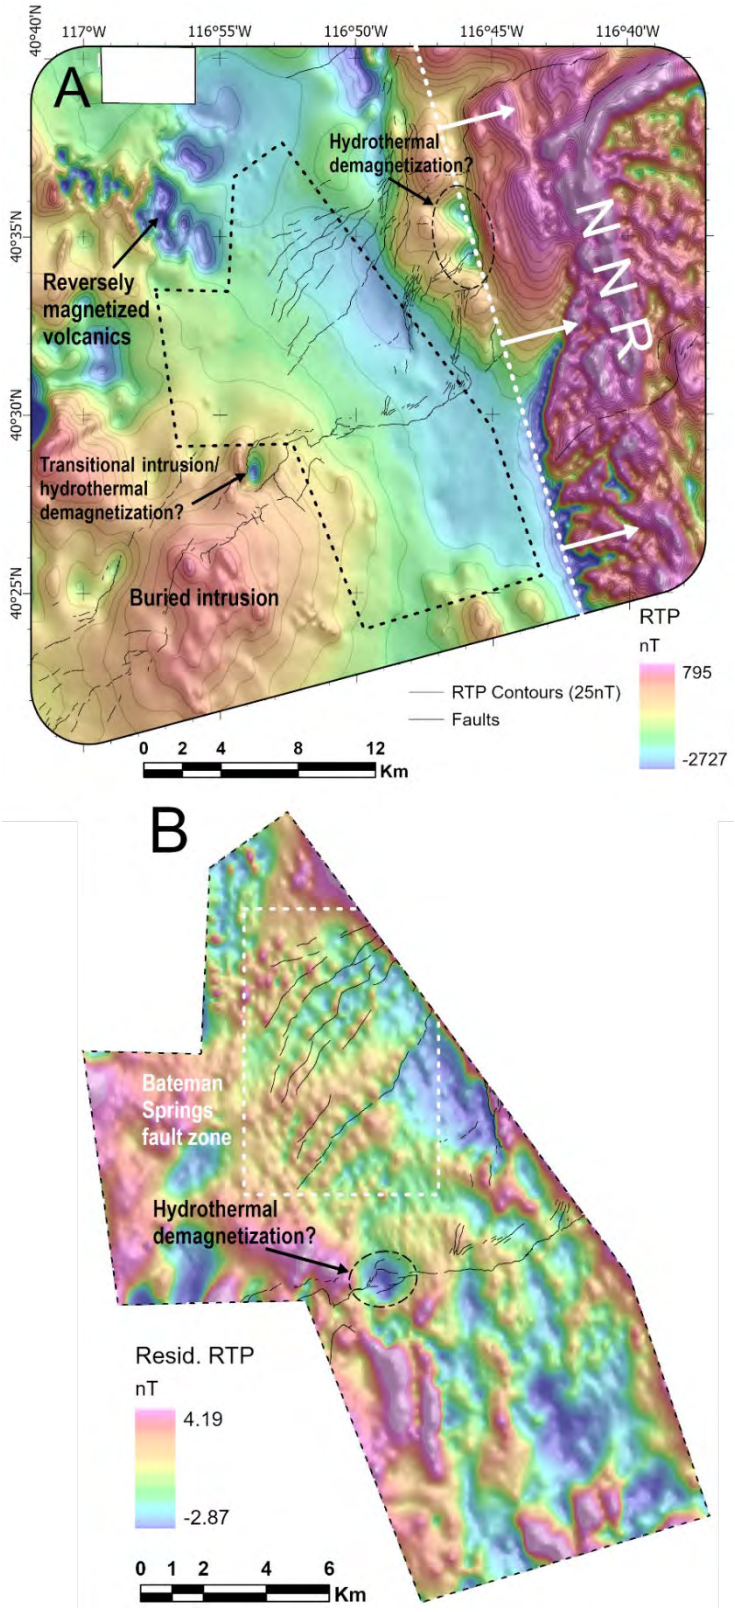

Figure 3: RTP magnetic anomaly (A), and residual RTP magnetic anomaly (B) overlain by faults (black lines). Dashed black line on panel A indicates the extent of the grid in panel B. Features pertinent to this study are labeled and described in the Discussion section of this manuscript.

3.3 Magnetotellurics

Magnetotellurics (MT) is a passive electromagnetic geophysical method that can be used to infer subsurface electrical conductivity structure by measuring the Earth's electrical response to natural time-varying magnetic fields. The MT method is particularly well suited for geothermal studies as it can facilitate imaging of subsurface clay caps, zones of hydrothermal alteration, heat sources, hydrothermal fluids, and thermally enhanced zones (Newman et al., 2008; Munoz, 2014).

In May 2022, MT data were collected at 43 locations spanning an area of ~200 km^2 across the core of the study area. Magnetic fields were measured with Zonge International Inc. ANT4 induction coils (Tucson, AZ). Electric fields were measured with Borin Stelth 1 Ag-AgCl electrodes (Culver City, CA) placed in saturated bentonite clay bags for better contact resistance. Both the magnetic and electric fields were recorded with ZEN data loggers developed by Zonge International Inc. (Tucson, AZ). The instruments were left recording for about 24 hours, providing reliable resolution of the subsurface conductivity structure for the upper two to three kilometers of the Earth's crust. MT data were used to generate a 3D electrical conductivity model of the subsurface using ModEM (Kelbert et al., 2014). From the 3D model, we extracted 2D plan maps at pre-determined depths (relative to sea level) to highlight conductive anomalies at various depths of investigation that might indicate the locations of hydrothermal fluids or their alteration products (Figure 4). Additionally, we extracted 2D cross sections from the 3D model along our 2D geophysical profiles to facilitate the interpretation of which structures may host hydrothermal fluid flow in the shallow subsurface.

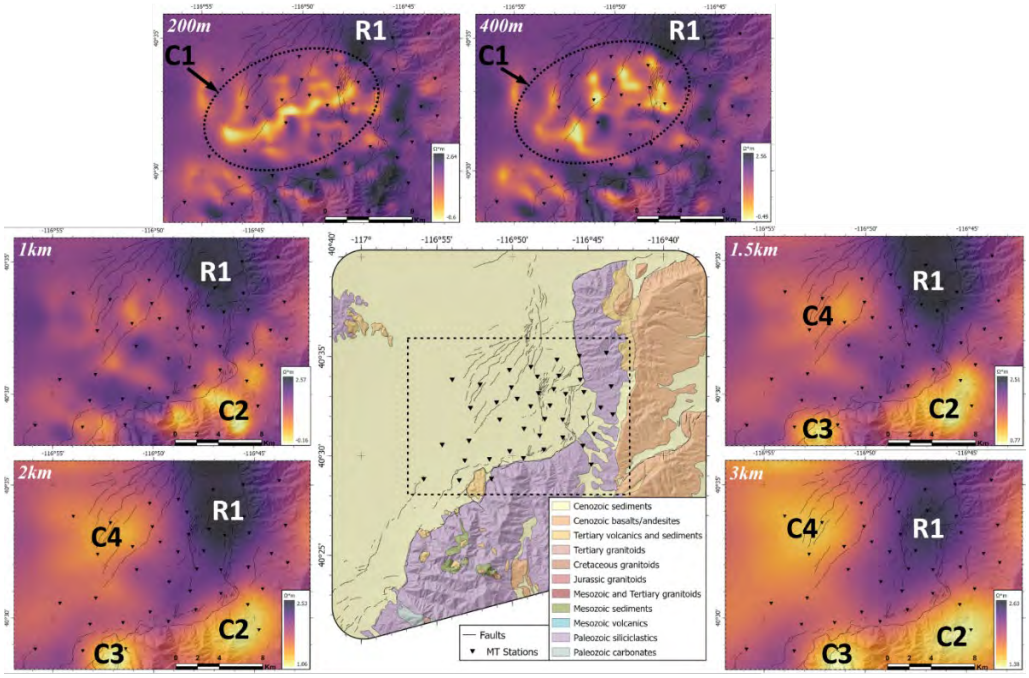

Figure 4: Depth slices through 3D conductivity model. (Center) DEM (U.S. Geological Survey, 2021) hillshade overlain by the generalized geologic map, faults (black lines) and MT stations (inverted black triangles). The dashed black rectangle indicates the extent of the depth slices. These images highlight the conductivity structure at depths of 200 m (upper left), 400 m (upper right), 1 km (mid left), 1.5 km (mid right), 2 km (lower left), and 3 km (lower right) beneath Argenta Rise. Conductive and resistive anomalies (i.e., C1-4, R1, respectively) are described in the Discussion section of this manuscript.

4. Structural Mapping

We performed a horizontal gradient analysis of the gravity and magnetic grids to detect abrupt lateral changes in density and magnetization, and thereby elucidate subsurface structural patterns. Subsurface structures typically manifest as steep gradients in potential field data, and can be mapped by analyzing horizontal gradient maxima (HGM; Grauch and Cordell, 1987; Cordell and McCafferty, 1989; Blakely and Simpson, 1986), which tend to lie over sub-vertical structures. For the TF magnetic data, we first calculated the pseudogravity (Blakely, 1995). The pseudogravity transformation effectively centers TF magnetic anomalies over their respective source bodies, and simplifies their interpretation. We then calculate horizontal gradient maps of the gravity and pseudogravity grids, and following Phillips et al. (2007), calculate HGM using a routine that identifies laterally continuous ridges in horizontal gradient maps. Discrete maxima were then connected into continuous lines (or lineations) based on user specified distance and azimuth tolerance relationships to adjacent maxima (Athens, 2018; Figure 5).

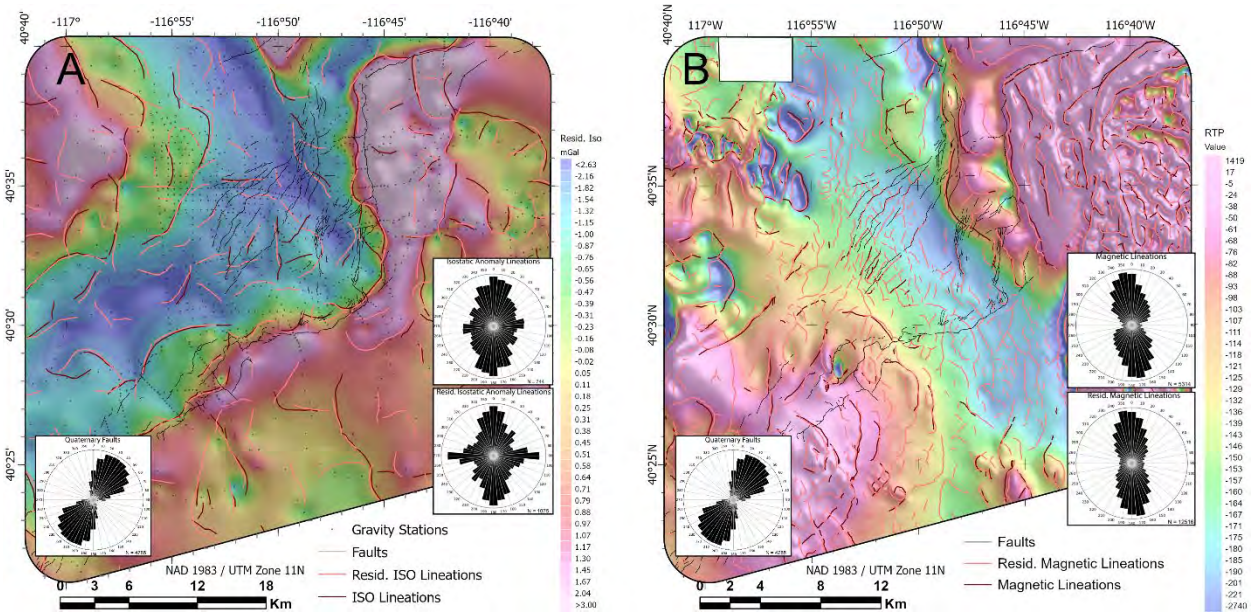

Figure 5: A) Residual isostatic anomaly overlain by gravity stations (black dots), faults (black lines), and lineations derived from the isostatic and residual isostatic anomalies (dark red and light red lines, respectively. Rose diagrams show trends of Quaternary faults (lower left), lineations derived from the isostatic anomaly (upper right) and lineations derived from the residual isostatic anomaly (lower right). B) RTP magnetic anomaly overlain by faults (black lines) and lineations derived from the magnetic and residual magnetic anomalies (dark red and light red lines, respectively). Rose diagrams show trends of Quaternary faults (lower left), lineations derived from the pseudogravity anomaly (upper right), and lineations derived from the residual pseudogravity anomaly (lower right).

5. Geophysical Modeling

To characterize subsurface stratigraphy and structure we constructed 2D and 3D potential field models utilizing both forward and inverse methods. Physical property measurements (density, magnetic susceptibility, magnetic remanence) from hand samples and outcrops of relevant geologic units throughout the region informed model parameters. All models are consistent with the mapped surface geology represented in the generalized geological map.

5.1 Depth to Basement

We perform a 3D inversion of gravity anomalies, using methods described by Jachens and Moring (1990), to estimate the geometry of the pre-Cenozoic basement surface beneath the northern Reese River basin (Figure 6). This method is an iterative procedure that combines gravity data, surface geology, and an estimate of the density of Cenozoic deposits to approximate the thickness of young basin fill. We separated the isostatic anomaly into two components: 1) a basement gravity field (representing crystalline, pre-Cenozoic, and intrusive rocks); and 2) a basin fill gravity field (representing overlying Cenozoic basin fill deposits). We simplify the surface geology of the Nevada state geologic map (Crafford, 2007), and reclassify all units into two categories: basement (generally any crystalline, pre-Cenozoic, or intrusive rocks) and Cenozoic deposits. For the purposes of this project, we reclassify all Cenozoic volcanics as Cenozoic sediments being that there are no volcanic units that are both thick enough (greater than several hundred meters) and dense enough to appreciably affect the regional gravity field in the study area. During the inversion the basement density is allowed to vary laterally while a vertical density gradient function (Jachens et al., 1996) is enforced in the basin fill deposits (see 'Quaternary Sediments', Table 1). To constrain the inversion solutions, we incorporate publicly available well data from three sources: oil and gas (Nevada Bureau of Mines and Geology, 2023b), geothermal (Nevada Bureau of Mines and Geology, 2023a), and water wells (Nevada Division of Water Resources, 2023).

This style of depth to basement estimate contains a substantial amount of uncertainty and is often only accurate to within 20% of the total basin depth in areas without well constraints (Jachens et al., 1996). Ambiguity in the gravity method, local density-depth variations in overlying basin fill deposits, and the assumption that basin fill density varies in the vertical direction only will often lead to an underestimation of true basin depth. Furthermore, basement lithologies, while modeled as a single unit in the inversion, are highly variable and heterogeneous throughout the study area, representing a wide range of densities. Nonetheless, our inversion results provide a qualitative characterization of relative variations in the basement surface. We use that characterization to guide regional interpretations of basin geometry and inform the development of our 2D and 3D geophysical models.

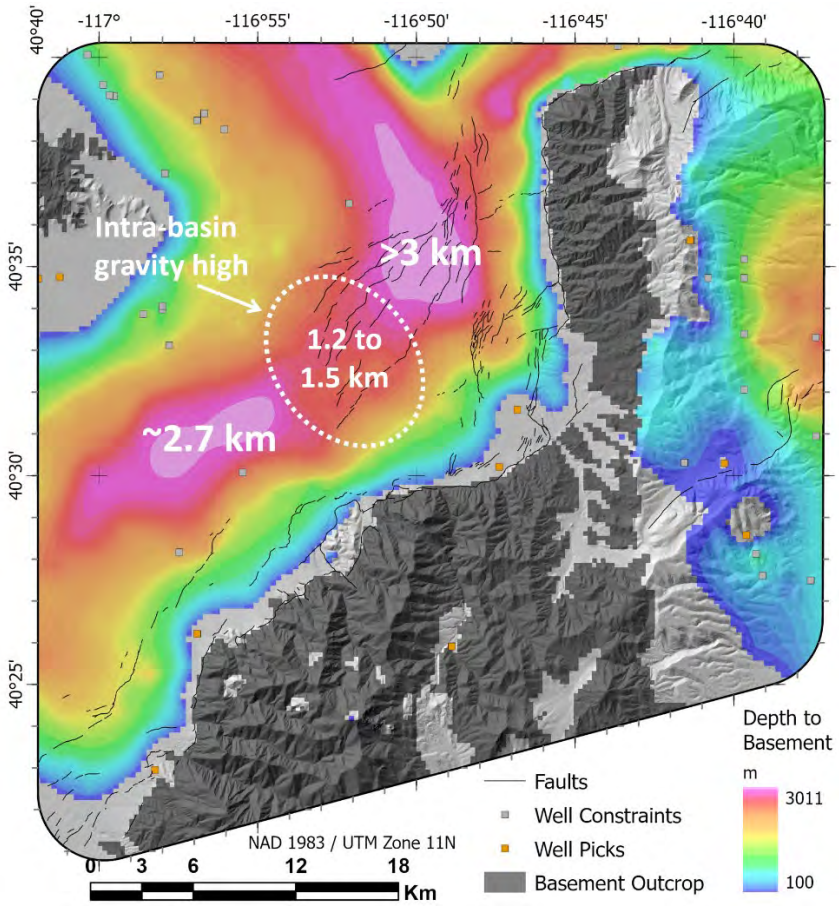

Figure 6: DEM (U.S. Geological Survey, 2021) hillshade overlain by depth to pre-Cenozoic basement map, faults (black lines), minimum constraint wells (i.e., wells not intercepting the basement; grey squares), basement intercepting wells (orange squares), and locations of basement outcrop (dark grey areas). Light grey areas are locations where basement is interpreted to be <100 m below the surface.

5.2 2D Modeling

A series of 12, 2D joint gravity and magnetic potential field models were created along profiles spanning the northern Reese River basin (Figure 7). Six of these profiles (WV1, WV2, WV3, WV4, WV5 and NNRA) were adapted from Watt et al., (2007) and updated to be consistent with the modeling goals of this study. Although geophysical models are typically placed orthogonal to the primary structural trend that is being characterized, we also consider the underlying gravity data density and attempt to focus on regions with dense data coverage that still captures key features and structures that may be important for controlling hydrothermal activity. Profile data are extracted from the gravity (isostatic anomaly) and magnetic (total field anomaly) grids with a sampling interval of 100 m along the profiles. Model bodies are assigned densities and magnetic susceptibility and remanence values based on physical property measurements when available (Table 1). Model body geometries are made to be consistent with the generalized surface geology. A total of 31 geologic units are modeled, representing 23 generalized 2D model layers with differing densities based on depth, and different remanent magnetizations. The model bodies are adjusted iteratively using a process of forward and inverse methods to reproduce the observed potential field anomalies within the limits imposed by the physical property data and surface geology (Figure 8).

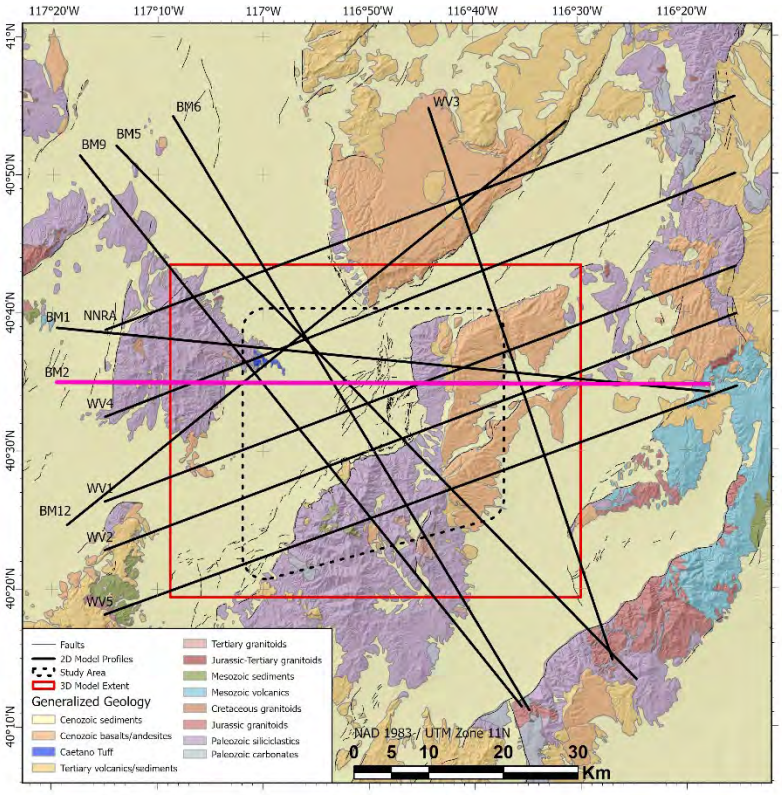

Figure 7: DEM (U.S. Geological Survey, 2021) hillshade overlain by generalized geologic map, faults (thin black lines), 2D model profile locations (thick black lines), the Argenta Rise study area (dashed black polygon), and the 3D model extent (red polygon; Figure 9). The 2D model profile indicated by the thick pink line (BM2) is presented herein (Figure 8).

Table 1: Physical property values used in 2D and 3D modeling. Physical properties include density (measured in kilograms/meter^3), magnetic susceptibility (Susc.; unitless, values reported in 10^{-3} SI), magnetic remanence (Rem.; measured in Ampere/meter), inclination (Inc.; measured in degrees), and declination (Dec.; measured in degrees). Values determined by measurements performed on hand samples and outcrops for this project.

Unit	Description	Density kg/m^3	Susc. ($x10^{-3}$) SI	Rem. A/m	Inc. degrees	Dec. degrees
QTs	Quaternary sediments: 0 – 200 m	2,020	*	*	*	*
	Quaternary sediments: 200 – 600 m	2,120	*	*	*	*
	Quaternary sediments: 600 – 1200 m	2,320	*	*	*	*
	Quaternary sediments: >1200 m	2,420	*	*	*	*
QTba	Quaternary - Tertiary basalts/andesites	2,550	0.025	1	64	12.5

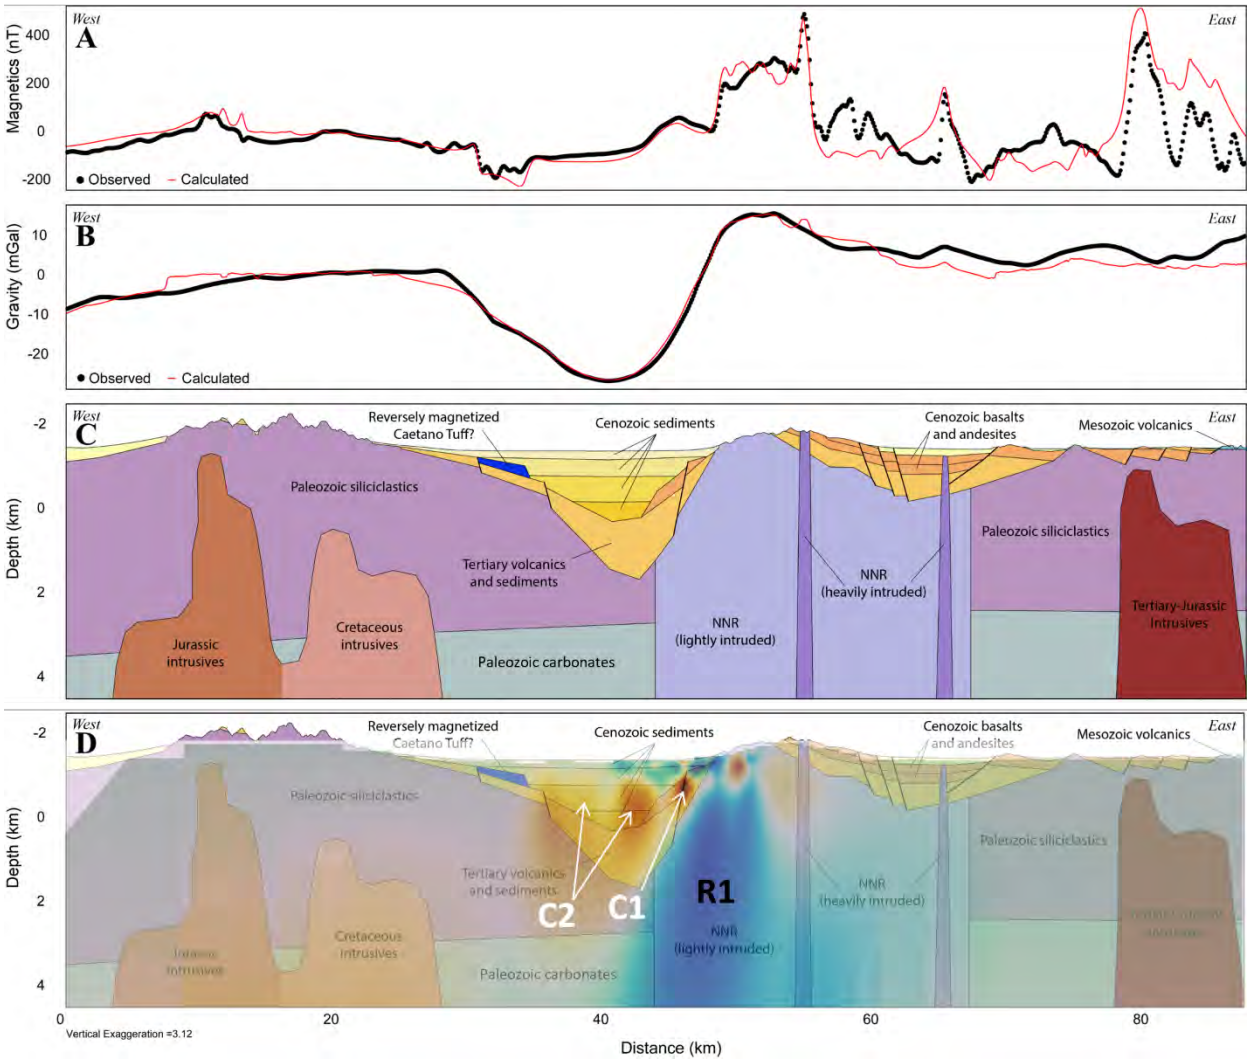

Figure 8: Joint gravity and magnetic potential field model along profile BM2 (profile location indicated by pink line on Figure 7). Magnetic data (panel A) are extracted from the total field anomaly and gravity data (panel B) are extracted from the isostatic anomaly. Observed anomalies are indicated by the black dots, and the calculated model responses are indicated by the red lines. Model bodies (panel C) are assigned densities and magnetic susceptibility and remanence values based on physical property measurements performed on outcrops and hand samples collected in Reese River basin and surrounding ranges. Resistivity anomalies (panel D) overlain on model bodies highlight near surface conductors that could represent hydrothermal fluids and/or zones of alteration along faults and contacts. Conductive and resistive anomalies (i.e., C1, C2, and R1) are described in the Discussion section of this manuscript.

5.3 3D Modeling

A 3D joint gravity and magnetic potential field model is developed using the Oasis Montaj® GM-SYS 3D Modeling software extension (Seequent, 2023). The 23 generalized 2D model layers are further simplified to 10 layers for the 3D model and provide initial constraints. Surfaces in the 3D model are adjusted through structural inversions to minimize misfit between the observed and calculated anomalies (Figure 9). There are several ambiguities in the model area related to the depth and geometry of sources. One of the layers, representing young, reversely magnetized

volcanics, did not reproduce either the geometry, or magnitude of the magnetic low at the southeast corner of Battle Mountain (see 'Reversely magnetized volcanics' on Figure 9). We attribute this to the fact that this anomaly is relatively small, isolated, and not adequately represented in the 2D models. Therefore, we removed this layer from the 3D model, and instead created a voxel model over this anomaly and inverted on magnetic susceptibility, deriving a closed body isosurface, which when imported back into the 3D model, reproduces the magnetic low quite well. Another ambiguity pertains to the geometry and depth of the granitoids. Surficial outcrops of these units are relatively small, and we do not have an extensive inventory of physical property information on them. The density contrast between the granitoids and surrounding basement lithologies is presumed to be minor. However, some of the granitoids appear to have distinct magnetic anomalies associated with them. To model the granitoids in 3D, we performed a series of magnetic structural inversions on the granitoid layer, creating a tiered geometry in which the granitoids are more voluminous at depth, and more laterally restricted closer to the surface.

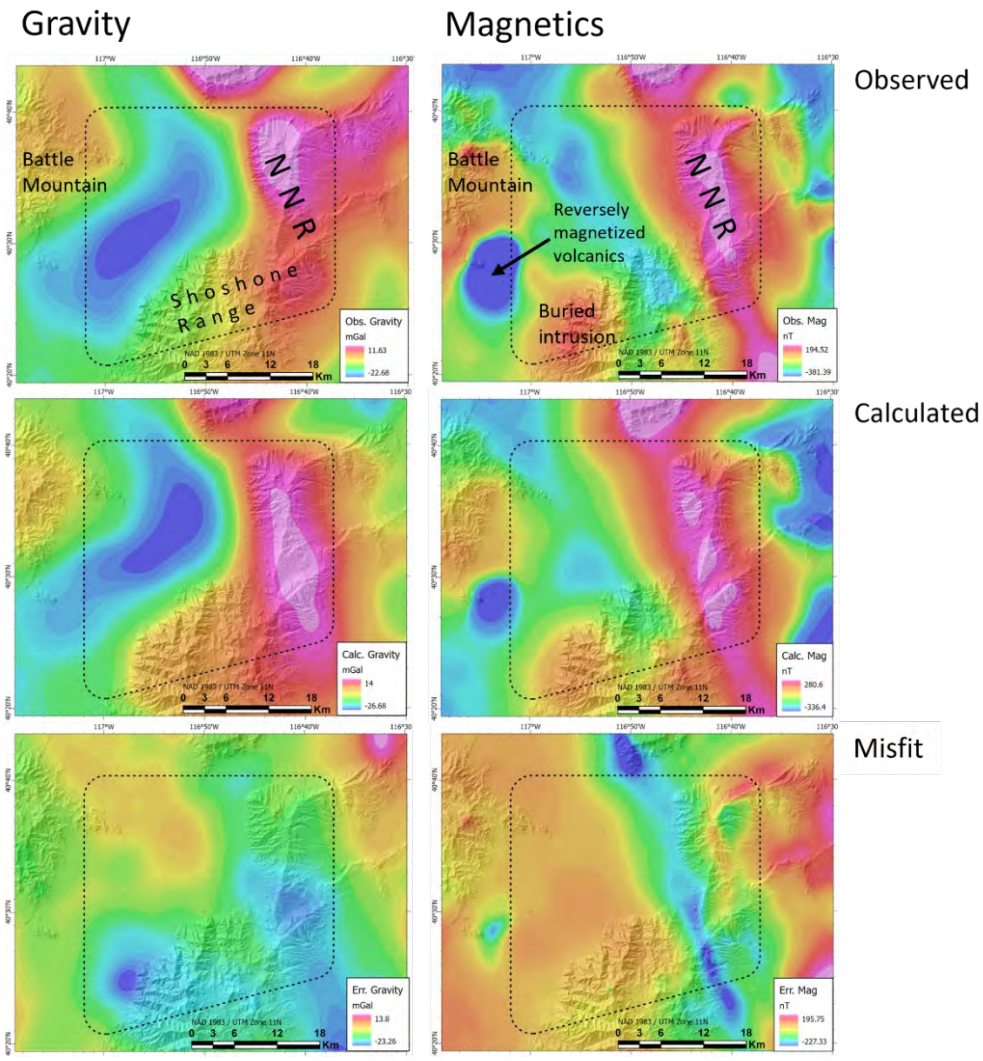

Figure 9: DEM (U.S Geological Survey, 2021) hillshade overlain by results of 3D joint gravity and magnetic potential field model showing observed gravity and magnetic anomalies (top), calculated model responses (middle), misfit between the observed and calculated anomalies (bottom). The Argenta Rise study area is indicated by the black dashed polygon. Model extent is indicated on Figure 7.

6. Discussion

The geophysical data and models presented here-in, reveal basin-bounding and concealed intra-basinal structures that may influence the development of a hydrothermal system at Argenta Rise. Anomalies observed in the gravity, magnetic and magnetotelluric datasets are used to constrain basin geometry and basin depth, delineate concealed contacts, faults, and fault extensions, and identify regions with subsurface fluid flow and/or hydrothermal alteration. Interpretations of these features are incorporated in the 2D and 3D models to provide a robust characterization of subsurface geology at Argenta Rise.

The gravity maps and depth-to-basement results constrain basin geometry and basin depth in the northern Reese River valley. The highs (areas 1A, 1B, and 1C on Figure 2) correspond to outcrops and near surface bodies of Paleozoic siliciclastic and carbonate rocks and middle Miocene NNR-related mafic intrusives, which tend to be relatively dense compared to other lithologies in the region. The two most prominent gravity lows (areas 2A and 2B on Figure 2) delineate two structurally controlled sub-basins beneath the northern Reese River basin; one trending NNW (area 2A) and the other trending ENE (area 2B). The NNW-trending sub-basin is asymmetric, with the trough of the gravity low displaced towards the east relative to the central axis of the basin between Battle Mountain and the northern Shoshone Range. The eastern edge of the gravity low has a distinct NNW-trend, which is notably different than the much more northerly trend of the current range-front fault zone bounding the western edge of the northern Shoshone Range. We interpret this gradient to represent the concealed, southeastward extension of the NNW-trending range-front fault zone bounding the west side of the southern Sheep Creek Range. Gravity values in this sub-basin gradually increase to the west, suggesting vertical deformation is primarily accommodated by the eastern range-front fault zones. The ENE-trending sub-basin is relatively more symmetric and truncated along its eastern extent by an approximately 10 km wide series of subtle intra-basin gravity highs (area 3 on Figure 2) that also delineate the west side of the southern portion of the NNW-trending sub-basin. The intra-basin gravity highs form a ridge-like feature across the Reese River basin and may be indicative of structural relief in the basement surface.

Our gravity derived depth-to-basement results (Figure 6) indicate maximum basin depths of >3 km in the southern portion of the NNW-trending sub-basin and ~2.7 km in the ENE-trending sub-basin. An intra-basin gravity high (area 3 on Figure 2; Figure 6) is situated between these two regions. Basin depths above the intra-basin gravity high are 1.2 to 1.5 km. If this feature is structurally controlled, it suggests that there could be 1.2 to 1.8 km of cumulative vertical displacement across the structures inferred along its periphery. The intra-basin gravity high could be a barrier to lateral flow of subsurface fluids between the NNW- and ENE-trending sub-basins or, alternatively the structural complexity may locally enhance permeability, promoting the vertical transport of fluids between the deep and shallow subsurface (Earney et al., 2018; Craig et al., 2021).

One of the most prominent features apparent in the GeoDAWN aeromagnetic data (Glen and Earney, 2023, 2024) is a NNW-trending region of magnetic highs in the eastern portion of the study area (labeled ‘NNR’ on Figure 3A). Numerous aforementioned studies (Stewart et al., 1975; Zoback and Thompson, 1978; Zoback, 1979; McKee and Noble, 1986; Blakely and Jachens, 1991; Glen and Ponce, 2002) have concluded that this feature is caused by a highly magnetic, mafic dike swarm that was emplaced in the middle Miocene. Large-scale crustal features, such as the NNR, typically have highly faulted and fractured boundaries which can serve as conduits for deep

circulating hydrothermal fluids. Numerous other features are interpreted from the aeromagnetic data, including shallowly buried, reversely magnetized volcanics (Figure 3A), buried intrusive bodies (Figure 3A), zones of possible demagnetization due to hydrothermal alteration (Figure 3A and 3B), and very subtle anomalies associated with young Quaternary faults along the Bateman Springs fault zone (Figure 3B). The residual magnetic lineations overall show a very strong northerly trend (Figure 5B). However, over the basin where magnetic gradients are much lower, there are numerous lineations with a distinct NNW-trend, a trend that is not well represented in Quaternary fault patterns within the study area. This trend is very similar to the trend of the NNR. Therefore, we interpret these features to represent relatively older structures that may relate to emplacement of the NNR. Many of the NNE-trending intra-basin faults associated with the Bateman Springs fault zone have subtle, but mappable anomalies associated with them (Figure 3B). Furthermore, the horizontal gradient analysis reveals that many of these faults extend further than they are currently mapped, in addition to identifying new structures that are currently unmapped. The recognition of these features and, more importantly, where these features intersect with northerly- and NNE-trending Quaternary faults may help identify additional areas with enhanced structural complexity that could support the development of a hydrothermal system.

Overall, the MT results (Figure 4) correlate well with the gravity derived depth-to-basement results (Figure 6) with nearly all of the conductors lying within the basin or slightly above the basement-basin fill contact (bottom panel on Figure 8 shows one example of this). As an exception, however, we note that strong conductors appear within basement lithologies at depth in the southern portion of the survey area (C2 and C3 on Figure 4). As there are currently no mapped hot springs in these areas, we interpret these anomalies as possible recharge zones, where meteoric fluids are entering the subsurface through a network of deep-seated fractures in the basement. Shallow and deep conductors (C1 and C4 on Figure 4, respectively) within the basin appear to line up nicely with the region of dispersed NE-striking faults associated with the Bateman Springs fault zone, and may represent the presence of saline groundwater or, alternatively, could be due to hydrothermal upwelling. A resistive body (R1 on Figure 4) is consistently present at all depths in the northeastern portion of the survey area, becoming more pronounced and expanding south and westward at deeper depths. This resistive body is interpreted to reflect the geometry of the basement surface at this location.

The 2D geophysical modeling we performed constrained the locations and relative amounts of offset along major faults and highlights which faults may be more conducive to hosting hydrothermal fluid flow. One of the primary advantages of 2D geophysical models is the ability to leverage high resolution geophysical data where available to make detailed structural interpretations that can be difficult to characterize in 3D. The 2D geophysical model presented here (Figure 8), has several correlations with the MT data that may indicate the presence of shallow hydrothermal activity. The strongest conductive anomaly (C1 on Figure 8) along the profile is co-located with a major, northerly-trending fault on the east side of the basin. The anomaly appears confined to a perched volcanic unit that overlies a package of mixed sedimentary and volcanic basin fill (Cenozoic basalts/andesites and Tertiary volcanics/sediments). However, the conductive anomaly does not appear to extend much deeper than the perched volcanic unit, suggesting that if this anomaly is due to the presence of hydrothermal fluids and/or alteration, the primary zone of upwelling may be occurring off-axis of this profile. Alternatively, this anomaly may reflect the presence of a shallow groundwater aquifer that is confined to the volcanics and localized around the fault due to an enhancement of permeability. The slightly less conductive, but more extensive

anomaly just to the west (C2 on Figure 8), correlates spatially with the Bateman Springs fault zone, and may indicate hydrothermal activity, or the presence of sediment-hosted meteoric groundwater. The large resistive body (R1 on Figure 8) is interpreted as NNR-intruded basement.

The 2D geophysical models provide discrete, detailed structural information about the subsurface. However, subsurface geology is inherently complex and difficult to characterize via 2D methods alone. The 3D geophysical model, presented here (Figure 9), provides a more robust means of testing the validity of our 2D models and, by extension, our conceptual model of the subsurface. Overall, the calculated gravity and magnetic responses of our 3D model layers agree quite well with the observed data as indicated by the relatively low error estimates. Inconsistencies within the 3D model are largely due to poor data distribution (primarily the sparse gravity data coverage in the south and southeastern portion of the Shoshone Range), and the complex, heterogeneous nature of the geology being modeled. Some of the misfit could be minimized by incorporating additional 2D model constraints. Nevertheless, the data from the 2D and 3D geophysical models provide insight regarding stratigraphic, structural and physical property relationships of subsurface geology at Argenta Rise.

7. Conclusions

We characterize the subsurface geology, constrain basin geometry, and map basin-bounding and concealed intra-basin structures at Argenta Rise using high-resolution geophysical data (i.e., newly collected gravity, MT, and physical property data and aeromagnetic data) to model geophysical anomalies and assist with identifying structural settings that are favorable to hydrothermal fluid flow. The gravity and depth-to-basement maps reveal two sub-basins beneath Argenta Rise with a potential structurally controlled, intra-basin high separating these two basins. Maximum basin depths are near 3 km. The horizontal gradient analysis of the aeromagnetic data suggests the presence of previously unmapped intra-basin structures (e.g., new faults and extensions of mapped faults), as well as extensions to mapped faults, and highlights subsurface structural complexity. When combined with the 2D geophysical models, the MT data indicate regions of potential hydrothermal activity, in some cases with strong conductive bodies co-located with faults and contacts. The 3D geophysical model shows that our conceptual model of basin geometry and structure (represented in the 2D geophysical models) is relatively accurate throughout the study area as indicated by the low error estimates. These data will support our planned development of a 3D geological model and aid the process of selecting sites for temperature gradient drilling.

Reducing Costs and Mitigating Risk for Geothermal Energy with Permeable Fracture Imaging

Jeffrey Eppink, James Geiser, Peter Geiser, Peter Malin, Austin Mathews, Anastasia Stroujkova

Enegis, LLC

Keywords

Permeable Fracture Imaging, Reservoir Characterization, Permeability, Fractures, Seismic Imaging, Geothermal Reservoir

ABSTRACT

To mitigate risk and maximize the chances for sustained fluid flow in geothermal reservoirs, knowledge of permeability field architecture is vital. We achieve this by mapping permeable fractures with a non-microearthquake seismic listening method: Permeable Fracture Imaging, PFI. Enegis has demonstrated the viability of PFI technology on a lease operated by AltaRock Energy at the Newberry Volcano in Oregon and funded by the Advanced Research Projects Agency–Energy and Quaise Energy.

The PFI signal is created by minute elastic vibrations of fluid-filled voids and fractures activated by the propagation of episodic stress waves through the crust. The PFI directly addresses the knowledge gap of the heterogeneous permeability field—not by modeling—but by directly mapping the permeable fractures. The result is a five-dimensional (space, time, energy) map of fracture permeability.

In October 2023, we conducted a ~1,000 geophone survey over a ~27 km^2 area on the west flank of Newberry caldera. Passive recording was conducted over 4 ½ days. The survey imaged a 1.6 x 1.6 km target zone centered on a lease well. Our deepest imaging volume was at 2200 m depth.

Based on independent near-well observations, the PFI survey recorded active permeable fractures along the well and mapped them far beyond the well. Sub-regional NNW-SSE fault and fracture zone trends are clearly observed. Further, the PFI results correlate with independent lithology, density, and resistivity data. They also are consistent with a lower-resolution map of the magnetotelluric-delineated clay cap and observed Bouguer gravity anomalies.

The PFI method is empirical and repeatable, supplying actual data, not simulations, which contrasts with traditional reservoir modeling. The technique also can provide accurate reservoir

monitoring. Except for the velocity model, the PFI technique requires no modeling assumptions. Relative to microearthquake techniques, which require three component geophones at similar grid size to PFI surveys, PFI is less costly. It also is not subject to the need to have the sensors in-place during MEQ swarms. Compared to the linear geometry of single fiber optic DAS cable, the 2D PFI geophone grid provides significantly better target locations.

We have performed technoeconomic analyses for PFI surveys using cost data from DOE models. These studies show that the PFI technique could reduce reservoir development life-cycle costs and monitoring by 40% compared to the status quo for seismic methods. The PFI technique materially helps minimize the "drilling blind" problem that has plagued geothermal development, leaving it behind in the race for investment compared to wind and solar. The PFI technique results in a direct mapping of permeability field architecture as opposed to computer simulations, which can be driven by assumptions. The PFI technique also has potential for application in geologic carbon storage, wastewater injection and delineation of blind mineral deposits.

1. Introduction

Enegis, LLC, (Enegis) applied for and was awarded an ARPA-E Small Business Innovative Research (SBIR) grant under the Supporting Entrepreneurial Energy Discoveries (SEED) program in September 2022. The award is entitled Ambient Seismic Imaging (ASI) Technology for Low Cost and Effective Geothermal Resource Exploration, Development, and Management. A geothermal lease on Newbery Volcano in Oregon is the site of the project. Of note, Enegis re-branded ASI as Permeable Fracture Imaging (PFI) as a means of focusing technology's impact on the critical technical geothermal reservoir parameters of active permeability and fluid flow.

Permeable Fracture Imaging technology uses seismic emission tomography methods and passively listens to vibrations due to stress-change-induced fluid-rock interactions. These interactions are episodically created by the earth's flux of stresses that form the Transient Stress Field (TSF) whose variation is at a time scale measured in seconds (P. Geiser and P. Malin, personal communication, 2024). The data comprising the TSF are part of the seismic "noise" or endogenous radiation spectrum, which in recent years has also been called "seismic emissions". This noise is the subject of considerable interest, e.g., Chebotereva (2000). Research has revealed that the noise is the product of natural non-random sources of seismic energy that affect the brittle crust and manifest in the seismic record e.g., oceanic waves, e.g. (Aster, R., C., et al, 2023), atmospheric loadings, e.g. (Rodrigues 2007), Earth tides, volcanic tremors, etc.

Wavelet analysis by J. Geiser (2024, personal communication) of the natural rock permeability-associated vibrations shows that they are episodically periodic with episodes common over periods of many minutes. The heterogeneous permeability field of the Earth's brittle crust has long been a challenge for the extraction of fluid resources. Our seismic method solves this problem—not by modeling—but by directly mapping the permeability field architecture quantitatively and temporally. The PFI signal is due to minute elastic vibrations of fluid-filled fractures and voids activated by the near-continuous movement of episodic stress waves through the crust. We note that the PFIs we develop are active surfaces that can be associated with fractures. Our product is a five-dimensional (space, time, energy) permeability field map, taken from Geiser et al. (2023), which the broader group of us recently published. (Figure 1).

This article describes the geological setting, previous germane, technical work conducted on the West flank of Newberry Volcano, our data acquisition process, the field survey, data processing, interpretation, and results. Of note, given the funding limitations of the ARPA-E grant, we could only design the field survey to confidently image to depths of ~2100 m, which is shallower than the target objective of the NWG 55-29 well.

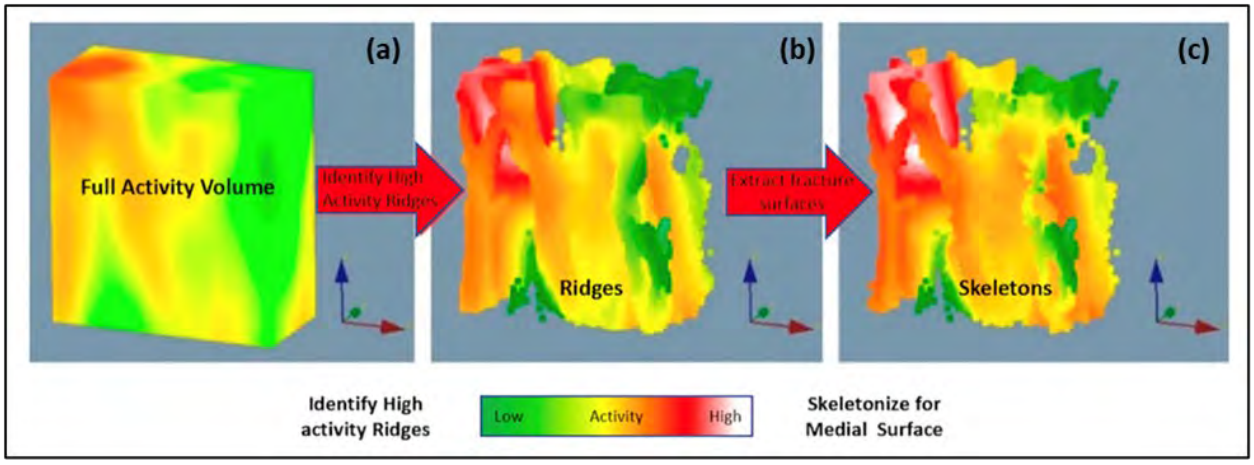

Figure 1. Processing of survey data for semblance full activity volumes (FAVs). (a) FAV, (b) Isolation of ridges, (c) Peak picking on the FAV to find local areas of connected high activity voxels. In 3D form "clouds" of high-activity permeability field (HaPF) emissions, which are skeletonized to form 1-voxel-thick medial HaPF surfaces (from Geiser et al., 2023).

2. Geological and Geophysical Background

Located within central Oregon, Newberry Volcano (Figure 2b, Newberry shown as point "A") is situated near the conjunction of three distinct geologic zones, including the Cascade Volcanic Arc to the west, the Basin and Range province to the south and southeast, and the Columbia Plateau in the northeast and east. Newberry Volcano is a large shield construct located approximately 60 km east of the axis of the Cascade Range, and approximately 35 km from the city of Bend, Oregon.

As a broad shield volcano, Newberry has shown evidence of volcanic activity for the last 600,000 years. The volcano is bimodal in nature skirted with predominantly felsic, caldera-centered eruptions, and mostly mafic eruptions on the flanks, generally composed of ash/lahar deposits, as well as basalts, andesites, and cinder cones, while the caldera contains obsidian flows, rhyolitic tephra, cinder cones, maars, and vents, with heavy faulting penetrating the units in the caldera. A geologic map of the Newberry volcano is depicted in Figure 2a.

Newberry's youngest lava flow is called the Big Obsidian Flow, which is approximately 1,300 years old (Robinson et al., 2015). Due to Newberry's recent volcanic activity, the United States Geological Survey (USGS) has classified it as the 13th most threatening volcano in the United States (Ewert et al., 2018).

2.1 Structural Trends

The stress state of the Newberry region has been examined in previous work using focal mechanisms from earthquakes. Regionally, the least compressive stress (σ3) is generally oriented ENE/WSW (264° ± 29°), the principal compressive stress (σ1) is near vertical, and the intermediate stress (σ2) is oriented approximately north to south (or NNW/SSE) (Crider, 2001). Other stress indicators, such as dikes, cinder cones, and the orientation of faults (such as the Sisters fault zone near Bend, Oregon) suggest similar stress orientations (Newberry Geothermal Energy, 2016).

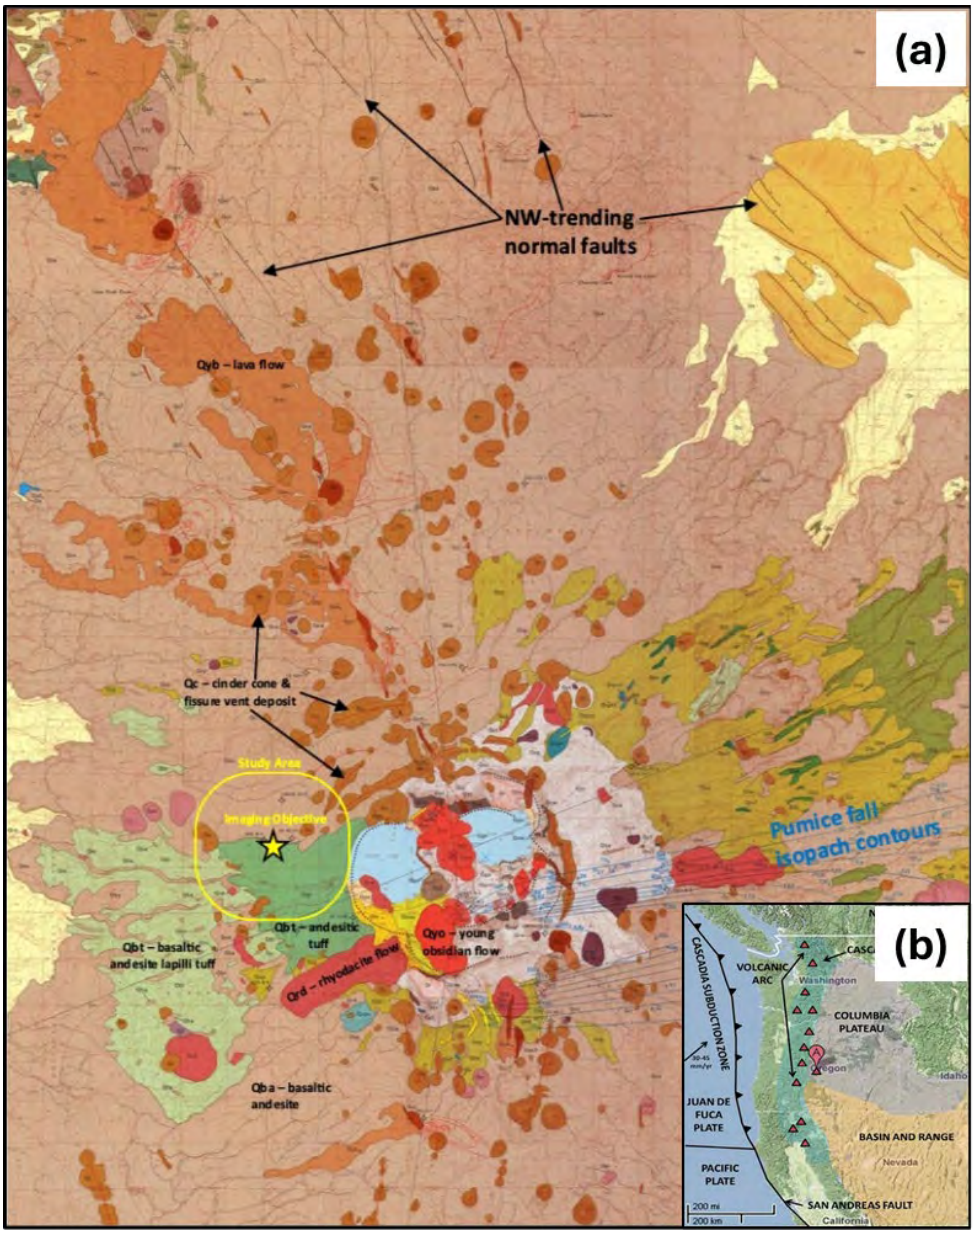

Figure 2. (a) Geologic Map of Newberry Volcano (MacLeod et al., 1995). (b) Geologic Provinces of the Pacific Northwest (Newberry Geothermal Energy, 2016).

The faults in the region are characterized by two dominant orientations (Figure 3a), including a set of tectonically related northwest-striking faults (shown in yellow), and a separate set of faults and fractures that developed as a result of volcano formation (shown in red and orange). Scarps around Newberry volcano are generally oriented N-S and the fissures tend to be oriented NNW (Cladouhos et al., 2011). The recent lava flows of Newberry volcano also strike in the NNW/SSE direction in what is known as the Northwestern Rift Zone (Figure 3b). This NNW structural trend is also reflected in several surficial lineaments within LiDAR imagery.

Well NWG 55-29, the imaging objective of the study, underwent a stimulation in 2014 and gathered microearthquake (MEQ) data to characterize the fault-slip kinematics of the reservoir (Figure 3c). The distribution of P (compression) and T (extension) axes form a thrusting fault-plane solution with slight obliquity that strikes NNW and accommodates ENE-WSW shortening. The fault set exhibits structural trends that generally match the regional stress orientation.

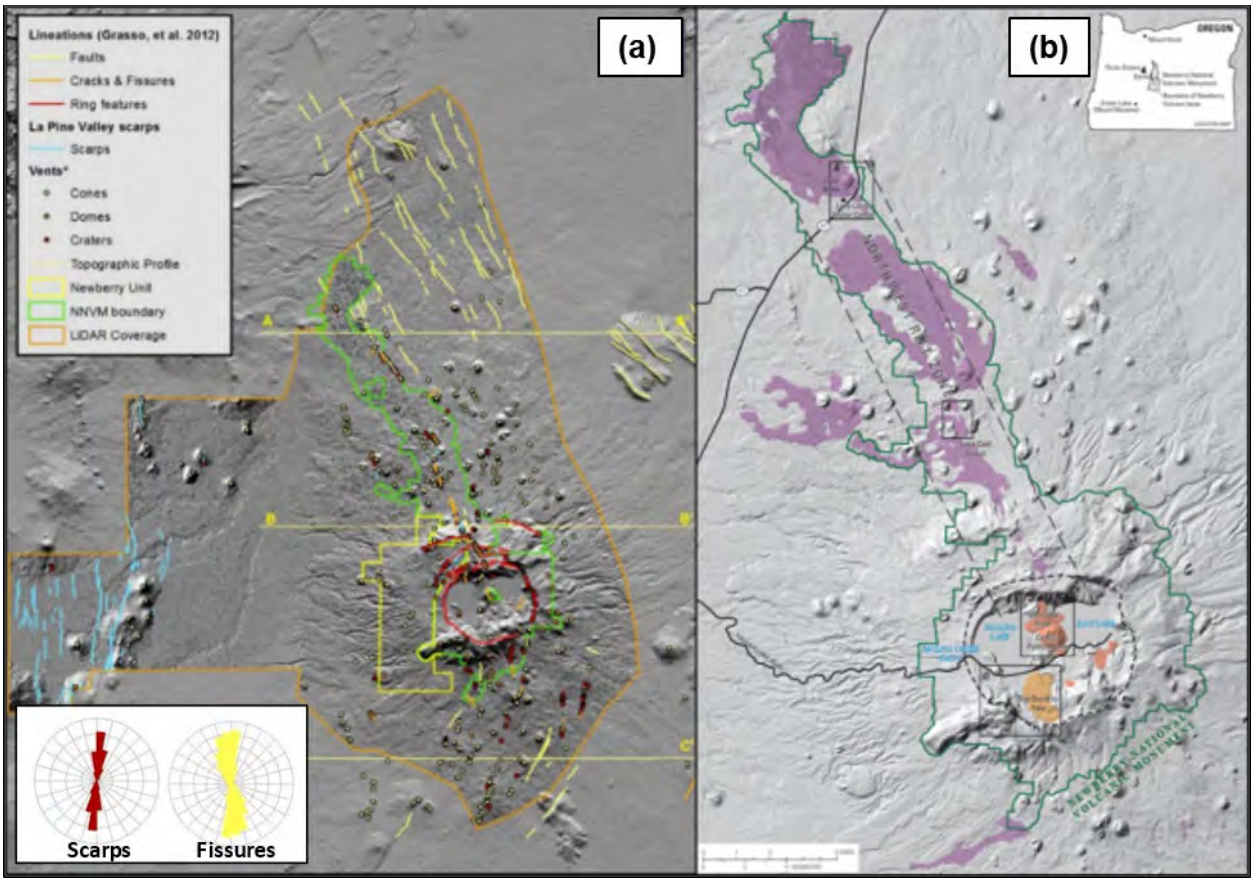

Figure 3. (a) Newberry Fault Zones (from Newberry Geothermal Energy, 2016; Cladouhos et al., 2015). (b) Northwestern Rift Zone (from Robinson et al., 2015).

2.2 Volcano-scale Geophysics

Several geophysical investigations have been conducted on the west flank of Newberry Volcano in attempts to elucidate the nature of the subsurface geology. Gravity surveys, collected in 2007 and 2010, are presented in the complete Bouguer Anomaly map in Figure 4a (Waibel et al., 2012).

The edge of the volcano's structure is inferred from gravity data trends NNW/SSE, consistent with the regional stress orientation. The high-density rocks (shown in purple) and high geothermal gradients present in the western flank of the volcano suggest that the pluton is young enough to still maintain its high heat. Taverna et al. (2024) found gravity anomalies were present beneath the caldera and on the western and northwestern flank, and these coincide with areas of high favorability for enhanced geothermal systems (EGS) development.

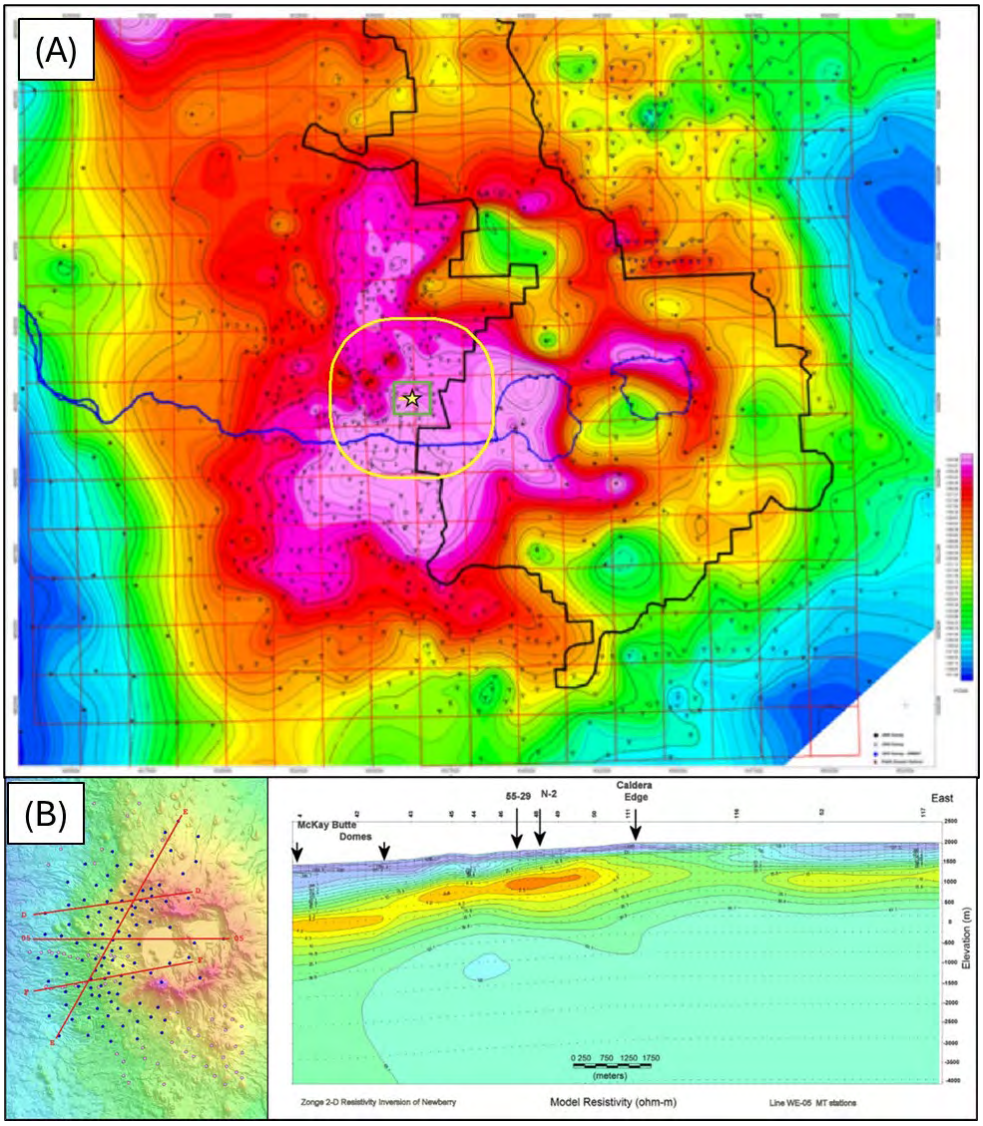

Figure 4. (A) Complete Bouguer Anomaly with density reduction value of 2.5 g/cc (Waibel et al., 2012) (B) 2D MT slice, Line 05 (Waibel et al., 2012).

The electrical resistivity of the reservoir beneath Newberry volcano was studied using magnetotelluric (MT) surveys (Figure 4b), which are affected by the presence of fluids, rock composition, temperature variations, porosity, and permeability. At Newberry, there is a shallow, electrically conductive layer on the west flank of the volcano that is underlain by an electrically resistive mass. Generally, the base of the shallow conductive layer is indicative of an interface

between lower temperature clay/zeolite alteration and high temperature greenschist facies alteration (Waibel et al., 2012). NWG 55-29, the target objective of this study, is located at the western edge of this zone.

3. Data Planning and Acquisition

3.1 PFI Net Design

We designed the survey using a nominal 175 m spacing based on imaging objectives and economic constraints for the number of geophones that we could use for the project. We then raytraced our nominal layout based on certain criteria, including:

- land access
- the physical and ecological geography of the field area
- randomization
- efficient positioning of the geophones

The final survey layout depicted in Figure 5 covers 25 km^2 and comprises about 1000 stations. Each station was to be occupied by a geophone, recorder, and battery as a single unit called a Nodal Recording Unit (NRU).

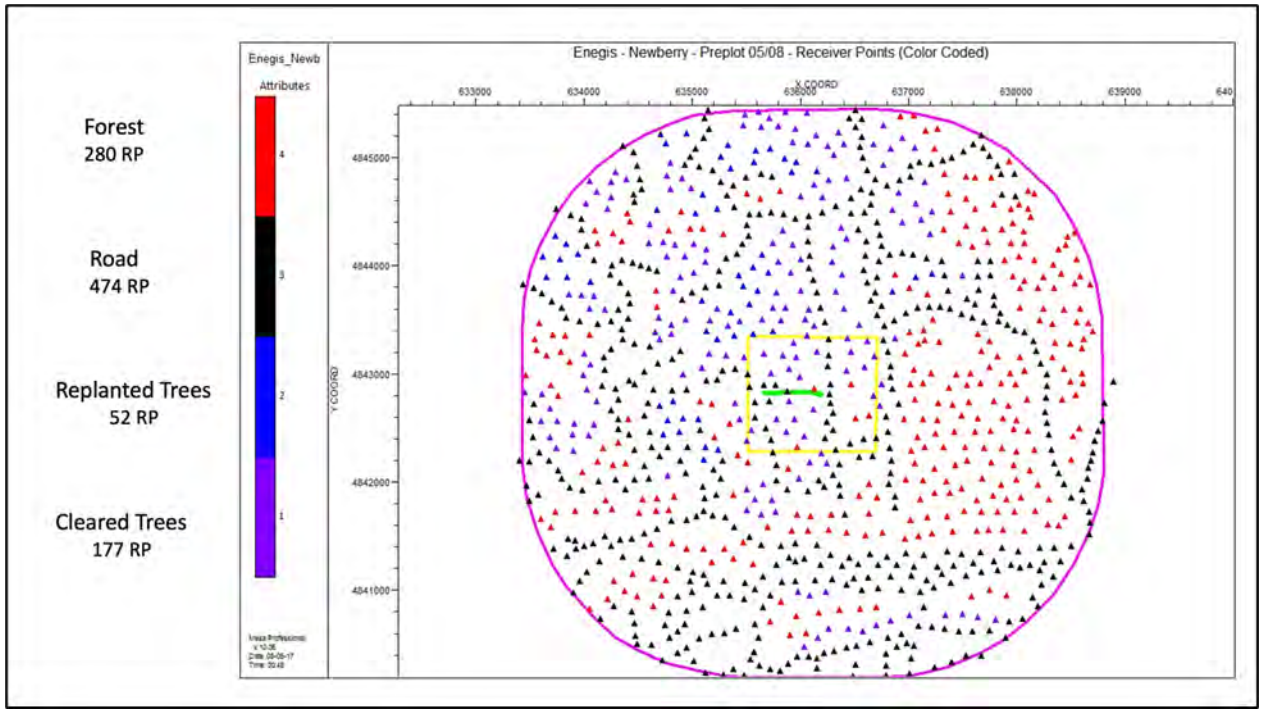

Figure 5. Nodal Recording Unit layout

3.2 Permitting and Field Survey

Material difficulties were encountered in obtaining land access permits from the U.S. Forest Service (FS) due to bureaucratic delays beyond Enegis' control. Upon our field permit issuance

28 September 2023, Enegis mustered multiple field crews and implemented the survey from 7 to 19 October, allowing for 5.5 days to emplace nearly 1000 geophones, recorded for 4.5 days and 3 days of pick-up. Each NRU was emplaced in a shallow (~10 cm) hole that was dug with a slide hammer ((b) in Figure 6), geopositioned with a Juniper Geode unit (c). The computed field positioning of the NRUs is shown in (d). Four days following our survey, the survey area was covered in about 15 cm of snow (e).

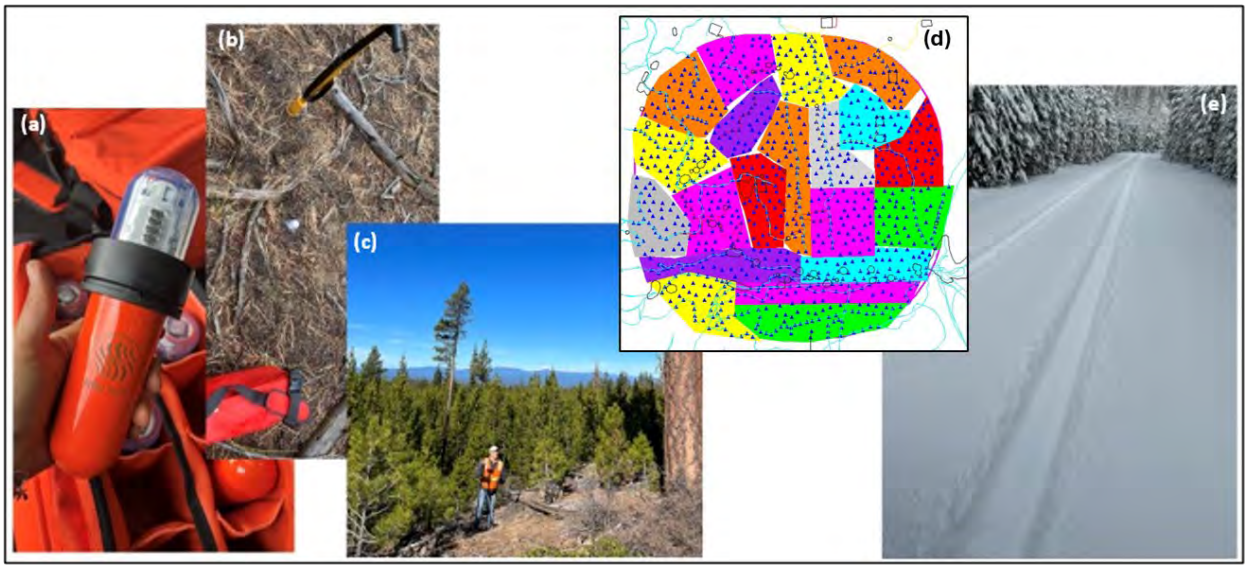

Figure 6. Newberry Volcano field program. (a) a typical NRU, (b) an emplaced NRU, (c) geopositioning of the node, (d) the emplaced field nodal array and (e) field conditions 4 days following the survey

The full array comprised 982 geophone nodes, for which we had a 99.5% success rate for recording, resulting in 977 NRUs with recorded data. Figure 7 depicts the semblance fold at 2100 m aperture in our imaging cube, which is the number of receivers that a given depth point has available to it for imaging. The fold coverage in red is over 600, which provided an excellent basis for developing PFIs.

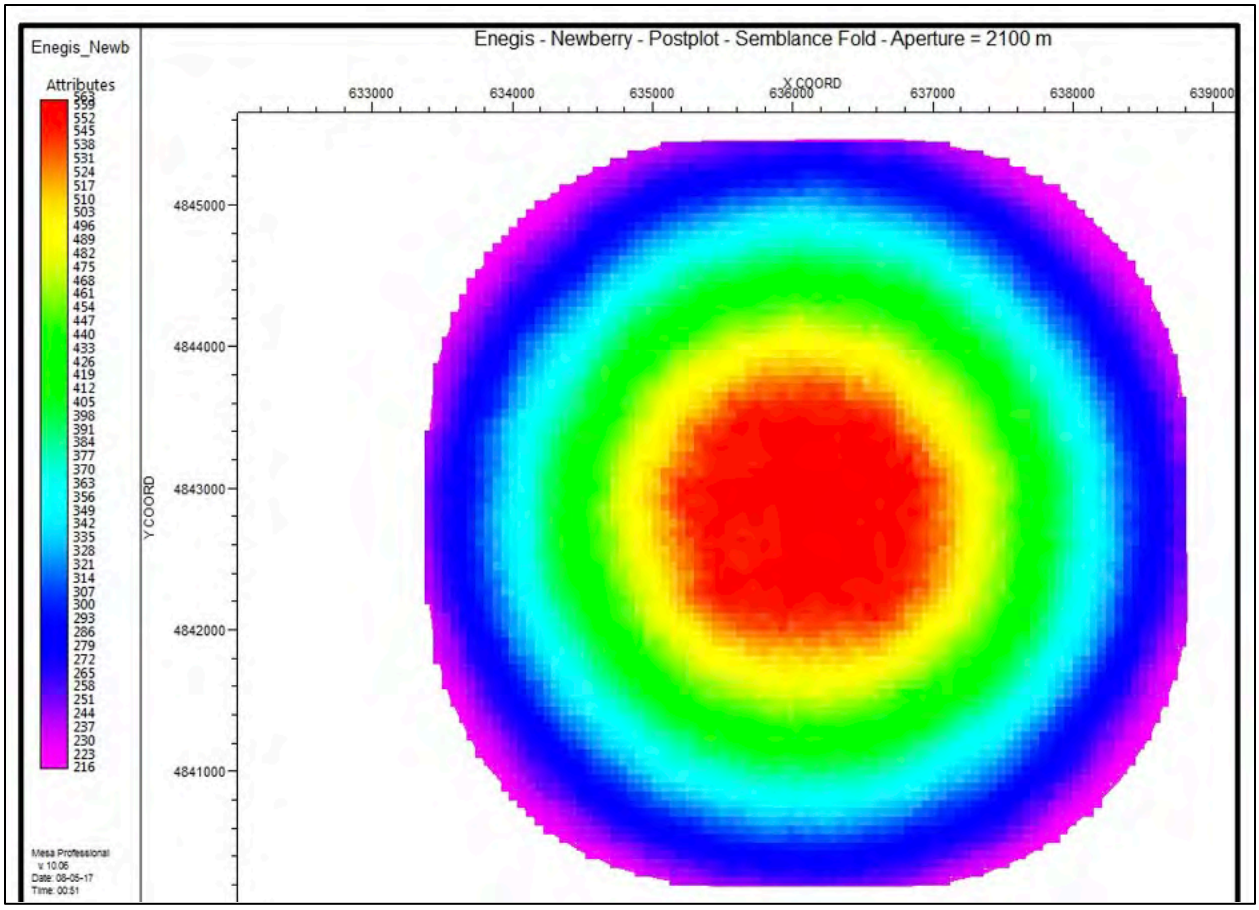

Figure 7. Survey fold coverage.

3.3 Noise Analysis

Seismic noise can significantly degrade the quality of seismic measurements and affect the performance of ambient noise imaging. Cultural noise from moving vehicles and operating machinery (pumps, generators etc.) poses problems during the day. Other noise sources include rain, wind, running water in the creek, local and remote earthquakes and microseisms.

We analyzed seismic amplitudes from all array nodes during the time of the experiment to determine the noisy locations and time intervals. Figure 8a shows the full grid root mean square (RMS) amplitudes averaged over each minute during the full array spread. Notice the diurnal pattern with higher amplitudes during the day and lower amplitudes at night. Figure 8b-e shows the amplitudes for each node averaged over 6-hour intervals highlighted in a. Strong cultural noise is observed on Saturday afternoon (b) with the highest amplitudes following the road and various tourist attractions in the southern part of the array. Figure 8c and e show the array amplitudes between midnight and 6AM on 15 and 17 October. The noise level during these time intervals is significantly lower than during the Saturday afternoon. Figure 8d shows the array amplitudes between 6 AM and noon on 16 October. High noise level observed during this time interval is spread over the entire array, although the amplitudes vary between the nodes. 15 October appears to be the quietest day overall.

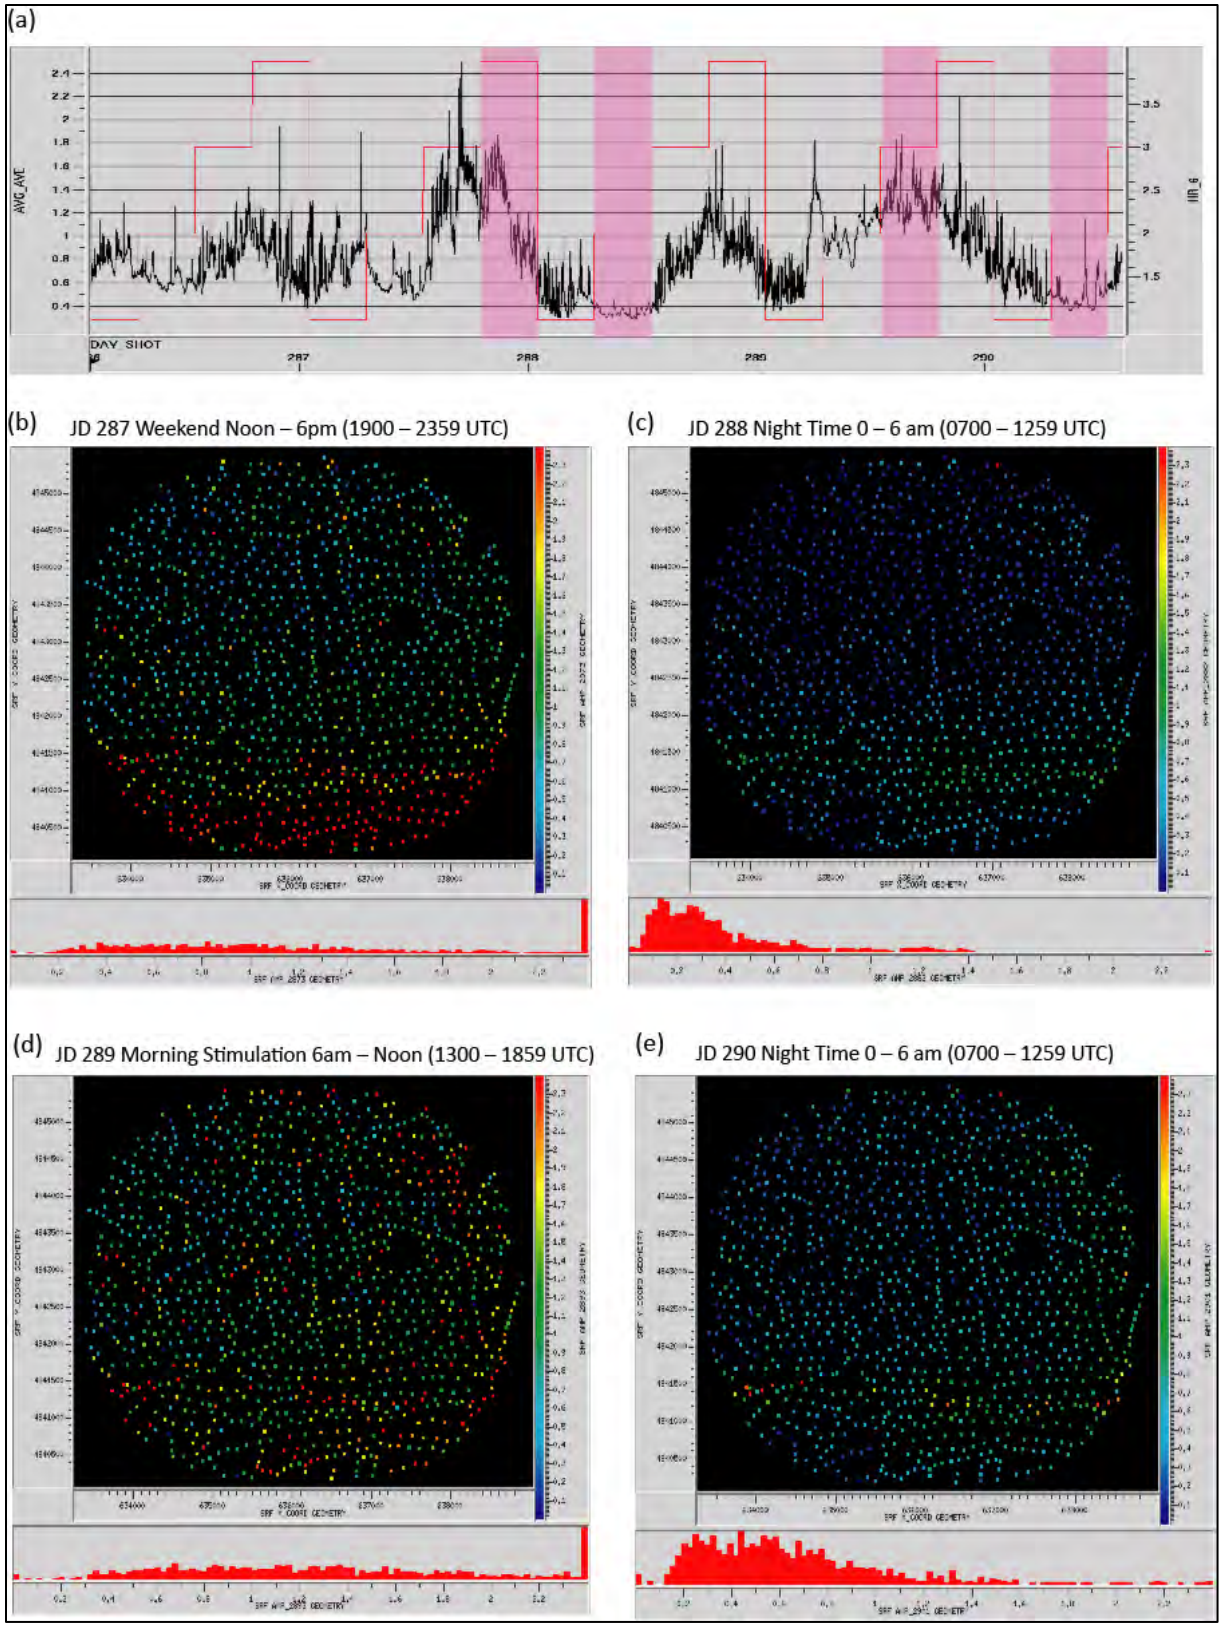

Figure 8. (a) Full grid RMS amplitudes. (b) Array amplitudes on 14 October 2023. (c) Quiet time interval on Sunday, 15 October 2023. (d) Monday, 16 October (e) Quiet time on Tuesday, 17 October.

4. Data Processing

The PFI method used to identify regions with high fracture density is based on conventional reflection seismic signal processing algorithms modified to deal with one-way travel times between the fracture sources and the receivers. The processing of the seismic data is performed in the following major steps: (1) Noise suppression: (2) estimation of elevation and residual statics; (3) building the earth velocity model; and (4) one-way travel time depth migration for a continuous signal source. The processing steps are outlined below.

4.1 Signal Denoising, Enhancement, and Quality Control

Data from 977 nodes were recorded during the array deployment. We used the data acquired during the full array spread between 13 and 17 October 2023 to analyze and reduce the noise. Success in using fracture seismic recordings for mapping fractures requires extensive trace editing, signal enhancement and noise suppression (Sicking et al., 2016). To identify high- and low-noise time intervals we calculated RMS amplitudes averaged over each minute for each receiver during the array full spread period and then summed them over time.

The first step in the preprocessing, involving removal of the bad traces, train noise and unexplained high amplitudes, resulted in some reduction in the noise amplitude. Significant improvements have been achieved after applying a median filter and dropping individual receivers in noisy locations.

The next step in noise reduction is cepstral filtering, which is used to remove stationary noise persistent for long periods of time. This type of noise is common in populated areas and appears as noise background added to the consistent, slowly changing, harmonic character of fracture seismic signals. The noise is significantly reduced after the filter application. Using the full grid array average, we identified the low-noise 5-hour time intervals used in the final processing steps. These quiet intervals occurred during the nighttime on 15 and 17 October 2023. The intensity volumes were then estimated during these low-noise time intervals.

4.2 Estimation of Elevation and Residual Statics

Elevation and residual statics are used to account for the differences in the elevation and near-surface velocity variations between the array geophones. The elevation statics are applied by taking the difference between the surveyed elevation of each geophone and the chosen constant elevation datum, then computing the travel time for the elevation difference using the near surface velocity. The computed travel time shifts are applied to the traces before the one-way depth migration.

4.3 Building the Earth Velocity Model

Our velocity model is set within the geologic context of Newberry Volcano. Existing velocity data comes from several seismic experiments utilizing both active and passive sources, including a 1983 seismic refraction profile (Cotton and Catchings, 1989), a 1984 active source seismic experiment (Dawson and Stauber, 1986), and a 2008 active source seismic experiment (Beachly et al., 2012). A comparison of several existing velocity models is presented in Figure 9b. In this study we used a model modified from Beachly et al. (2012) by warping on topography.

Due to significant topographic features in the study area, estimation of 3D seismic travel times is required to perform the imaging. Using 3D raytracing is computationally intensive compared to

using a simple layered velocity model. A 3D velocity model was developed using a flat image datum at the elevation of 2000 m. To build the velocity model, small time shifts were added to re-datum the receiver data from the surface to a smoothed elevation-based surface. The final step involves filling the shallow velocity layer to the datum elevation. Figure 10 shows the slice through the final 3D velocity model.

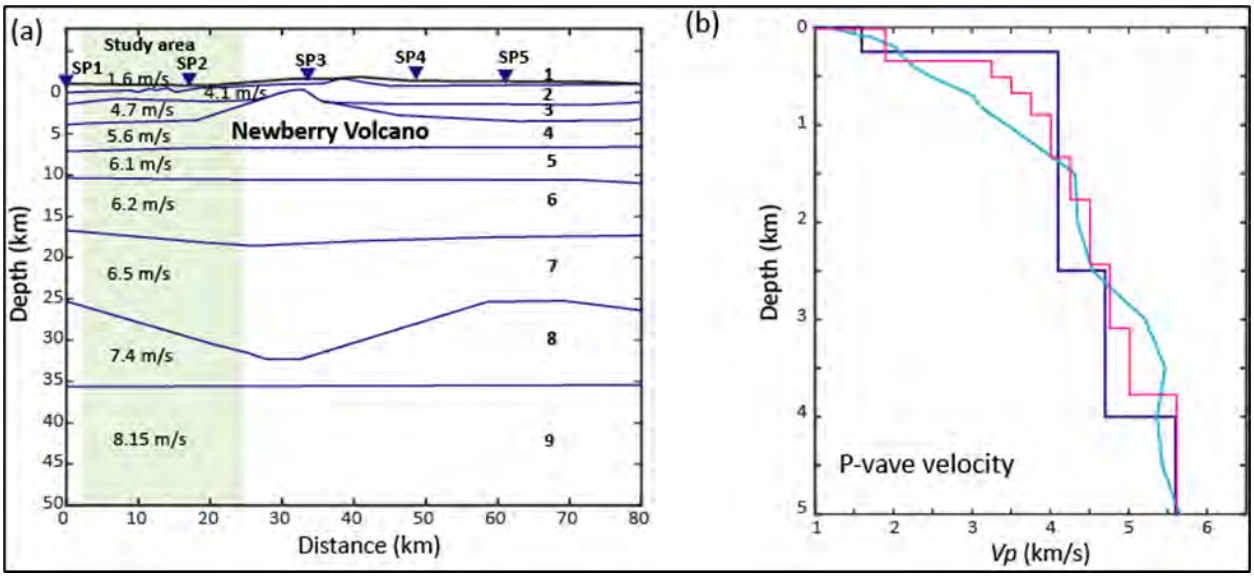

Figure 9. (a) Seismically derived crustal velocity model (from Catchings & Mooney, 1988). Numbers 1-9 refers to layers 1-9 described in the text. (b) Seismic velocity structure for the Newberry area: blue – from Catchings & Mooney, 1988; magenta – from Beachly et al., 2012; cyan – from Templeton et al., 2014.

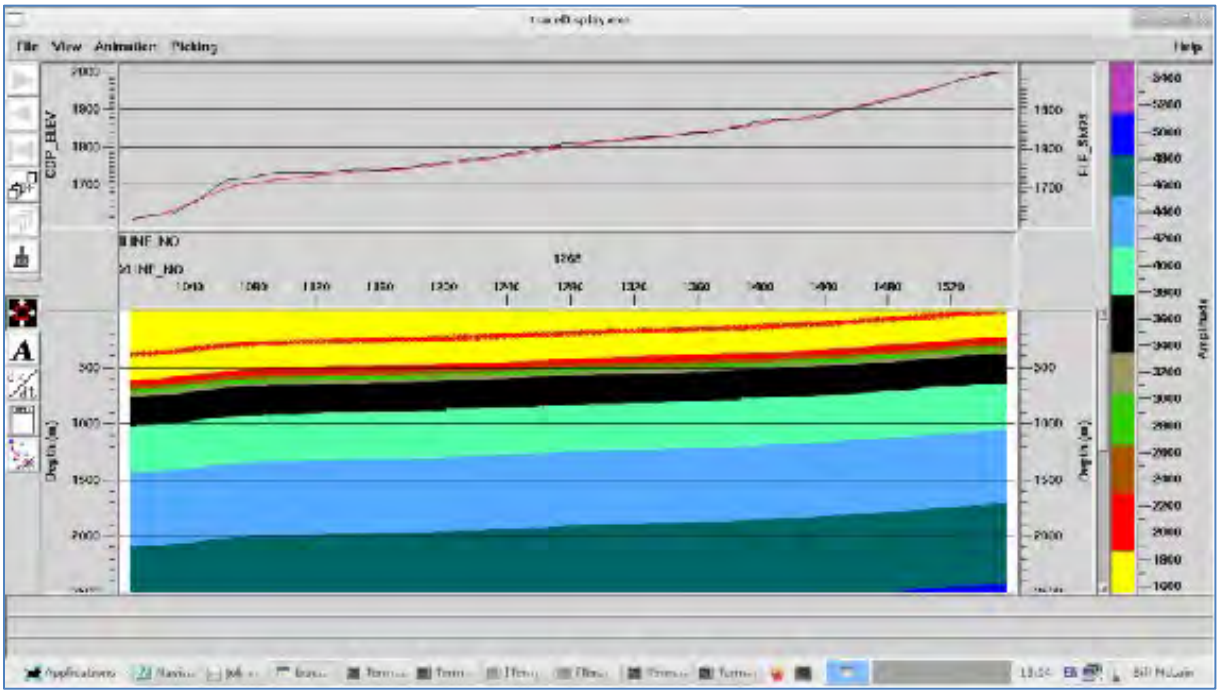

Figure 10. 3D velocity model based on Beachly et al (2012) with the velocity of 1575 m/s in near-surface layer

4.4 One-way Travel Time Depth Migration for a Subsurface Signal Source

The PFI volumes are produced using Kirchhoff depth migration with one-way travel times computed from each voxel within the volume to every receiver on the surface. Kirchhoff migration is a two-step process that first applies a time shift to each trace equal to the travel time from the voxel to the surface geophone and then images across all the time shifted traces.

Figure 11 schematically shows the processing steps used to compute the 3D seismic intensity volumes. An intensity volume is computed for each 200-millisecond time window of the trace data with a move up of 100 milliseconds between the intensity volumes. This produces a new fracture seismic intensity depth volume at 100 millisecond steps.

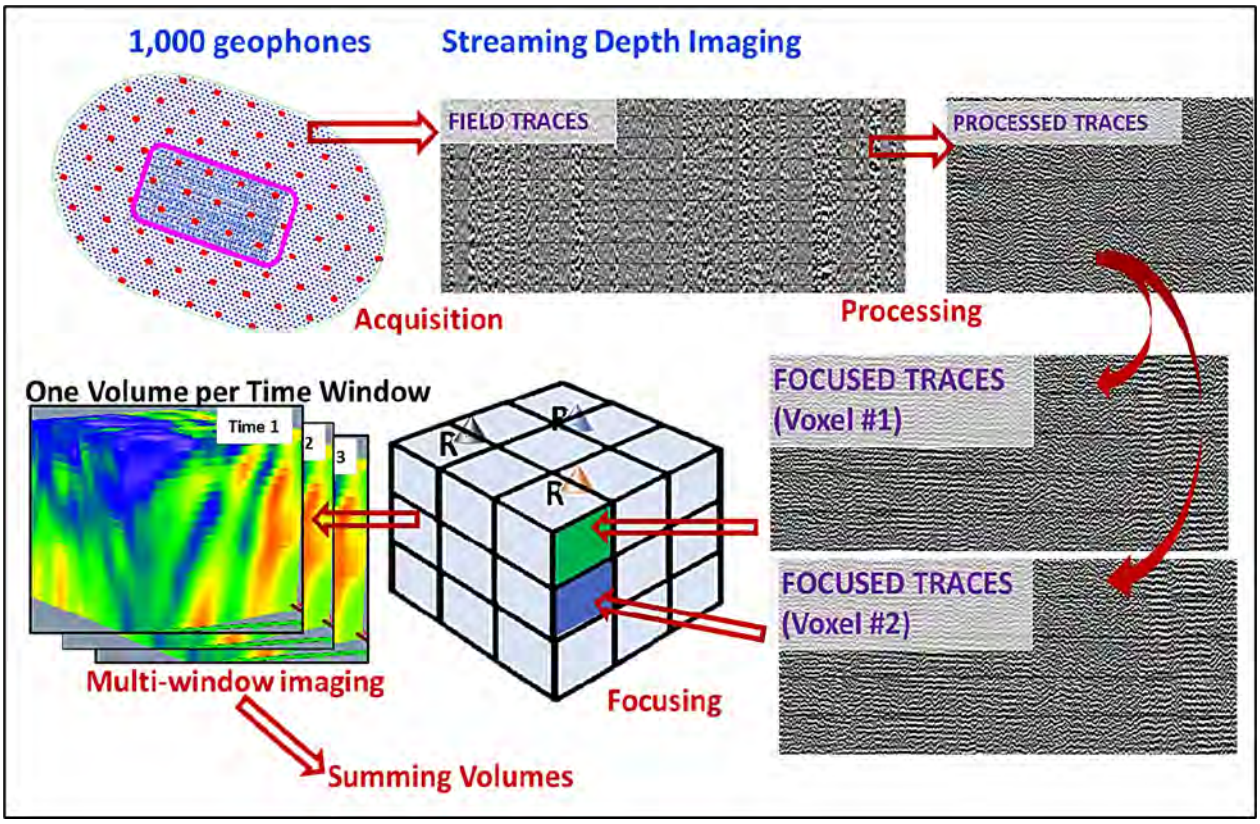

Figure 11. Workflow for one-way travel time depth migration. After trace processing and velocity model building and calibration, the traces are depth-migrated for each time window and each depth voxel for the time interval that will be summed; (from Sicking & Malin, 2019).

The survey was focused on a 1.5 x 1.5 km area at depths of 450 to ~2200 m and processed to achieve voxel sizes of 40 x 40 x 40 m and interpolated down to 10 x 10 x 10 m. The resolution of the survey is estimated to be 37 to 50 m. The final fracture seismic intensity volume is computed by summing all the volumes that are not deleted to create FAVs.

Figure 12a-b shows the horizontal slices thorough the semblance volumes stacked over the 5-hour periods with the lowest noise for 15 and 17 October. The 3D images of the intensity volumes with semblance values greater than 605 are shown in Figure 12c.

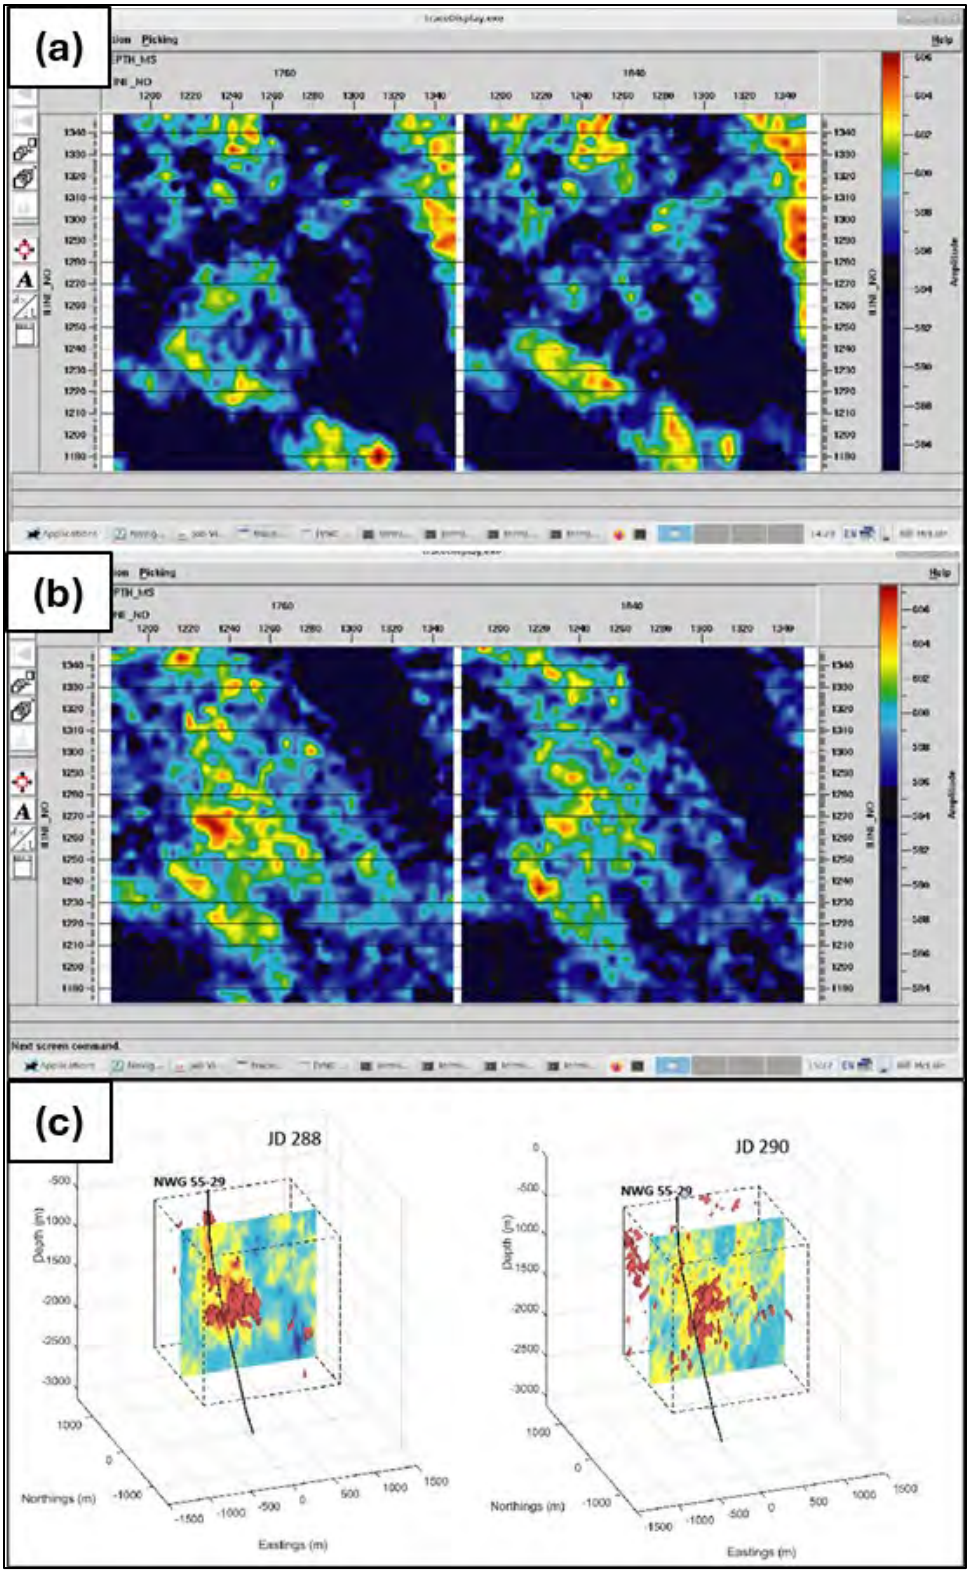

Figure 12. Five-hour stacks for the depth slices Z = 1760 m (left panels) and Z = 1840 (right panels) for the time intervals: (a) 15 October, 07:40 – 12:39 UTC and (b) 17 October, 07:40 – 12:39 UTC. (c) Five-hour semblance FAV volumes for the time intervals: 15 October, 07:40 – 12:39 UTC (left) and 17 October, 07:40 – 12:39 UTC (right).

5. Data Interpretation

5.1 The Aperture Imaging Volume Schematic

A schematic of the relative imaging quality of Newberry PFI survey is shown in Figure 13. The relative quality values shown by the color scheme are based on the number of signals included in the 2.1 km aperture centered on each subsurface point - the stack fold. This aperture was found to provide the optimal improvement of PFI signal to noise: larger apertures included low signal traces, and smaller apertures reduced the stack fold. The depth imaging capabilities of the PFI method also depend on three other factors: (1) the maximum offset from the edges of the target zone, (2) the accuracy of the seismic velocity versus depth, and (3) local control of near-surface travel time differences between individual stations.

Compared to the East and West edges of the Newberry survey, the relative signal-to-noise improvement in the NWG 55-29 well target box was a factor of ~9 greater. As the available aperture diminishes near the survey boundaries, both the stacking fold and depth imaging quality diminishes. The progressive graying – loss of signal quality and resolution – can be seen at the bottom and edges of the PFI imaging ellipsoid.

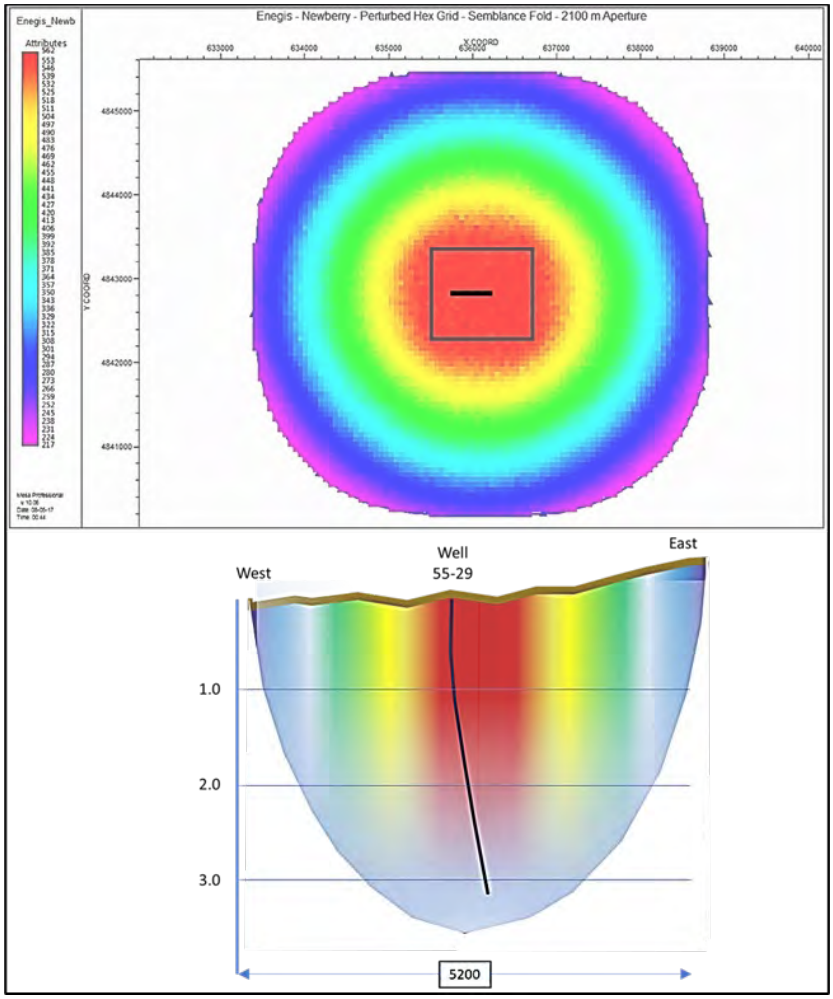

Figure 13. A map and cross section of the relative PFI image quality resulting from the stacking folds and aperture offsets of the Newberry survey. (Surface area designation is in meters. Depth is in kilometers.)

5.2 Density and Stratigraphy Log Correlation

The density and lithology logs shown below (Figure 14) are part of the well logs previously done in the NWG 55-29 borehole (Cladouhos et al., 2015). It is present here and used later as a significant marker in our first pass interpretation of the Newberry PFI data.

Comparison of the two logs suggest that crystalized flow and welded and lithified extrusive rocks have the highest and least scattered densities. Similar relations have been found in many equivalent volcanic systems.

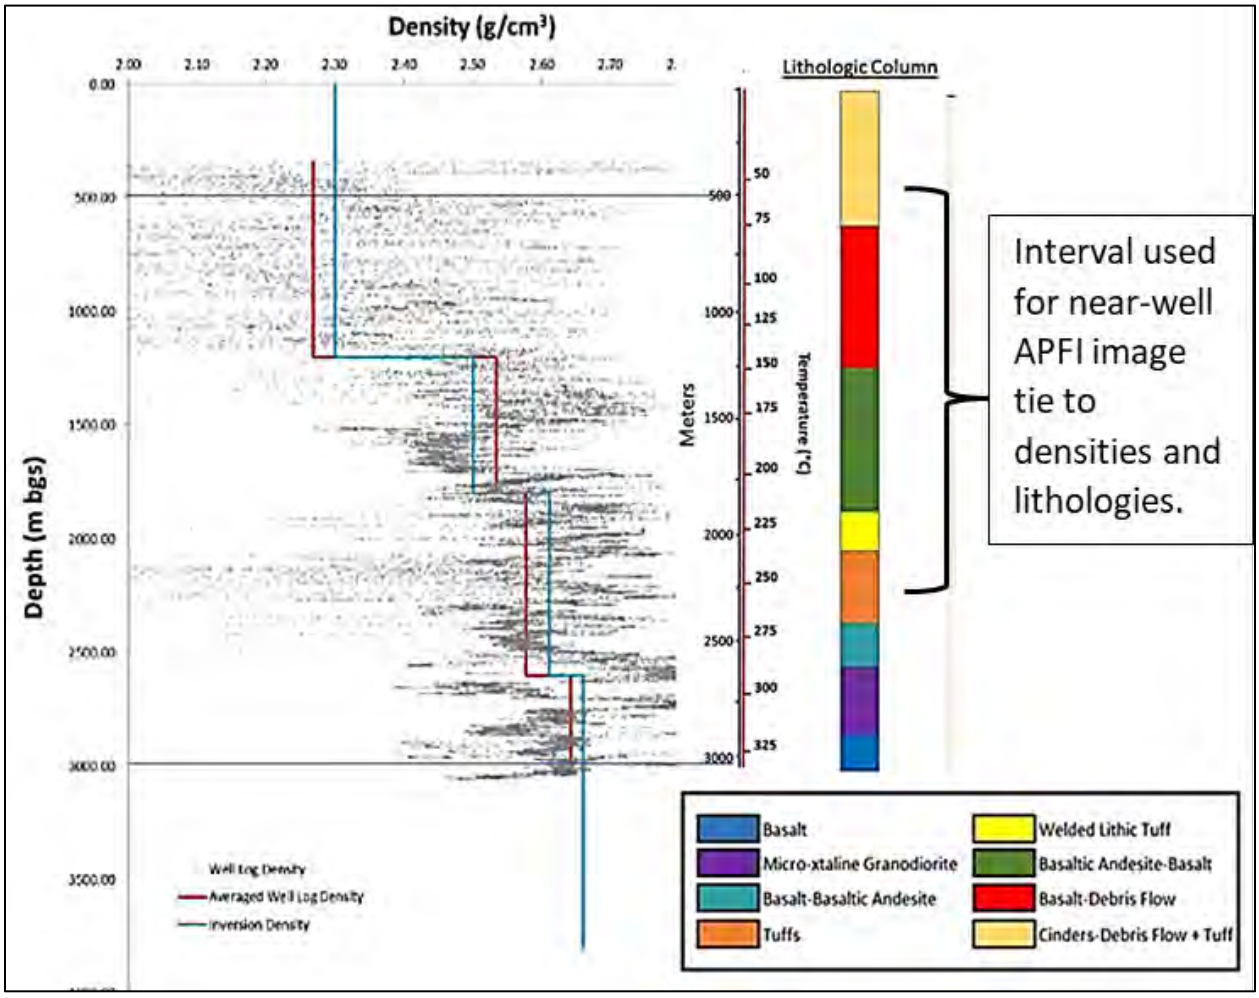

Figure 14. Density and lithology log observed in well NWG 55-29 (Cladouhos et al., 2015)

Well lithified and uniformly dense rocks have well defined fractures and are mechanically more coupled, allowing for connected fluid flow channels and efficient, low energy loss wave propagation. Therefore, naturally flowing geothermal systems are consistently associated with fractured basalt, igneous, and metamorphic rocks.

5.3 Near-well PFI

Geophysical methods such as PFI that map broad areas are difficult to interpret if they cannot be tied to some form of collocated physical property and lithology observations. Thus, in this section we show that significant PFI features are present in the near well environment of borehole NWG 55-29 – the target zone of the Newberry PFI survey. We subsequently interpret these features in the near well environment of NWG 55-29 in terms of the rock density and lithology observed in this well, and their association with ambient seismic signals from fluids in permeability structures – the Active Permeability Field. The observed correlations and their PFI interpretation are then used to extend the near well results to other portions of the target zone.

The vertical sections in Figure 15 below were taken at decreasing offset from well NWG 55-29. The sections span the density and lithology log interval shown above. They reveal the link between the Newberry PFI observations and the density/lithology of NWG 55-29 logs. This correlation is used to extend the near well result to other areas in the target zone.

Reading from the left to the right, the vertical sections in the upper and lower rows in this Figure are as viewed from the south. The section offset is listed and indicated on the map in the central row. As indicated in Figure 15 and the density/lithology log, the vertical section covers the basalt-debris flow, unwelded tuff, and cinder/volcanic ash as well as the basaltic andesite-basalt and welded tuff.

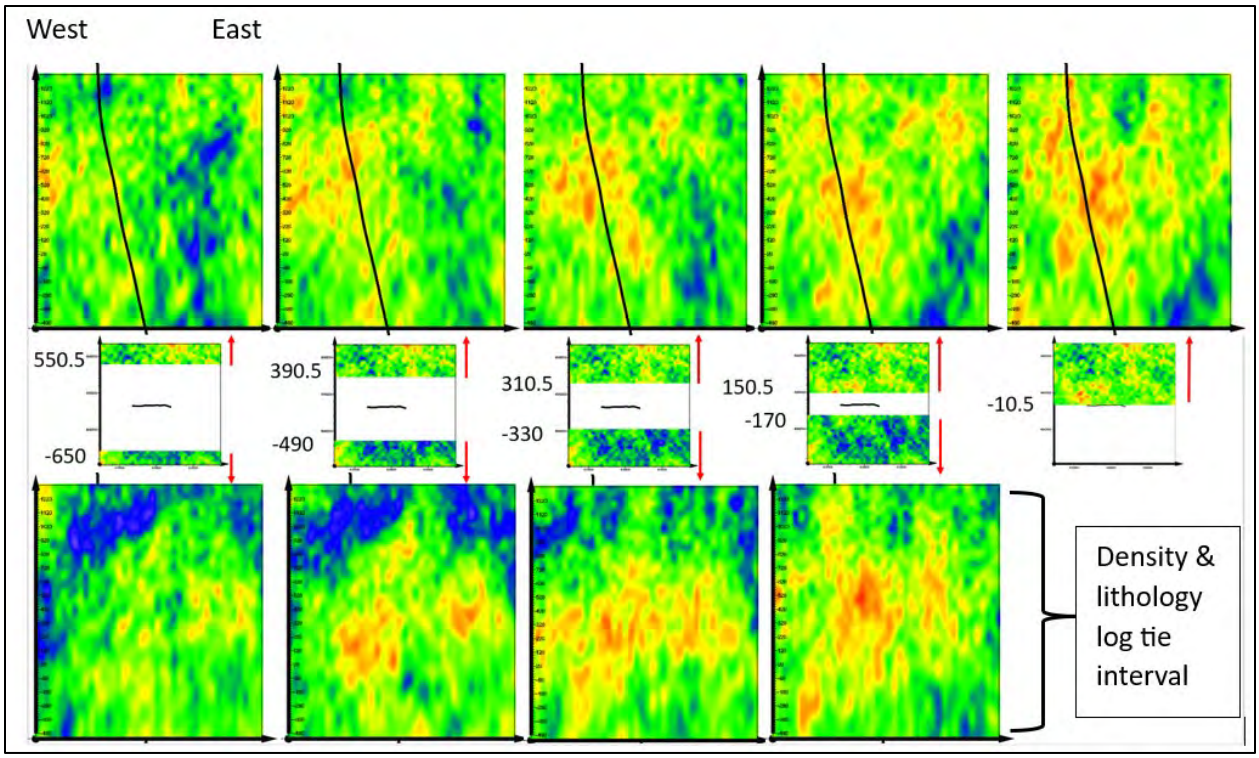

Figure 15. West to East vertical PFI X-sections. The orange color intensity depicted correlates with lithology.

These specific relations are not the focus of this section as they will be made directly explicit in the following sections. Here the important result is observation of responses from permeable fractures near the ground truth of the NWG 55-29 well logs. As seen on the right-hand side of the vertical sections, there is a significant signal response contributing to PFI directly associated with NWG 55-29.

The active volume cube, comparing map slices and PFI volumes with vertical slices above is shown in Figure 16. The numbered features in Figure 16 are also shown annotated in the vertical offset sections within Figure 17.

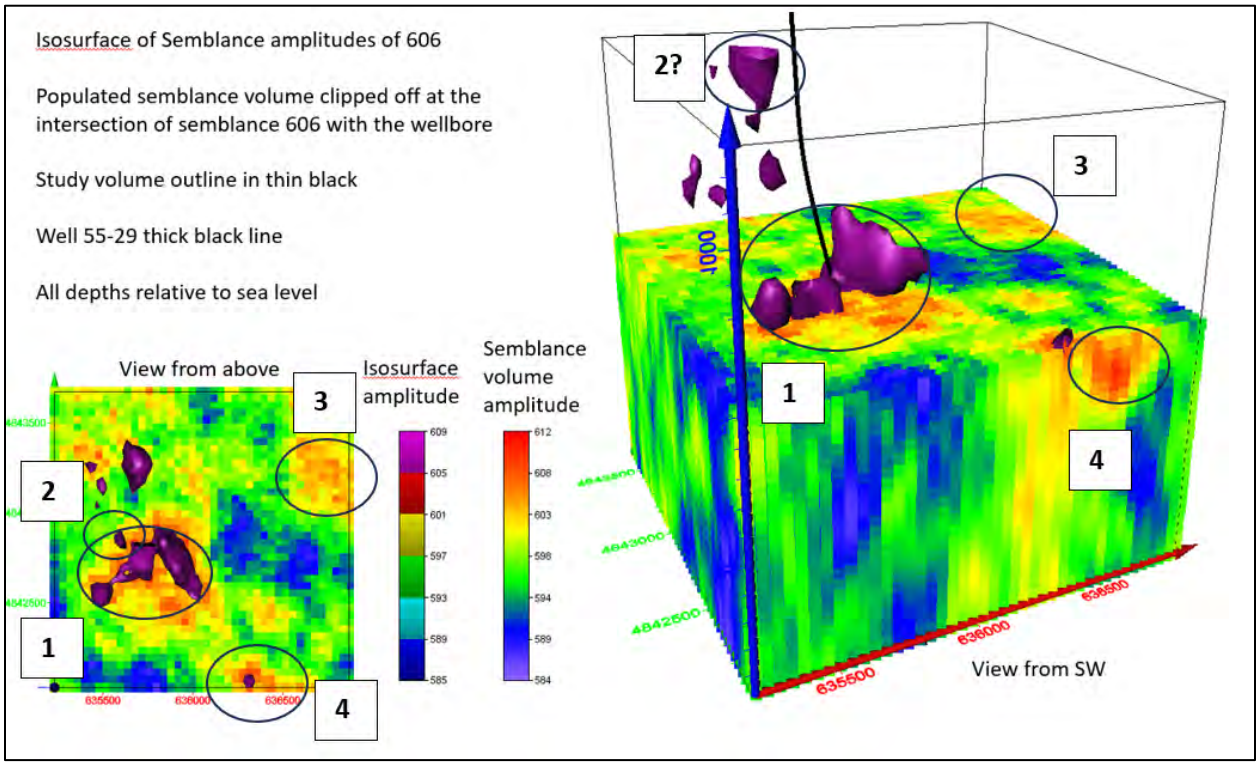

Figure 16. Active volume cube. The vertical slice and block figures above (Figure 15) reveal four notable PFI permeability isosurfaces (Geiser, et al, 2023). The map slice at 1400 m below ground surface (bgs) and block diagram shows higher semblance, near well, NNW trending and connected, conjugate, SW trending PFI structures. There are also higher semblance features to the NNW of NWG 55-29 and to the NE of this well. Numbered features indicate of high relative permeability.

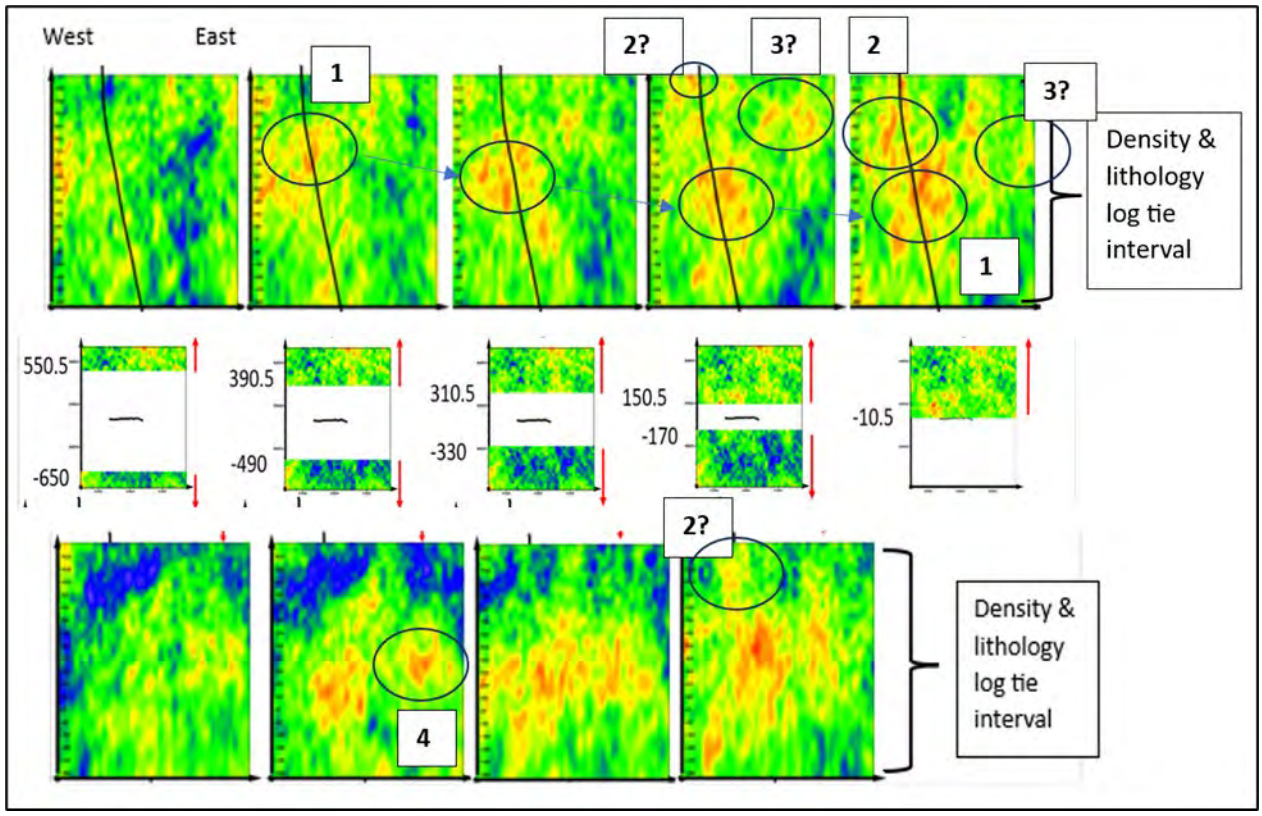

Figure 17. As the progressive vertical slices approach the NWG 55-29 from the north, a high semblance PFI feature, labeled 1, progresses to deeper depths and connects with the well. A second feature, indicated by 2, appears to follow along NWG 55-29 downward, but begins a few hundred meters above the one that approaches from the north. Features 3 and 4 appear respectively north and south of the well.

5.4 Near-well tie to well logs and lithology/stratigraphy

As noted by several studies (e.g., Geiser et al., 2023; Geiser et al., 2012; Engelder et al., 2022), the variation of rock mechanical properties and fracture density result in differences in energy emission that are reflected by the semblance value. We use these relations to interpret our PFI images.

The geological cross section model of the Newberry volcanics suggests a layered, but laterally heterogeneous, lithology column. As shown in the near well vertical section below (Figure 18), which is coordinated with the density and lithology logs, the layering shown by the high semblance amplitudes is consistent with the geology. Feature 1 appears to be associated with the higher, more uniform density basalt-andesite-basalt and welded tuff layers. Accordingly, this feature may in fact be mapping fluid filled permeability structures. Tracing this high semblance zone back to the north, where it appears to be at shallower depths may reflect a general rise in the andesite-basalt layer.

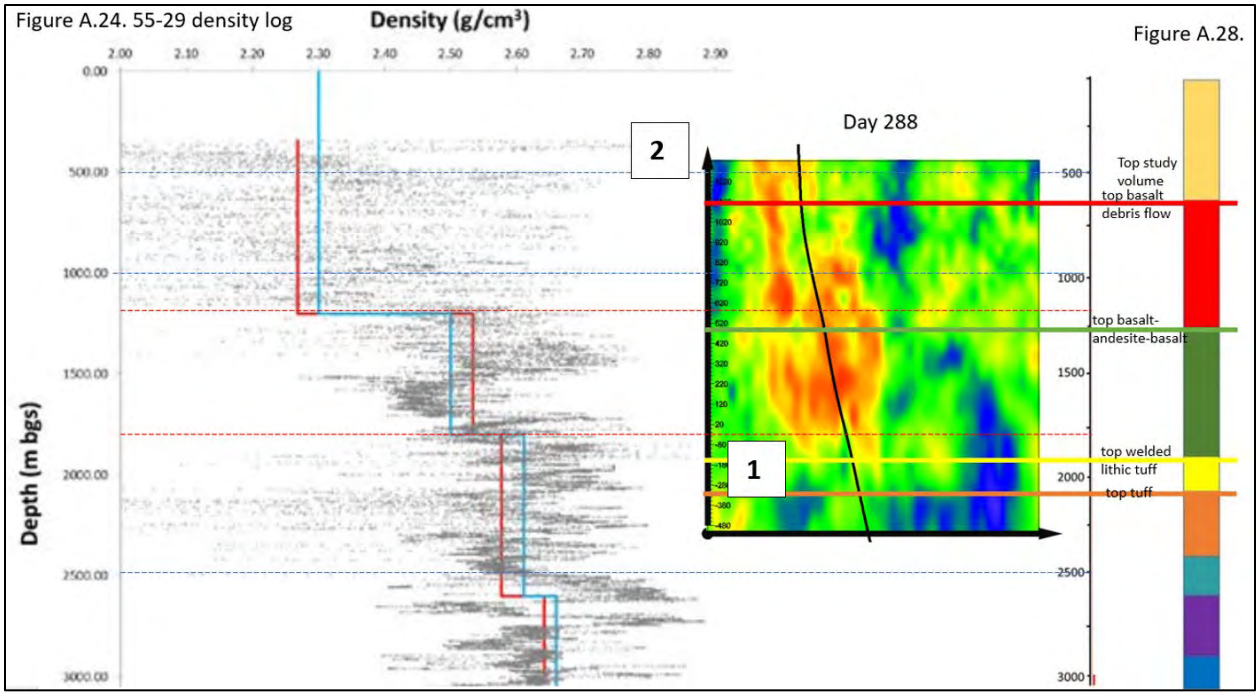

Figure 18. Correlation of density and lithology of Newberry well NWG 55-29 to a vertical PFI slice along the well

The most noticeable and consistent PFI features are labeled as in the figures above. The main association appears to be with the more uniform density basalt-andesite-basalt and welded tuff layers. As discussed in the next section, the more linear feature labeled 2 may result from fluid filled fracture along normal faults in the overlying debris flows and unwelded tuff.

5.5 Tie to Regional Geology

The set of successive map slices shown below (Figure 19) are spaced 80 meters apart, at 800, 880, and 960 m depth. They show that the NNW - SSE trending clouds of maximum semblance have a clear linear boundary on their eastern side. This boundary becomes sharply defined with increasing depth. This suggests that this boundary is one of the many NNW-SSE normal faults seen in regional geology. A second more diffuse but also generally NNW-SSE area occurs to the northeast of the sharply defined trend near well NWG 55-29.

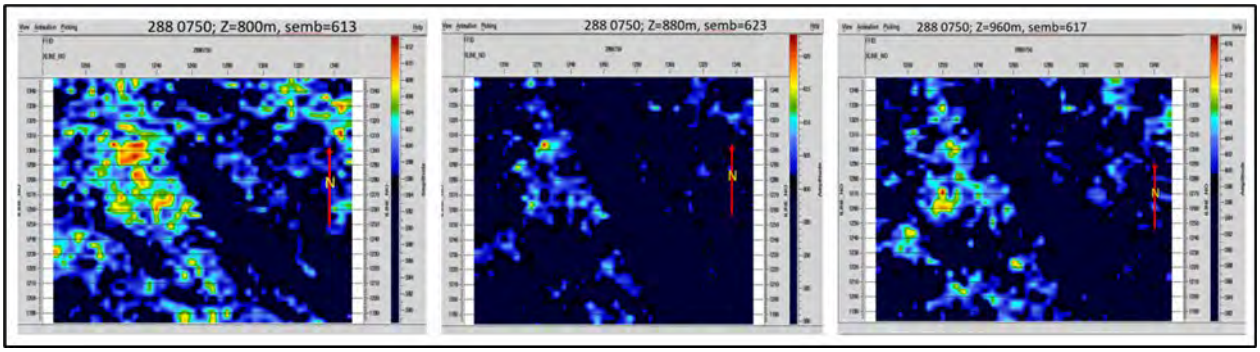

Figure 19. Shallower, 800-960 m bgs PFI images

Two other features are present in these images: a SE-ward deepening of the highest semblance features and secondary SW-NE trending edges in the semblance clouds. All three features are seen in the map and vertical section views below in Figure 20. In map view (left hand Figure 20), the NNW-SSE and SW-NE trends are interpreted as part of the regional faulting structure. In block diagram view, the NNW-SSE PFI features are interpreted as the normal faults that extend up into the debris flows and unwelded tuffs.

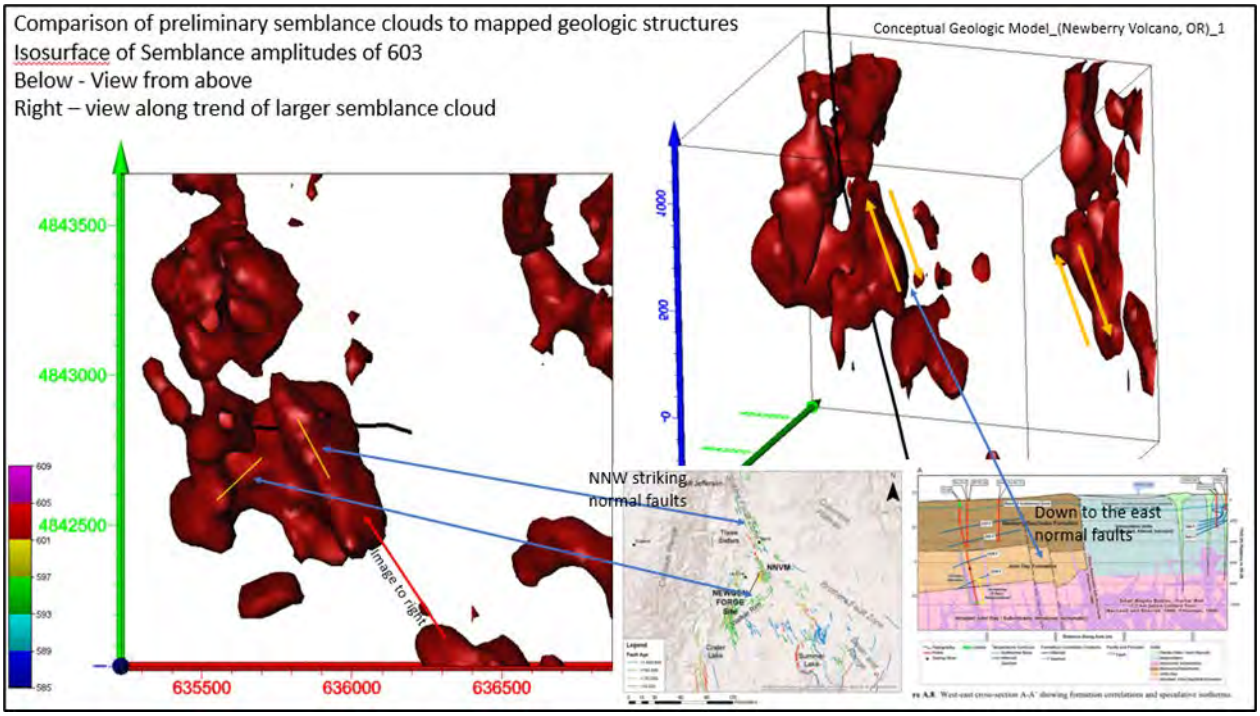

Figure 20. Map projection and block view of 3 significant PFI features suggestive of normal faulting in the near-well volume of 55-29

Figure 21 shows active permeable fractures. In the image at 1200 m (a), this is near the top of the andesite/basalt layer. At a depth of 2000 m, which is below the casing shoe in the well within a slotted liner, the depth slices are reflective of the andesite-basalt layer (b).

The region immediately north of the Newberry Volcano is (or was) under a Regional Stress field with the Maximum Horizontal stress (SHmax) oriented NNW resulting in NE – SW extension. This results in normal faults that strike NNW – SSE, essentially parallel to the dominant orientation of maximum semblance trends shown in the map slices. This structural trend is also reflected in the strike of the recent lava flows of Newberry, stress orientations from earthquake focal mechanisms, surficial lineaments in LiDAR imagery, and the orientation of MEQs because of the 2014 stimulation of NWG 55-29.

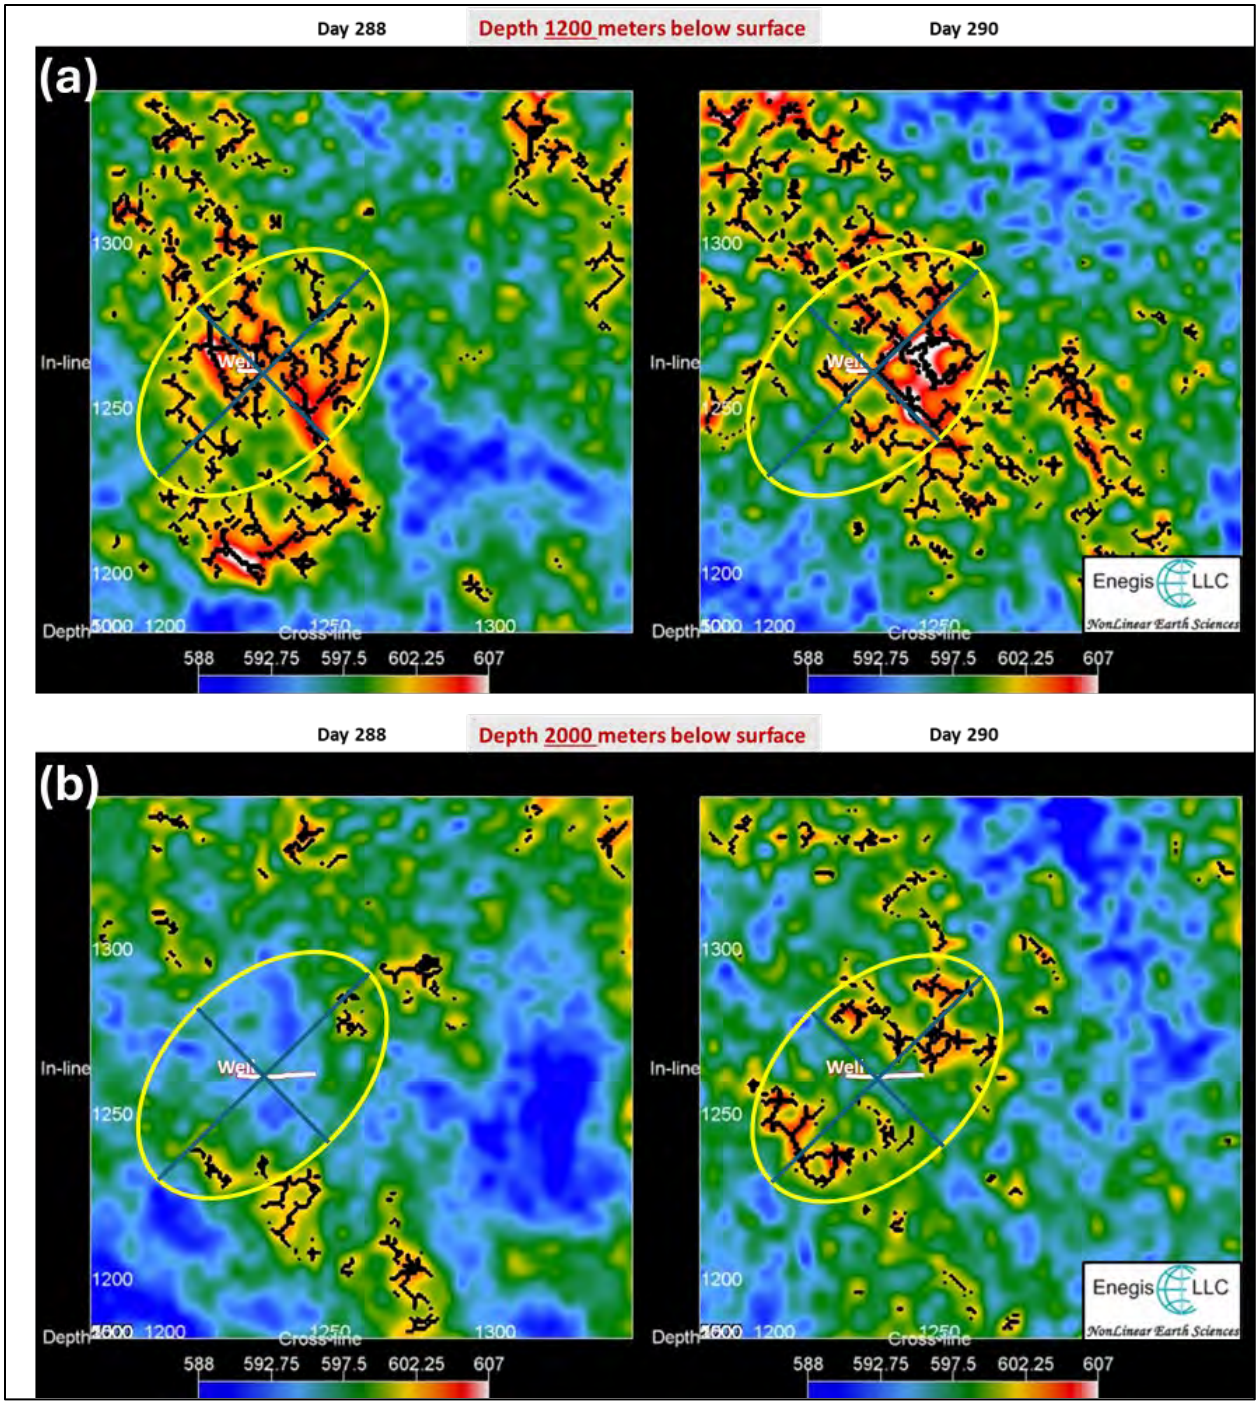

Figure 21. Depth slices of skeletonized FAVs with maximum fracture density delineated in black lines

6. Conclusions

6.1 Summary of Results

As the result of the field program, the Newberry project has provided robust results in a technically challenging environment. The ARPA-E project has provided a viable demonstration of the PFI technique in geothermal application, notably:

- The PFI technique results in markedly improved imagery showing the extent of active fluid filled fracture systems that extend beyond the NWG 55-29 wellbore on the order of a few hundred meters. The results correlate with the density and lithology logs from NWG 55-29
- Comparison of the PFI results with MT data leads to the conclusion that PFI resolution is about two orders of magnitudes greater and differentiates the fracture system between the heterogeneous debris flow and the more homogeneous andesite/basalt layer (Figure 22). The lower resistivity of the MT data is interpreted as the result of hydrothermal alteration (hydrated clays). This zone is seen to lie above the active PFI zone, which we interpret as having lower permeability and hence reduced active fluid flow pathways.

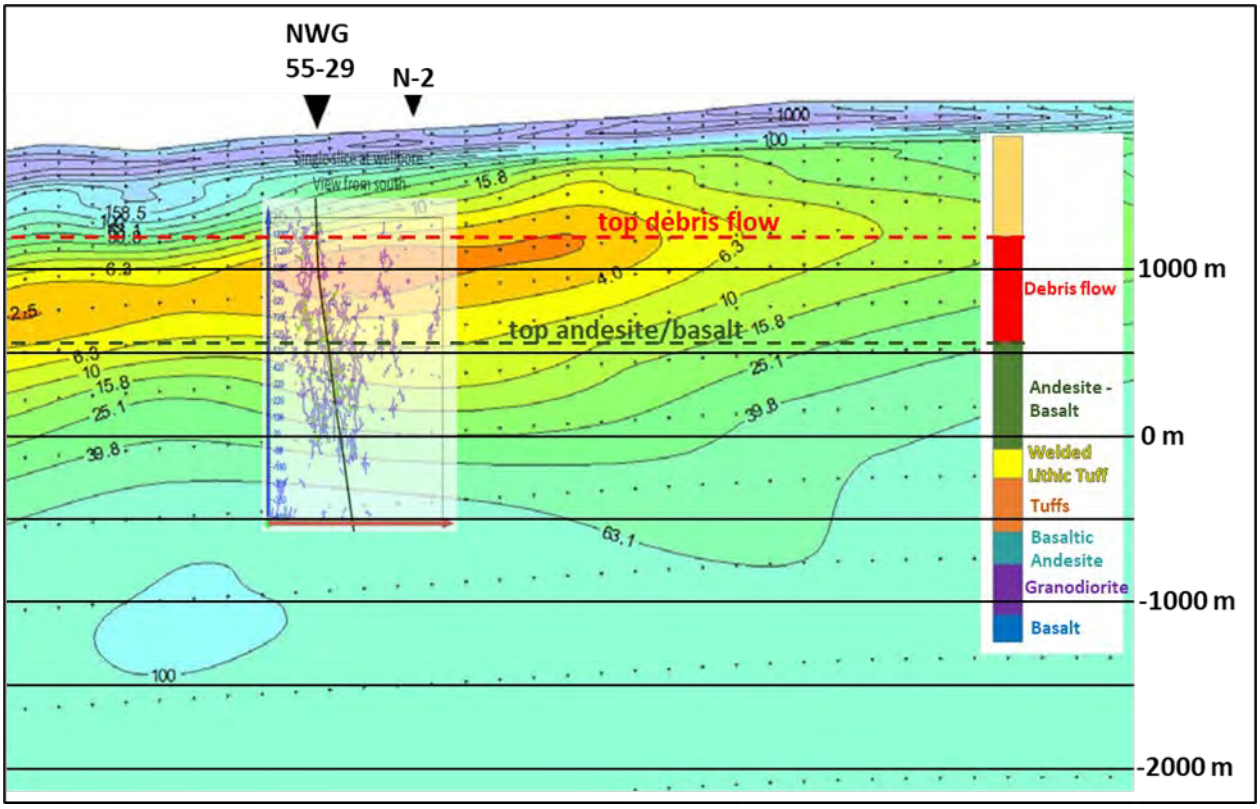

Figure 22. PFI and MT datasets correlated with lithology.

Our ARPA-E project has achieved its purpose—that of demonstrating the viability of PFI technology in a geothermal application. Resource limitations of budget constrained our ability to image deeper than ~2100 m. To extend PFI down to the ~2600 m objective of well NWG 55-29,

we recommend that the survey radius be increased by about 20% resulting in an approximate 38 square km area compared to the 25 square km achieved with this project.

6.2 What practicably differentiates PFI technology?

The PFI technique results in a direct mapping of permeability field architecture as opposed to computer simulations that can be driven by assumptions. In terms of the geothermal marketplace, in contrast with traditional reservoir characterizations, the PFI method is empirical, supplying actual data, not driven by assumptions. It does not depend on modeling (except for a velocity model, a standard in seismology), and contrasts with traditional reservoir modeling, which takes far more steps and assumptions (Figure 23). Further, the PFI technique is not dependent on MEQs since it utilizes ambient seismic emissions.

We believe that, based on technoeconomic modeling, that geothermal project development life-cycles costs could be >50% less compared to the status quo. Additionally, we believe PFI technology can provide reliable reservoir monitoring that enhances public trust concerning issues such as induced seismicity.

There are also additional energy sectors where the PFI technology can have application:

- Geologic carbon storage (GCS) requires an understanding of the target reservoir's properties to minimize risks during sequestration efforts. Also, the injection and disposal of wastewater requires subsurface characterization and monitoring. There are growing concerns about induced seismicity due to fluid injections, with seismic events up to M 3.5 caused by fluid injection occurring in the U.S. (Verdon & Bommer, 2021). PFI can be used to record the micro and macro-seismic events and measure their magnitudes, monitor fluid injections over time, and even take advantage of any seismic emissions from the induced seismicity to image the reservoir
- PFI technology could be useful for delineating ore bodies, where the boundaries provide seismic velocity contrasts and could be the sites of fluid flow that the PFI technology could image
- PFI can be used in compressed air energy storage (CAES) projects to image the potential air storage reservoirs and monitor the reservoirs during operations

Keywords

Magnetotelluric, Inversion Model, Sibayak, Bottom of Clay Cap, Enhanced Conductivity, Pyrite, Saline Fluids

ABSTRACT

Re-evaluating the Sibayak geothermal reservoir in North Sumatra, Indonesia, this study utilizes recent magnetotelluric (MT) data in 2023 to refine the existing 2D model into a 3D model. Compared to the 1996 model, a significant feature, an enhanced conductive body (0.1-1 Ω.m) was identified extending from outside the Singkut Caldera towards Mt. Pratektekan. Though past studies did not identify this conductive body, this discovery was confirmed by 1D and 2D MT inversions and intersects existing wells. The delineation of the base of the clay cap with the underlying enhanced conductive body presents a challenge due to the absence of a distinct boundary between the two in our 3D resistivity model. Meanwhile, 1D models could separate the bottom of clay cap and enhanced conductive body. While the exact cause remains under investigation, there are two possible causes of an enhanced conductive body which are saline fluids and sulfide minerals. This study emphasizes the value of updated geophysical data in understanding geothermal reservoirs and paves the way for further exploration and development in the Sibayak field.

1. Introduction

The Sibayak geothermal field, situated in North Sumatra, has been a contributing factor to Indonesia's geothermal energy production since 1996. Initially generating 2 MW, the field's capacity expanded to 12 MW in 2008 with the addition of two 5 MW units. However, an inactive steam sales contract with an Independent Power Producer (IPP) since 2012 prompted Pertamina Geothermal Energy (PGE) to re-evaluate Sibayak's potential to contribute to its ambitious 1 GW geothermal target.

Pertamina had conducted several geophysical data acquisitions. Initially, DC resistivity (Schlumberger) surveys were conducted to explore geothermal prospects with depth of investigation around 1000 meters, continued by an MT survey in 1992 and time domain electromagnetic (TDEM) for static shift correction in 1997 (Mulyadi, 2000). A gravity survey was also conducted by PT. Gondwana in 1989 – 1990 using a Lacoste Romberg gravity-meter (Daud, et al., 2001). In addition to the geophysical surveys, PGE undertook an update of the Sibayak reservoir model. The original model, developed in 2001, incorporated data from 10 wells drilled in the field (Atmojo, et al., 2001). Recognizing the potential impact of production history on reservoir characteristics, PGE created a new model in 2024 utilizing the available data since 2008 from the same 10 wells and incorporating post-production conditions. (Firanda, et al., 2024).

A team of geoscientists and reservoir engineers from PGE re-evaluated the Sibayak geothermal field's potential. This re-evaluation employed updated magnetotelluric (MT) data acquisition and resistivity inversion techniques to analyze the depth of the clay cap. Well cutting data from 10 wells provided information on clay content, which will be useful in evaluating the clay cap. The updated resistivity model revealed a previously unidentified, enhanced conductive anomaly (less than 5 ohm.m) extending from the surface to a depth of approximately 4,000 meters below sea level with a lateral extent of about 4,000 meters. This anomaly exhibits an oval shape and trends southwest-to-northeast beneath Mount Sibayak. Notably, this anomaly was absent in previous resistivity models, However, PGE's recent MT data acquisition and resistivity model was thoroughly evaluated, resulting in minor data masking for all decades above 160s (0.01 Hz) which PGE considered as satisfactory. It is also challenging to delineate the bottom of clay cap on our 3D resistivity model due to this high conductive body positions near the clay cap, resulting in a more smoothed and lower resolution view of the bottom of the clay cap (Cumming & Mackie, 2010). The nature of the high conductive anomaly remains an open question. This paper will study delineating the base of the clay cap including potential causes for enhanced conductivity based on well data.

1.1 Field Overview

Sibayak field is a volcanic geothermal system inside Singkut caldera which formed at ~44 ka (Forni, et al., 2024) with two small conduit strato-volcano (Hochstein & Sudarman, 2015). Figure **1** shows two schematic conceptual models describing a volcanic hosted system and isotherms with alteration zone background derived from temperature log of the wells. The conceptual model was also used to update the numerical simulation of Sibayak Field (Firanda, et al., 2024) which consists of geothermal upflow beneath Mt. Sibayak outflowing towards southeast and northeast. Sibayak complex manifestations were found in the crater of Sibayak Mountain and flank of Sibayak inside the Singkut caldera (Fahmi, et al., 2021). Figure 2 is the geological map of Sibayak with structure orientation NW-SE. Although Sibayak is a volcanic hosted system, tertiary sediments play major roles for the permeability in Sibayak reservoir.

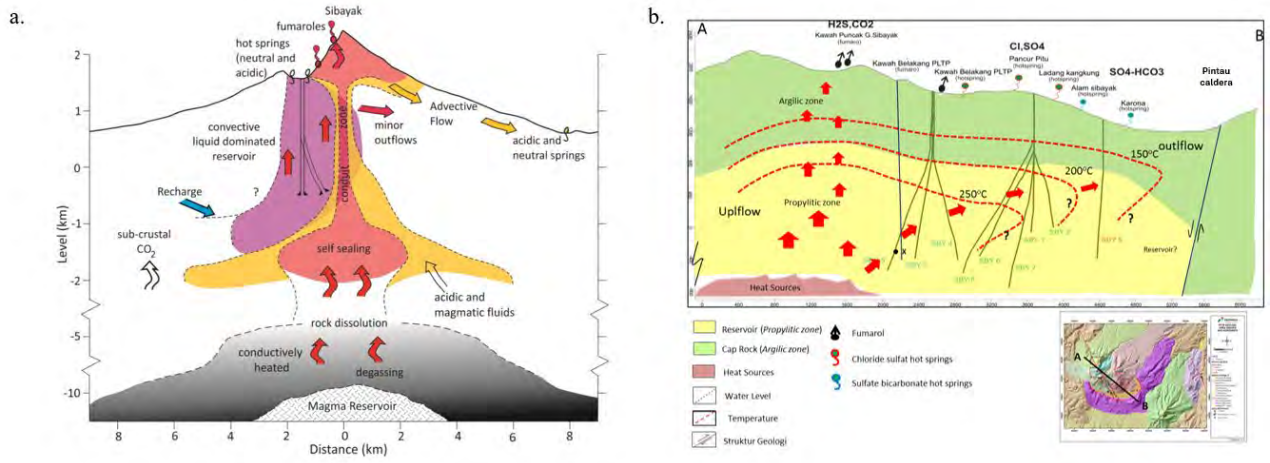

Figure 1. a. Sketch of Sibayak volcanic hosted conceptual model (Hochstein & Sudarman, 2015) and b. Isotherm conceptual model with hydrological setting of Sibayak along the alteration zone background developed from well temperature log (PT. Pertamina Geothermal Energy Tbk, 2022)

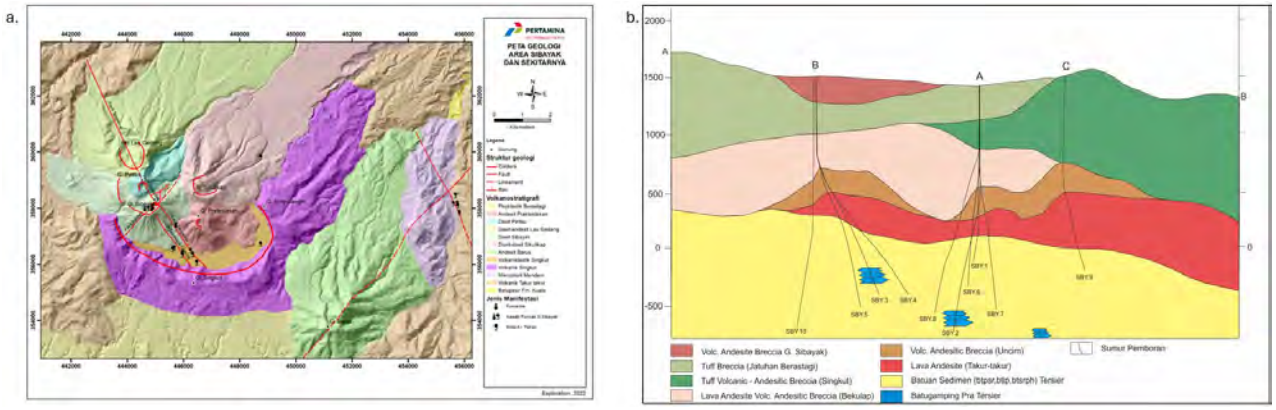

Figure 2. a. Updated geological map with stratigraphy of Sibayak field (PT. Pertamina Geothermal Energy Tbk, 2022) and b. Geological cross section interpreted from well cuttings data (PT. Pertamina Geothermal Energy Tbk, 2016)

2. Sibayak MT Surveys

Sibayak's MT data, acquired in 1991 by PT Alico and in 1997 by PT Qodharwan Wirasta Konsultan, with total 51 MT stations, were utilized for 2D inversion techniques to verify the reservoir structure and its extent (Daud, et al., 2002). To achieve a more comprehensive understanding of the Sibayak geothermal field using modern software and technology, a 3D inversion approach was carried out. This re-modeling process aimed to enhance the three-dimensional visualization of the Sibayak Field, improving the accuracy of the geothermal resource assessment. However, limitations were encountered due to the incomplete recovery of historical MT data. To address this challenge and refine the remodeling efforts, a new MT data acquisition campaign was conducted. PGE's in-house geophysics department acquired 54 MT stations using proprietary tools and standardized acquisition procedures.

A three-receiver magnetotelluric (MT) system, including two operational units and one backup, facilitated simultaneous data acquisition at two stations per day in Sibayak. Each station utilized

three MTC-80H coils with a frequency range of 1 kHz to 10,000 seconds and 4 electrode pots. Time series data processing was run in-house using SSMT software resulting in 4 excellent datasets, 48 good datasets and 2 fair datasets.

Figure 3 shows MT stations designed for characterizing the Sibayak reservoir. The station distribution was expected to be grid spaced or spread evenly with a target of 500 to 1000 m spacing in the inner core and 1500 m to 2000 m for the outer core with area of surveys around 100 m^2. Overall, the data acquisition met the target although in some areas such as in the northeast of Sibayak Mountain and south of Singkut Caldera MT data could not be acquired due to dense forest with minimum access and densely populated areas with high voltage power line.

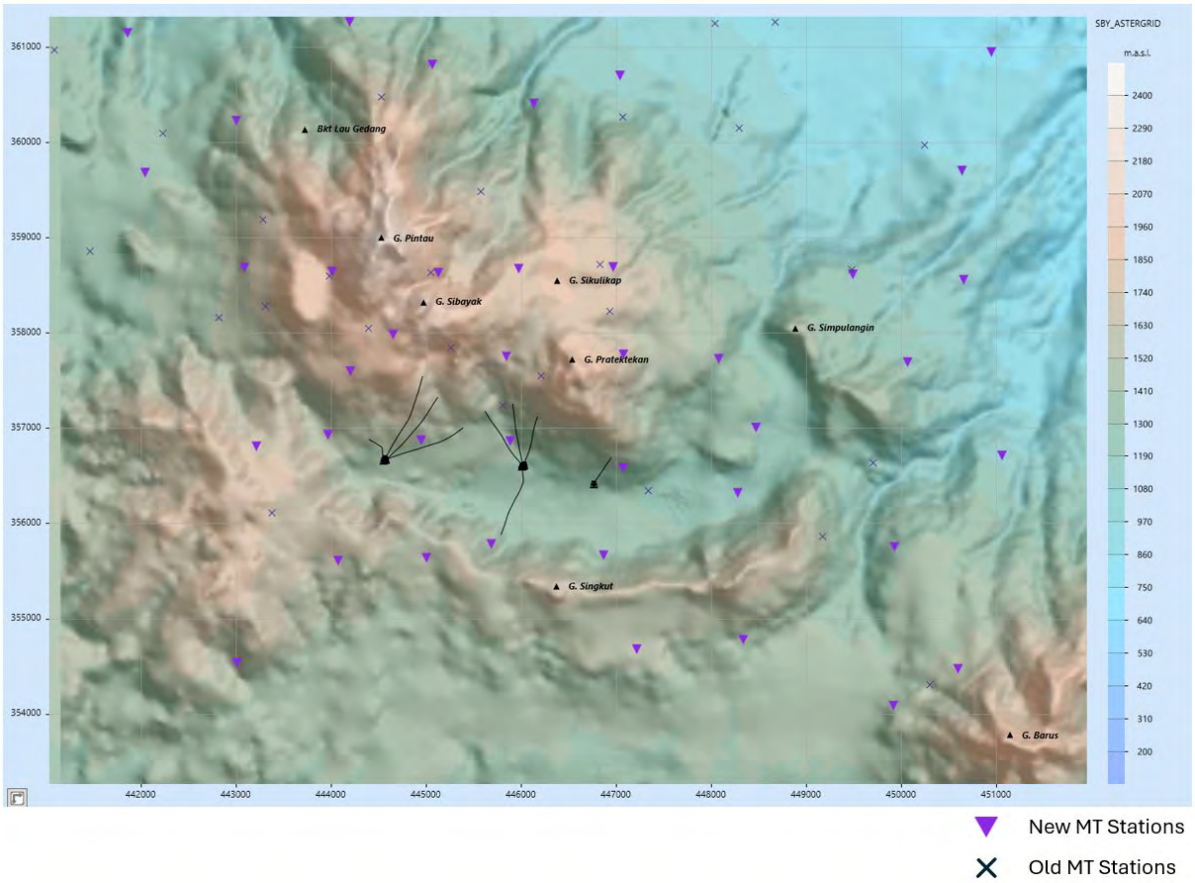

Figure 3. Distribution of MT stations from data acquisition in 2023 (purple triangle) and 1991 & 1997 (cross).

3. Sibayak MT Inversions

Prior to this study, previous MT datasets from the Sibayak geothermal field had undergone several analyses. The first study showed that 1D inversions could be used to delineate the clay cap, reservoir and subsurface structure (Mulyadi, 2000). Understanding the limitation of 1D inversion, 2D inversions were carried out to improve the interpretation of reservoir and basement from 1D inversions due to strong indication of 2D or 3D effects (Daud, et al., 2002). Advancements in technology have facilitated the routine application of 3D inversion techniques in recent years. Using a well-prepared MT dataset with recent technology, PGE conducted 3D inversion to create a better understanding of Sibayak reservoir.

Prior to 3D inversion, the data were rotated to 0 degrees (North) and edited to mask out noisy data, which was was only necessary for frequencies below 0.006 Hz due to anomalous behavior in the YX component at lower frequencies (Figure 4**)**. Both MT impedances and the vertical magnetic transfer function (tipper) were inverted. Additionally, we carried out in-house 1D and 2D inversions using Geotools software. The resulting 3D resistivity model revealed a previously unidentified, enhanced conductive anomaly extending from the outer Singkut Caldera towards Sibayak Mountain. The validity of this anomaly was investigated through further analyses such as comparing it to the previous model, conducting 1D and 2D inversions and lastly conducting a 3D sensitivity analysis.

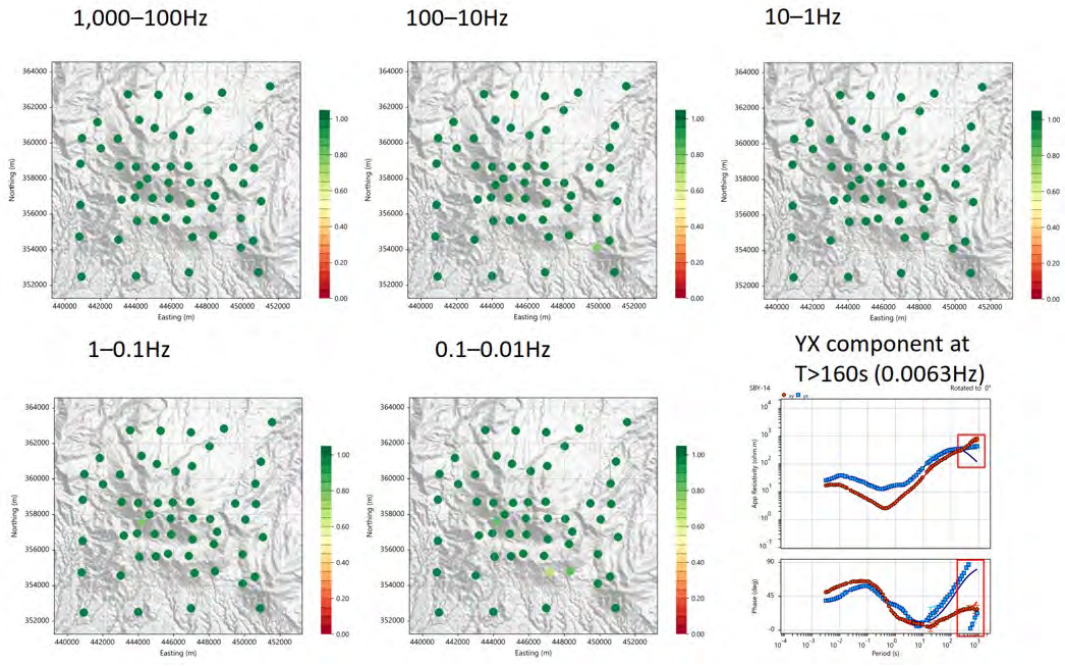

Figure 4. Data masking of MT datasets in every frequency start from 1000 – 0.01 Hz. Color bar green-red describing the percentage of data masked, value 1 or green means no data masking performed.

3.1 Comparisons of MT Inversion Models

To verify the existence of the newly identified high conductive anomaly, several attempts were made to reconcile it with previous findings. As the original MT datasets used to generate the old 2D resistivity model were unavailable, the datasets of the old MT stations were plotted on the new 3D model, and the published image of the old 2D model was visually compared (Figure 5). Stations SBK-205, SBK-216, SBK-211, and SIB-128 are located within the footprint of the anomaly on the new 3D model. However, the old 2D model did not image a conductive body at these locations. This could be due to several reasons. First, the highly conductive anomaly might exhibit a 3D effect that could not be adequately captured by the older 2D inversion algorithms. Second, due to the deep 3D nature, input data for the 2D model were restricted from 0.003 down to 30 seconds period (Daud, et al., 2002).

An additional effort to reconcile the anomaly with previous findings involved comparing published old MT curves to new MT curves nearby. Around 200 meters from SBK-211 is SBY-20 station

with the same MT curve response (Figure 6). The most notable difference observed was a significantly higher initial resistivity (around 750 ohm.m) in the new SBK-211 curve compared to the old SBY-20 curve (around 40 ohm.m). This discrepancy could be attributed to the application of static shift correction using TDEM data in the processing of the old MT data, which was not employed for the new dataset. Both curves exhibited a deflection in the Rho-YX component at a period of 1 second, while the Rho-XY component deflection occurred before 1 second in both datasets.

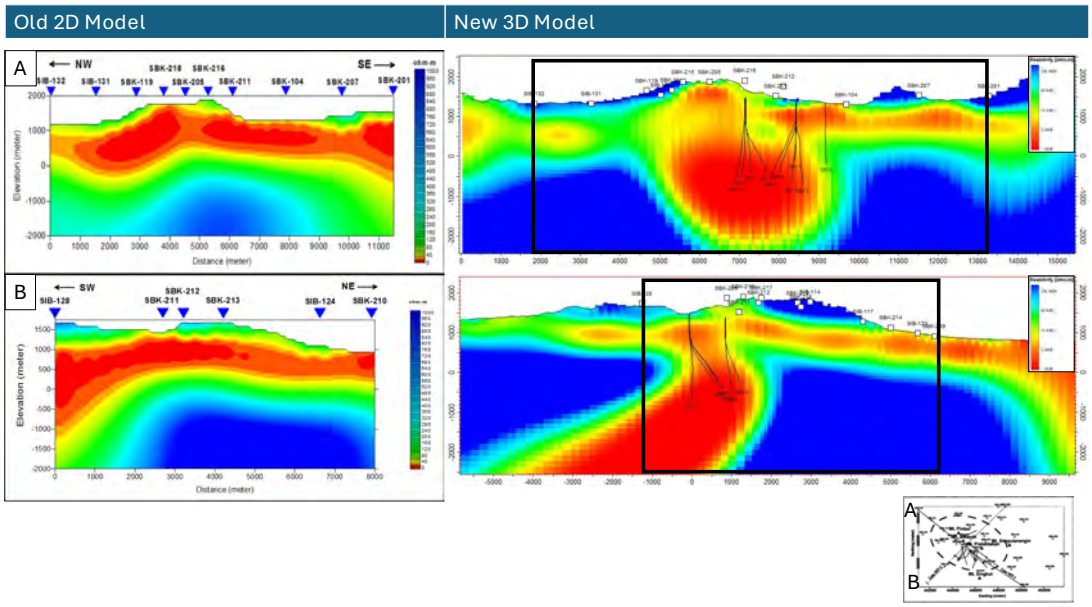

Figure 5. Cross-section comparation between old 2D model (left) and new 3D model (right). The boundary of the old 2D model is visualized in a black box.

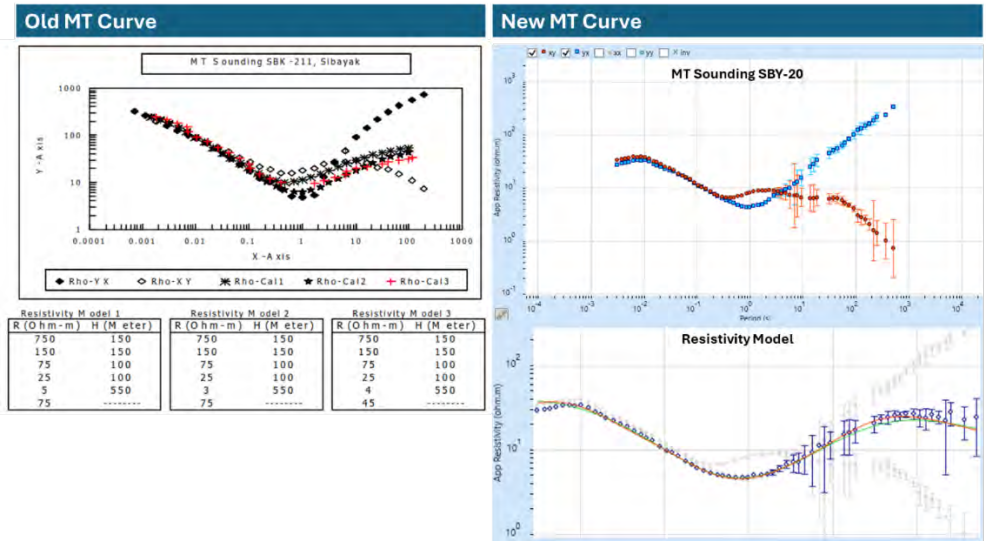

Figure 6. Comparison of nearby station between SBK-211 (old MT dataset) and SBY-20 (new MT dataset) including each 1D inversion.

3.2 New MT Inversions of 1D, 2D and 3D Models

While 1D and 2D MT inversions using Geotools software offered a complementary approach, they presented limitations compared to 3D inversion. Unlike 3D models, which invert for distortion matrices, 1D and 2D inversions relied on static shift corrections obtained from TDEM surveys. This dependence on the type of static shift correction can potentially introduce distortions in the geometry of the geothermal clay cap as interpreted from the 1D and 2D models. However, the information derived from 1D and 2D models, when combined with alteration mineral data from wells, could still contribute to a comprehensive interpretation of the geothermal system.

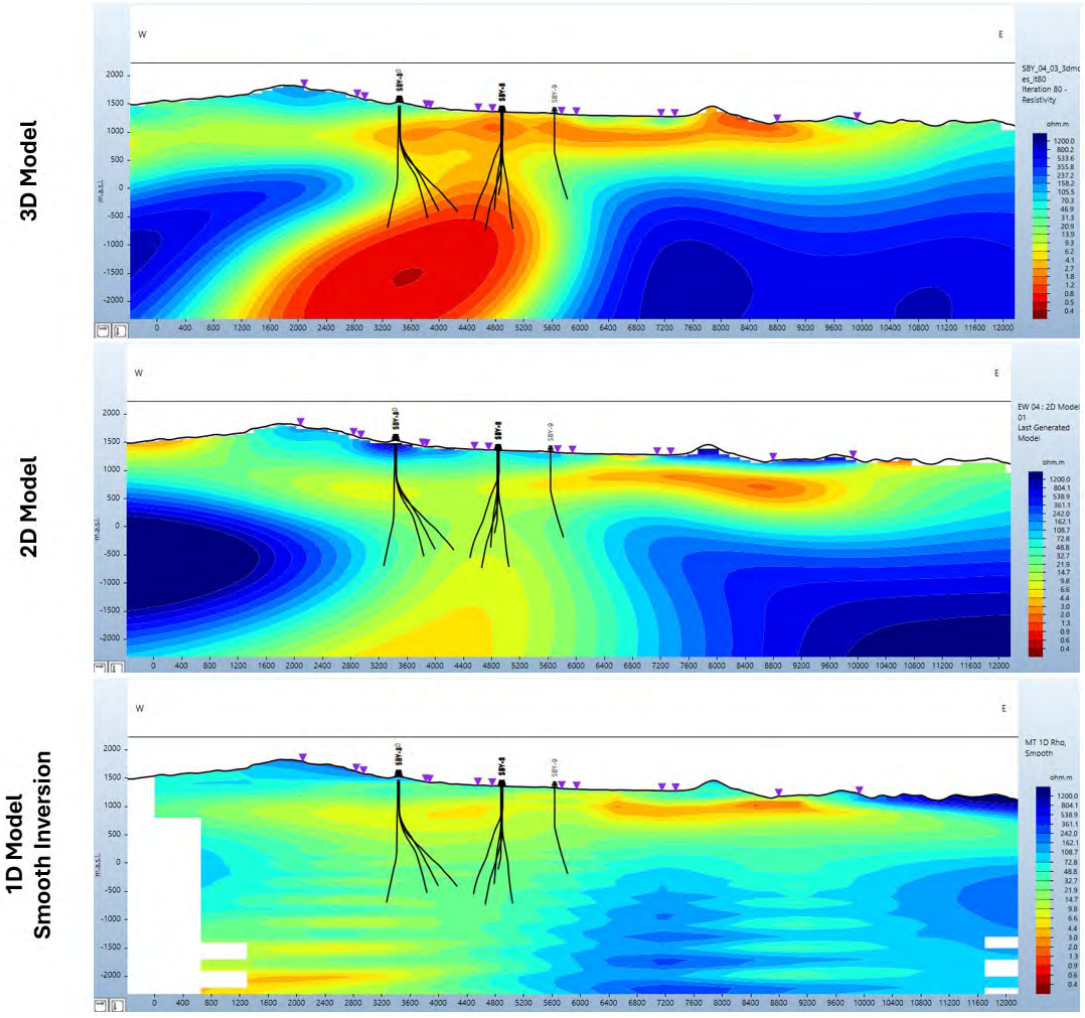

Figure 7. Three West-East Cross-Sections, crossing wells trajectory from 3D, 2D and 1D model sequentially.

To generate 1D models, a smooth inversion (Occam) method was performed as it was good enough to delineate the resistivity of the geothermal clay cap (Cumming & Mackie, 2010). These 1D models were generated for all data within a frequency range of 1000 Hz to 0.001 Hz, incorporating a 5% apparent resistivity noise floor. Subsequently, the 1D Occam models were horizontally interpolated to create a cross-sectional image (Figure 7**).** The resulting 1D model provides a smooth representation of the resistivity down to a depth of approximately 1000 meters, with

increased scatter at greater depths. This scattering might be attributed to the influence of 2D and 3D effect.

A 2D inversion was conducted utilizing TE and TM mode curves within the frequency range of 1000 to 0.01 Hz, as determined by data masking. Typically, 2D inversions serve as a preliminary step to refine inversion parameters before progressing to 3D modeling.

The 3D inversion was initiated with a uniform 50 ohm-m initial model and a 5% error floor, converging after 80 iterations to a root mean square (RMS) value of 1.08. By incorporating data from 0.006 to 251 Hz, reliable depth resolution was achieved to a depth exceeding 5000 meters. This depth coverage adequately captured the high conductive anomaly extending from outside the Singkut Caldera towards Sibayak Mountain. Notably, nine of the ten wells are located within the outer core of this conductive anomaly. However, a cautious interpretation is warranted due to the age of the well reports, which precludes further detailed analyses such as X-ray diffraction (XRD).

3.3 Sensitivity Test

To assess whether the deep conductive anomaly was an artifact of the inversion process or parameters, a sensitivity analysis was conducted (CGG Geoscience, Multiphysics, 2023). A modified 3D resistivity model (Figure 8.a) was created by replacing the enhanced conductive anomaly with a less conductive body (50 ohm.m). The impact of this modification on the forward response was evaluated by comparing the TE-TM mode curves of the original and modified models at stations within the southwestern study area (Figure 8.b). The apparent resistivity and phase curves from the original model (points) displayed significant deviations from those of the modified model (solid lines). This substantial difference in the forward responses demonstrates that the MT data possess sensitivity to the enhanced conductive body, suggesting its presence is required to accurately fit the observed data.

4. The Bottom of the Clay Cap from 1D and 3D MT

Delineating the bottom of the clay cap using 3D resistivity models is often straightforward and typical for geothermal field evaluations. However, in the Sibayak field, the presence of an enhanced conductive body positioned near the clay cap in the 3D model presented a significant challenge. This proximity resulted in a blurred interface between the conductive clay cap and the anomaly, hindering clear separation. To address this limitation, 1D MT inversions were employed to provide a higher-resolution characterization of the clay cap (Figure 7). Figure 7 illustrates a clear separation between the bottom of the clay cap (interpreted at 10 ohm.m) and the enhanced conductive body in the 1D model, in contrast to the ambiguity observed in the 3D model.

The absence of static shift correction in the 1D model presented a significant challenge. While the integration of well data, including alteration zones, enhanced the interpretation of the geothermal system, the direct correlation between the 1D and 3D model-derived clay cap depths and well data proved to be inconsistent (Figure 9). The lack of Methylene Blue tests (MBT) in the legacy well reports, an uncommon practice at the time, hindered a more precise correlation between the clay cap and the argillic alteration zone.

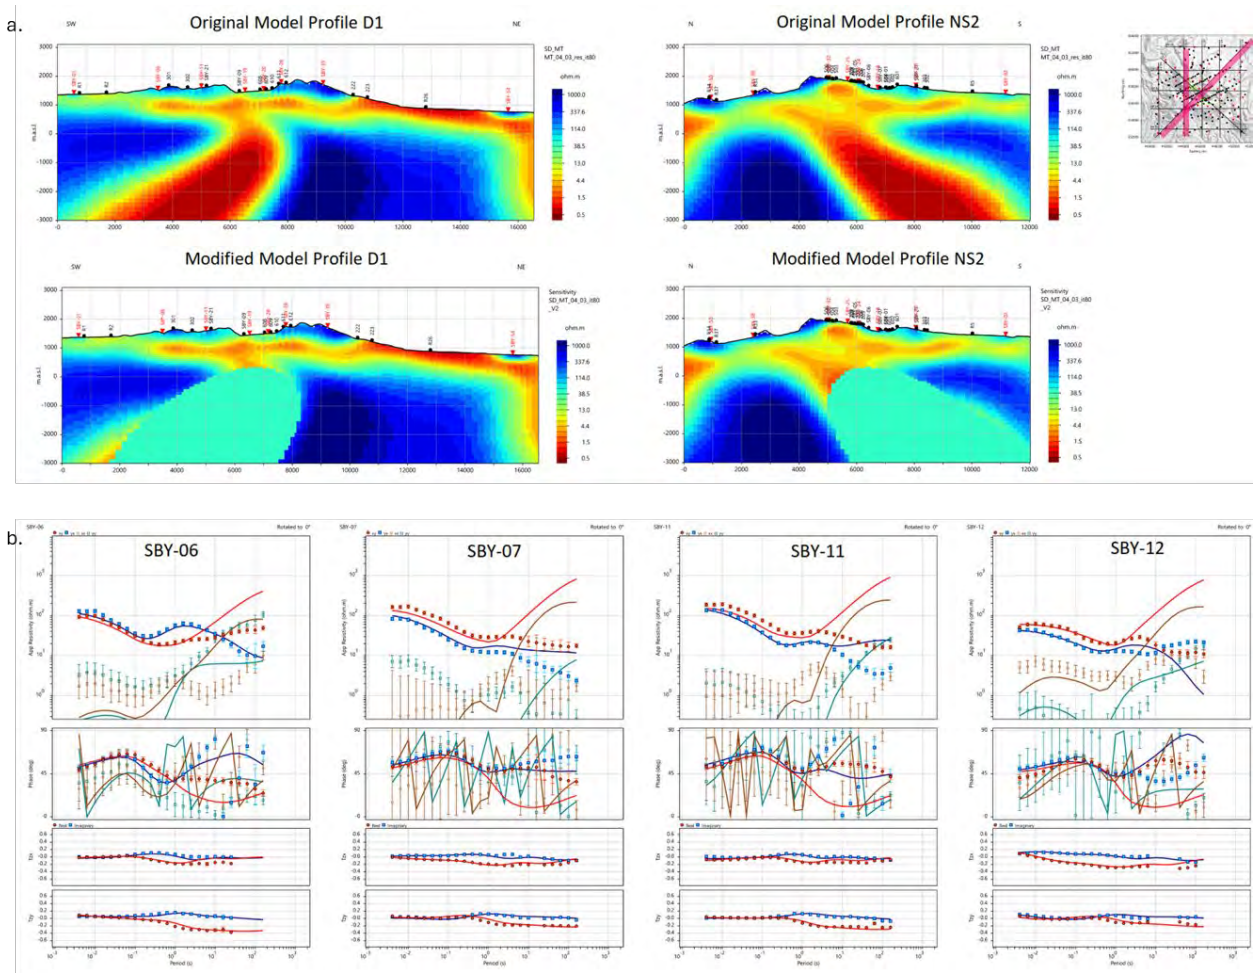

Figure 8. a. Cross-sections of two profiles comparing between modified 3D model from high conductivity into 50 ohm.m body. b. MT-curves sampled from MT stations above the high conductive body with MT curve from forward modelling of the modified body (solid lines) and original data (dots).

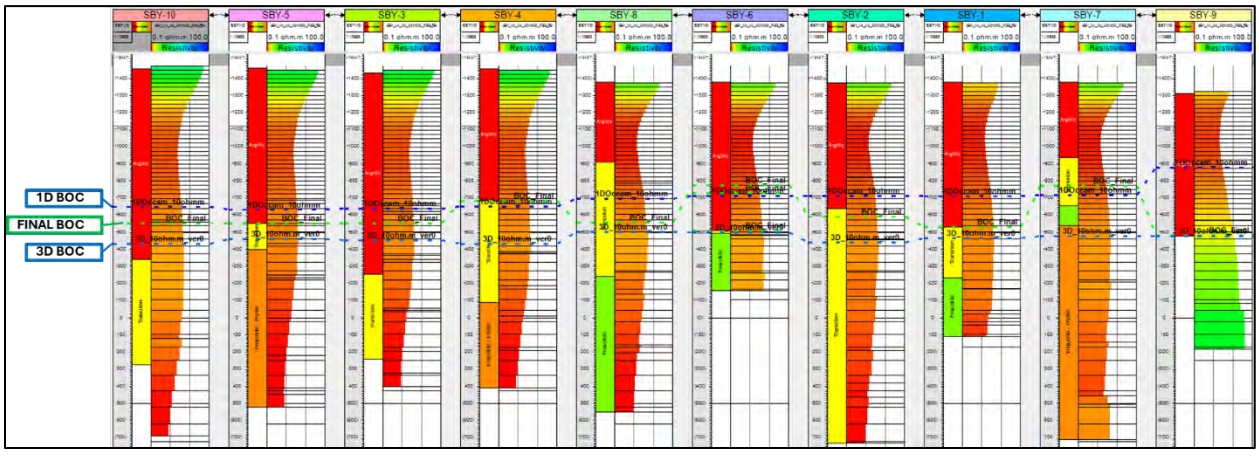

Figure 9. 1D and 3D interpreted bottom of clay cap with alteration data from Sibayak wells.

To address these limitations, a combined approach was adopted. The bottom of the argillic alteration zone was used as a primary constraint, and the general trend of the bottom of clay cap from the 1D model was incorporated into the 3D model using minimum curvature interpolation. This strategy aimed to mitigate the negative impacts of the low resolution associated with blurred resistivity value of the high conductive body and the clay cap on the 3D model Figure 10.

5. Possible Causes for Enhanced Conductivity

Potential causes for enhanced conductivity include graphite, ore minerals, saline fluids, and partial melting (Schilling, et al., 1997). However, given the likely presence of an impermeable barrier confining fluids, saline fluids are considered the most plausible explanations (Jones, 1992). A modeled electrical conductivity of sandstones saturated with NaCl solution (3.5wt% – 4wt%) as a function of porosity show electrical resistivity ranging from 1 to 5 ohm.m with 25% porosities (Jenkins, et al., 2023).

The other possible cause is that laboratory studies have established a correlation between high electrical conductivity and the presence of ore minerals, particularly sulfides. However, while this association is commonly observed, it is not universally applicable. Numerous case studies demonstrate that high conductivity can occur both with and without the presence of detectable sulfides (Lin, et al., 2023).

5.1 Saline fluid

Deeper geothermal brines sampled from Sibayak wells contain average sodium (Na^+) and chloride (Cl^-) concentrations of 500 and 1300 ppm, respectively, equivalent to a salinity of 0.18 wt%. These salinity levels are typical for geothermal brines. Yet, Figure 2.b presents a simplified geological model of Sibayak based on well cuttings data. Upper tertiary sandstones were found on those wells

ranging from 800 to 0 masl. Although sandstones should have high permeability, permeability derived from well productivity in Sibayak were found to have small to intermediate permeability (< 30 milliDarcy) (PT. Pertamina Geothermal Energy Tbk, 2016) based on permeability category (Wheaton, 2016). This discrepancy is likely attributed to silica or calcite scaling within the sandstone formations. Such scaling may create impermeable barriers, potentially trapping saline fluids and consequently enhancing electrical conductivity as observed in the resistivity model.

5.2 Sulfide

Pyrite is a sulfide mineral commonly appearing and reported during geothermal drilling. By utilizing this data, we can map the distribution of Pyrite within the Sibayak model. Figure 11a illustrates the distribution of Sibayak wells, incorporating alteration models, Pyrite content (ranging from 10 to 30 wt% as indicated by pink to red shading), and resistivity logs derived from 3D MT inversions. A horizon of Pyrite with 10wt% was mapped from the wells to know the distribution of Pyrite.

Figure 11b is a West to East cross-section presenting Sibayak wells with Pyrite content and a filtered <10 ohm.m 3D resistivity model as a background. An interpreted horizon of Pyrite > 10wt% was delineated with a dotted line and coinciding with the top of a conductive dome-shaped body. This correlation suggests a potential link between the enhanced conductivity and the presence of a sulfide body, warranting further investigation.

6. Discussions

In this study, 2D inversion was used to verify the presence of the highly conductive body identified in the 3D model, particularly its position relative to the production wells. The 2D inversion confirmed the existence of the conductive body, although its depth was estimated to be greater than that observed in the 3D model (Figure 7). This discrepancy underscores the importance of accurate static shift correction in both 1D and 2D inversions. Although static shift correction was not applied, the interpolated BOC is a success as shown in Figure 10 & Figure 11b.

To know more about the relationship between porosity, salinity, resistivity and temperature we could refer to a study by Ussher, et al., 2000. It is clear that the resistivity of Sibayak well brine sample data from Figure 12a could be ranging from 10 – 3 ohm.m, while an effective model in Figure 12b with temperature ranging from 250 – 300 ^{o}C, Sibayak sandstone should have porosity more than 20%. Unfortunately, porosity data for Sibayak sandstones are currently unavailable.

The other possibilities are using a model generated by Clennell, et al., 2010 with 100% brine saturated sandstone with Pyrite bearing sandstones. By incorporating Pyrite contents ranging from 10 to 30%, as observed in Sibayak, resistivity values below 10 ohm.m can be simulated (Figure 13). This modeling approach can be further refined by incorporating detailed mineral composition data from the Sibayak wells.

If the high conductivity is attributed to trapped saline fluids, future development efforts should prioritize targeting the conductive body. This approach is supported by the observation that production wells are located within the conductive zone, while non-production wells (e.g., SBY-9) are situated outside this area.

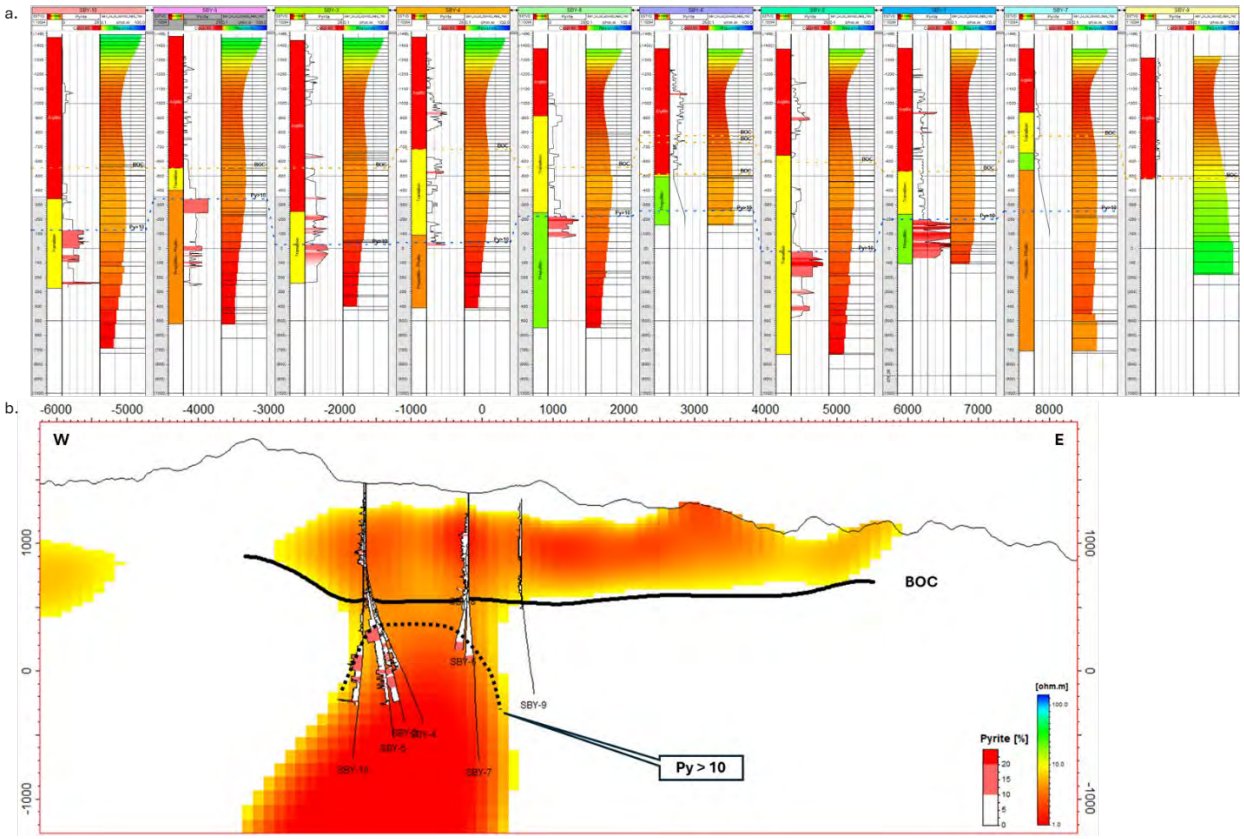

Figure 11. a. Distribution of Pyrite content in percentage (%) : pink to red is more than 10% contents, b. W-E cross-section with a filtered less than 5 ohm.m resistivity model background and Sibayak wells with each Pyrite content, a dotted line is an interpreted line of Pyrite with more than 10% content.

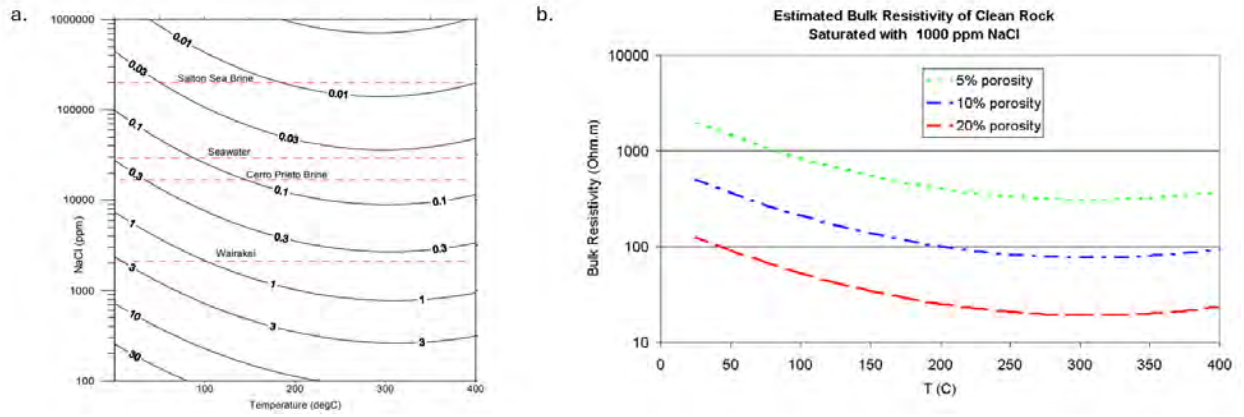

Figure 12. Relationship of salinity, porosity, temperature and resistivity (Ussher, et al., 2000) a. Variation of resistivity in ohm.m of Nacl solutions from measurements (Ucok, et al., 1980) modified by (Ussher, et al., 2000). b. a modelled Archie's Law bulk resistivities for "clean" rocks containing saturated 1000 ppm NaCl.

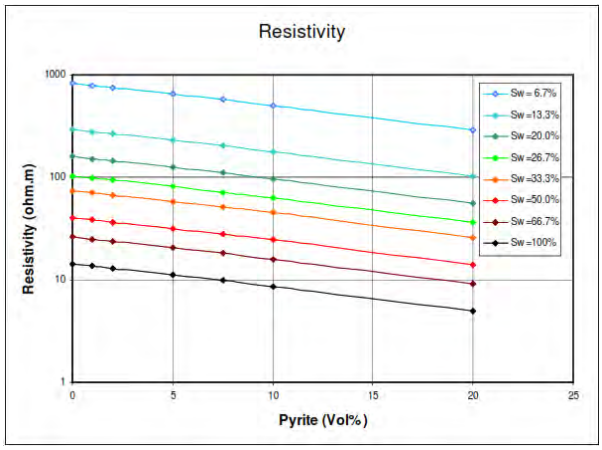

Figure 13. Resistivity of brine-saturated Pyrite bearing sandstones model with variable gas saturation, using Hanai-Bruggeman method (Clennell, et al., 2010).

Conversely, if sulfide mineralization is the primary cause of the enhanced conductivity, a comprehensive exploration program focused on identifying and evaluating rare mineral potential is warranted. Regardless of the underlying mechanism, drilling a new well into the core of the conductive body is essential to advance understanding of the system and assess its economic viability.

7. Conclusions

The integration of 1D and 3D inversion results with well data has significantly improved the delineation of the bottom of the clay cap (BOC), particularly in differentiating the clay cap from the underlying, highly conductive zone. Even though the causes of a deep enhanced conductivity in Sibayak are unclear, an enhanced conductive body is visible in all 1D, 2D and 3D MT inversions.

To explain the origin of enhanced conductivity, a combination of approaches is recommended. Drilling a new well targeting the conductive zone, coupled with resistivity logging, would provide direct evidence of the causative factors. Alternatively, rock physics modeling using methods like Hanai-Bruggeman or Archie's law could be employed to estimate formation factors for the Sibayak Tertiary sandstone. However, the lack of detailed rock property data limits the accuracy of such models.

Keywords

Blind geothermal system, magnetotellurics, helicopter transient electromagnetics, gravity, shallow low resistivity zones, geothermal outflow.

ABSTRACT

Blind geothermal systems are believed to be common in the Basin and Range province and represent an underutilized source of renewable green energy. Their discovery has historically been by chance but more methodological strategies for exploration of these resources are being developed. One characteristic of blind systems is that they are often overlain by near-surface zones of low-resistivity caused by alteration of the overlying sediments to swelling clays. These zones can be imaged by resistivity-based geophysical techniques to facilitate their discovery and characterization.

Here we present a side-by-side comparison of resistivity models produced from helicopter transient electromagnetic (HTEM) and ground-based broadband magnetotelluric (MT) surveys over a previously discovered blind geothermal system with measured shallow temperatures of ~100°C in East Hawthorne, NV. The HTEM and MT data were collected as part of the BRIDGE project, an initiative for improving methodologies for discovering blind geothermal systems. HTEM data were collected and modelled along profiles, and the results suggest the method can resolve the resistivity structure 300 – 500 m deep. A 61-station MT survey was collected on an irregular grid with ~800 m station spacing and modelled in 3D on a rotated mesh aligned with HTEM flight directions. Resistivity models are compared with results from potential fields datasets, shallow temperature surveys, and available temperature gradient data in the area of interest.

We find that the superior resolution of the HTEM can reveal near-surface details often missed by MT. However, MT is sensitive to several km deep, can resolve 3D structures, and is thus better suited for single-prospect characterization. We conclude that HTEM is a more practical subregional prospecting tool than is MT, because it is highly scalable and can rapidly discover shallow zones of low resistivity that may indicate the presence of a blind geothermal system. Other factors such as land access and ground disturbance considerations may also be decisive in choosing the best method for a particular prospect. Resistivity methods in general cannot fully characterize the structural setting of a geothermal system, and so we used potential fields and other datasets to guide the creation of a diagrammatic structural model at East Hawthorne.

1. Introduction

Blind geothermal systems are those that have no active surface manifestations such as hot springs, fumaroles or steaming ground. A subset of these, referred to as hidden systems, may have exposures of young or relict sinter, travertine, silicified sediments or acid-sulfate alteration. Going as far back to the mid-1800s in the western U.S., such systems have been discovered by chance by drilling water wells (e.g., Humboldt House) and later by petroleum exploration wells and mineral exploration holes in the 1900s.

Blind and hidden geothermal systems represent an underutilized source of renewable green energy in the Basin and Range province. Some have estimated that about 70% of the convective geothermal resources in the Basin and Range province (Coolbaugh et al., 2006a) are blind resources and that only about half of these blind resources have been discovered thus far in the Basin and Range. Over the past decade, exploration strategies for these systems have evolved towards a unified methodology. Examples of recent contributions have been made using targeting key structural settings (Faulds and Hinz, 2015; Hinz et al. 2015), Play Fairway analysis (Faulds et al. 2015, 2016; Siler et al. 2017 and others) by using machine learning (Faulds et al. 2020; Ayling et al., 2022) and by large-scale prospecting using airborne EM methods (Schwering et al., 2022, Sewell et al., 2023, Folsom et al., 2024). In this study, we examine how helicopter transient electromagnetics (herein referred to as HTEM) compare with ground based Magnetotellurics (MT). The objectives of this paper are twofold: (1) Perform a real-world side-by-side comparison of the two methods in the context of a classic blind geothermal system, and (2) to advance the understanding the blind geothermal system at East Hawthorne, NV.

Central to this effort is the basic observation that geothermal systems in the Basin and Range, blind or not, are frequently overlain by shallow zones of low resistivity (generally < 10 – 15 ohm.m). These zones can extend above the local water table, they occur largely within unconsolidated alluvium, and they tend to correlate with shallow thermal anomalies. The mechanism responsible for this pattern is the generation of low-resistivity hydrated smectite clays, which is enhanced above boiling or near-boiling shallow fluids that are exsolving gas. In systems that are well understood, these zones do not always occur directly over power-capable reservoirs. Instead, they are found where hot fluids rise near the surface, such as along outflow paths or near current or relict springs. The offset between these features and a typical geothermal reservoir can be several kilometers long. It is important to note that there are other geologic causes for shallow zones of low resistivity besides those of geothermal origin.

The dominant method for resistivity exploration used by the geothermal industry has been MT, a ground-based, passive technique that has a depth of investigation of many kilometers. The method

has practical advantages for the explorer. The acquisition systems are reliable, easy to transport and install without specialized tools, and cause minimal ground disturbance. Contractor costs are very reasonable. Challenges include long permitting timelines, requirements imposed by regulatory agencies, and the need to model the data with specialized codes. Modeling MT data in 3D, which is generally recommended for larger datasets, is computationally intensive and can be expensive, although costs are declining. When best practices for data processing and modelling are not followed, the results can contain artefacts that are misleading. Finally, MT surveys collected with wide station spacing (> 1 km) can easily miss the alteration associated with a geothermal system, which can sometimes encompass small areas (< 2 km^2). For this reason, MT can be a poor tool for reconnaissance of larger areas.

An alternative to using MT is to deploy an HTEM method instead. Transient electromagnetic systems are active-source, sending a large current in discrete pulses though a coil to generate a vertical, time-varying magnetic field that induces electrical currents in the subsurface. Secondary fields created by these currents are measured in a receiving coil. The depth of investigation for the system deployed in this study is generally 300 m – 500 m deep in the basins of Nevada (Sewell et al., 2023). Advantages to the explorer include excellent resolution, zero ground disturbance, a simple and fast permitting workflow, and the ability to rapidly cover large areas. Disadvantages include a limited depth of investigation, and high mobilization costs that make smaller surveys less practical.

Regardless of the method, resistivity alone is not sufficient to characterize the structural and stratigraphic setting of a geothermal system, which controls the distribution of permeability and ultimately guides well targeting efforts. Other methods must be deployed to accomplish this goal, such as geologic mapping, LiDAR analysis and potential fields geophysics (gravity and magnetic methods).

The BRIDGE project (Schwering et al., 2022) is part of a DOE-funded program to improve exploration efficiency in the discovery and characterization of blind geothermal systems in the Basin and Range province. The primary tool of this project was the deployment of a regional-scale HTEM survey, (Figure 1) which has been followed by a multidisciplinary exploration methodology.

An example of the results is shown for one HTEM line that bisects Gabbs Valley, NV, and crosses both the developed Don A. Campbell geothermal field, which is a blind system, and the Rawhide geothermal prospect, which has a hot spring. The resistivity model, shown in the lower panel of Figure 1, shows that shallow low-resistivity zones drape over both systems. In this figure and others like it in this report, a depth of investigation cut-off is denoted by a transition from solid to transparent colors. This is determined by the inversion algorithm, and values below this transition may be poorly constrained. The transparent portions extend to a constant depth of 600 m.

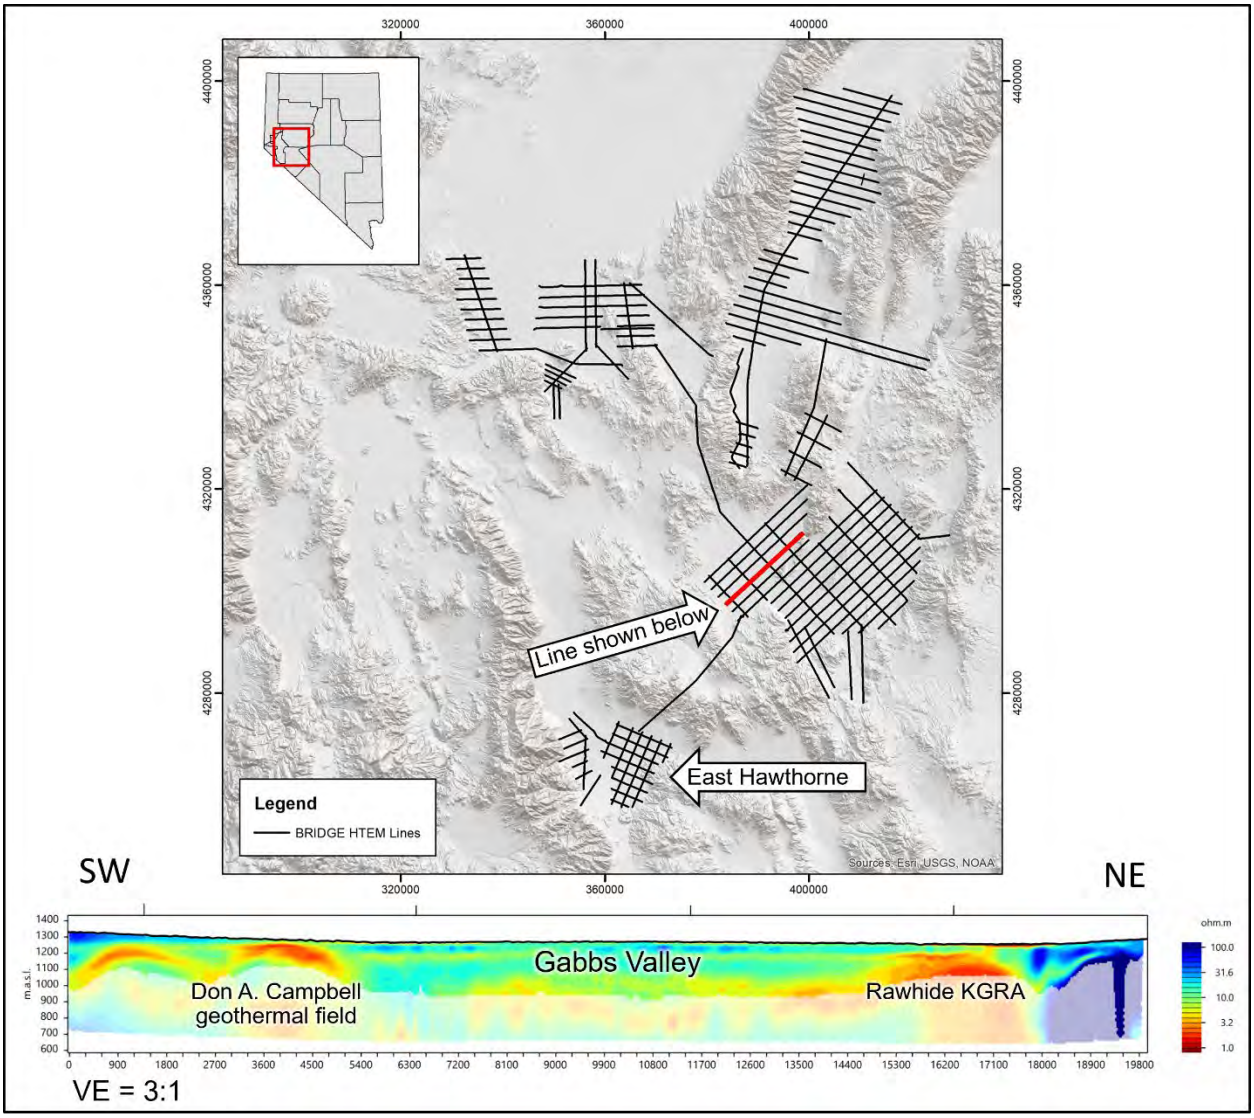

Figure 1: BRIDGE HTEM flight lines, and one sample resistivity profile from a transect crossing Gabbs Valley, NV. The approximate locations of the Dan A. Campbell geothermal field and the Rawhide known geothermal resource area (KGRA) are shown for reference. Note the 3x vertical exaggeration (VE) of the THEM resistivity profile.

1.1 Background

The blind geothermal prospect at East Hawthorne lies on the northwestern edge of the Garfield Hills, within the Walker Lake Basin near the town of Hawthorne, and inside the Hawthorne Ammunition Depot. A shallow temperature anomaly was defined in detail by a 2m temperature probe survey commissioned by the U.S. Navy in 2008 and 2009 (Kratt et al., 2010) that followed a thermal anomaly identified by water wells and temperature gradient drilling by the University of Nevada, Reno (Trexler, 1981). Additional surface studies were also conducted in 2009 in parallel

with the 2m temperature probe survey and that included geologic mapping, geochemistry studies, geophysical surveys, and 3D modeling (Hinz et al., 2010, Bell and Hinz, 2010; Kratt et al., 2010; Moeck et al., 2010; Lazaro et al., 2010; Penfield et al., 2010; Schoffner et al., 2010; 2011). Following these surface studies, a temperature gradient drilling program was completed in 2010 (Meade et al., 2011). A maximum temperature of 83.4°C was encountered at 55 m deep above a cooler deeper aquifer, indicating that hot lateral cross-flow was occurring at this location. Also in 2010, a slim well, HAD-1, was drilled to 914 m depth at East Hawthorne (Figure 2). This well encountered drilling losses 167 m depth at the contact between alluvium and quartz diorite. It is uncertain if the contact is depositional or a fault contact, however it is co-located with the highest temperatures in the well of 98.9°C above a temperature reversal (Figure 2; Meade et al., 2011; Blake et al., 2017). To date, there has been no geochemical analysis of fluids from East Hawthorne, limiting estimates of potential resource temperatures without having geothermometry calculations available.

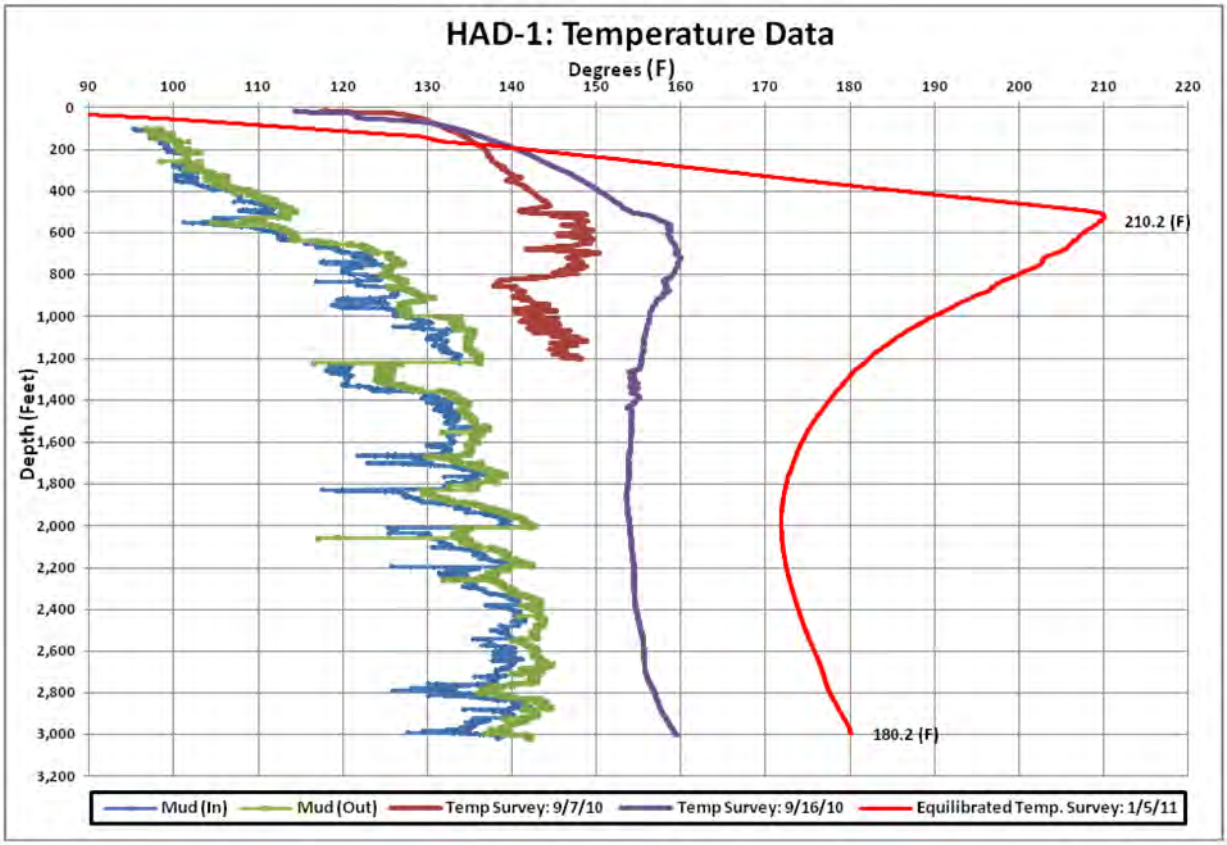

Figure 2: Drilling mud temperatures and temperature survey data for HAD-1 (figure from Meade et al., 2011).

XRD clay analysis of cuttings from HAD-1 confirmed smectite clay alteration in the alluvial section, which terminates at the contact with Mesozoic quartz diorite (Blake et al., 2017). Below this, the alteration regime switches to mixed-layer clays of illite-smectite, and illite-chlorite. The smectite clay zones that overlay the near-boiling outflow were shown to align with low-resistivity zones imaged by the HTEM (Sewell et al., 2023). Hence, the shallow low-resistivity zones here were confirmed to be of geothermal origin. The mixed layer clay alteration in the Mesozoic rocks

may be related to relict higher temperature alteration as noted in adjacent surface outcrops (Hinz et al., 2010).

The BRIDGE project followed up this observation with a 61-station MT survey, conducted in two phases. Data were then modelled in 3D, enabling a deeper image to be generated, and allowing direct comparison with the HTEM results.

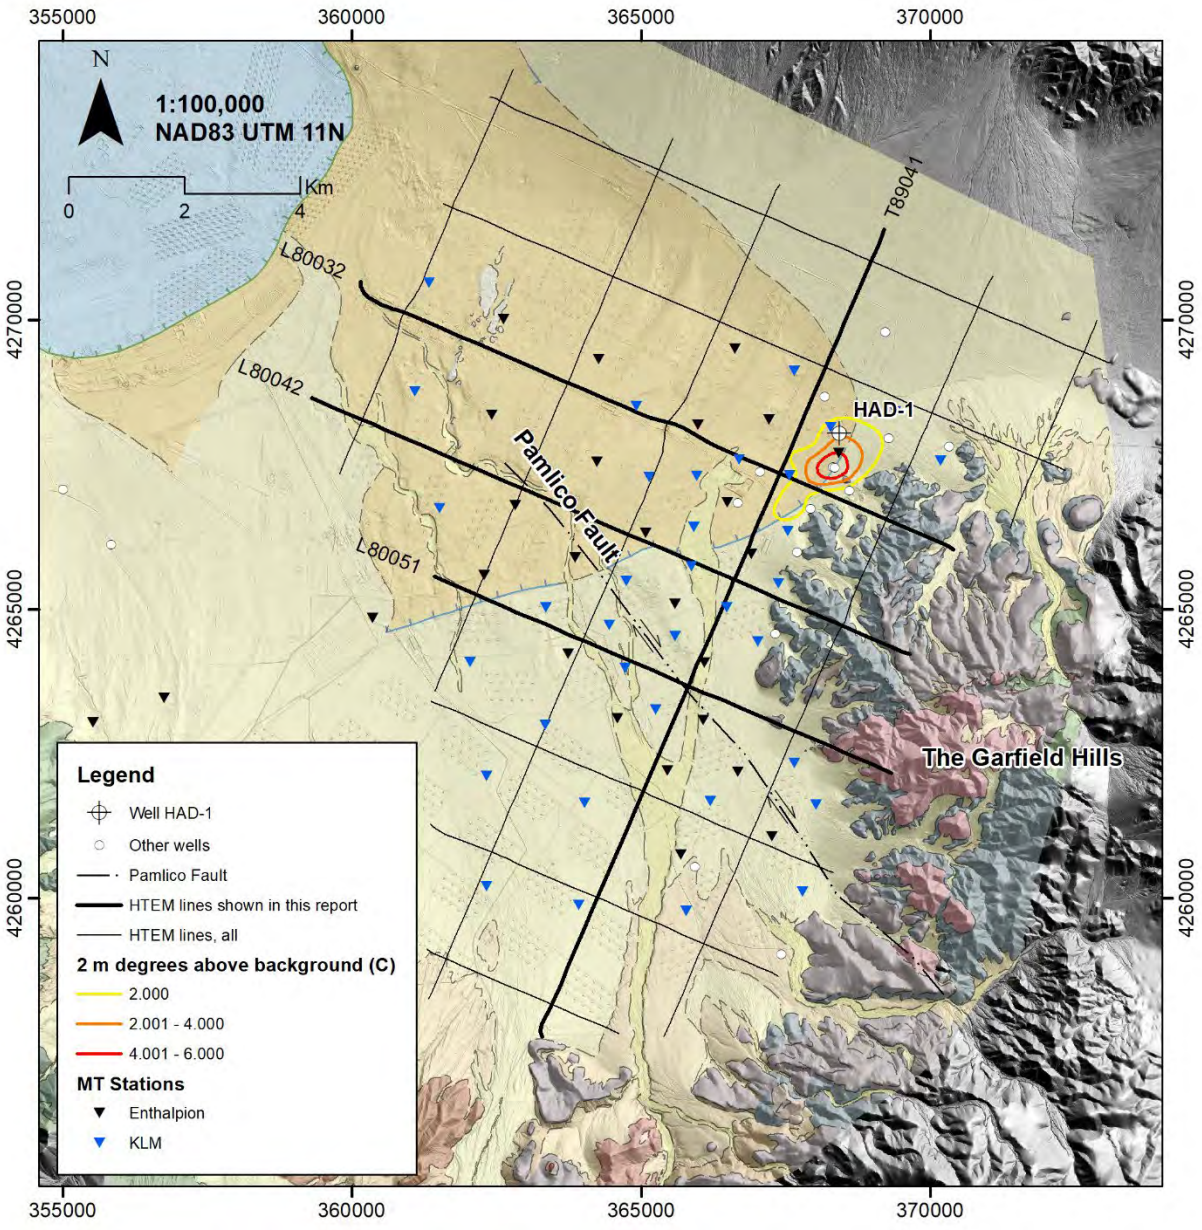

Figure 3: Map of East Hawthorne, including wells and HAD-1 locations (white circles), MT stations (triangles), HTEM flight lines (black lines), contoured 2-meter temperature results (yellow, orange and red lines), and select geologic features from Hinz et al., 2010.

1.2 Geologic Setting

The Walker Lake Basin lies on the western margin of the Walker Lane, which is a sub-unit of the Basin and Range Province dominated by NW-striking dextral strike slip faults. These strike slip features are often kinematically linked with normal faults. The basin is inferred to be a complex half-graben (Hinz et al., 2010), bound on its western side by the Wassuk Range-front fault. The Garfield Hills are composed of thin Tertiary volcanics overlying mostly of Mesozoic metamorphic rocks with some granitic plutons, including one intersected by HAD-1 (Blake et al., 2017). The NW corner of the Garfield hills are cut by NW-striking dextral faults and NE-striking sinistral oblique faults. The Pamlico Fault (Figure 1) is a NW-striking strike-slip fault that is both mapped at the surface (Hinz et al., 2010; Hinz 2024, personal communication) and is observed to correlate with a strong gradient in the gravity data. This gradient implies that the Pamlico Fault also drops low density alluvial fill against higher density basement rocks. Strong gravity gradients also suggest a concealed NE-striking, NW-dipping normal fault zone across NW margin of the Garfield Hills. No evidence of this fault zone is apparent at the surface, but its shallower extent may have been encountered by HAD-1.

2. Data

2.1 HTEM

HTEM data were collected along 1,877 line-km in the western Basin and Range (Figure 1). 2 km line spacing was considered adequate for prospecting purposes and enabled a large area to be surveyed for reasonable cost. One downside to the large line spacing is that the results cannot be contoured in plan-view without aliasing features. Lines were chosen to be perpendicular to structures. In the East Hawthorne area only, tie-lines were spaced equally at 2 km.

HTEM data were contracted through Xcalibur Multiphysics using their HELITEM™ system. This system deployed a 962 m^2 loop with four turns of wire. A 7.5 Hz, 146 A current with 50% duty cycle was transmitted to the coil. Returns were measured in 25 time-gates at a central-loop, multicoil (X, Y, Z) receiver. An independent magnetometer was also deployed just aft of the receiver coil. Flight speed averaged 110 km/h with an average sensor height of 35 m.

2.2 MT

MT data were collected in two phases. 26 sites were collected in 2022 by Enthalpion Energy using customized 32-bit receivers, custom magnetic field sensors and PbCl non-polarizable electrodes. Each station recorded vertical magnetic data. Stations were left to record for two nights each and recorded simultaneously with two sets of remote reference coils at distant locations. A ‘far’ remote was operated in northwestern Oregon, and a ‘local’ remote was installed approximately 70 km east of the survey center. All data were processed using dual-remote references, which is an approach designed to reduce the impact of geomagnetically induced currents in grounded power transmission lines. The contractor noted, however, that there was little evidence of bias in the results due to these sources. Final transfer functions include MT responses from 440 Hz – 0.00055 Hz.

In a second phase, KLM Geoscience was commissioned to add 35 MT locations to the original grid, reducing the station spacing to ~800 m. KLM deployed Phoenix RXU-8A receivers, MTC-155 broadband magnetic sensors and Cu-CuSO4 porous pot electrodes. Vertical magnetic data was

not collected. Each station collected data overnight and each were recorded simultaneously to a single remote reference station located 20 km to the east of the survey grid. Final transfer functions include MT responses from 10,000 Hz – 0.001 Hz.

Figure 4 shows sample transfer functions from both deployments. Apparent resistivity and phase are shown as edited prior to the modeling routing, with masked points in grey. Solid red and blue lines represent the rho+ synthetic model, which is used as proxy for data quality, although it makes certain 1D assumptions. (Parker and Booker, 1996).

Phase tensors (Caldwell et al., 2004) from all stations are shown over a range of periods in Figure 5. Because they are computed from edited data, many are missing at longer periods and within the dead band. Ellipses are colored by the geometric mean of the phase. Phase tensors are derived from components of the impedance phase, are rotationally invariant and are free from the effects of galvanic distortion. Parameters extracted from the phase tensors provide useful insights on the dimensionality of the structure. The long axis of the ellipse denotes the preferred direction of current flow, which are skewed some by 3D effects if they are present. Data quality is good to excellent for the majority of stations, with few outliers.

2.3 Gravity and Magnetics

Gravity data were compiled from the open-source dataset described by Ponce (1997) and from two separate deployments collected by the U.S. Navy in 2001 and 2009 (Schoffner, 2011). For this project, data were re-merged from the original files, terrain corrections were re-calculated digitally using LiDAR data, and the results were reduced to complete Bouguer anomaly (CBA) using standard methods (Hinze et al., 2007). After editing some spurious points, a total of 998 gravity stations covers the southern portion of the Walker Lake Basin. The CBA, along with its horizontal gradient magnitude (HGM) and first vertical derivative (1VD) are shown in panels A-C of Figure 6.

Aeromagnetic data was clipped out of the GeoDAWN dataset collected by the USGS (Glen and Earney, 2024). In this region, line spacing is 400 m and the mean terrain clearance was 237 m above ground. Flight lines were oriented east-west. The reduced-to-pole magnetic residual (RTP) is shown in panel D of Figure 6.

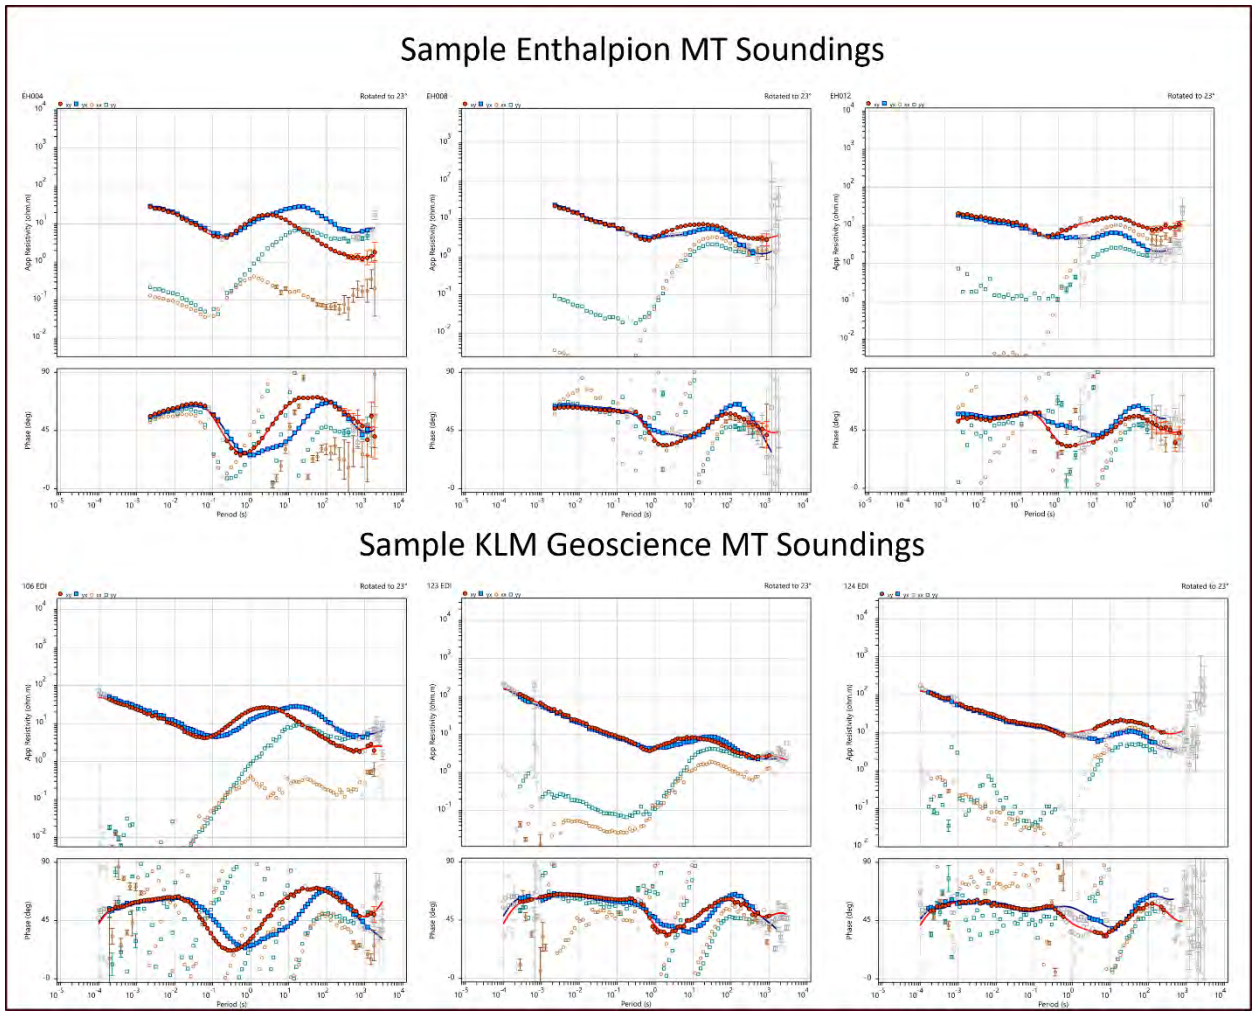

Figure 4. Sample MT sounding plots from the Enthalpion and KLM surveys. The upper portion of each sub plot shows the apparent resistivity, and the lower portion shows the impedance phase. All tensor components are shown. Solid red and blue lines are the Rho+ synthetic model, which is used a proxy for data quality.

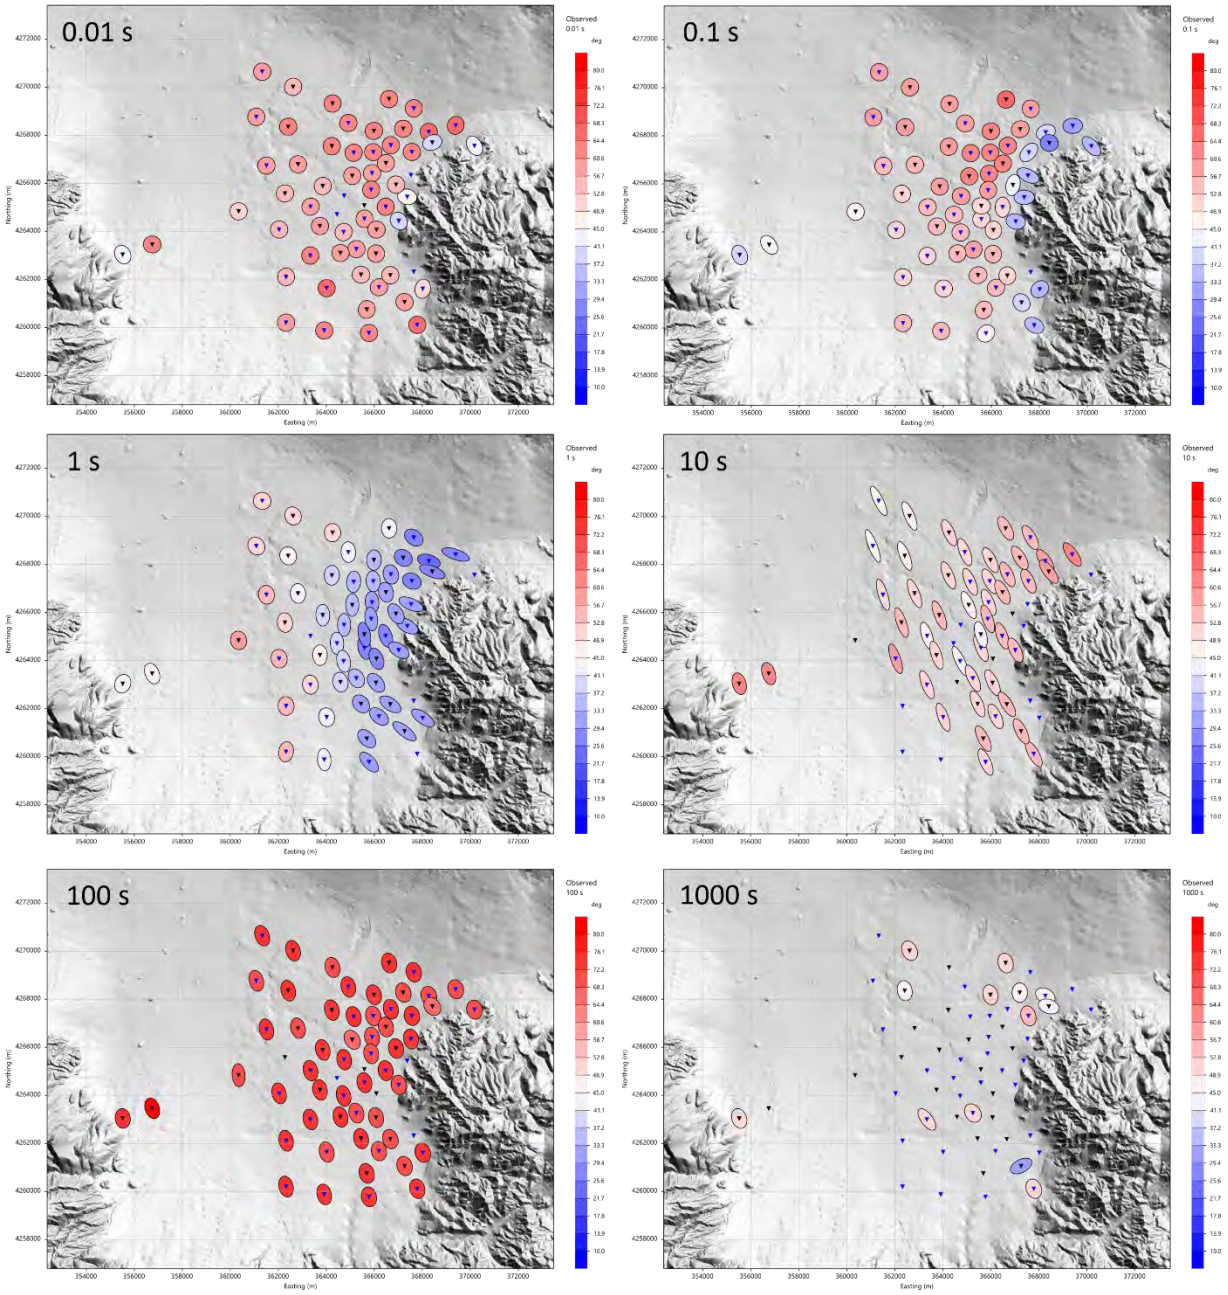

Figure 5: Phase tensors at select periods, noted in the upper left corner of each panel in units of seconds. Ellipses are colored by the geometric mean of the phase. Phases above 45° (red) indicate a decrease in resistivity with depth, and phases below 45° (blue) indicate an increase in resistivity with depth. This is true only where the data are 1D in nature.

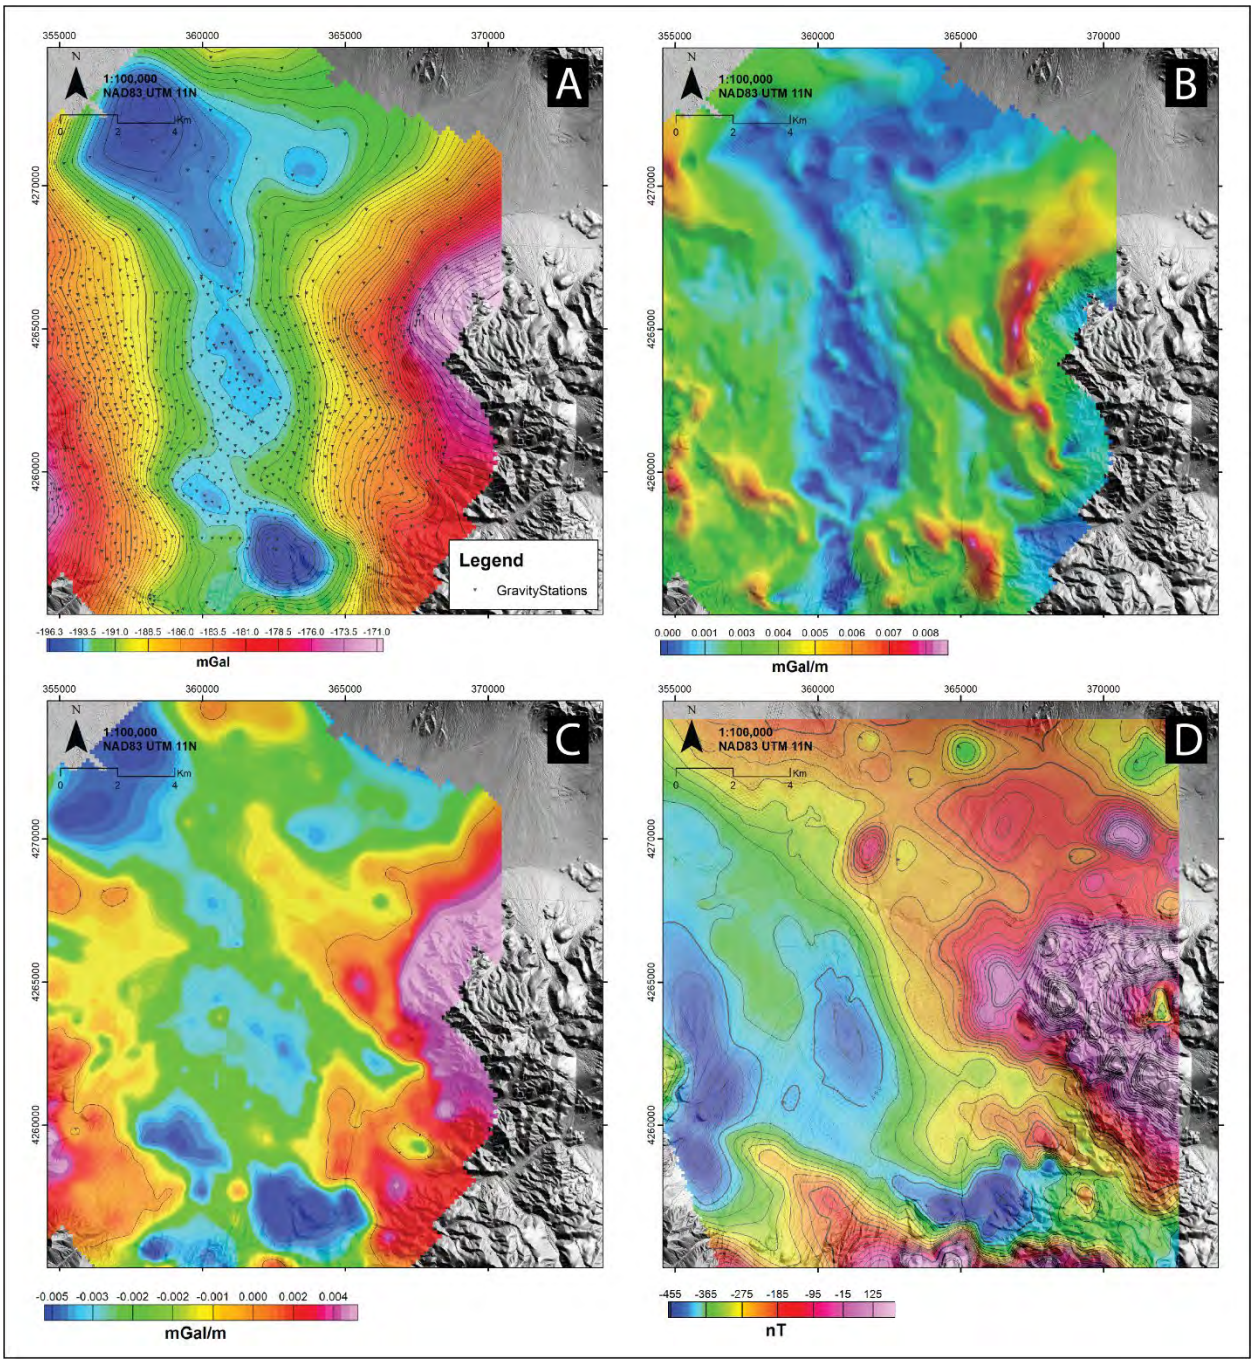

Figure 6. Gravity and magnetic data from East Hawthorne. Panel A: Complete Bouguer anomaly (CBA) reduced at 2.45 g/cc and gridded at 150 m, with gravity station locations shown as small black triangles. Panel B: Horizontal Gradient Magnitude of the CBA. Panel C: First vertical derivative of the CBA. Panel D: Reduced-to-pole magnetic anomaly from the GeoDAWN dataset (Glen and Earney, 2024).

3. Methods and Results

3.1 HTEM

Laterally constrained, 1D deterministic inversions of the HTEM data were carried out by the USGS using the Aarhus Workbench Airborne TEM module. The depth of investigation was determined, which is an estimate of the depth at which the modelled results can resolve the resistivity structure given local signal and noise levels. This is shown in the HTEM figures in this report as a transition from opaque to transparent. Note that this depth is variable and dependent on the overlying resistivity values. In areas with near surface conductors, the depth of investigation is decreased.

In many areas at East Hawthorne, noise from anthropogenic sources such as railways, ammunition bunkers, power lines and buried utilities caused problems with the results. These issues are generally easy to identify and present themselves as localized early-time transients in the receiving coil. Care was taken to edit these points prior to modeling, which results in blank strips in some of the models. Induced-polarization (IP) effects are also present in the data, which can occur in strong central-loop TEM systems. This effect causes rapid decay of transient voltages followed by a polarity reversal (El-Kaliouby, 2001).

3.2 MT

The model mesh used to perform the 3D inverse modeling was rotated to align with the HTEM flight lines (Figure 7). The mesh accounts for topography and was constructed using a finer inner core and coarser outer core to reduce the total number of cells. Padding cells extend for 50 km in the X, Y and Z directions. The total number of model cells is about 1.2 million. Data were rotated 23° CW from north to align with the mesh, and then edited of spurious points prior to modeling.

The data were then modelled using the RLM-3D inversion code (V.3.3.3.12526) as described in Soyer et al., (2020). This code follows a minimum structure Tikhonov approach (Tikhonov and Arsenin 1977), deploying regularized least-square methodology, where an objective function is iteratively minimized using the method of non-linear conjugate gradients.

A summary of the model mesh, inversion parameters and data fit results are shown in Figure 7. A total of eight models were run to explore the inversion space. The final model started from a homogeneous 20 ohm.m subsurface resistivity and ran for 50 iterations using a higher (smoother) vertical regularization setting (tauV). The model was then re-started using a smaller tauV setting and ran for 30 more iterations, achieving a final RMS fit of ~1.2 while using a 3% error floor on all tensor components.

Constant elevation map slices through the final 3D MT model are shown in Figure 8.

3.3 A Direct Comparison of Results

Figure 9 and Figure 10 show direct comparison of the HTEM results to the 3D MT model, extracted along four lines. Select wells are projected to the cross sections, including HAD-1. 1D layered models of the MT data, made from the invariant mode are shown over the cross-sections for reference.

Both the 3D MT model and the HTEM models can clearly resolve shallow low-resistivity features associated with the blind geothermal system at East Hawthorne. In cross-section, the HTEM

models have superior resolution, and image complexities not seen in the MT. In several cases, the MT sees a single low resistivity body, but the HTEM results suggest it is made from two discrete layers. Often, the HTEM places a flat-lying conductors ~100 m deep within the alluvium. These are only sometimes resolved within the MT model. Interpretation of such features remains incomplete, but they may indicate soil horizons, the water table, or geothermal outflow features. In several instances, the HTEM results match the shallow 1D models from the MT data better than they do the 3D MT model. This effect was made worse on 3D inversions run with smoother regularization settings, and so it seems likely to be related to the nature of minimum structure modeling techniques. Despite these doubts about shallow results in the 3D resistivity model, the MT model appears to be well constrained to several km in depth.

In plan-view, the 3D MT model provides valuable observations on the extent of the shallow low resistivity zones and can be compared directly with other mapped data such as results from gravity. This would be possible using HTEM also, had closer line spacing been deployed.

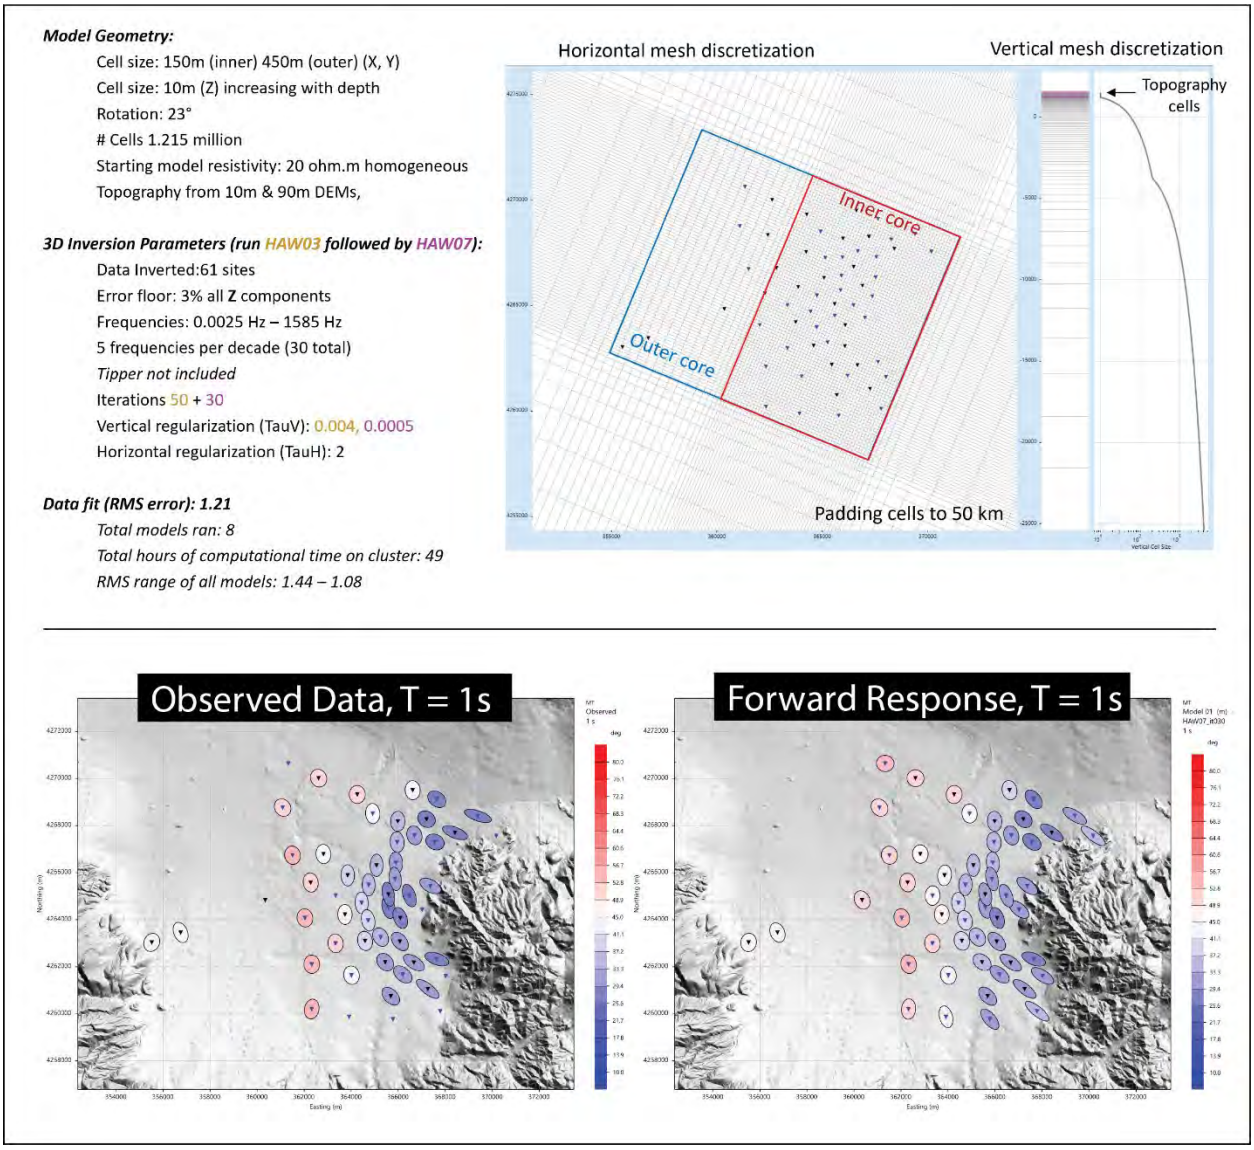

Figure 7. Summary of mesh geometry, inversion parameters and resulting data fit. Lower panels show phase tensors at a period of 1 second, from the observed data (left) compared to the forward response (right).

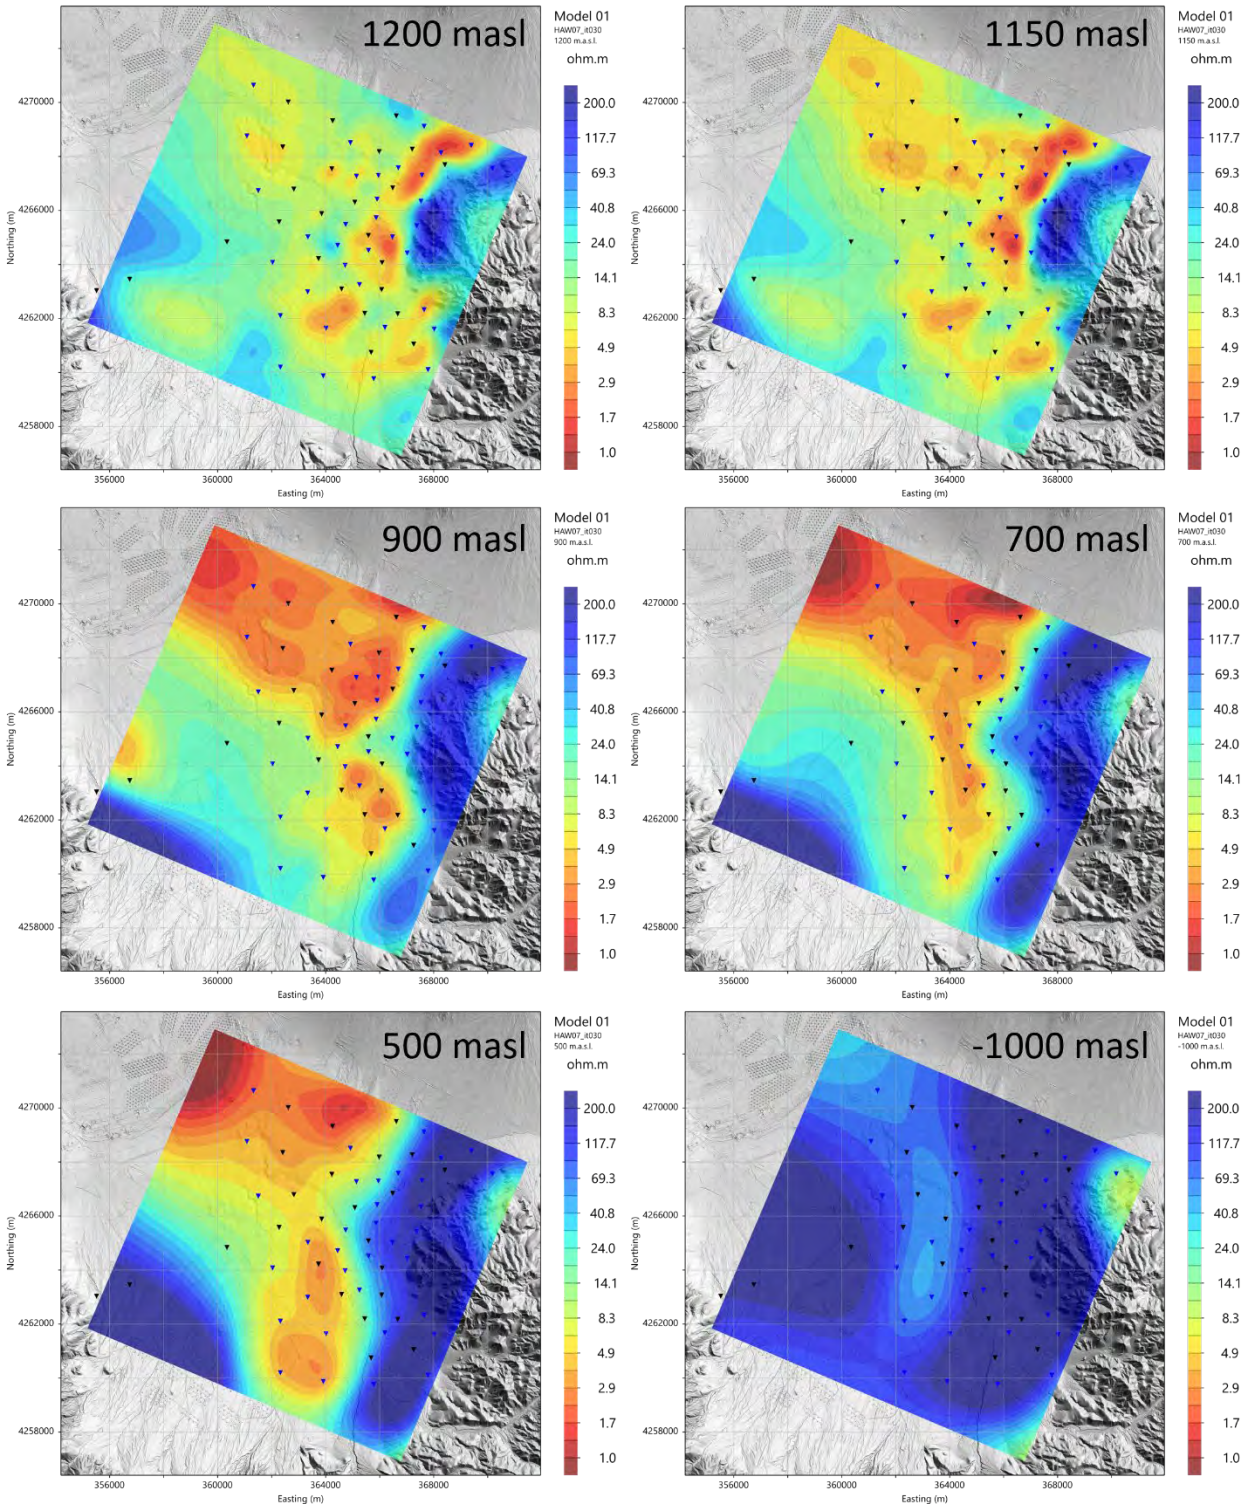

Figure 8: Constant elevation slices, noted in meters above sea level (masl), at select intervals through the final 3D MT model.

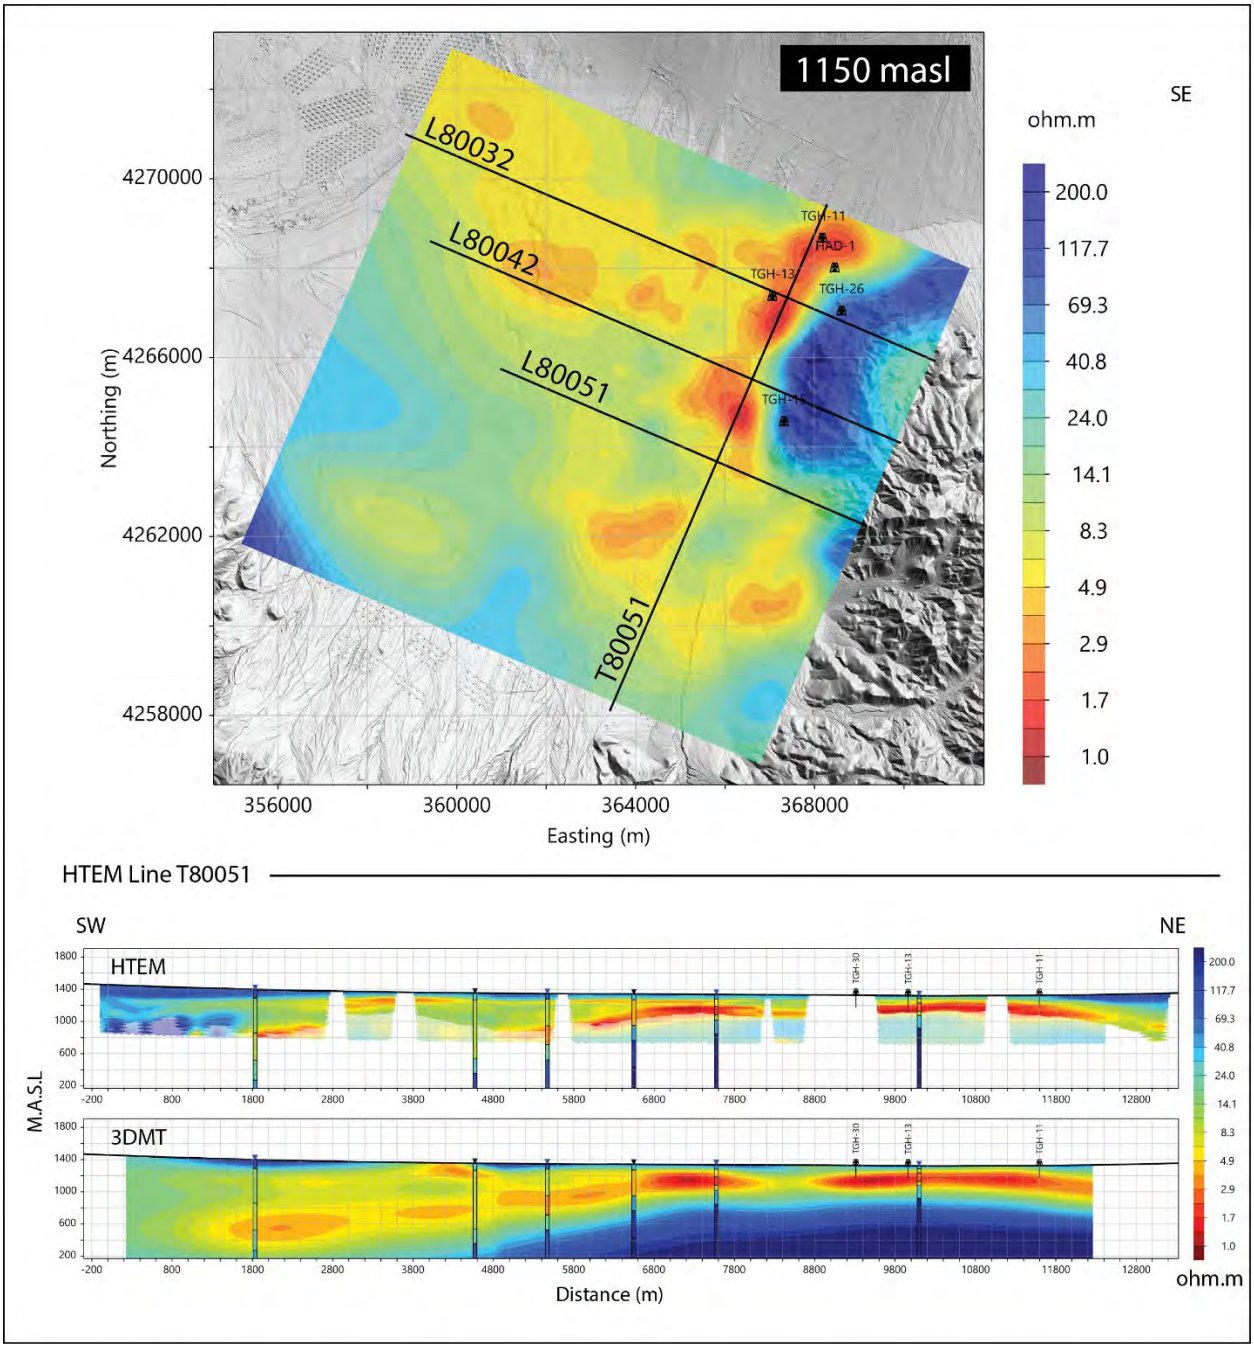

Figure 9: A direct comparison of HTEM and 3D MT results. Upper panel shows the 3DMT model sliced at 1150 masl, with select profiles chosen for comparison. Wells projected onto to the cross sections are shown with black symbols. Lower panel compares the two results on HTEM line T80051. Layered results from 1D MT models of the invariant mode are shown as colored bars.

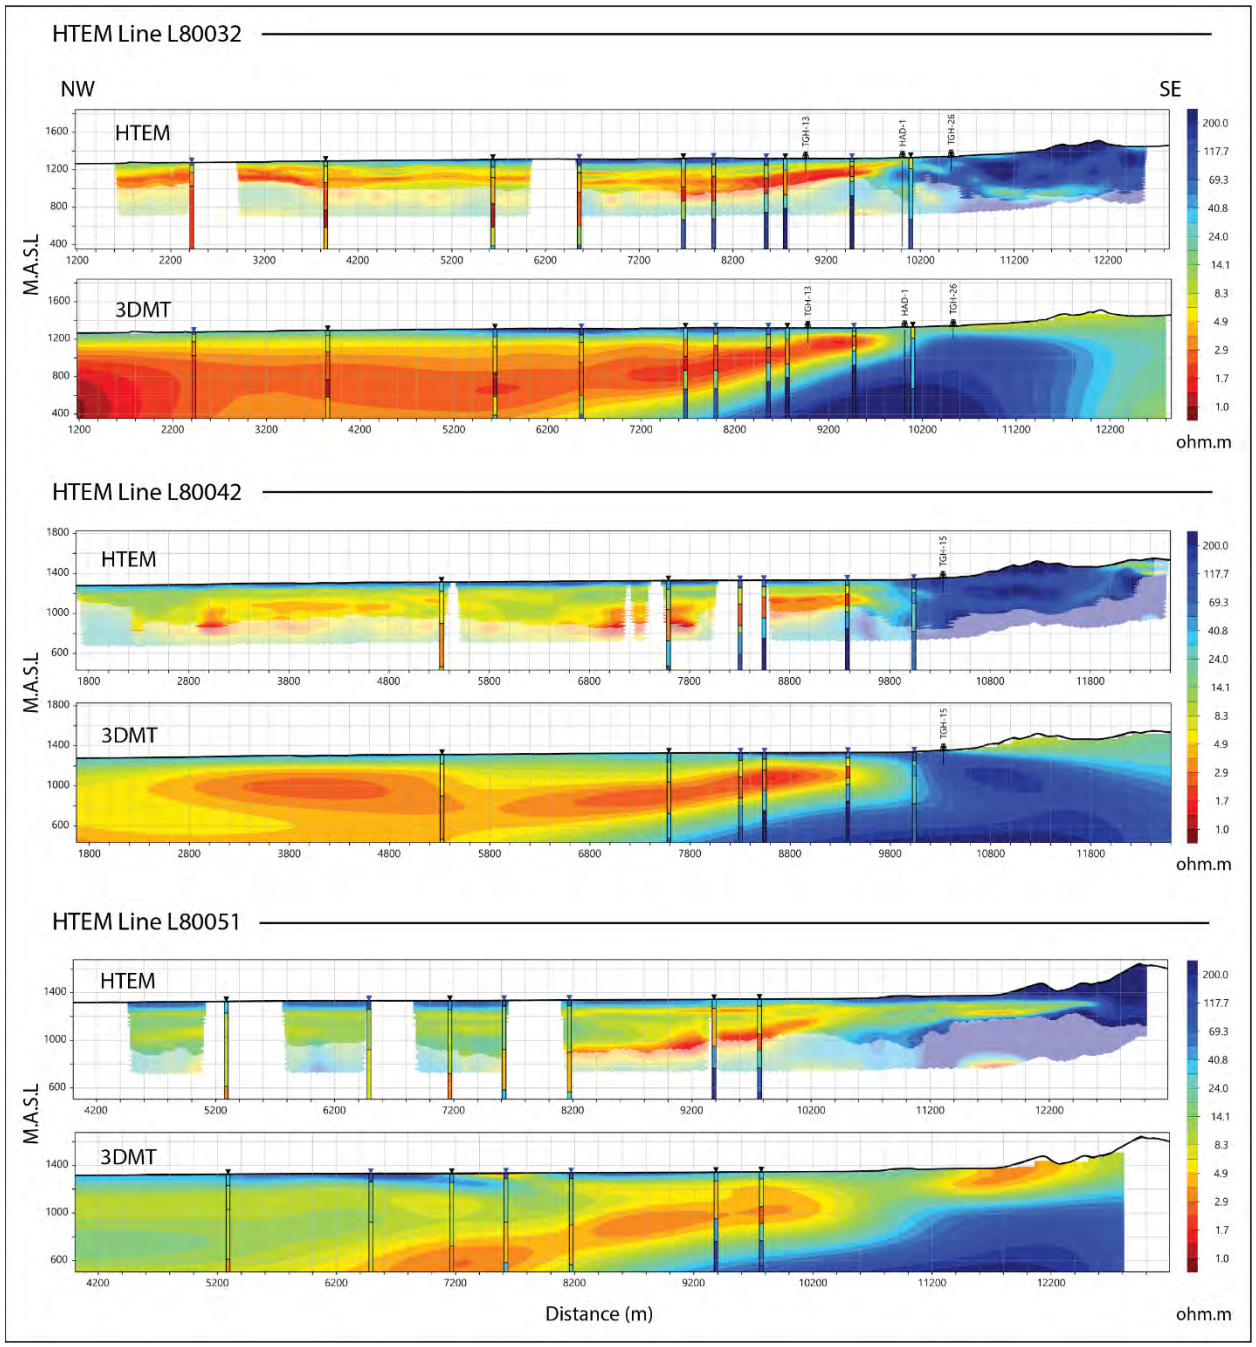

Figure 10: A direct comparison of HTEM and 3D MT results on lines L80032, L80042 and L80051. Layered results from 1D MT models of the invariant mode are shown as colored bars.

4. Interpretation and Discussion

Combining the results from the HTEM, MT and potential fields datasets provides an opportunity to construct a preliminary structural model at East Hawthorne and guide some conceptual model elements of the geothermal system there. The horizontal gradient magnitude of the gravity CBA indicates two strong, nearly perpendicular high gradient zones, which we interpret as major, basin-offsetting faults (Figure 11, panel A). These faults are also suggested by mapped contacts on the ground in the case of the Pamlico Fault, and an inferred fault contact at the base of alluvium in HAD-1, supporting the NE-striking normal fault. These observations follow from the so-called horizontal gradient method, where such contacts are picked along gravity gradient maxima (Cordell, 1979; Cordell and Grauch, 1985). Similar conclusions can be derived from the magnetic data (Figure 11, panel B). Finally, this pattern of two intersecting fault zones is echoed in the MT model, where at shallow depths the low-resistivity zones are confined to the down-dip portions of the normal fault, and north of the Pamlico Fault (Figure 11, panel C). At an elevation of 900 masl in the MT model, a sharp corner intrudes into the low resistivity zone, also suggesting an intersection here. Other faults in Figure 11 are mostly diagrammatic and meant to convey a zone of complexity that likely occurs where these two fault zones intersect.

In the Basin and Range Province, certain structural settings have been shown to correlate with active geothermal systems and epithermal mineral deposits (Faulds et al., 2021; Faulds and Hinz, 2015). These settings include fault step-overs and relay-ramps, among others. The system at East Hawthorne is categorized by these studies as a fault intersection, however, work from this paper suggests that it is a displacement transfer zone instead. In this setting, a strike-slip faulting is kinematically linked to near-perpendicular normal faulting. Producing fields that share this type of geometry include Don A. Campbell, Wabuska, and Blue Mountain. Notable prospects that are believed to host similar setting include South Gabbs (Craig et al., 2021) and Rhodes Marsh (Faulds et al., 2021).

Interpretation of the results suggests two possible end members for the location of an up-flow and geothermal reservoir. The first is that the system lies near the 2-meter temperature anomaly, down-dip along the NE-striking normal fault. HAD-1 encountered near-boiling lateral outflow, and it appears to have been targeted too far up-dip to encounter the resource.

An alternative model is that the system lies closer to the junction of the Pamlico and NE-striking normal faults. Where these two faults meet, a shallow zone of low resistivity is also located, and it overlies an intermediately resistive corner (20 – 40 ohm.m) that intrudes into a conductive background. This geometry is characteristic of other analogue geothermal up-flow zones. This model implies that the observations at HAD-1 and the 2-meter survey are caused by a ~ 4 km long geothermal outflow plume, traveling along-strike with the NE normal fault, although potentially channelized by stratigraphic layers. Such an outflow is not unprecedented in Basin and Range systems. For example, a ~5 km boiling outflow plume is well documented at the San Emidio Field (Folsom et al., 2020, Rhodes et al., 2010, Matlick, 1995) and an 8 km long 140 to 90°C shallow (<150 m deep) outflow is documented at Salt Wells, which is part of a 12 km long shallow thermal anomaly (Edmiston and Benoit, 1984; Coolbaugh et al., 2004, 2006b; Hinz et al., 2014).

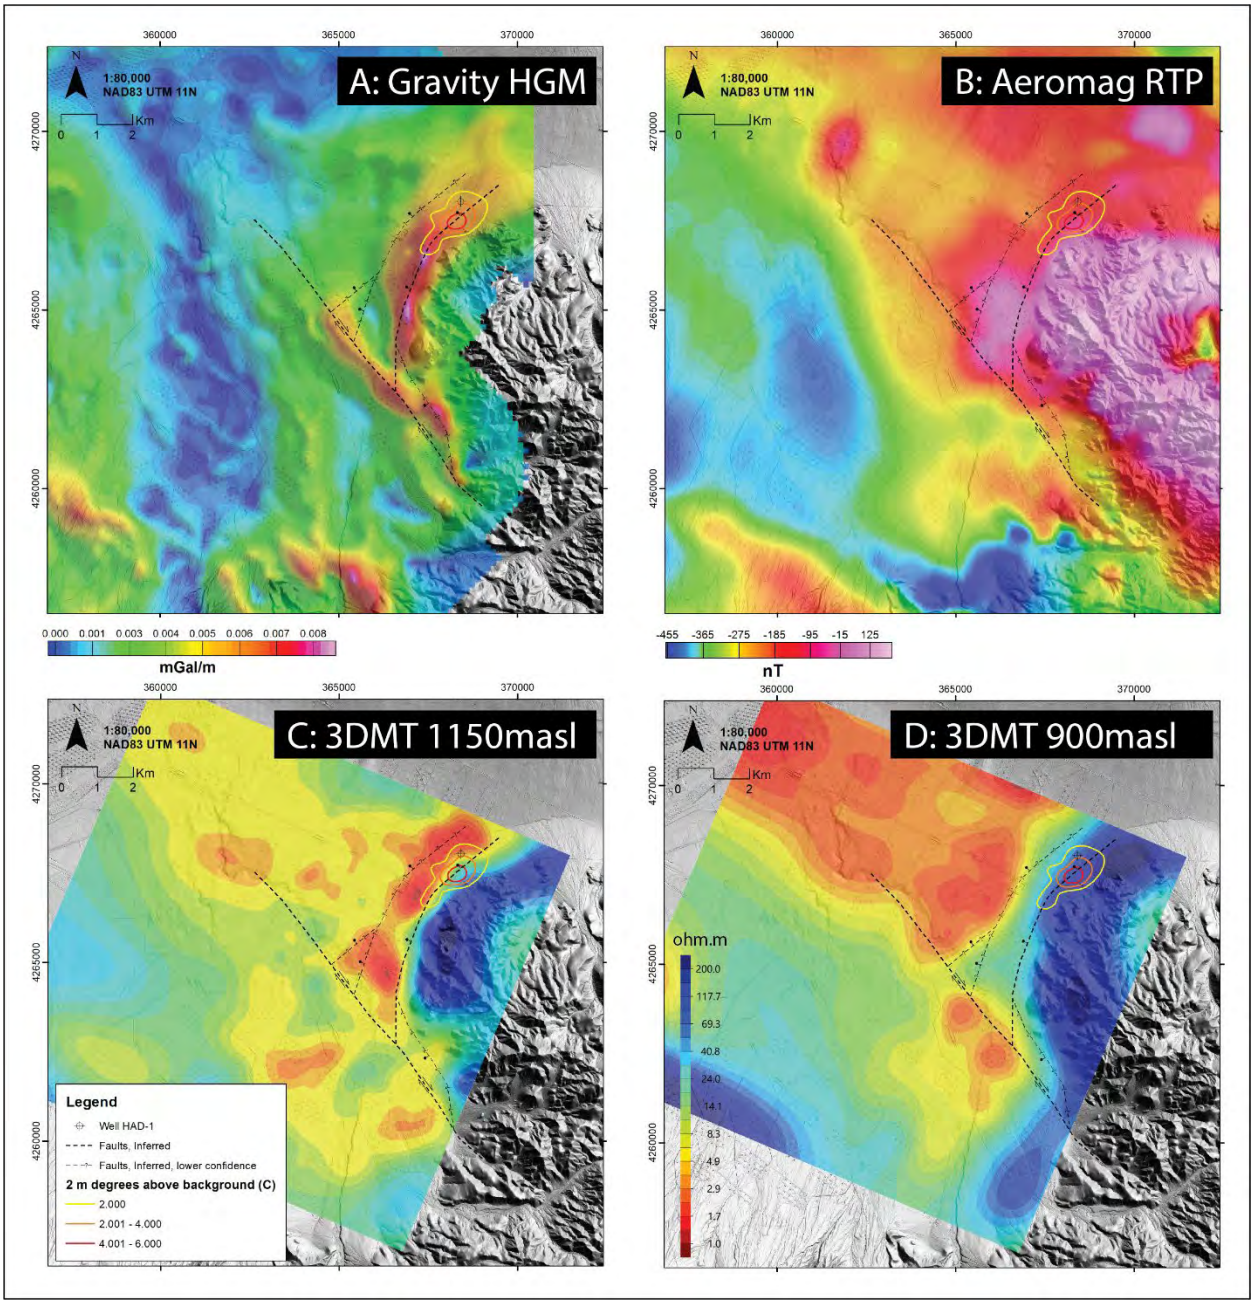

Figure 11: Preliminary structural model informed by geophysics. In each panel, inferred faults and the 2-meter temperature anomaly are shown against different geophysics results. Panel A: Gravity horizontal gradient magnitude (HGM). Panel B: Reduced-to-pole aeromagnetic anomaly (Aeromag RTP). Panel C: Elevation slice at 1150 masl from the 3DMT model. Panel D: Elevation slice at 900 masl from the 3D model.

5. Conclusions

The blind geothermal system studied at East Hawthorne is characterized by low resistivity zones (< 5 ohm.m) that extend across a large area (~8 km^2 at 150 m depth). At the location of well HAD-1, these zones correlate with smectite clay alteration. A preliminary analysis of MT, gravity and magnetic data, supplemented by observations from mapped faults and well data, suggests that the system is hosted within a displacement transfer zone, consistent with generalized models for this area (Hinz et al., 2010). This structural setting is favorable for hosting geothermal upflow as illustrated by both producing fields and prospects elsewhere in the Basin and Range (Faulds and Hinz, 2015). Although several geothermal conceptual models are consistent with the data at East Hawthorne, we prefer a model where an up-flow is hosted near the intersection of the Pamlico strike-slip fault and a NE-striking, NW-dipping normal fault, and below the shallow low-resistivity zone here. This implies a ~4 km long outflow path that connects with the 2m temperature anomaly.

Shallow, low resistivity features relevant to the geothermal system at East Hawthorne are successfully imaged by models created from both HTEM and MT data. Direct comparison of the results demonstrates that, while they each have advantages and limitations, they are ultimately complementary methods for the explorer. The 3D MT model, owing to its survey geometry, is better at characterizing the extent of the shallow low-resistivity zones. In cross-section, the HTEM results have superior resolution, and can resolve the upper portions of typical Basin and Range geothermal systems. Given that HTEM causes no ground disturbance, is straightforward to permit, can access remote locations and rapidly cover large areas, we conclude that it is a better method for geothermal prospecting than MT. However, MT is more practical and cost-effective for assessing a single prospect, it can see much deeper than HTEM and inherently contains 3D information. Despite difficulties with permitting and the complexities of modeling MT in 3D, we conclude that it remains a better choice for developing conceptual models, assessing well targets and estimating resource capacity.
