Surprise Valley, Basin and Range, aeromagnetics, gravity, geophysics, geothermal resources, Nevada, California, Great Basin, dike swarm, faulting, magmatism

ABSTRACT

Surprise Valley, located in the northwestern Great Basin, is an asymmetric extensional basin that marks a major tectonic transition between the relatively un-extended volcanic Modoc Plateau to the west, and the Basin and Range to the east that has undergone 10-15% extension. In addition, it sits just north of the Walker Lane which accommodates up to 20% of dextral slip associated with Pacific-North American plate interactions.

Thermal springs issue from eight areas within Surprise Valley. Most of these occur within the basin and are not situated on the main basin forming range-front faults. As a result, efforts to resolve the structural setting of the valley's hydrothermal system have relied on geophysics to characterize basin structure and geology.

Extensive efforts to map the basin with ground and airborne magnetics have revealed a >35 km-long linear, intra-basin magnetic high, interpreted as a buried dike swarm. Geothermal springs on the eastern side of the valley, including Seifert hot springs, Leonards hot springs, and Surprise Valley hot springs (SVHS), are all situated along the magnetic high and occur at local breaks and bends in the anomaly, suggesting that fracture permeability is enhanced along the feature and particularly at these discontinuities.

Recent studies, including drilling over the anomaly near SVHS that likely intersected dike material, as well as subsequent mapping and sampling of dikes outcropping along the anomaly on the playa surface south of SVHS, confirm (as previously inferred) that mafic intrusives are the

principal source of the anomaly. Similar interpretations made in two other valleys (in southern Oregon and northwestern Nevada), where inferred intra-basin dikes appear to be spatially correlated with hot springs or prospective geothermal resource areas, suggest that the impact of pre-existing basement structure on hydrothermal activity may pertain more generally to other hydrothermal settings throughout the Great Basin. If so, efforts to map basement may enhance understanding structural controls on some geothermal systems.

Furthermore, similarities across these disparate sites suggest that magmatism may play a much larger role in accommodating extension and influencing basin evolution across the western Great Basin than previously recognized.

1. Introduction

1.1 Geologic Setting

Surprise Valley is located in northeastern California and situated between the relatively un-dissected Modoc Plateau to the west, and the Great Basin to the east, forming the westernmost deep extensional graben of the Great Basin that is characterized by basin and range physiography (Figure 1). The valley also marks a major tectonic transition from north to south, as it sits immediately north of the Walker Lane, which accommodates up to 20% of dextral slip associated with Pacific-North American plate interactions, and just south of the low-strain High Lava Plains region (Hammond and Thatcher, 2005, 2007).

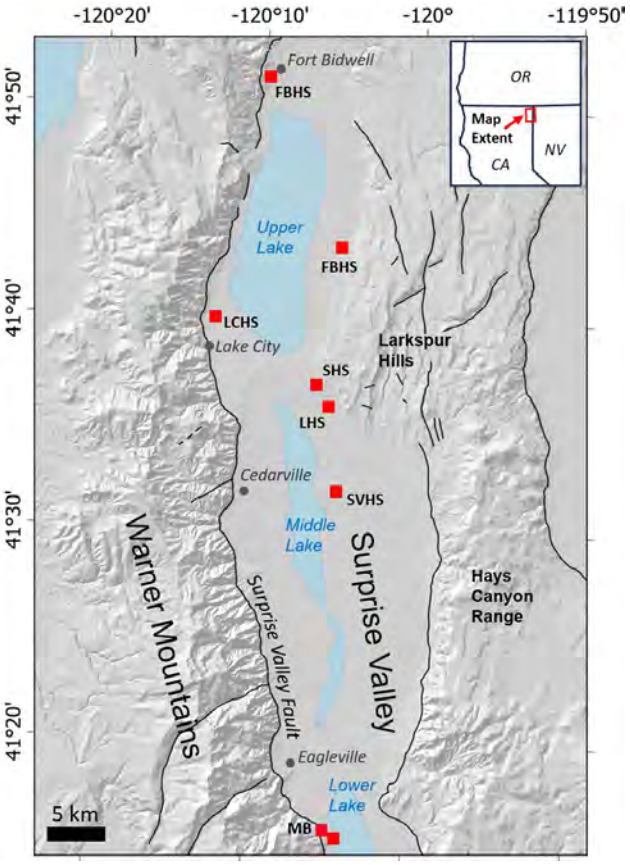

Figure 1. Index map of study area showing the location of faults (black lines, after Egger and Miller, 2011) and hot springs (red squares). SVHS – Surprise Valley hot springs, FBHS – Fort Bidwell hot springs, LCHS – Lake City hot springs, SHS – Seifert hot springs, LHS – Leonards hot springs, MB – Menlo Baths.

The valley is bounded to the west by the Warner Mountains that form the footwall of the east-dipping Surprise Valley normal fault (SVF). The SVF is the dominant basin-forming structure that has experienced at least 8 km of dip-slip offset (Egger and Miller, 2011; Personius et al., 2009). Several parallel secondary structures have been identified within the basin outboard of the SVF (Glen et al., 2008) that may have developed to accommodate more recent extension in response to continued tilting of the Warner Mountains Range and shallowing of the SVF. The valley is flanked on the east by the Larkspur Hills and Hays Canyon Range, which have been exhumed along a west-dipping normal fault, and dissected by numerous Quaternary faults that indicate the area is still actively extending (Hedel, 1984). However, most of the extension has been accommodated along the SVF resulting in an asymmetric basin that is deepest to the west and comprised of west-dipping stratigraphy.

Geochronologic studies (Carmichael et al., 2006) reveal that basalt volcanism occurred in the region during three episodes at 3–4.5 Ma, ~6 Ma, and 7–8 Ma. Faulting initiated ~14-12 Ma (Egger and Miller, 2011), though the faults in the Larkspur Hills were mainly active over approximately the same time period as basalt volcanism and are no longer active (Ritzinger, 2014). Extension in Surprise Valley likely occurred in two episodes, initiating in the mid-to-late Miocene as horst and graben style faulting that resulted in roughly a third of the total basin extension (Egger and Miller, 2011; Colgan et al., 2008). The second phase of fault activity began after ~3 Ma. Slip on the Surprise Valley fault is interpreted to have begun during the early phase of extension ~14 Ma.

This was reactivated during Pliocene extension and has continued to the present. Together, this has resulted in an estimated 8 km of dip-slip offset on the SVF that has contributed to an accumulated extension of roughly 15% across the basin (Egger and Miller, 2011).

1.2 Geothermal resources

Surprise Valley hosts numerous thermal springs throughout its extent, though exploration of the valley's geothermal resources first began following a remarkable mud volcanic eruption near Lake City in 1951 (White, 1955). Exploratory drilling occurred in the 1970's and again in the early 2000's, mostly focused near Lake City on the west side of the valley where near-boiling geothermal fluids and hydrothermal siliceous deposits occur at the surface. Drillholes at Lake City reveal temperatures as high as 165 ºC at depths between 686 and 1,036 m, and the presence of alteration minerals at >1,415 m that are indicative of formation temperatures over 260 ºC (Benoit et al., 2005). Results from a drillhole (WME-E1) taken on the east side of the valley near the Surprise Valley hot springs (Holt et al., 2023) yield reservoir temperature estimates from geothermometry ranging from 90˚C to 143˚C, and a maximum borehole temperature of 110˚C. These estimated reservoir temperatures suggest there is potential to support electrical generation in addition to applications for municipal and residential heating, agriculture and other commercial needs, though to date, resources in the valley have yet to be developed beyond limited direct-use purposes.

Many of the thermal springs occur within the basin and do not appear to be directly related to the main range-front fault (Figure 1). As a result, more recent studies of the valley's geothermal systems have focused on geophysical methods (gravity, magnetic, seismic, paleomagnetic) aimed at characterizing subsurface geology and structure that may control hydrothermal fluid flow (Egger et al., 2010, 2014; Glen et al., 2008, 2013). These structures include a NW-trending accommodation zone that intersects hot springs on both sides of the valley, and a prominent NNW-trending linear intra-basin magnetic high interpreted as a buried dike or dike swarm that appears to control several hot springs on the east side of the valley (Glen et al., 2013; Athens et al., 2016).

Based on the presence of young silicic volcanic rocks on the eastern margin of the valley, Duffield and Fournier (1974) suggested that the geothermal system may be related to residual heat associated with Tertiary magma chambers, but more recent published age data indicate that the youngest volcanic rocks are 3.8 Ma (Carmichael et al., 2006). Although a magmatic source cannot be ruled out, it seems more likely that present-day geothermal fluids originate from deep crustal circulation of meteoric water, similar to other Basin and Range extensional systems that exhibit higher-than-average crustal heat flow (e.g., Kennedy and van Soest, 2006).

2. Geophysics

Past regional geophysical investigations in Surprise Valley have involved gravity, magnetotelluric, seismic, and paleomagnetic studies across the basin (Glen et al. 2008, 2013; Egger et al., 2010, 2014; Athens et al., 2011, 2016; Lerch et al., 2008, 2010; Ritzinger, 2014) aimed at constraining basin geometry, structure and geology, to better understand basin tectonics and evolution, and to study the area's geothermal resources.

It is widely considered that geothermal springs in extensional geothermal systems commonly occur in complex structural settings, such as at fault terminations or intersections (Curewitz and Karson,

1997; Faulds et al., 2010), thus much of the research on the valley's geothermal resources has relied on geophysical methods to resolve subsurface geology and structure that is concealed beneath young basin fill.

Progress in understanding the controls on hydrothermal fluid flow, in the eastern part of the valley, has come from efforts to map the magnetic field. Earliest efforts conducting hiked profiles with portable magnetometers revealed a prominent magnetic high within the basin that was traceable between multiple profiles across several kilometers. Subsequent efforts using ATV-borne magnetometer systems (Athens et al., 2011), that permitted rapid data collection on the playa surface, revealed the magnetic anomaly formed a long narrow prominent magnetic high spanning over 35 km (Figure 2). These data also showed that the major hot springs in the eastern part of the valley (Seifert, Leonards, and Surprise Valley) were coincident with the magnetic anomaly, suggesting that the magnetic source, interpreted as a shallow buried mafic dike (Glen et al., 2013), had some influence on hydrothermal fluid flow. Support for the dike interpretation came from recent mapping in the Hays Canyon Range, located 7 km east of the anomaly, of numerous mafic dikes having similar trends to the overall basin magnetic anomaly trend (Sawyer, 2022). Joint gravity and magnetic modeling across the anomaly, combined with a coordinated seismic survey (Athens et al., 2016) indicated the anomaly in the upper basin is most likely due to a shallow (150 m) buried, fault-controlled dike or dike swarm.

Significant gaps in coverage of the magnetic high, however, remained in the most critical areas around hot springs where access on the ground was limited by vegetation, surface water, dangerous thermal conditions, and private lands. Mapping these areas was necessary to better understand the relationship between the source of the magnetic high and the springs. This was achieved by employing the use of drone-based magnetometer systems that were able to overcome limited ground access. The first such surveys were conducted in 2012 with the use of a relatively large NASA fixed-wing platform (Glen et al., 2013). The combined ground and airborne magnetic mapping provided key details around the springs on the east side of the valley that revealed they lie along the edge of the magnetic high, at structural transitions where the high undergoes steps, bends, or breaks (Glen et al., 2013).

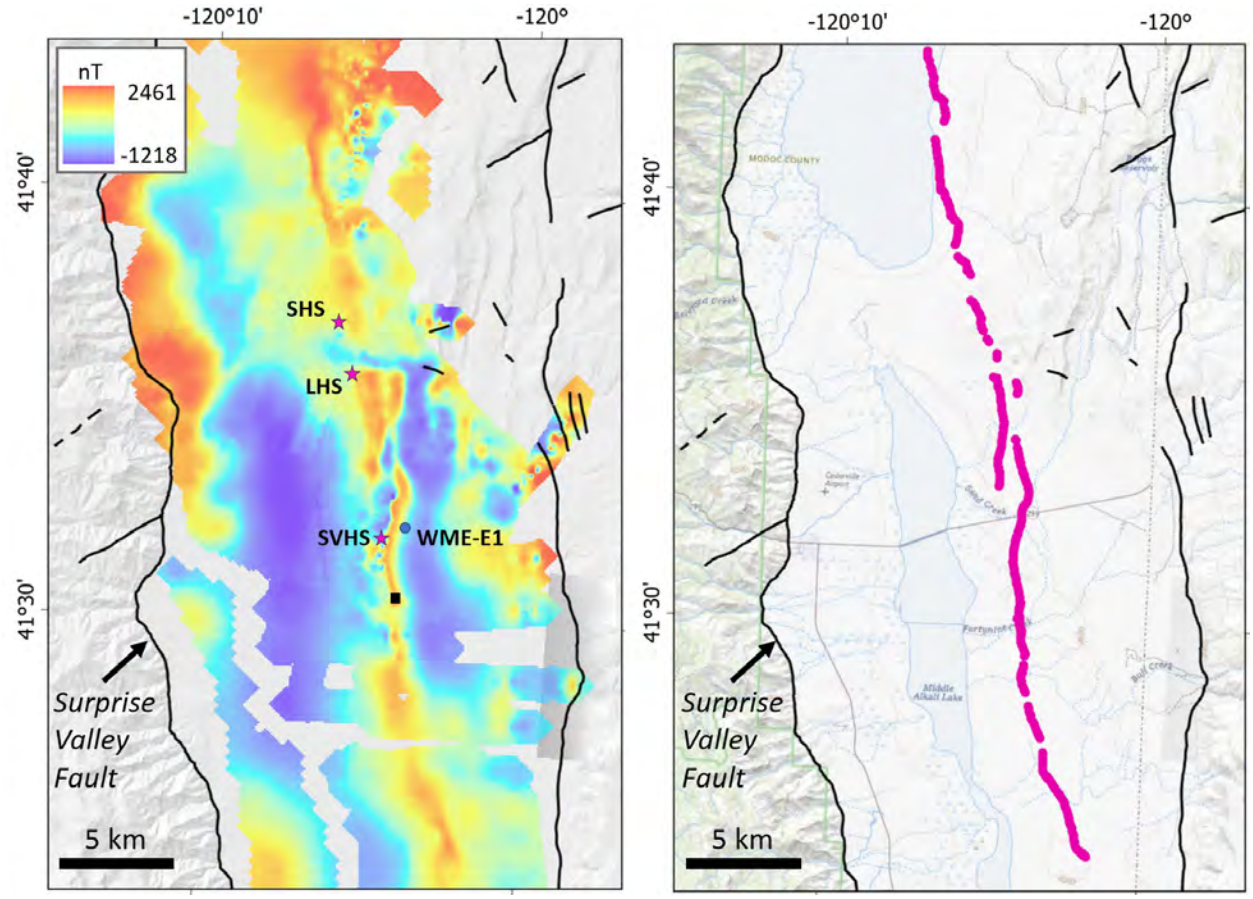

Figure 2. (Left) Magnetic anomaly map that reveals a prominent narrow basin magnetic anomaly resulting from a strongly magnetic mafic dike swarm. Also shown are faults (black lines), hot springs (pink stars), drillhole WME-E1 (blue circle), and the location of figure 3 (black square). (Right) Figure showing the crest of the magnetic anomaly derived from horizontal gradient minima. Base map is from the ArcGIS online map server (Esri, 2024).

Additional support for the dike interpretation for the basin magnetic high comes from an exploratory well (WME-E1; Holt et al., 2023), situated on the magnetic anomaly near the Surprise Valley hot springs. After completing the well, a borehole televiewer was employed to map fractures, cracks and breakouts, and determine stress orientations. The tool, which got stuck at the bottomhole depth at 1,097 m was eventually freed. When the tool was extracted from the hole, it was discovered that a 5-cm long rock chip was stuck between the tool and the centralizers used to align the tool in the borehole. Thin section and chemical analyses of the rock chip identify it as serpentinized peridotite (M.Clynne, U.S. Geological Survey, written comm. August 2019), that we interpret was most likely sourced from an inclusion within the dike, because no outcrops of peridotite exist in the region.

Confirmation of the dike interpretation was ultimately made when a string of low-relief outcrops of dikes, having the same trend as the anomaly, were discovered immediately south of the SVHS and situated on the anomaly (Figure 3). Our most recent efforts have entailed sampling, photogrammetry, detailed ground-based magnetic and gravity surveys, and airborne magnetic surveys of the basin dikes and those outcropping in the Hays Canyon Range. Paleomagnetic, geochemical and geochronologic analyses of these samples are planned. Although the poor

exposure precludes direct observation of faulting, preliminary structural mapping and modeling of potential field data across the playa dike outcrops support a model of faulting coincident with the dike swarm that may reflect dike-capture by a pre-existing fault, as was inferred >15 km north along the anomaly in the upper basin (Athens et al., 2016). Further field measurements and observations are planned in order to refine modeling of the dikes.

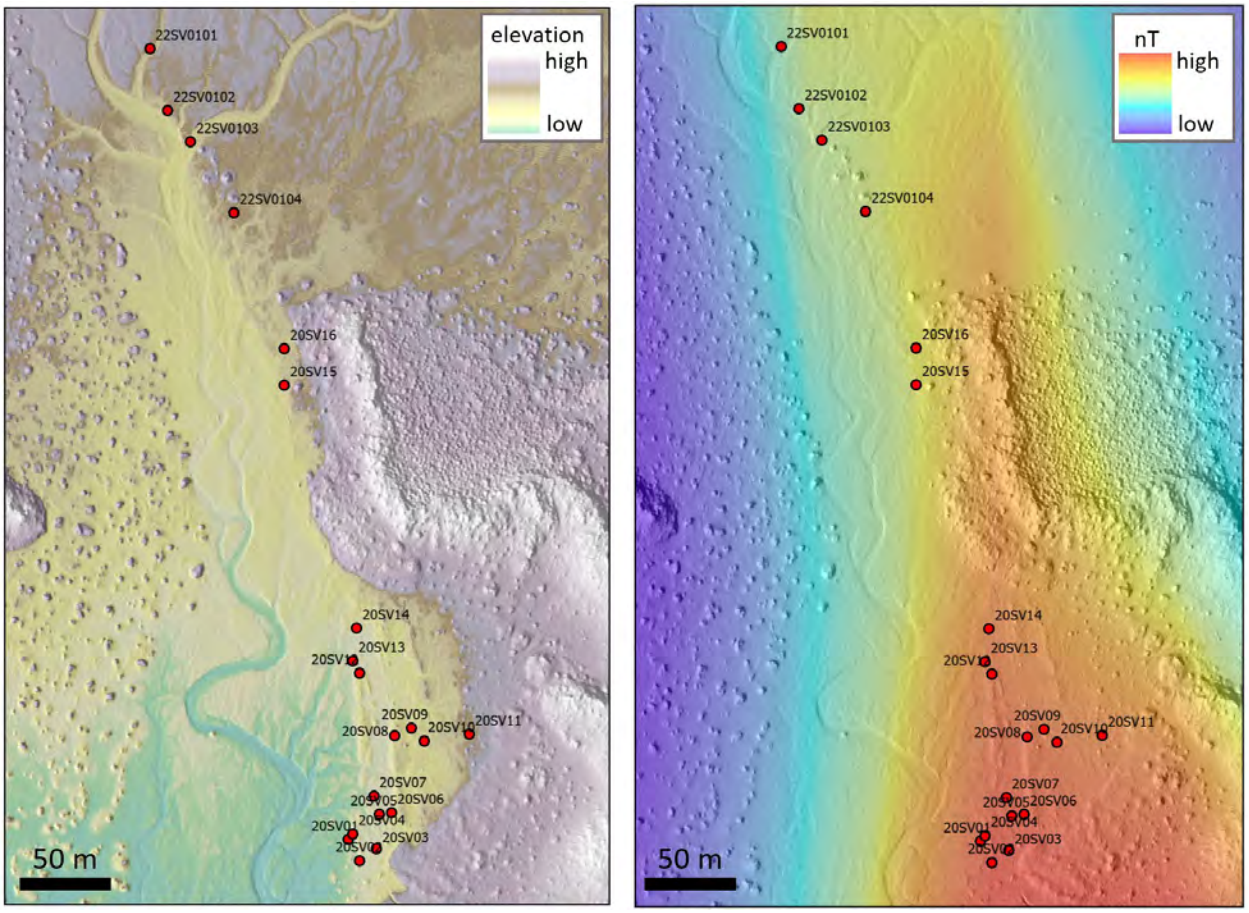

Figure 3. Paleomagnetic sampling sites of dikes outcropping along the basin magnetic high (red dots) plotted on (Left) color shaded relief and (Right) magnetic anomaly grid. The location of these figures is shown on Figure 2.

3. Discussion

Recent field and geophysical mapping of dikes within the basin and across the Hays Canyon Range reveals a potentially important component of extension accommodated through magma-injection. Furthermore, magma-assisted extension may be substantially underestimated, because it is likely many smaller dikes have gone undetected. It has been proposed that the cumulative amount of extension on numerous small faults can be significant (e.g., Marrett and Almendinger, 1992; Scholz et al., 1993; Athens et al., 2016). A similar case can be made for dikes, namely that substantial extension may be accommodated by as yet undetected dikes, provided their distribution is subject to similar scaling laws as for faults. Regardless, the influence of presently mapped and geophysically inferred dikes across Surprise Valley likely has important implications for basin evolution in Surprise Valley beyond their impact on the estimated total basin extension.

Lerch et al. (2010) speculated that initial rapid slip along the SVF would have raised the brittle-ductile transition (Figure 4). This in turn, may have promoted asthenospheric melting that fed diking across the eastern basin. The fact that the mapped dikes reside east of the depocenter of the basin is consistent with the expected displacement of the asthenosphere that would occur at the deepest reaches of the SVF where the fault extends under the eastern basin (Figure 4). Furthermore, diking would presumably have alleviated extensional stresses and suppressed faulting across the eastern part of the valley, which may explain the pronounced basin asymmetry. Feedback between magma addition to the east, that would inhibit brittle faulting across the eastern bounding range-front faults, and continued faulting along the SVF, that would drive continued melting, would promote basin asymmetry.

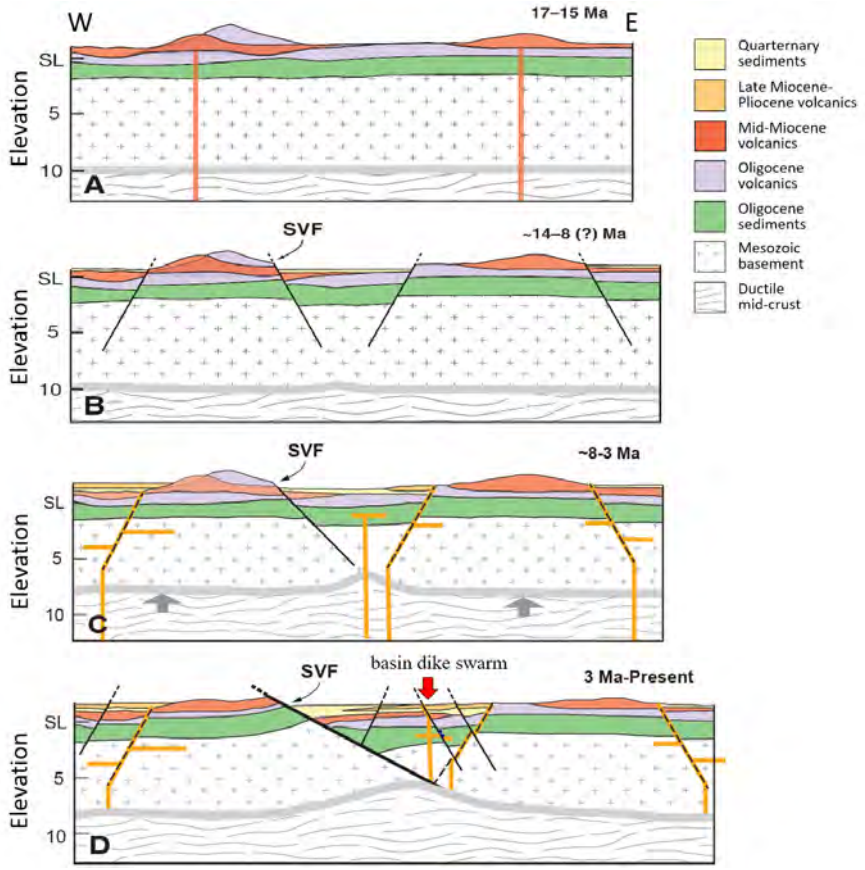

Figure 4. Cartoon showing the extensional history of Surprise Valley showing time periods from 17-15 Ma (A), ~14-8 Ma (B), ~8-3 Ma (C), 3 Ma to Present (D). Faults are shown as black lines (solid – active; dashed – inactive), intrusives (dikes and sills) are shown as orange lines. The brittle-ductile transition is shown as a thick grey line. Figure modified from figure 7 of Egger and Miller (2011).

The Surprise Valley Fault is a major basin and range style normal fault that has accommodated up to 8km of dip-slip motion since the middle Miocene. Paleoseismic studies across the fault reveal Holocene rupture (Personius et al., 2009) that indicate the fault is still active. This is consistent with geodetic measurements (Hammond and Thatcher, 2005) that document strong present-day velocity gradients suggesting active extension across Surprise Valley. Although the geodetic data indicate dominantly EW-oriented extension, a component of right-lateral strike-slip is predicted (Hammond and Thatcher, 2007) across the valley.

The high-resolution magnetic maps provided by the drone surveys reveal details of the basin magnetic high that may support a claim for longer-lived strike-slip deformation. Overlapping strands of the anomaly south of the SVHS resemble a left stepping pair of en echelon segments that may indicate extension was oblique to the trend of the regional anomaly (Glen et al., 2013). Such en echelon segments can form when dikes undergo shear stress during emplacement. If this was the cause for this feature along the intra-basin magnetic high, the relative offset of the anomaly segments would indicate right-lateral shear present at the time of dike emplacement.

If strike-slip deformation is occurring across Surprise Valley, it is unlikely to be accommodated on the SVF, given the lack of evidence from trenching, and the highly corrugated trace of the fault that precludes oblique slip on the fault (Egger and Miller, 2011). Likewise, mapping in the Larkspur Hills shows no evidence of strike-slip motion (Ritzinger, 2014). Egger et al. (2010) suggest that strike-slip motion may be partitioned on buried intrabasin faults. Strike-slip motion may alternatively be distributed more diffusely across a wide network of normal faults or through block rotation (Wesnousky et al., 2012). If strike slip is occurring, we suggest that the dike swarm is a probable candidate for accommodating some or most of it. Indeed, the dike swarm's north-northwest orientation, steep dip, and relatively straight trace (compared to the corrugated nature of the SVF and faults in the Larkspur Hills) are favorable for accommodating NW-oriented slip, both during emplacement when traction along the plane of the dikes is low, and subsequently via faulting that might exploit weaknesses along the dike margins (e.g., by reactivating fractures induced in the country rock during dike emplacement). Indeed, modeling results from Athens et al. (2016) indicate there is strong evidence for dike-fault interactions (involving both syn- and post- dike-emplacement faulting). Preliminary modeling in the Middle Basin south of the SVHS indicates a very similar relationship revealing intra-basin faulting coincident with the margin of the dike swarm. Dike-induced damage to country rock, and subsequent post-emplacement faulting along the dike, may both contribute to enhanced permeability that could explain the close correlation between hot springs in Surprise Valley and the intra-basin dike swarm.

The tie between the valley's geothermal system, dike swarm, and faulting suggests that basin tectonics and hydrothermal activity are influenced by pre-existing basement structure. This relationship may pertain more generally to other hydrothermal settings throughout the Great Basin. If so, a focus on mapping basement geology and structure may enhance understanding of structural controls on a class of geothermal systems. Indeed, two other examples in Summer Lake, Oregon (Figure 5; Earney and Glen, 2024), and Granite Springs Valley, Nevada (Figure 6; Glen et al., 2022) show striking similarities to Surprise Valley. Both sites are also characterized as north-south elongated asymmetric basins that developed dominantly by slip along a principal west-bounding range front fault that resulted in the deepest parts of the basins being displaced to the west, while to the east they display evidence for significant diking. The surprising similarity of these valleys suggest that they may be characterized by similar tectonic conditions. Indeed, the basins are all regionally aligned (with each other and with the trend of inferred dikes) and situated between areas characterized by shear across the Walker Lane and more classical basin-and-range extension (Figures 7&8). Although speculative, this may indicate that oblique extension has played a key role in influencing basin evolution in these settings.

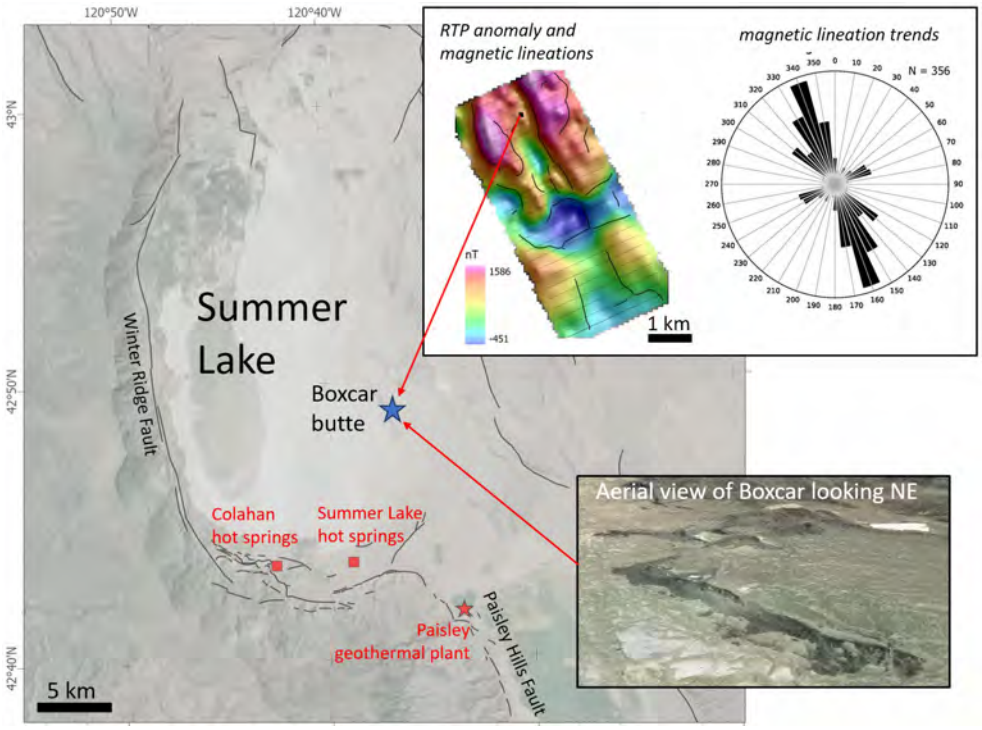

Figure 5: Digital elevation model (DEM) hillshade of Summer Lake (U.S. Geological Survey, 2024) overlain by aerial imagery (Esri, 2024), showing the Boxcar butte feature interpreted as a mafic dike (blue star), Quaternary faults (black lines; U.S. Geological Survey, 2024), hot springs (red squares), and the Paisley Geothermal plant (red star). Insets show: a shaded reduced-to-pole (RTP) magnetic anomaly map of the region around the Boxcar (Earney and Glen, 2024), rose diagram of magnetic lineations (Earney and Glen, 2024), and oblique aerial view of the Boxcar (Google Earth Pro, 2024).

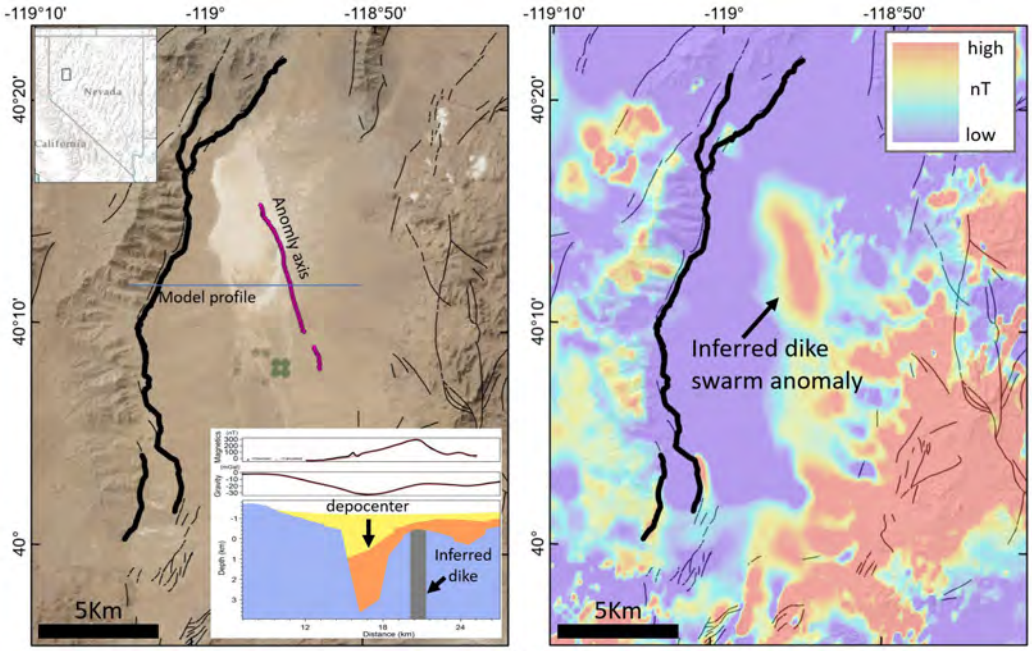

Figure 6. (Left) Digital elevation model (DEM) hillshade (U.S. Geological Survey, 2024) of Granite Springs Valley, NV overlain by aerial imagery (Esri, 2024), showing the axis of an intra-basin magnetic high (pink lineations), faults (black lines; U.S. Geological Survey, 2024), and location of potential field profile. Thick black line represents the main west-bounding range-front fault. Inset shows potential-field model that indicates inferred dikes east of the main depocenter (after Glen et al., 2022; depicting basement rocks in blue, volcanics in orange, and basin fill in yellow). (Right) magnetic anomaly map (Glen and Earney, 2024) of Granite Springs Valley, NV, showing faults (black lines).

Figure 7. Topographic map showing the locations of Surprise Valley, CA-NV, Summer Lake, OR, and Granite Springs Valley, NV. Base maps come from the ArcGIS online map server (Esri, 2024).

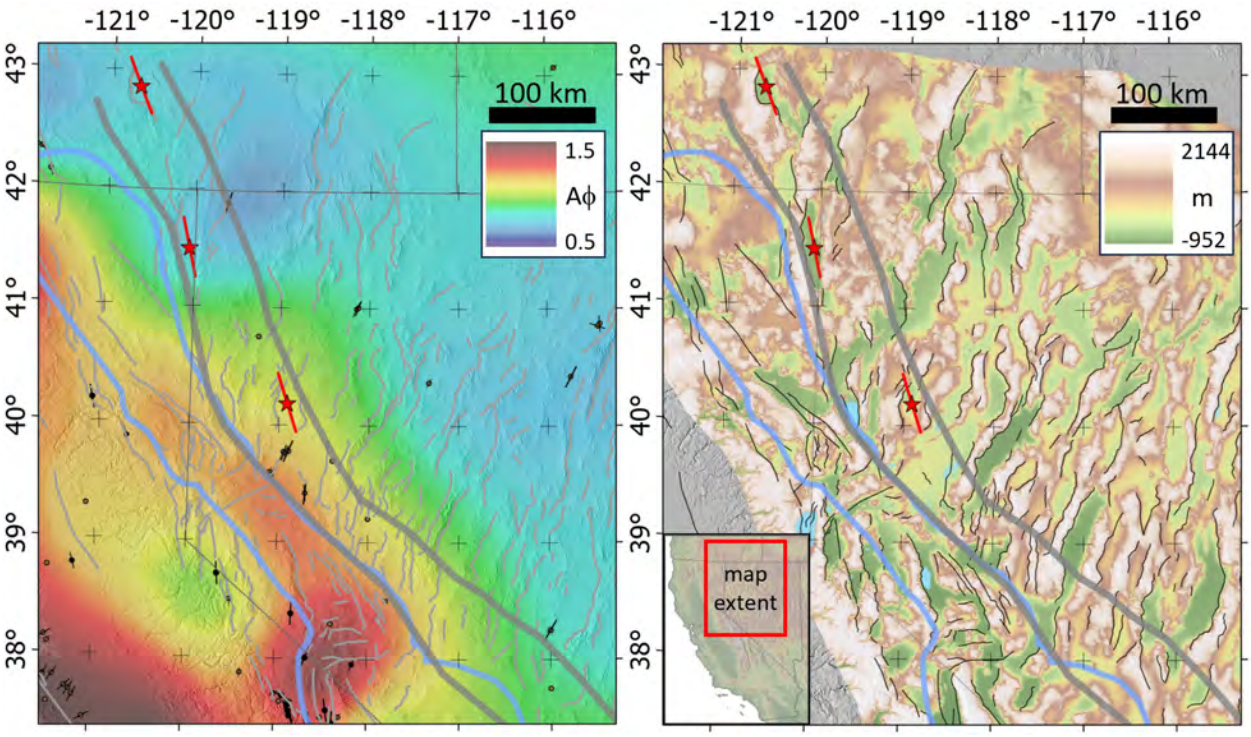

Figure 8. Map showing the locations (from north to south) of Summer Lake, OR, Surprise Valley, CA-NV, and Granite Springs Valley, NV (red stars) and the trends of their associated magnetic anomalies (red lines) displayed on (Left) a base map of relative stress magnitudes [based on Aϕ stress values ranging between normal faulting (0.5) and strike-slip faulting (1.5); Lund Snee and Zoback (2020)]; and (Right) a base map of detrended topography (DeAngelo et al., 2023). Also shown are faults (grey on left and black on right), extent of Walker Lane (light blue polygon, after Faulds and Henry, 2008), and a zone, inferred here, marking the transition between the Walker Lane and Great Basin that is mostly characterized by north-south oriented basins (delineated by thick grey lines).

Acknowledgments

We are grateful to Roy Mink for showing us outcrops of the playa dikes. We thank William Schermerhorn, Jacob Anderson, Karen Christopherson, and Randall Mackie for constructive reviews of this manuscript. ABSTRACT

This review paper focuses on applying the Traffic Light System (TLS) in managing induced seismicity, particularly geothermal energy development. Induced seismicity, a consequence of human activities such as geothermal energy production, poses significant challenges to the environment and surrounding communities. Inspired by its conventional use in road traffic management, the TLS offers a promising approach to mitigate these risks by categorizing seismic events based on their magnitudes and dictating operational responses.

This paper presents a comprehensive workflow for implementing the TLS in geothermal projects, starting with the initial seismic monitoring and ending with the application of operational controls based on predefined seismic thresholds. This workflow emphasizes the importance of continuous monitoring, real-time data analysis, and adaptive management of geothermal operations to minimize the risk of significant seismic events.

Further, the paper reviews several case studies from around the world, showcasing the effectiveness of the TLS in diverse geological settings. These case studies highlight the system's flexibility and potential to be tailored to specific project needs and seismic risk profiles.

This review argues that the TLS enhances the safety and sustainability of geothermal energy production and serves as a crucial tool for gaining public trust and regulatory approval. By systematically managing the risk of induced seismicity, the TLS contributes to the responsible development of geothermal resources, aligning with global efforts to transition to renewable energy sources.

1. Introduction

Geothermal energy has seen a steady increase in electricity generation, expanding at an average rate of 3.5% per year, culminating in a global installed capacity of roughly 15.96 gigawatts electric (GWe) by 2021. Despite this growth, geothermal energy only constitutes about 0.5% of the total installed capacity for renewable electricity and heating/cooling systems worldwide. Conversely, the use of geothermal energy for heating and cooling applications has experienced more robust growth. From 2015 to 2020, it expanded by an average of 9% annually, achieving an installed capacity of 107 gigawatts thermal (GWth) 2020. However, this rapid expansion has also brought increased attention to the challenge of induced seismicity associated with geothermal operations. According to recent studies, pore-fluid pressure in rocks weakens and reactivates existing faults, and the injection of wastewater and stress perturbations lead to earthquakes (Ellsworth, 2013; Grigoli et al., 2017). Figure 1 shows a distribution of the induced seismicity caused by these factors. Twenty-one events are from exploration for geothermal energy. These seismic events, ranging from small tremors to moderate quakes, have posed considerable challenges to the sustainability and public acceptance of geothermal energy.

In some cases, induced seismicity has caused damage to local infrastructure, disrupted project operations, and heightened concerns among affected communities about geothermal development's safety and environmental impacts (Majer et al., 2007). To address this issue, the geothermal industry, in collaboration with researchers and policymakers, has been actively exploring various technological solutions, including advanced seismic monitoring systems (i.e., traffic light systems) (Braun et al., 2020; Cesca & Grigoli, 2014; Chang & Yoon, 2021). The adoption of these mitigation approaches has shown promising results in various geothermal projects around the world. Still, ongoing efforts are needed to refine and standardize best practices for managing induced seismicity risks in the growing global geothermal sector (Wang et al., 2023).

This review paper focuses on applying the Traffic Light System (TLS) to manage induced seismicity risks, particularly in worldwide geothermal energy development. The objective is to comprehensively assess the TLS workflow to mitigate the challenges of induced seismic events associated with geothermal operations. The scope of the review covers the mechanisms and impacts of induced seismicity, the importance of effective risk management for the continued growth of the geothermal industry, and the current best practices and case studies demonstrating the application of the TLS. This paper presents a detailed workflow for implementing the TLS, emphasizing the system's flexibility and potential to be tailored to diverse geological settings and project-specific seismic risk profiles. By examining real-world case studies from various countries, the review highlights the effectiveness of the TLS in enhancing the safety, sustainability, and public acceptance of geothermal energy production. The findings aim to guide geothermal practitioners, policymakers, and researchers on the responsible development of this renewable energy technology.

2. Principles and Conceptual Framework of the Traffic Light System

The TLS has been widely used to manage reduced seismicity activity, risk, and hazards and develop a seismicity mitigation plan (Bommer et al., 2006). It is a site-specific, real-time, and multi-level seismic risk management system.

The TLS has failed in the past. For example, in May 2006, the first critical TLS was utilized in a

geothermal energy project at Basel, involving the injection of approximately 11,500 cubic meters of water into a 5 km deep well at high pressure (up to 30 MPa). The injection triggered significant seismic activity recorded by local and regional monitoring networks. A magnitude 2.6 earthquake occurred during peak injection, exceeding the safety threshold of a four-level "traffic light" system designed to prevent dangerous seismic events. Consequently, the infusion was halted (Häring et al., 2008). Similar events occurred at Blackpool and St. Gallen. The effectiveness of the traffic light systems utilized in Basel, Blackpool, and St. Gallen was not high. In 2014, an advanced TLS was developed by Evans et al. (2014) and is currently in development. However, this system could not suit micro-seismicity events. In 2023, Wang et al. (2023) the Gutenberg-Richter law was applied as a parameter in the TLS system, and it was confirmed that the optimized TLS system could work for either large or small magnitudes.

2.1 Definition and Critical Components of the TLS

A basis of TLS consists of three thresholds for governing the level of risk:

- Red means stop. The injection/operation should be stopped.
- Yellow means caution. The process should be reviewed and watched, and injection/related activities, such as injected pressures, may need to be reduced.
- Green means normal. The operation/activities/injection can be continued as planned.

These thresholds should be determined based on different input parameters, such as peak ground velocity (PGV), peak ground acceleration (PGA), and the frequency of induced seismicity. Another critical parameter in this system is ground-motion prediction equations (GMPEs) for ground-motion amplitude. Those parameters can be used to assess the potential impacts of induced seismic events and inform mitigation strategies and operation adjustments to minimize the risk of damaging seismic events (Bommer et al., 2015; Grigoli et al., 2018; van Thienen-Visser & Breunese, 2015; Verdon & Bommer, 2021).

PGA refers to the maximum acceleration experienced by a particle at the ground surface during an earthquake. It is a critical parameter for evaluating the potential damage to structures and infrastructure. Due to gravity, PGA is typically measured in acceleration units and is an essential input for the seismic hazard and risk analysis (Bommer, 2015; Crowley and Pinho, 2015).

GMPEs, also known as attenuation relationships, are mathematical models that predict the expected ground motion parameters, such as PGA and PGV, at a site based on various factors, including earthquake magnitude, source-to-site distance, and site-specific characteristics (Douglas, 2003). These equations are essential for estimating the potential ground shaking and associated risks in seismic hazard and risk assessments.

The three thresholds of TLS were typically determined differently by area. In the UK, the red light was set at 0.5 (Clarke et al., 2019). In Finland, TLS thresholds were based on acceptable ground motion levels and associated probabilities, triggering Amber alerts for a PGV of 1 mm/s with an ML $\geq$ 1 event and Red alerts for a PGV of 7.5 mm/s with an ML $\geq$ 2.1 event (Verdon & Bommer, 2021). In the Western Canadian Sedimentary Basin (WCSB), hydraulic fracturing set the red-light threshold much higher at an ML of 4.0 (Roy et al., 2021). In Canada, the Alberta Energy Regulator (AER) and BC Oil and Gas Commission established five Traffic Light Protocols (TLPs) for hydraulic fracturing (HF) operations at various locations. These included a TLP near Fox Creek,

Alberta, with a red-light threshold at a magnitude (ML) of 4.0; near Red Deer, Alberta, at an ML of 3.0; near Brazeau Dam, Alberta, at an ML of 2.5; near the community of Pink Mountain, British Columbia, at an ML of 4.0; and near Dawson Creek, British Columbia, at an ML of 3.0 (Kao et al., 2018; Yaghoubi et al., 2024). In Oklahoma, US, the red-light threshold was an ML of 2.0 (Johnson et al., 2021).

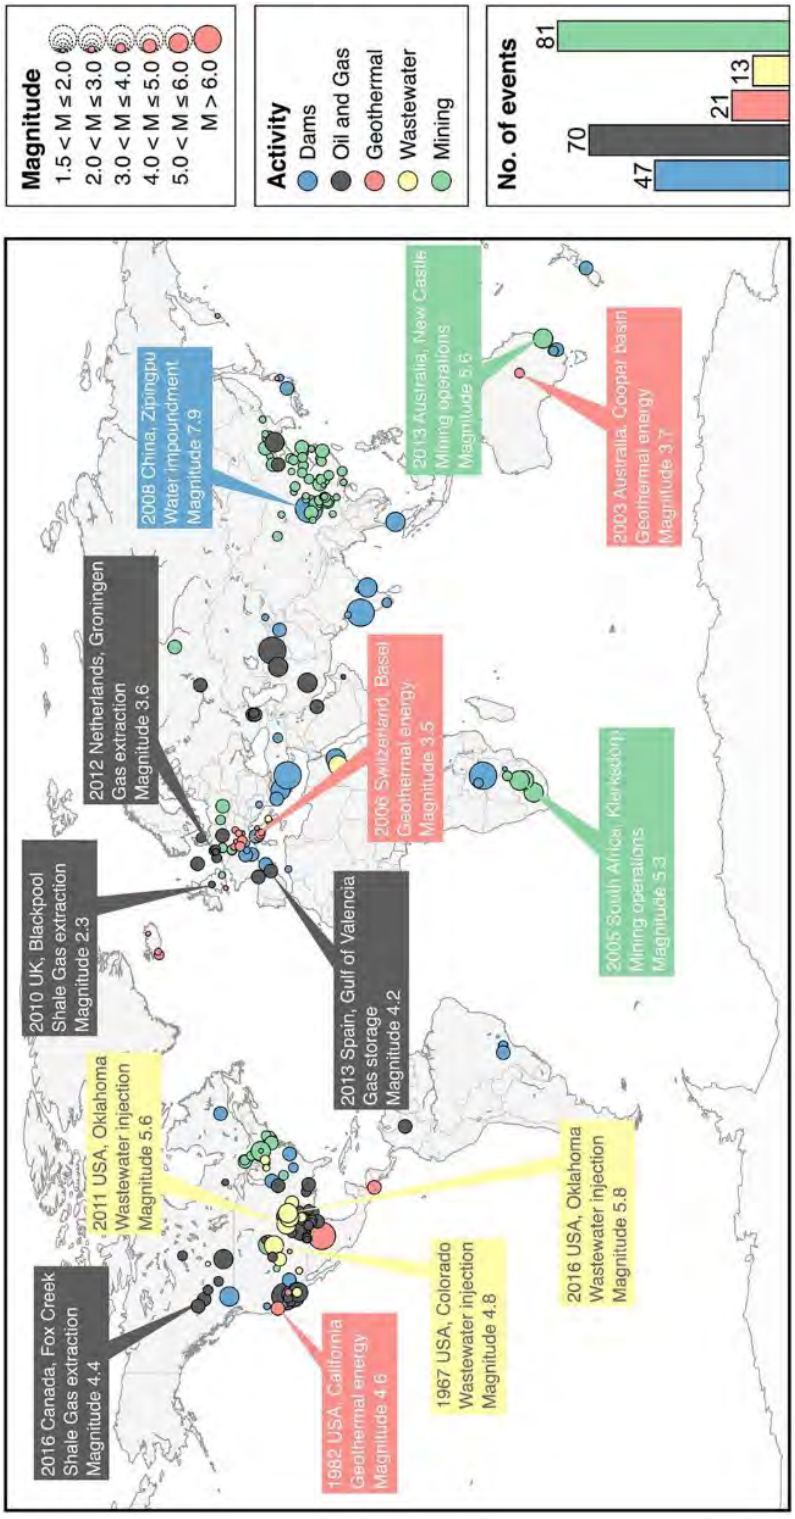

Figure 1: The Distribution of The Induced Seismicity Caused by Industrial Activities (Grigoli et al., 2017)

3. Review of Global Case Studies on TLS Application in Geothermal Energy Production

3.1 Finland

The dataset collected during the simulations contained location, magnitude levels, hypocenters, etc. The authors establish thresholds based on the ground motion. The authors selected PGV as the main parameter to estimate the ground motion. They analyzed the historical PGVs and preliminary screening of the 3 thresholds:

Green: PGV = 0.3mm/s or 0.13mm; Yellow: PGV = 1mm/s; Red: PGV = 7.5mm/s.

However, they considered two additional parameters for addressing false positives and negatives: Joint PGV and Magnitude. A false positive is that high vibrations not caused by induced earthquakes at the geothermal well could be recorded. These vibrations might result from surface blasting, road traffic, equipment malfunction, distant natural earthquakes, or other unanticipated sources. A false negative is that PGV can only be measured at specific locations where instruments are installed. As a result, PGV thresholds could be exceeded at locations without instruments, leading to missed recordings of such events.

The authors calculated the magnitudes and negotiated with regulators. Finally, they set up:

Yellow: PGV >= 1mm/s and M >= 1; M>1.2

Red: M >=2.1

The method provided the benefit of requiring agreement with the regulator on only two parameters: the PGV thresholds and the acceptable probability levels to reach these thresholds.

In Figure 2, they used this system in the well OTN-3, which started on 4 June 2018 and ended on 22 July 2018. A total of 18,160 m^3 of drinking-quality water was injected through five stages in the open-hole section of the well, inducing 1,357 seismic events with $\mathbf{0} \geq \boldsymbol{M} \geq \mathbf{1}$, shown in Fig.3. The injection rate typically ranged from 400 to 600 liters per minute. Still, during stage 2, it was increased to approximately 800 liters per minute for a couple of hours, rapidly increasing seismic activity.

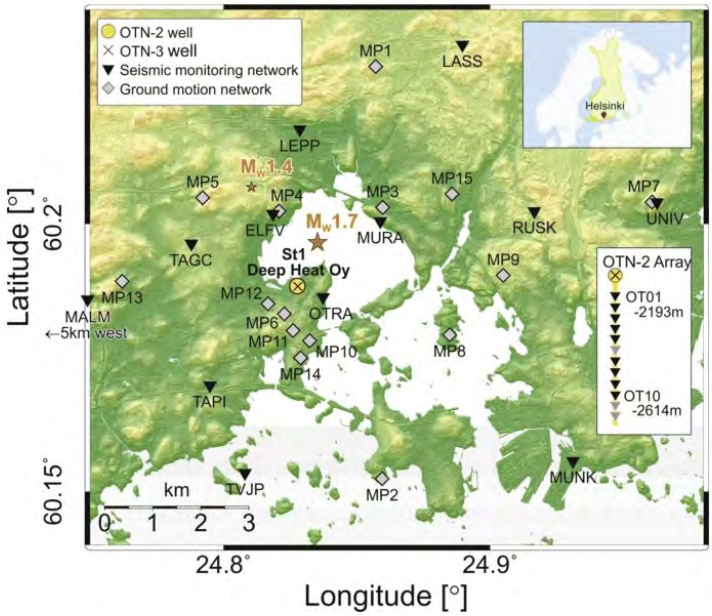

Figure 2: The Location Of The Seismicity Network And Geothermal Wells (Ader et al., 2020)

Stage	Start date	Net injected volume (m^3)	Max injection pressure (bars)	Mean depth (m)	Number of events $M_L \geq 0$	$M_L \geq 1$	$M_L \geq 1.2$	$M_L \geq 2.1$
1	4 June 2018	3783	890	6056	173	5	3	0
2	16 June 2018	4023	900	5973	280	11	6	0
3	23 June 2018	1537	850	5884	131	8	4	0
4	1 July 2018	4411	860	5771	361	14	9	0
5	12 July 2018	4406	870	5625	412	18	14	0
Total	22 July 2018	18,160	-	-	1357	56	36	0

Figure 3: The Table Of The Seismic Events During Injection And Stimulations (Ader et al., 2020)

During stimulations, the events shifted horizontally and vertically slightly, as shown in Figure 4. The yellow light was clearer around the depth of 500 meters on the horizon and 1000 meters in the vertical hypocenters, as shown in Fig.5.

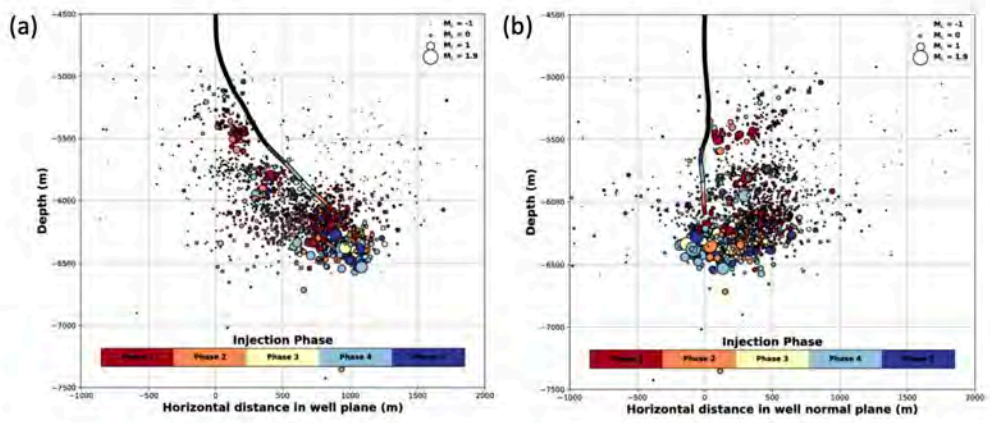

Figure 4: The Map for Micro-Seismicity Using TLS Implementation. (A) The Shift Is Horizontal, And (B) The Shift Is Vertical. (Ader et al., 2020)

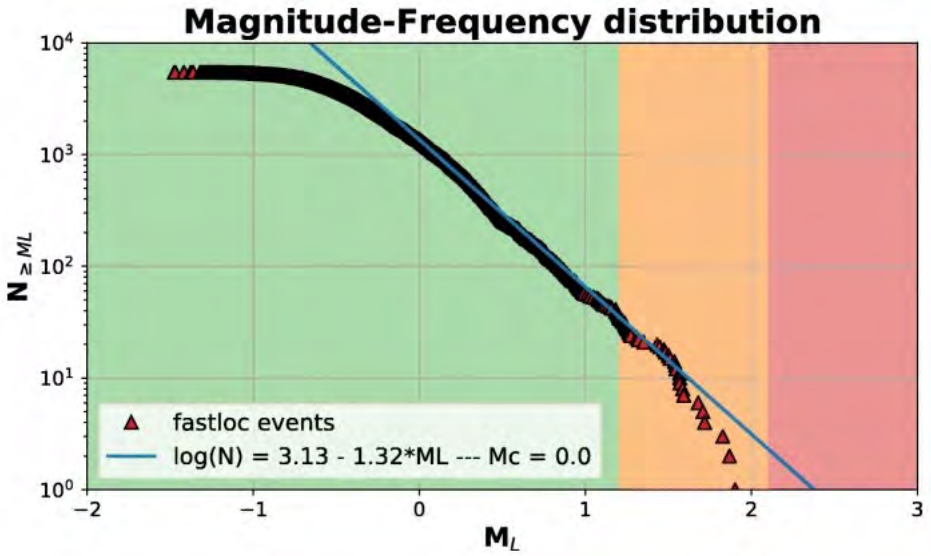

Figure 5: The Map For Magnitudes In The Traffic Light System (Ader et al., 2020)

They obtained 37 alters in green, 36 in yellow, and 0 in red during the stimulations. Of the 36 yellow alters, only 6 of the yellow events reached a PGV >1mm/s, as shown in Fig.6. The most minor event generating a PGV ≥ 1 mm/s was an ML 1.55 event, which caused a maximum PGV of 1.19 mm/s. The highest PGV recorded during stimulation was 2.99 mm/s, following an ML 1.87 event. Events started to trigger alerts at magnitudes lower than those required to exceed the PGV threshold of 1 mm/s. This suggests that the magnitudes associated with the PGV thresholds were reasonably conservative.

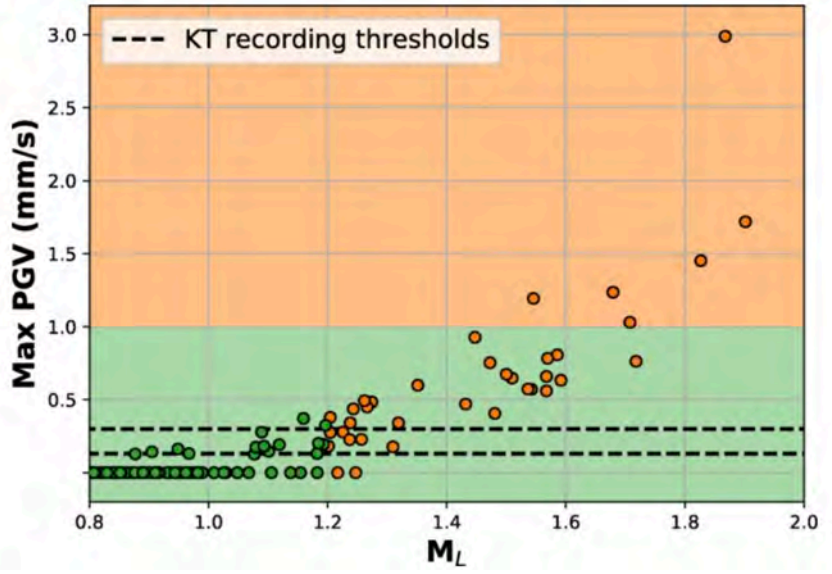

Figure 6: The PGV Events in Green And Yellow Lights (Ader et al., 2020)

3.2 Alberta, Canada

The Alberta No.1 Geothermal Project study area is highlighted in a red box in Figure 7. Colored circles represent reported earthquakes, with their magnitudes indicated by a scale bar. Major induced earthquake focal mechanisms are shown. Green triangles mark seismic stations. Several

identified faults are depicted by thick black lines, shown in Figure 7.

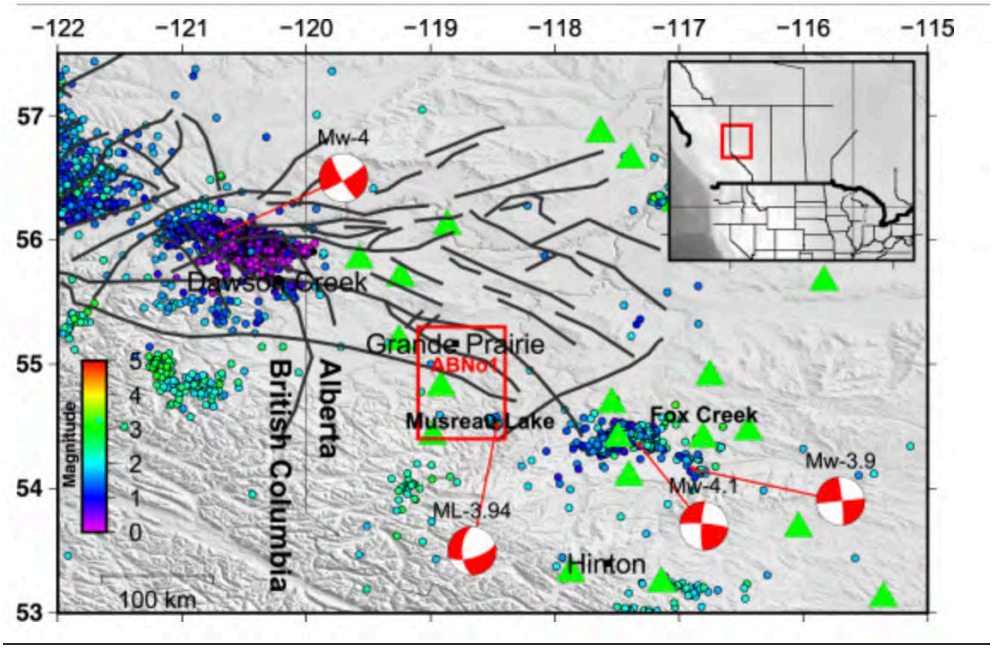

Figure 7: The Map Of The Seismicity Network And Well Locations (Yaghoubi et al., 2024)

They integrated formation depth, site amplification, ground motion prediction equations (GMPEs), fragility functions, nuisance functions, and population distributions to establish red-light thresholds. Additionally, they performed numerical simulations to estimate risk metrics like potential damage, nuisance impacts, and local personal risk (LPR) related to injection-induced earthquakes, using a method like estimating fatalities in significant seismic events.

3.2.1 Data Collection and Workflow for Determining the Thresholds

The risk-based framework determines the red-light threshold by integrating datasets that include spatial population distributions, earthquake ground motion prediction equations (GMPEs), details on the location, depth, size, and frequency of induced seismic events, site amplification factors, nuisance and fragility functions, and geological characteristics. Three key risk metrics are considered: Local Personal Risk (LPR), damage risk, and nuisance risk.

Local Personal Risk (LPR) assesses the likelihood of a person experiencing a fatal building collapse, which is crucial for community safety during induced seismicity. Nuisance impacts, which involve disturbances and discomfort caused by ground shaking, have significant social and economic implications, making their minimization vital for securing public acceptance for geothermal or injection activities. Damage impacts are directly linked to financial consequences, such as building damage and repair costs; minimizing these impacts helps protect infrastructure, property values, and overall economic stability.

The importance of each metric varies based on stakeholders' priorities, the nature of the community, and the built infrastructure. In some cases, prioritizing human life (LPR) may be paramount, while others may focus on minimizing social disturbances (nuisance) or economic losses (damage).

T_{DS1} and T_{DS2} are two parameters used to construct the damage maps, as shown in Fig.8. The combination map, displayed in Figure 8c, shows that the iso-damage red-light magnitude threshold ranges from 3.0 to 4.0 ML. The assessment also evaluates the iso-LPR risk, which measures the probability of a fictional person inside a building experiencing a fatal collapse. To determine the tolerances for LPR, we adopt a likelihood of 10^{-6}, representing the highest value from Figure 8c and commonly used for this specific risk metric.

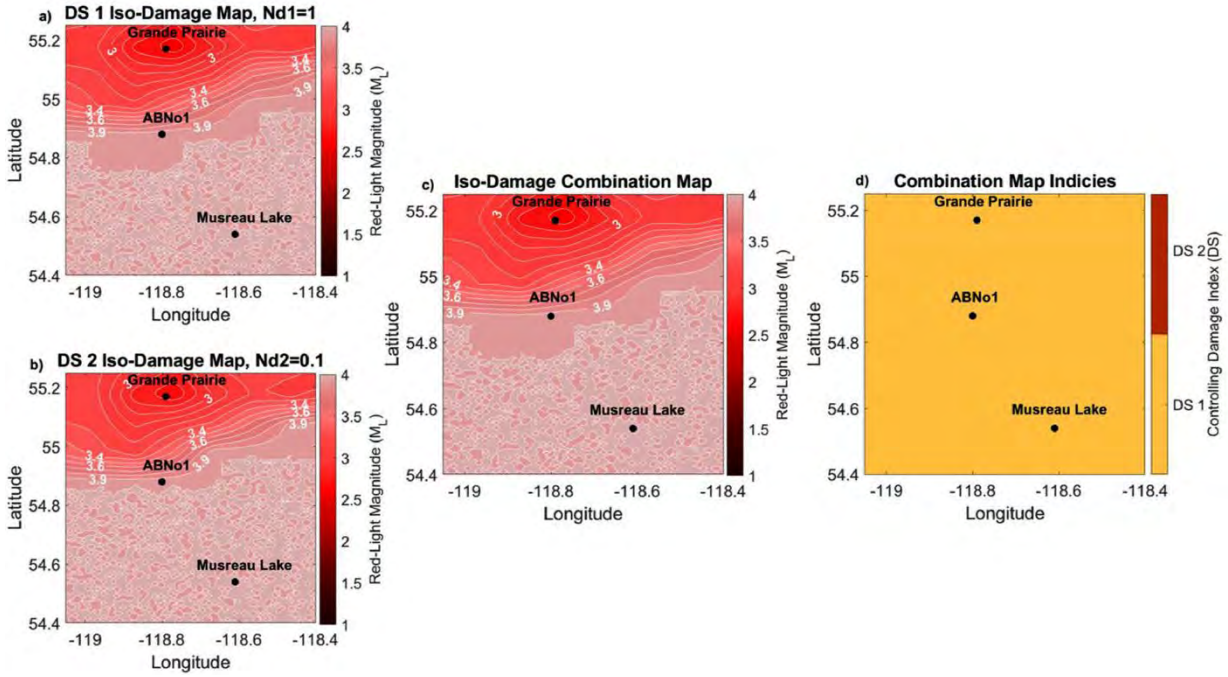

Figure 8: Damage maps (Yaghoubi et al., 2024)

Fig 9 shows a magnitude of 3.55, representing the red-light threshold for nuisance risks, indicating the level of ground shaking that causes disturbances. The LPR (Local Personal Risk) threshold is set at an ML of 4, indicating the risk of fatal building collapses. The damage risk threshold is an ML of 4.1, signifying potential economic consequences such as building damage and repair costs.

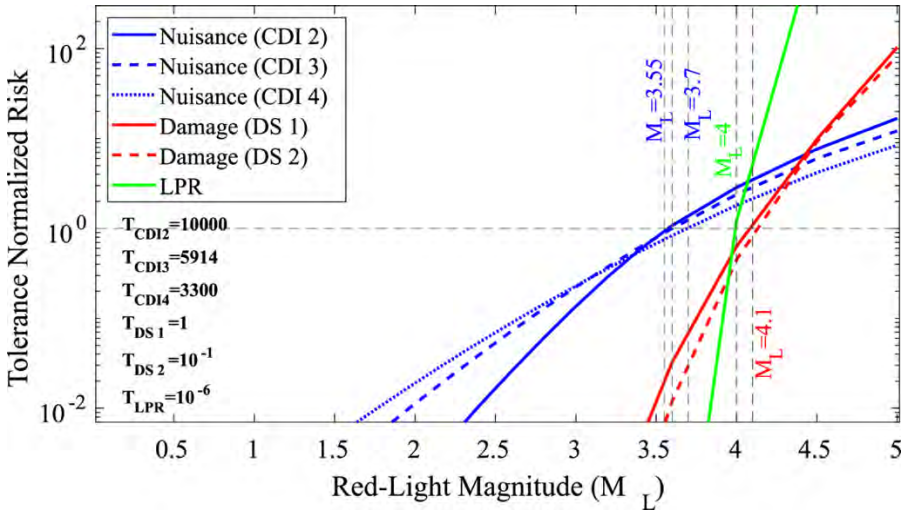

Figure 9: The Determination of Red-Light System (Yaghoubi et al., 2024)

Based on the analysis in Figures 9 and 10, this project's risk-based traffic light protocol suggests a red-light threshold of ML 3.5. This indicates the seismic activity level at which induced seismicity poses a significant risk to infrastructure or public safety, requiring immediate mitigation actions. To allow operators sufficient time to respond, yellow-light thresholds are two magnitudes lower than red-light thresholds. For the ABNo1 site, the yellow-light threshold is suggested at ML 1.5 to prevent sudden jumps from green to red scenarios that bypass the mitigation plan (Schultz et al., 2021). Operators can adjust the yellow-red gap size based on their risk tolerance, with a more significant gap being more conservative and a smaller gap indicating a less conservative approach with a potentially higher level of risk.

> 3.5 ML	Immediately report the event to AER (communication).Assess potential damage (communication).AER must receive real-time seismic waveform monitoring data (communication).Stop injection, pump fluids out of the well, and bleed off (operational action).Return the well to a safe state (operational action).Determine the hypocenter of the earthquake. Is it in the basement rock or nearby the injection zone? (seismic analysis).Analyze spatial and temporal connections between the event and the ABNo1 operation. Determine if the event connects to HF or wastewater disposal operations in the immediate vicinity of ABNo1 (seismic analysis).
> 1.5 ML	Immediately report the event to AER (communication).AER must receive real-time seismic waveform monitoring data (communication).Increase real-time earthquake monitoring and analysis; intensify observations (operational action).Use tracer and chemical monitoring to assess fluid balance between injector and producer wells (operational action).Monitor fluid recovery if fluid lost circulation is occurring; intensify observations (operational action).Reduce the injection rate, pressure, and volume, and pump fluids out of the well until seismicity remains below a certain threshold (operational action).Determine the hypocenter of the earthquake (seismic analysis)
< 1.5 ML	Pumping operations proceed as planned

Figure 10: The Proposed TLS (Yaghoubi et al., 2024)

4. Integrated Workflow from Cases

Seismic activity is monitored in real-time, and hydraulic data is collected alongside historical seismic catalogs. These datasets are integrated to perform seismic forecasting calculations using GMPEs. Probabilistic seismic hazard metrics such as PGV, PGA, potential damage, nuisance impacts, and LPR are computed. These metrics are assessed against predefined thresholds to determine the appropriate alert level. The traffic light system indicates low risk (green) for normal operations, moderate risk (yellow) for preparation, and high risk (red) for immediate mitigation, ensuring an effective and scientifically informed response to seismic events.

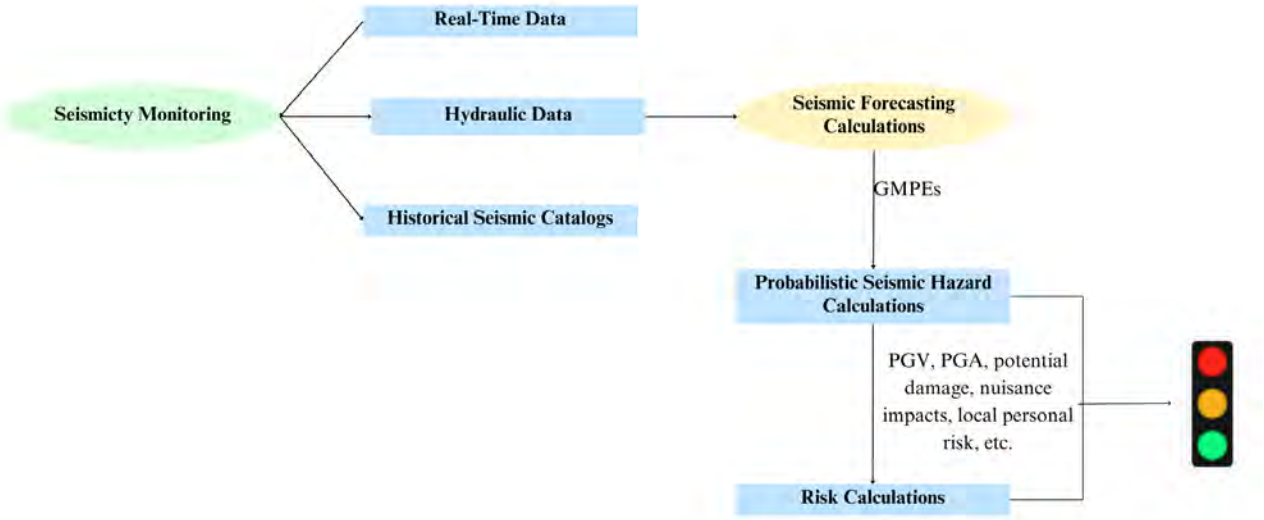

Figure 11: The Summary of Workflow of TLS

5. Benefits and Challenges of Implementing the TLS

Implementing a Traffic Light System (TLS) in seismicity management offers several significant benefits. It facilitates real-time monitoring and immediate response to seismic events, mitigating risks and enhancing public safety. By providing clear and actionable alerts, TLS helps maintain public confidence and acceptance of projects, particularly in sensitive urban areas. It enables operators to make informed decisions regarding the continuation, modification, or halting of activities based on the severity of seismic events, ensuring regulatory compliance and minimizing legal and financial risks. The TLS also enhances the ability to analyze and respond to seismic data, improving the overall understanding and management of induced seismicity. Furthermore, it helps distinguish between actual seismic events and other sources of vibrations, preventing false alerts and unnecessary interruptions. Lastly, the system protects infrastructure, reduces the risk of injuries or fatalities from seismic events, and promotes community safety.

However, the low levels of seismicity sometimes resulted in limited seismic data for calibrating and designing the Traffic Light System (TLS). Stimulation occurred under a large urban area with many sensitive receptors and high vibration noise from activities like construction blasting, posing a risk of false alerts. Additionally, the population's high sensitivity to earthquakes risked negative public perception, historically leading to the shutdown of geothermal projects.

6. Conclusions and Future Directions

After reviewing several cases, a workflow for implementing Traffic Light Systems (TLS) has been designed. The thresholds should be determined by considering various parameters and conditions. Several risk metrics, including population density, Local Personal Risk (LPR), and nuisance impacts, should be factored into risk-based assessments. Peak Ground Velocity (PGV) and magnitude levels are critical foundational parameters for evaluating seismicity risk.

The Canadian case successfully established the red threshold based on its risk analysis and developed a framework to manage seismicity during stimulation. The Finnish case designed its TLS using PGV

and magnitude levels derived from historical earthquake catalogs and real-time seismic events.

In the future, monitoring measures such as tracer and chemical tests can delineate subsurface fluid pathways and rock-fluid geochemical interactions. This information could help identify potential areas with a higher probability of induced seismicity, guiding actions to mitigate their occurrence. Additionally, tracer and chemical tests can monitor the effectiveness of mitigation measures and ensure the safety of surrounding communities by providing detailed insights into subsurface processes and the impact of operational activities.

ABSTRACT

From a high-level point of view, a geothermal project lifecycle covers several steps such as initial scoping (quick-look screening), evaluation (initial subsurface and surface evaluation), detailed design (e.g., plant, pipeline and well design, as well as subsurface static, dynamic, and geomechanical models), construction, operations (real-time updating and optimization for safe injectivity and production). Focusing on operations, the main objectives are to verify operations and assure the various stakeholders that all concerns are monitored and addressed as needed. Design of a monitoring system calls for understanding what is to be monitored (e.g., fluid injection, well integrity, leakage, fracture initiation, fracture network propagation, etc.), what are the changes in formation properties (e.g., temperature, resistivity, density, velocities, attenuation, seismicity, etc.) and how will those variations occur (e.g., over time, within a specific range (time and space); thus, what sensors need to be deployed (e.g., seismic, electromagnetic, temperature, pressure, etc.) and what specificities they need to meet (e.g., accuracy, precision, resolution, robustness, etc.) over what period of time for what frequency of interrogation.

Looking at real-time microseismic monitoring using DAS data, we deploy a system that consists in (a) “optimized data” issue from edge computation, (b) automated geophysical processing for continuous data stream from edge to office, (c) data connectivity between field and remote location. The “optimized data” includes depth-windowed enhanced data as well as mask traces containing probability information of seismic phase arrivals in continuous data stream. Taking advantage of data redundancy in densely sampled DAS data, we perform signal enhancement at the edge. Subsequently, we reduce the trace amount leveraging depth windowing to meet bandwidth limitations between wellsite and office. Such signal enhancement and data volume reduction enable real-time data inspection by a geophysicist sitting in a remote location. The

office-based multi-well simultaneous processing includes traditional migration-based event location followed or not by Geiger relocation (and/or any other processing scheme) as well as magnitude computation with intuitive QC visualization.

To achieve our energy needs, geothermal-focused efforts need to increase significantly over the next 20 years. Fiber optic is a cost-effective and easy-to-deploy monitoring system that can deliver on several answer products across several domains.

1. Introduction

Distributed acoustic sensing (DAS) has been widely applied to several areas of seismology. Passive seismic monitoring is one of the areas considering versatile deployment options and long aperture of one or more seismic arrays. Several successful passive seismic monitoring case studies have been reported by research organisms, academia and the industry at large with more recently a focus on new energy and geothermal-focused applications. However, there are several practical challenges associated to the utilization of a DAS-based network to perform real-time passive seismic monitoring. This is coming from the nature of DAS geophysics including its single component and strain response, redundant but relatively low signal-to-noise ratio (S/N) measurement, and high throughput of data from the acquisition system. We introduce our recent attempts to address those challenges and highlight key technology components.

2. Simulation in planning and preparation

Simulation has an important role to play in a real-time passive seismic monitoring campaign in terms of the survey design and system testing. Survey design is a critical step to plan field deployment of the sensor network. It is a recommended step in the conventional geophone area, and similarly when using DAS. We simulate the amplitude of passive seismic data and estimate signal to noise ratio using the ray theory with assumptions in terms of (1) area of interest, (2) placement of the fiber optics cable, and (3) its noise level (Mizuno and Le Calvez, 2023). A DAS response model is considered as single component strain measurement. We evaluate the limitation of sensitivity in terms of the magnitude of the passive seismic events. The uncertainty of event location could also be assessed. Figure 1 shows the example of the minimum magnitude distribution along the vertical DAS cable. Although each strain sensing point presents the anisotropic nature of sensitivity, distributed sensing along the fiber brings adequate detectability performance: minimum magnitude increases with distance from the cable.

The simulation technology is also critical to measure how reliable are the processing and reporting systems. There are two reliabilities issues to be concerned about. One is stability of the overall system under the high throughput of the data from the interrogator box. The other is the accuracy of the processing result. The real-time simulator presented in Mizuno et al. (2024) is developed to suite the afore mentioned considerations (Figure 2). The simulator outputs continuous DAS waveforms at real time speed assuming a statistical seismicity model (magnitude distribution, spatial-temporal distribution). Figure 3 shows am example of the data generated by the simulator. The system outputs a total of 4 Tb of continuous data for a dual well monitoring scenario per day. The data contains about 17,000 events.

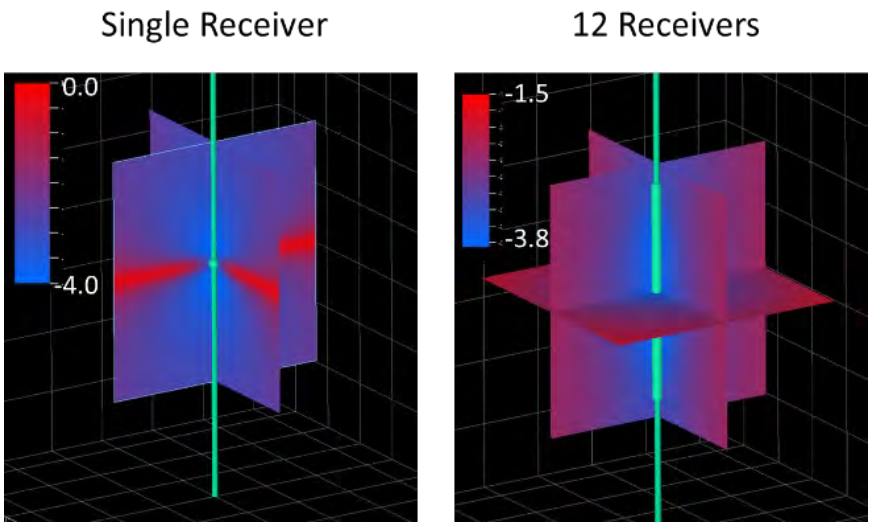

Figure 1: Detectability map comparison (minimum magnitude threshold in space) in single DAS receiver (left) and 40 'point' DAS receivers (right). The monitoring well is vertical (green trajectory) and receiver positions are represented as disks. Noise level is assumed to be of one nano strain.

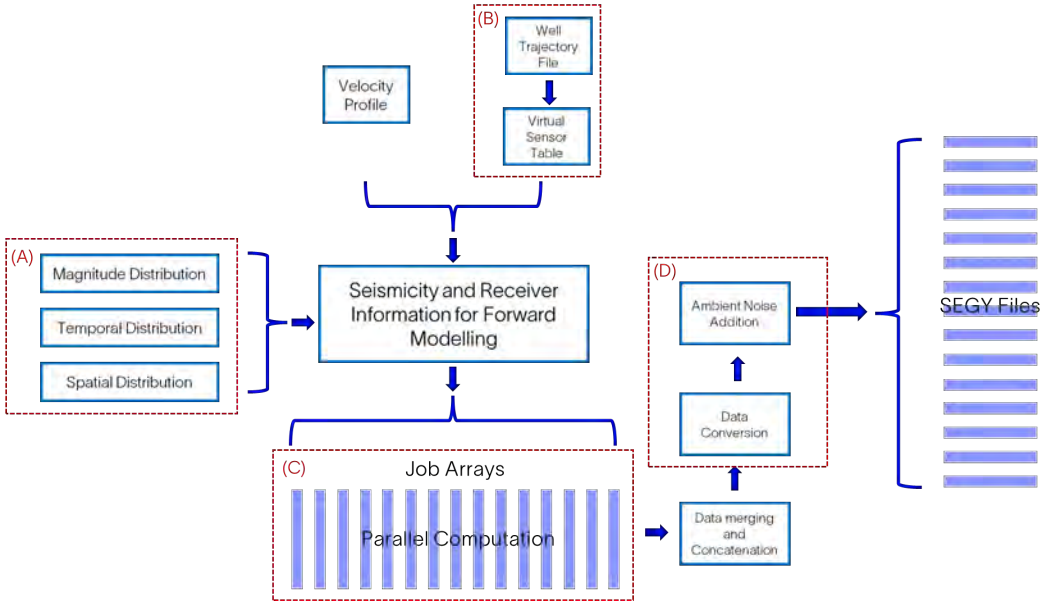

Figure 2: Real-time microseismic DAS simulator elements.

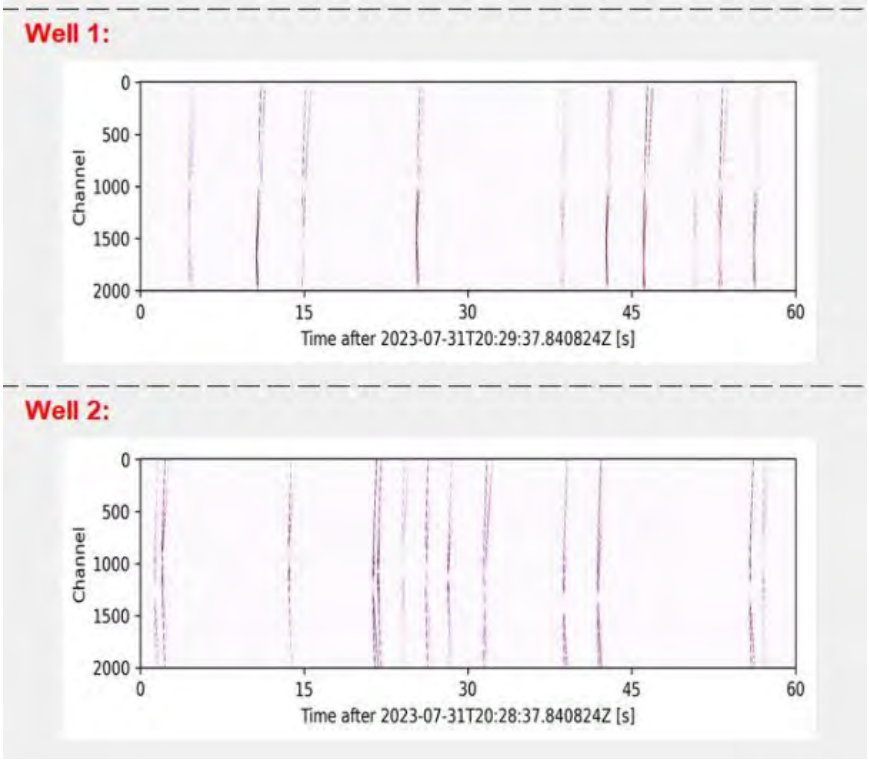

Figure 3: DAS synthetic example showing continuous waveforms as generated by the real-time simulator over a one-minute-long time window). Due to their hypocenter positions respective to the DAS arrays and their magnitudes, some events can be seen by both arrays (partially or in their entirety) while others are not.

3. Real-time DAS microseismic monitoring

Real-time geophysics is critical to perform passive and active induce seismic monitoring. During active and passive seismic monitoring, data should be recorded continuously. Therefore, the data volume could take terabytes of storage space each day for a DAS array. Processing should start as soon as acquisition is initiated to reduce lead time of processing. Additionally, data quality is to be monitored on a regular basis since the acquisition cannot be repeated as one an event has occurred, the same event will not occur again. A large volume of data is hard to review relying on human eyes only and is therefore difficult to QC. We need to implement robust processing for large volume of DAS data.

To reduce the data volume and to enhance the signal are two key elements to achieve. Those objectives are to be performed at the well site in real-time while acquisition is taking place. Figure 4 shows an example of a dataset prepared by the well site processing system. The data consist of two parts (1) strain waveforms which are depth-windowed and locally stacked. (2) the “mask” waveform which represents the probability of the phase arrival of the passive seismic signal in the original data. Comparing to the original continuous data generated from the interrogator box, this data take less volume and more information is available for the geoscientists for QC. The resulting dataset is adequate for further event location and magnitude computation at either the wellsite or the remote office.

Hypocenter and magnitude are to be estimated automatically in real time. We use a migration-based approach to determine the hypocenter without time picks needed. This approach is useful even if the network consists of a combination of geophone and DAS arrays (e.g., Mizuno et al. 2021). Several migration-based methods are proposed depending on the data to be migrated. One may use the "mask" trace prepared at the well site in the step above (Figure 5). In terms of moment magnitude estimation, we revised the geophone-based algorithm to support DAS data. To estimate moment magnitude, we need the signal moment defined in terms of a displacement spectrum. Because a DAS system measures the strain, we estimate the displacement spectrum from the DAS data through data conversion from DAS to 1C geophone. Having the event location estimated from the migration-based method described above, the algorithm applies a timing window for the P and S signal part of the DAS data to extract the P and S signals. Then, we invert the signal moment and corner frequency of the displacement spectrum for the P- and S-wave of each event assuming an omega-squared spectrum model which is commonly observed in passive seismic events. The magnitude distribution follows the Gutenberg – Richter law, which is often seen as characteristic of passive seismic events.

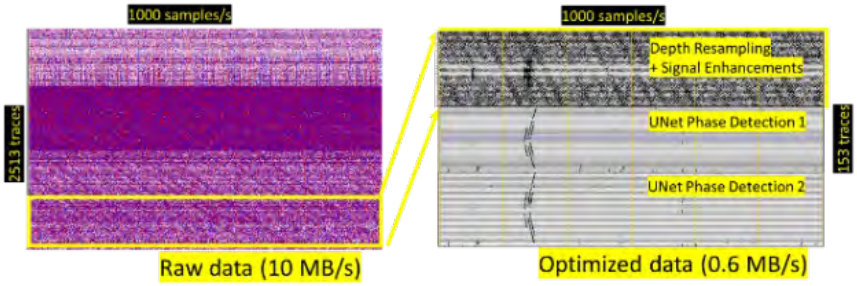

Figure 4. Example of (left) raw continuous seismic data from the DAS interrogator box and (right) waveform processing result at the well site. The depth trimming and signal enhancements are applied so that easily QC data and process using DAS waveform in the right. The "mask" trace is also computed at the well site and attached to the data to present probability of passive seismic arrivals in waveform.

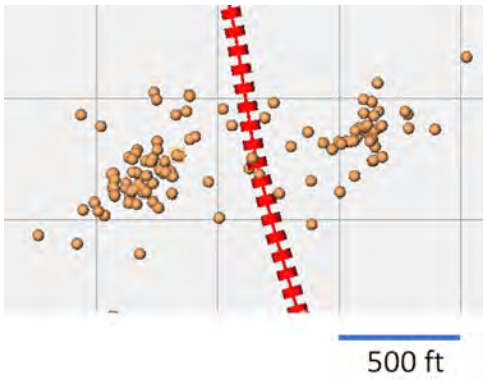

Figure 5. Example of the map view of the event location estimated from the migration-based method using the mask trace in Figure 3. Note that because this DAS is deployed only in a single borehole (red trajectory) and data at the horizontal section are processed (DAS sensing points are presented as red disks), events are assumed in the same depth as the borehole in this processing.

4. Distributed Temperature Sensing (DTS) and Distributed Acoustic Sensing (DAS) for geothermal fields

Integrated use of borehole and surface geophysics tools allow us to provide an end-to-end monitoring solution that can streamline and accelerate the vast expansion of site characterization and monitoring tasks needed for the success of geothermal-focused applications.

Repeat Microgravity Measurements, Reservoir Monitoring, Reservoir Simulation, Gravity Change Forward Calculation

ABSTRACT

Repeat microgravity measurements were conducted to elucidate the long-term gravity changes in the Beppu geothermal area, one of the most famous hot spring areas in Japan, where the use of geothermal energy remains prevalent. The gravity values in (2023) showed a decrease of 20 μgal to 40 μgal from 2015, mainly at the western survey points (D1, TERUYU, and B3). To examine the relationship between the gravity changes and behavior of reservoir, the reservoir model was created based on existing geological information and gravity basement elevations, and forward calculations of the gravity changes associated with production were performed. The current reservoir model did not fully reproduce the measured gravity changes, primarily around TERUYU and B3. It is thought to be due to the low permeability of the model on the north side and insufficient supply for the reservoir model. The measured gravity values must be explained by adding a structural survey on the north side, revising and/or optimizing parameters such as permeability. Although there is room for improvement in the current reservoir model in terms of reproducing the measured values, it was shown that the gravity change can be utilized for reservoir model evaluation by comparing the forward gravity calculation with the measured values.

1. Introduction

For the sustainable utilization of geothermal resources, understanding the geothermal model of the target area and the appropriate amount of production and reinjection is necessary. Continuously monitoring subsurface conditions, such as fluid increase/decrease is also crucial. As changes in density caused by increases or decreases in fluid appear as gravity changes at the surface, repeated microgravity measurements can be used to estimate changes in subsurface conditions. Compared with other monitoring methods, repeated microgravity measurements are advantageous because

they are low-cost, require minimal personnel, and provide information as a two-dimensional distribution. In this study, the Beppu geothermal area, where geothermal activity is active, and hot springs and small-scale geothermal power generation are still being actively conducted, was selected as the target area. We conducted repeated microgravity measurements starting in 2021 and compared the gravity values with those of the past to elucidate the long-term trends in gravity changes. Repeated microgravity measurements have been conducted in some areas (e.g. Oka et al., 2012; Nishijima et al., 2016), but few studies have combined reservoir analyses. Gravity change is one of the few observed values that reflect reservoir changes other than wellbore information and can be used to validate reservoir models. To utilize gravity changes for reservoir model evaluation, we constructed a reservoir model of the Beppu area and attempted forward calculation of gravity changes caused by production.

2. Beppu Geothermal Area

The Beppu geothermal area is one of the largest hot spring areas in Japan, with more than 2,000 sources. Geothermal energy is mainly harnessed from in hot springs. Several small-scale binary power plants have been in operation in Beppu area since 2014. The geology of the Beppu area is characterized by a Quaternary volcanic group consisting of Tsurumi-dake (Mt. Tsurumi) and Garan-dake (Mt. Garan), located at the northeastern end of the Beppu-Shimabara rift, and an alluvial fan area extending from the foot of these mountains to Beppu Bay (Figure 1). The Kannawa and Asamigawa faults are located on the northern and southern margins of the fan, respectively. The tuff, lava and pyroxene andesite are deposited in the lower part of the fan deposits, which are several hundred meters thick (Hoshizumi et al., 1988). Compositional analysis of hot spring water has revealed that fluid flows in multiple pathways from the upstream side where Mt. Tsurumi and Mt. Garan are located downstream to where the coast is located (Osawa et al., 1994; Osawa and Yusa 1996). The flow paths are largely divided into two parts on the north and south sides of the Beppu area, flowing along the Kannawa Fault on the north margin and the Asamigawa Fault on the south side. Hot springs are mainly distributed in the fan area. In particular, hot springs in the Myoban, Kannawa, Shibasaki, Kamegawa, Horita, Kankaiji, Beppu, and Hamawaki areas are known as representative hot springs in the city and are called Beppu Hattou. Nishijima and Naritomi (2017) conducted a gravity structure survey and mentioned the relationship between the gravity base elevation and Na-Cl hot spring flow paths (Figure 2).

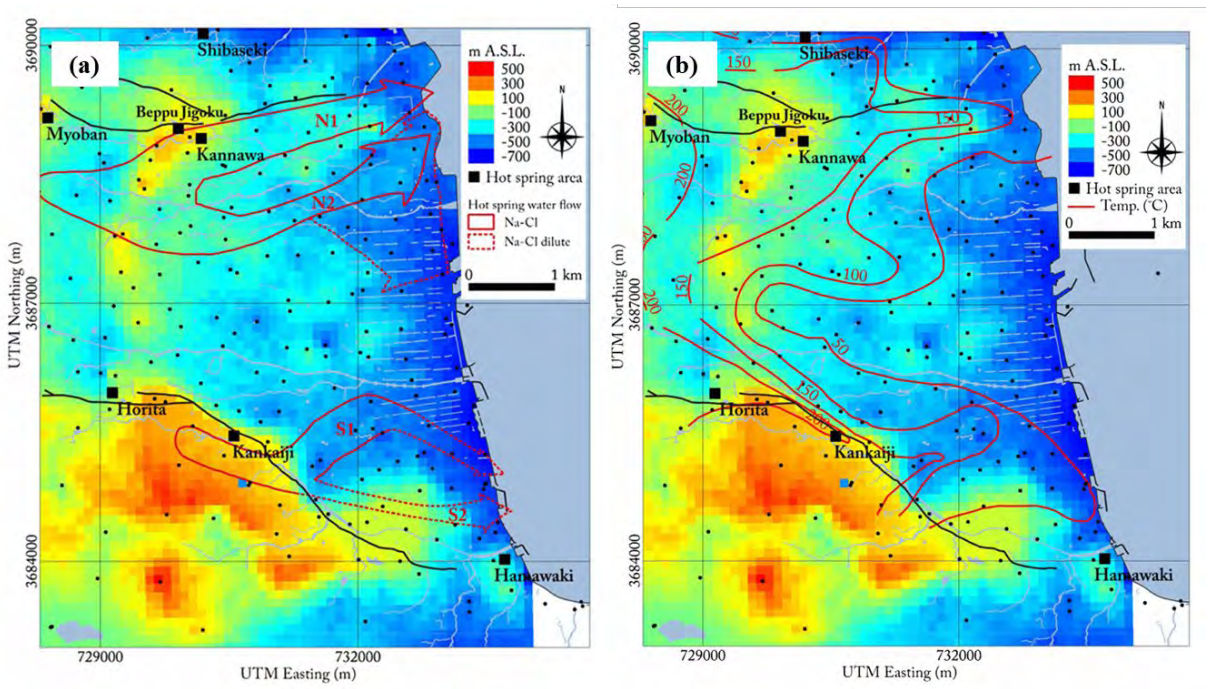

Figure 2: Comparison between the gravity basement and hot spring data (Nishijima & Naritomi, 2017) (a) The gravity basement and the subsurface flows of the Na-Cl type hot spring water, modified from Ohsawa et al. (1994) and Osawa and Yusa (1996). (b) The gravity basement and the isotherm at 100 m below sea level, modified from Allis and Yusa (1989).

3. Repeat Micro-gravity Measurements

In this study, repeat microgravity measurements were conducted, starting from October 2021, in the Beppu area. The measurement points were the same as those used in a previous study, which was conducted from 2014 to 2016, (Nishijima et al., 2018) to investigate long-term trends (Figure 3). A CG5 relative gravimeter (Scintrex, Ontario, Canada) was used until June 2022, and CG6 (Scintrex, Ontario, Canada) was used after September 2022, 3–4 times a year. Closed loops were formed with multiple measuring points and round-trip measurements were performed to effectively detect and analyze microgravity changes. In each of the outbound and return measurements, gravity values were measured multiple times until they settled within 10 μgal at each measurement point. After applying tide, machine height, and drift corrections to the obtained data, the relative gravity differences from a reference point were calculated. The reference point was C1, which was the closest to the sea and was considered to have the smallest change in groundwater saturation.

Figure 4–6 show the changes in gravity over time at each station. The measurement errors were large in March and June 2022, but the variation in the values for the subsequent measurement cycles was small. To observe the long-term trend, the time reference was April 2014, the start of monitoring by Nishijima et al. (2018), and the value at each time was shown as the gravity change from April 2014, the reference time. Many of the measurement points show repeated irregular fluctuations in the range of +-40 μgal (Figure 4, 5). The gravity values of C2, D1, TERUYU, and B3, in 2023 are decreasing from -20 μgal to -40 μgal compared to 2016, the year before the interruption of the measurement. Seasonal variations were observed for the BGRL stations, with gravity values increasing from November to December and then decreasing. Differences between the BGRL and other measurement points were noted during the 2014–2016 measurements. The BGRL reflects the shallow groundwater level in the unconfined aquifer, and gravity values in areas with active geothermal use, such as C3 and TERUYU, are influenced by saturation changes in both the unconfined aquifer and the hot spring aquifer.

Figures 7 and 8 show the distributions of gravity changes between the measurement periods of the previous study (2014–2016) and the present study (2022). To minimize impact of seasonal variations, differences were recorded for the same month each year and a two-dimensional distribution map of gravity change was obtained. The gravity values decrease at D1, TERUYU, and B3, which are located west of C3, compared to the area directly under the Kannawa area, which has the largest amount of production.

4. Forward Calculation of Gravity Change Using Reservoir Simulation

First, to understand the geothermal fluid flow regime before production, a geothermal reservoir model was constructed based on the results of geophysical surveys of the Beppu area, including geological and gravity base elevations. We conducted a natural-state simulation using the reservoir model in TOUGH2. Next, a production simulation was conducted based on the natural state model, and the gravity changes caused by the production were calculated by forward calculations using the Volsung simulator.

4.1 Natural-State Model

A region of interest was enclosed by a square of 8 km (200 m × 40) on each side, with a 1 km buffer region on the outside, making the entire model area 10 km × 10 km (Figure 9). The depth of the model was set at an elevation of -2000 m as the bottom and 1000 m elevation as the top of the model (100 m × 20 at the top and 200 m × 5 at the bottom). The geological model (Figure 1) and gravity base structure (Figure 2) were reflected in the model, and rock properties were determined based on Murata et al. (1991) and Yahara et al. (1994) (Table 1). Because the model was assumed to be porous, highly permeable geological domains such as the fault structure were assigned to high permeability (Figure 10). The fault structures are based on Chida et al. (2000) (Figure 1). Boundary conditions were fixed at atmospheric pressure and 17 °C for surface grids. The eastern side (bay) was set as permeable, whereas the other sides (watershed) were set as adiabatic or impermeable. A heat flux of 0.25 W/m^2 was given from entire bottom grids as the crustal heat flux, and a mass flow velocity with a specific enthalpy of about 300 °C was given at 15 kg/s to the bottom about 1.5 km southeast of Mt. Garan and 23 kg/s to the bottom about 1 km northeast of Mt. Tsurumi as heat fluid sources. Because the age of the hot spring system, calculated from the potassium concentration of the hot spring water, was estimated to be 50,000 years (Yusa, 2000), the calculated results at the age of 50,000 years were used as the natural state. Figure 11 shows the temperature distribution and fluid flow at elevations of -200 m and -100 m after 50,000 years. In the geochemical analysis of the hot spring water flow shown in Figure 2, the flow path is divided into two large channels on the north and south sides and high-temperature regions of 100 °C or higher are distributed along each channel. In the natural state model, the water flows from the west side of the source to the east in two separate north and south directions, and high-temperature regions of 100°C or higher are distributed along each flow path (Figure 11).

Table. 1: Rock properties used in simulation (Colors are the same as shown in Figure 10)

	Materials	Porosity	Heat conductivity [W/m・K]	Density [kg/m^3]	Specific Heat [J/kg・K]	Permeability [m^2]
	Fan deposit	0.15	1.8	1900	1000	10^{-14}
	Cap rock	0.15	1.8	1900	1000	10^{-17}
	Fault structure	0.09	2.1	2100	1000	10^{-13}
	Fracture in Andesite	0.02	2.4	2100	1000	10^{-15}
	Andesite (Bed rock)	0.02	2.4	2300	1000	10^{-16}

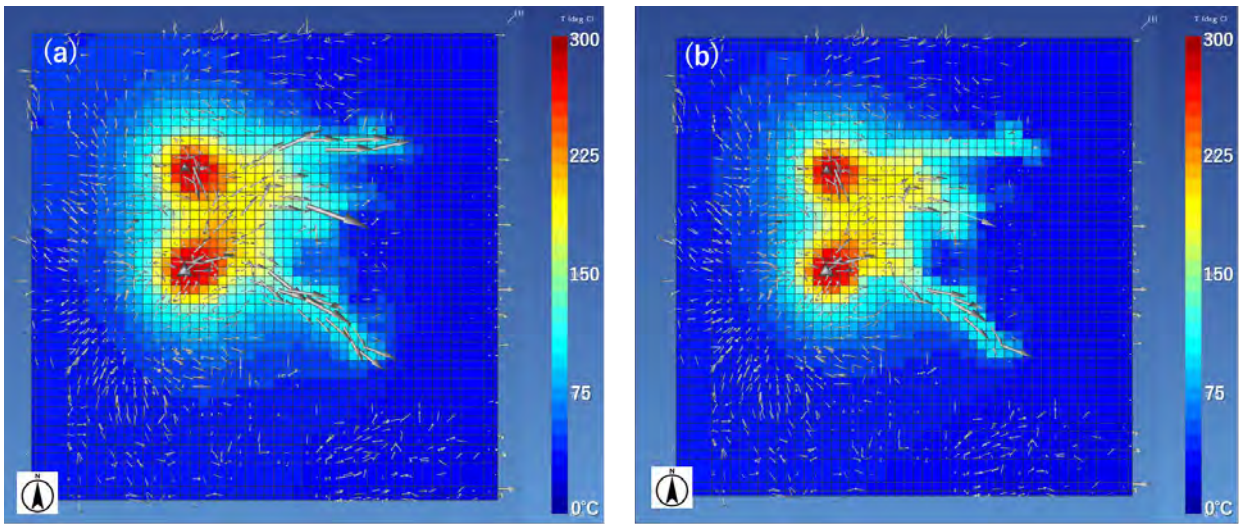

Figure 11: Temperature distribution and fluid flow over 50,000 years (a) Elevation -200m (b) Elevation -100m.

4.2 Production Simulation and Gravity Change

Possible causes of gravity changes during the measurement period in this study include changes in shallow groundwater levels and reservoir saturation associated with production. The annual shallow groundwater level fluctuation is about 2 m in Beppu area, and the corresponding gravity change is about 12.5 μgal (calculated with a porosity of 0.15). The observed gravity changes in Beppu were higher than this value (Figure 4–5), suggesting that a large proportion of gravity changes was associated with changes in saturation in the reservoir due to production. The simulation in this study reproduced the gravity changes associated with the saturation change in the reservoir due to production.

Hot spring water has long been used in the Beppu area, and the amount of hot spring water collected from 1949 to 1987 varied between 431 and 656 kg/s (Yusa et al., 2000). Currently, there are more than 2000 sources, because it is difficult to reflect all wells in the mesh, approximately 70 wells were placed based on the production distribution shown by Yusa (2012) (Figure 12). Each well produced 5–10 kg/s (432–864 ton/day), resulting in a production rate of 498 kg/s (43027 ton/day) for the entire simulated area. The volume produced was equivalent to the middle of the production volumes in 1949 and 1987, as documented by Yusa et al. (2000). Induction wells were not set because most of the hot-spring operators were not reduced. The production period was assumed to be approximately 70 years from 1950 to the present (2023), and production simulations were conducted. Changes in gravity with respect to July 2015 were obtained by the forward calculation (Figure 13).

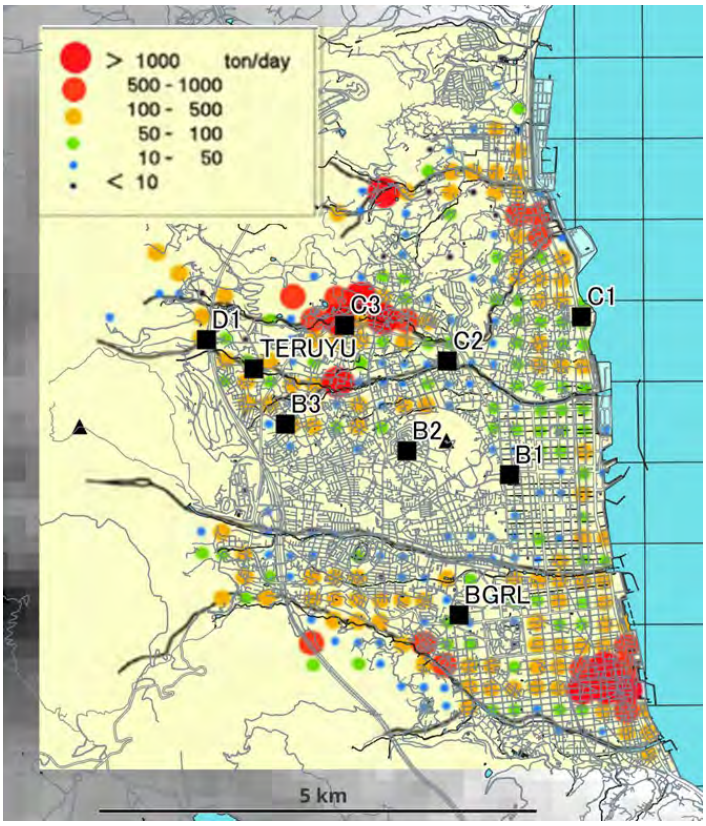

Figure 12: Distribution of production rate (Yusa, 2012)

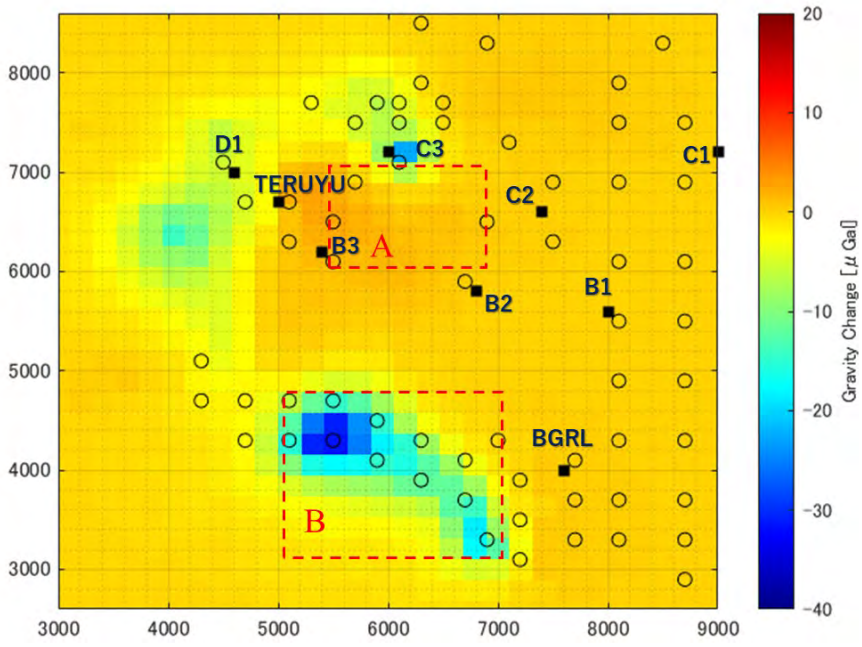

Figure 13: Gravity forward calculation result. Black circles indicate well locations.

5. Discussion

Comparing the two-dimensional distributions of the measured and forward calculation, the measured gravity decreases extended to the TERUYU and B3 measurement points, whereas the forward calculation showed no gravity decrease at TERUYU and B3 measurement points (Figure 7 and 13). One possible reason for this is that production wells could not be set in Region A on the southern side of Kannawa (C3). In the current production simulation, 43,000 tons/day were produced from the entire Beppu area, but the current model does not allow for further production, which is thought to be due to the low permeability of the model on the north side centered on the Kannawa area and insufficient supply for the reservoir model. The measured gravity values must be explained by adding a structural survey on the north side, revising and/or optimizing parameters such as permeability, and revising the supply (source mass flow rate) to the overall model to reproduce a more realistic production rate. Although there is room for improvement in the current reservoir model in terms of reproducing the measured values, the gravity change can be utilized for reservoir model evaluation by comparing the forward gravity calculation with the measured values. The gravity decrease observed in Region B (west of the BGRL) in the forward calculation did not fit the observations. Because there are no observation points in Region B, it is necessary to set the new measurement points over a wider area to capture gravity changes.

6. Conclusion

Repeat microgravity observations were conducted in the Beppu area, and the long-term trend of gravity was clarified by comparison with historical gravity values, showing that gravity has been decreasing mainly at the western survey points, such as D1, TERUYU, and B3. In addition, a reservoir model was developed based on existing geological information and basement elevations,

and forward calculations of gravity changes associated with production were performed. By comparing the forward gravity calculations with the measured values, it was shown that repeated microgravity measurements can be used to evaluate the reservoir model.

ABSTRACT

A recently collected high-resolution airborne magnetic survey provides insight into the structural setting of the Puna Geothermal Venture (PGV) on the Island of Hawai’i. Previous magnetic investigations of the eastern flank of Kīlauea predominantly relied on the ‘Puna Forest’ airborne magnetic survey conducted by the United States Geological Survey in 1978. Those data revealed that the Lower East Rift Zone (LERZ) of the Kīlauea volcano is characterized by a magnetic high anomaly extending from Kīlauea’s summit down its southeastern flank. That feature makes a notable left step near PGV in an area with enhanced permeability in the geothermal system. Ormat’s 2024 airborne magnetic survey improves on that legacy survey by utilizing denser line spacing (100 m flight lines), as well as advanced magnetic detection equipment and processing techniques, to delineate smaller-scale fissures and fractures in and around PGV. The new magnetic data have been correlated, where applicable, with magnetic intensity measurements, lithologic interpretations from drilling, and paleointensity data previously collected across the area of interest.

The magnetic signatures captured by this survey reveal pronounced positive magnetic anomalies along the major N63°E LERZ trend, as well as with cross-cutting features that strike perpendicular to this regional LERZ trend. The N63°E-trending fissures and fractures have been well-characterized by drilling and can host permeability associated with production, however the location, orientation, and size of the cross-cutting geologic structures are not well understood. These structures were first hypothesized as an explanation for results from reservoir tracer studies which showed rapid tracer returns from certain production and injection wells. This implies permeable pathways trending approximately perpendicular to the structural grain of the LERZ. The existence of NW-SE trending fractures was recently confirmed by an acoustic borehole image log, but additional studies are required to quantify their contribution to field permeability (Spake

et al., 2024). In a geologically homogeneous environment, a largely uniform magnetic signature would be expected. However, the basalts deposited across the LERZ present a contrast of strong magnetic highs flanked by broad magnetic lows (±6000 nT). This paper discusses the results of the recently acquired magnetic survey and the implications to the magnetic and structural environment at PGV.

1. Introduction

The Island of Hawai'i is part of the Emperor-Hawaiian volcanic chain and is formed by a group of five shield volcanoes, each shaped by lava accumulations from eruptive events. Our understanding of the island's subsurface geology is largely derived from geophysical data and sparse drill hole data (Hildebrand et al., 1993). At Ormat's Puna Geothermal Venture, a dense cluster of drilling allows for the testing and refinement of magnetic interpretations.

Magnetic surveys can be effective at measuring magnetic variations in volcanic regions like Hawai'i (Gudmundsson et al., 1997). This is due, in part, to significant variations in rock magnetization across the island (Hildebrand et al., 1993). Previous magnetic studies on the island have demonstrated the effectiveness of magnetic surveys and have been able to identify rift features, volcanic vents, conduits, and areas of alteration. The United States Geological Survey (USGS) conducted magnetic surveys over Hawai'i's volcanic regions in the 1960's (Malahoff & Woollard, 1966), revealing correlations between magnetic anomalies and volcanic structures. The 1978 'Puna Forest' survey provided a comprehensive magnetic dataset fundamental in understanding the island's magnetic features (Godson et al., 1981).

This paper analyzes the results of a detailed airborne magnetic survey conducted over PGV and part of the Lower East Rift Zone (LERZ). The goal of this survey was to map lateral variations in magnetic intensity to better understand subsurface geologic structure and strengthen the conceptual model for the geothermal system. This detail-oriented survey, like its regional predecessors, demonstrates that airborne magnetic mapping can effectively image intrusive dike complexes as well as areas of complicated deposition or alteration. There is good correlation between anomalies detected in the survey and geologic observations from the geothermal field. Magnetic intensity measurements indicate strong variations in rock magnetization, which likely represents conditions during deposition or changes that the rock has undergone over time. We have utilized various transformation and filtration techniques to help visualize and analyze the total magnetic intensity of the project area.

2. Geologic Setting

The Puna Geothermal Wellfield lies within the Lower East Rift Zone of the Kīlauea volcano (Figure 1). The LERZ hosts volcanic vents, craters, fissures, and fractures along a N63°E regional trend, mapped by Moore and Trusdell, in 1991. These volcanic features can act as conduits for both magma and hydrothermal fluids (Kenedi et al., 2010; Moore and Trusdell, 1991; Tilling & Dvorak, 1993). The PGV site is located in an area where eruptive vents appear to shift northward, suggesting the presence of north-south trending transform faulting (Moore, 1992; Spielman et al., 2006). This area is characterized by a magnetic high anomaly extending from Kīlauea's summit down its southeastern flank, with a notable left step in the magnetic field near PGV. This magnetic discontinuity may be an indicator of left-step transform faulting (Trusdell et al., 2009; Neal et al., 2019).

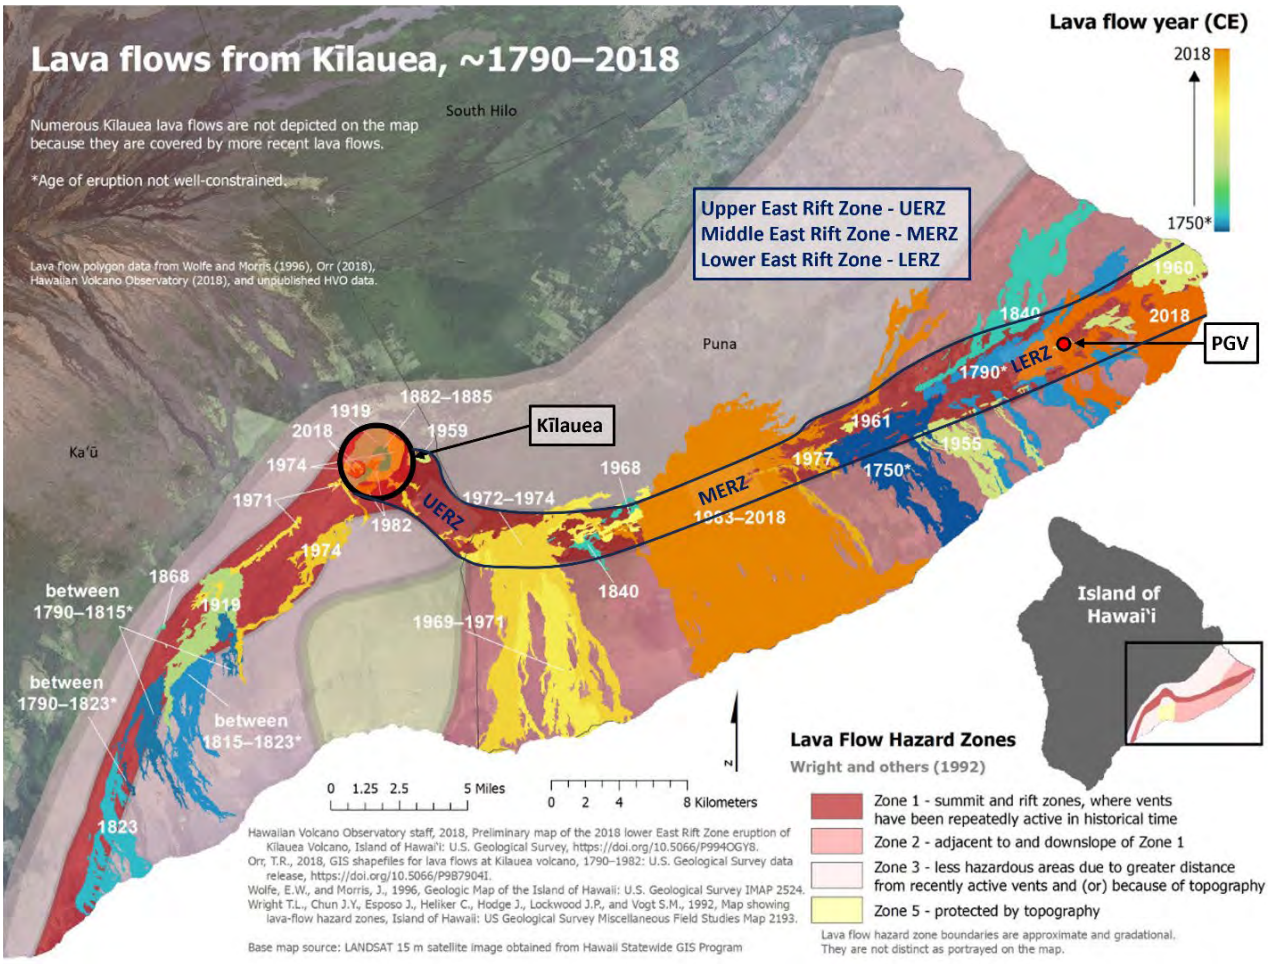

Figure 1: Annotated map showing the subaerial extents of lava flows and explosive deposits from Kīlauea, 1790–2018. Lava flow hazard zones, districts of the County of Hawai'i, the Upper, Middle, and Lower East Rift Zones are also depicted. Modified from Mulliken et. al, HVO (2024).

Tholeiitic basalts make up the overwhelming majority of the rock volume on the Island of Hawai'i and dominate the geology around PGV (Clague and Dalrymple, 1989). Notably, 80% of the LERZ is covered by basalt flows erupted within the last 500 years (Teplow et al., 2009). Most of the flows visible at the surface were deposited by eruptions in 1790, 1955, and 2018, all sourced from Pu'uhonuaula and Ahu'ailā'au craters (Figure 2). These events have resulted in ground deformation and changes in the subsurface, including fracture dilation, contraction, and reactivation of previously sealed fractures (Kauahikaua & Trusdell, 2020). The 2018 eruption was impactful, producing substantial changes in the landscape of the LERZ (Neal et al., 2019).

Subsurface lithology at PGV consists of four main units: subaerial basalts, a transitional sequence dominated by hyaloclastites, submarine basalts, and dike complexes intruded into basaltic host rock. Steeply dipping dacitic and diabase dikes associated with fissure eruptions have been linked to areas of high permeability (Teplow et al., 2009). The reservoir's permeability is influenced by en echelon, fracture systems oriented N63°E and dipping 85° to the NW. The intricate and long-lived nature of the geothermal system is evident from mineralogic studies of the reservoir rock (e.g., Iovenitti and D'Olier, 1985), which identify alteration due to contact metamorphism, low-temperature interaction with magma, and hydrothermal processes.

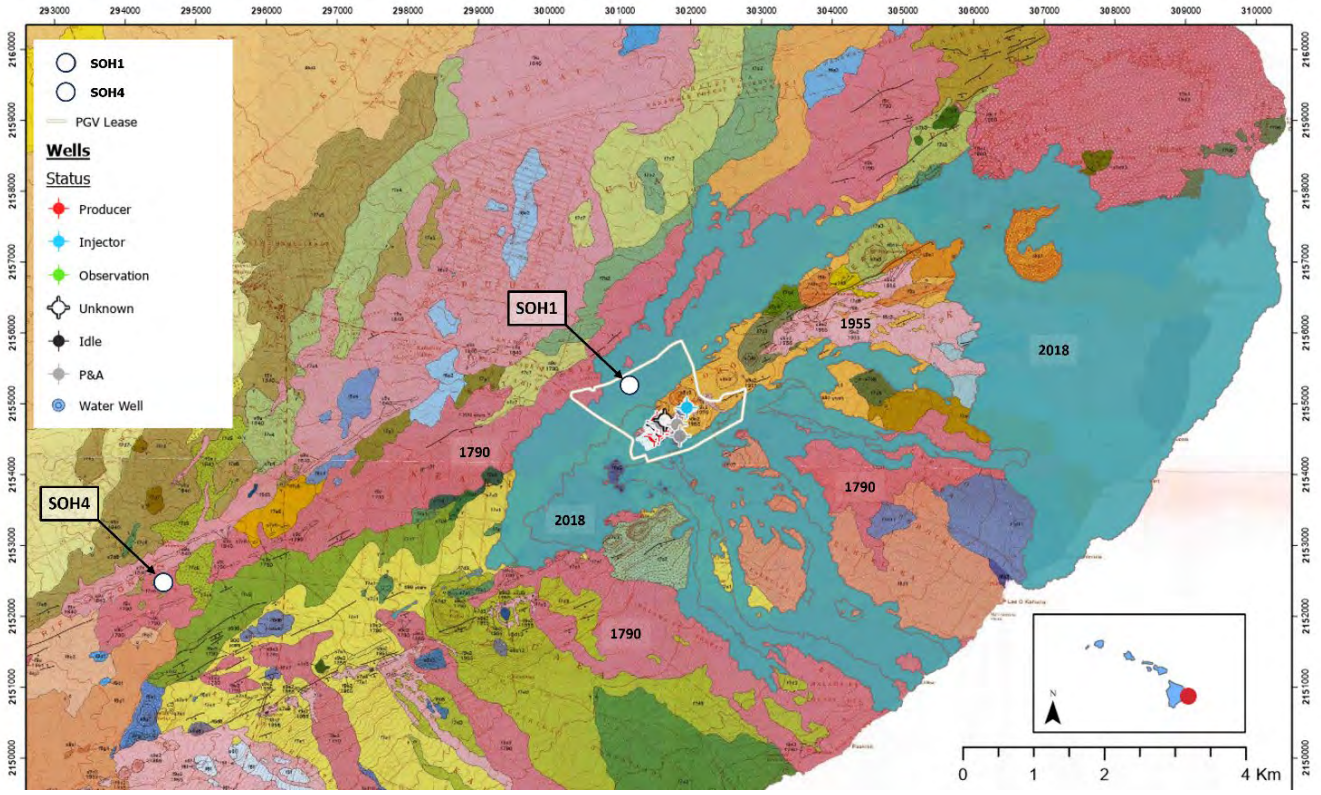

Figure 2: Annotated Map of the LERZ highlight recent impactful depositional events and Scientific Observation Holes SOH1 and SOH4. Modified geologic map from Moore and Trusdell, (1991). 2018 flow geospatial data from Zoeller et al, 2019.

Inflated pāhoehoe sheet flows, as found on the island and in the LERZ, can form when lava is injected beneath an existing, solidified crust (Self et al., 1998). Often, inflated sheet flows form in low-relief areas and can be the result of fluid pressure building within a cooling shell, as lava is injected into the interior of the flow (Holcomb, 1980; Hon and Kauahikaua, 1991). These flows cool relatively slowly, which likely has an effect on the quantity, distribution, and grain size of magnetic material within the flows (Audunsson et al., 1992). During the prolonged cooling process, ferromagnetic minerals like titanomagnetite have more time to align with the paleomagnetic field. This results in higher measured magnetic intensities compared to surrounding rocks.

‘A’ā lava flows, as characterized by MacDonald in 1953, form fragmented, rough surfaces, with clinkers often overlying an auto-brecciated base. The lava cools quickly and clasts topple along the flanks of the flow forming clinkers as a result of differential motion and shearing of the molten interior (Harris et al, 2016). This flow behavior results in a surface morphology that transitions from spiny fragments near volcanic conduits to loose, rubbly flow-breccia as the flow moves further away from the source (MacDonald, 1953). The irregularity and fragmented nature of these flows may affect the distribution, direction, and grain size of magnetic minerals, potentially leading to more variable magnetic signatures compared to other flow types (Hildebrand et al., 1993). ‘A’ā clasts that have tumbled and have varying magnetic orientation could lead to a mixed or suppressed measured magnetic intensity compared to pāhoehoe flows. The magnetic minerals

in these clasts may not have sufficient time to align with the magnetic field before rapidly cooling, creating a mixed domain state within the rock (Bücker et al., 1999).

3. Magnetic Data

The 'Puna Forest' airborne magnetic survey, (Figure 3), was conducted in 1978 by the USGS and has been integral to the design and justification of this survey. The USGS survey was predominantly flown at a height of 305m with 1600m spacing with lines oriented N27°W (Godson et al., 1981) and perpendicular to the main rift trend, at N63°E (Flanigan et al., 1986). The data provide a total magnetic intensity map suitable for regional analysis.

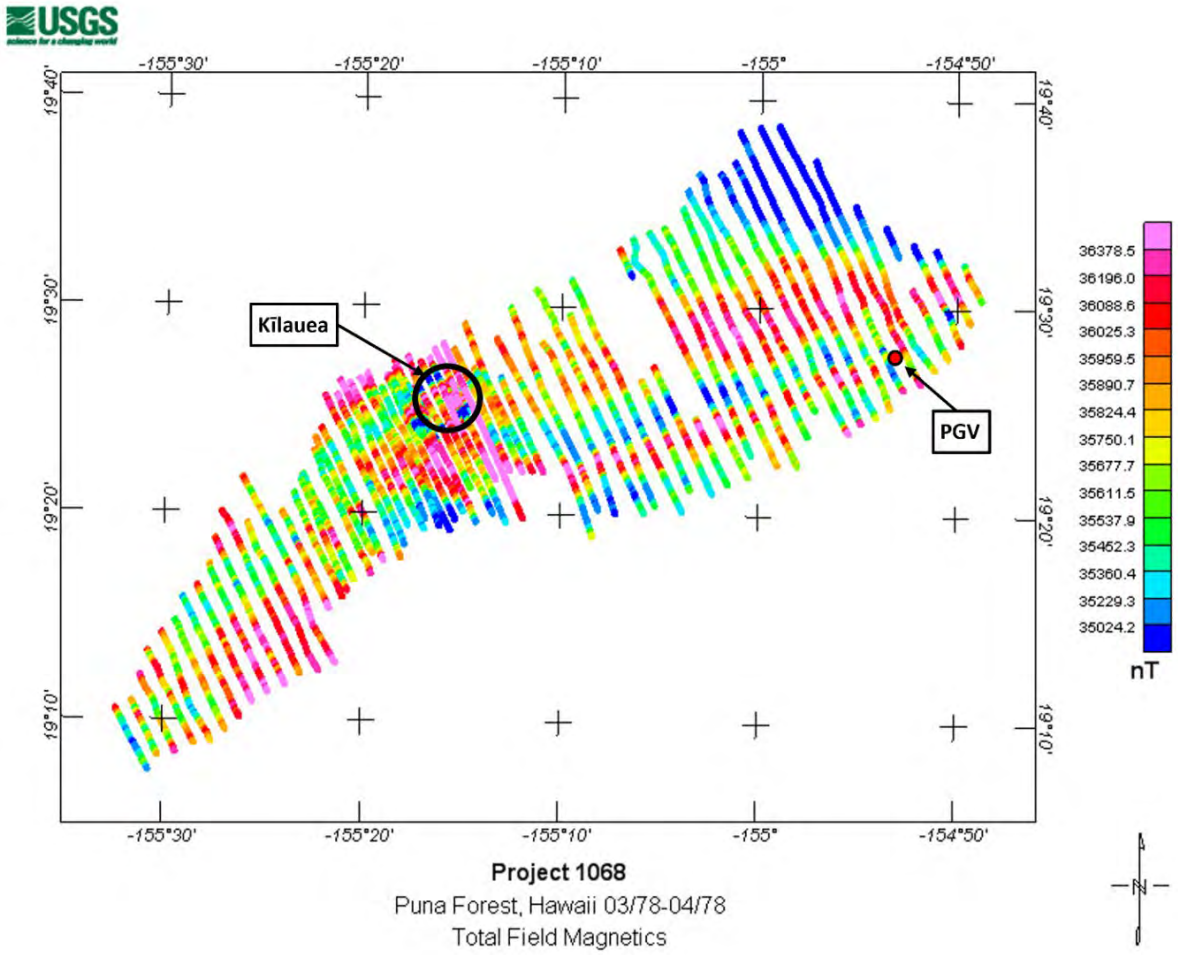

Figure 3: Map of the 1978 USGS 'Puna Forest' airborne magnetic survey with flight lines overlain with Total Field Magnetics.

In 2024, Ormat Technologies contracted MWH Geo-Surveys to collect an unmanned aerial system (UAS) magnetic survey covering 36 km² over PGV and the surrounding area (Figure 4). Total magnetic field data were collected using the Geometrics MagArrow, a laser-pumped cesium magnetometer specifically designed for UAS surveys with a sensitivity of 0.0005 nanotesla (nT).

Main flight lines for this survey, spaced 100 m apart and bearing N27°W, were flown perpendicular to the main LERZ trend, totaling 344 line-km. Tie-lines, flown perpendicular for

leveling and enhancing possible rift-perpendicular structures (Figure 4), covered 88 line-km, bearing N63°E and spaced 400 m apart. Flights were conducted at 140 m above ground level (AGL) to minimize localized magnetic effects from anthropogenic sources and highly magnetic fresh lava flows prevalent in the LERZ. Flight line drape was planned using a 1 m DEM model from the USGS, in an attempt to minimize terrain effect on the data.

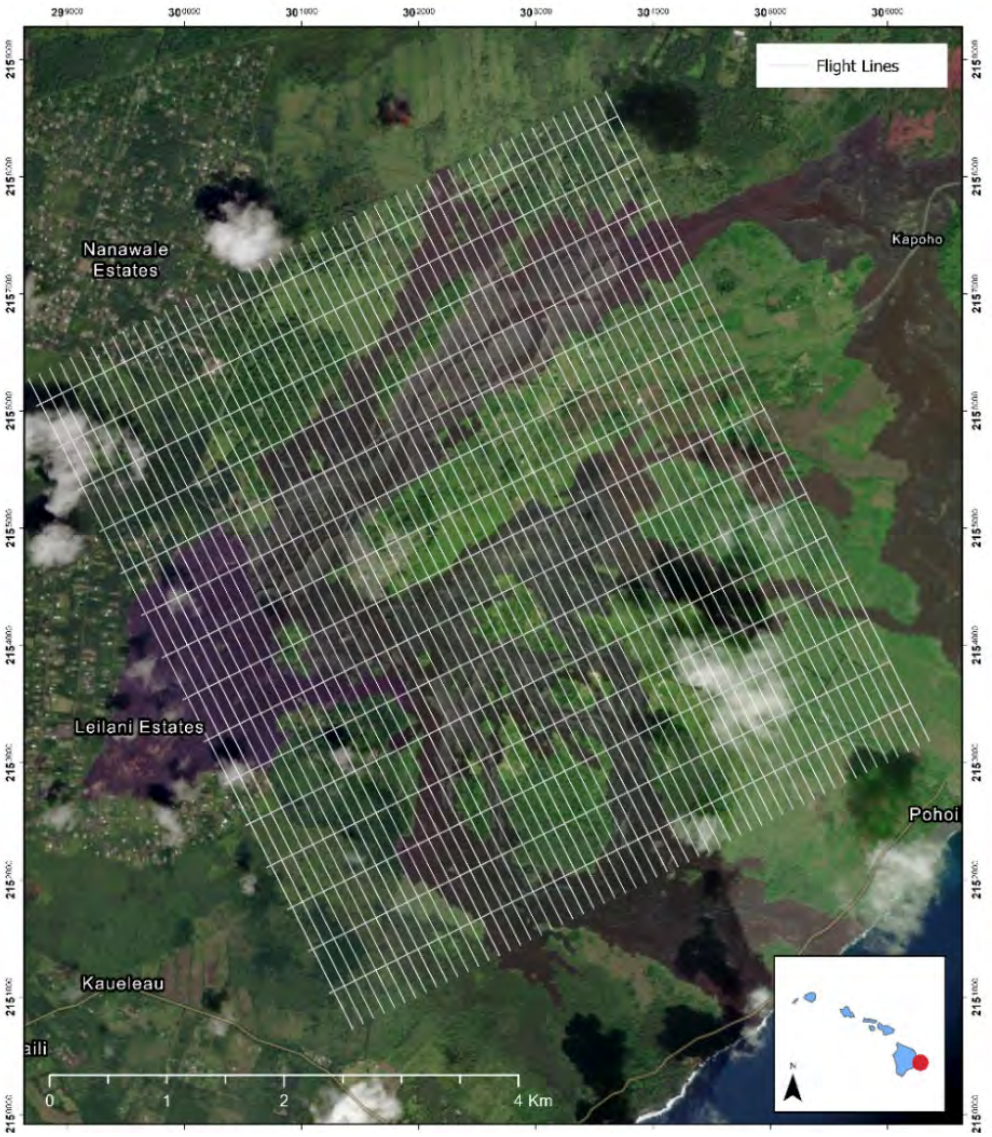

Figure 4: Flight lines from the 2024 Ormat UAS magnetic survey, spaced 100 m, with tie-lines every 400 m.

Total magnetic intensity (TMI) data were processed using minimum curvature gridding and reduced to the pole (RTP) (Figure 5) with a magnetic inclination of 36.5° and a declination of 9.5°. A map of total magnetic intensity, reduced to the pole reveals distinct magnetic anomalies interpreted to be associated with intrusive dike complexes, slowly cooled pāhoehoe basalt flows, ‘a’ā flows, and areas of possible alteration.

4. Data Analysis

Total Magnetic Intensity (TMI) was calculated for the high-resolution magnetic dataset by adding the International Geomagnetic Reference Field (IGRF), approximate value 34,302 nanotesla for the survey date and location, to the diurnally corrected magnetic data. Standard line-to-line leveling resolved herringbone effects, while tie-line leveling adjusted data values based on mis-tie values at line/tie-line intersections, ensuring consistency in the final maps.

At Hawai‘i’s low magnetic latitude, total magnetic intensity anomalies can present as dipolar in shape, with circular intrusions manifesting as magnetic highs closely flanked by magnetic lows, often in a north-south orientation. This can result in east-west oriented gradients that can be misleading in interpretation. The Reduction-to-Pole (RTP) transformation (Figure 5a) corrects for this by shifting positive anomalies over their sources (Bhattacharyya, 1965). For visualization and interpretation, magnetic data were gridded at 40 m intervals and contoured at 200 nT increments to accommodate high-quality data with very steep magnetic gradients.

5. Results

The magnetic data collected in this survey offer valuable insights into the magnetic and structural characteristics of the LERZ and PGV. The UAS magnetic survey highlights N63°E trending fissures and fractures as intermediate to low magnetic anomalies, which correlate well with the fissures and fractures mapped by Moore and Trusdell (1991). Cross-cutting anomalies are also apparent in this dataset, with the most significant rift-perpendicular lineament located east of PGV. Broad magnetic low anomalies are more common to the south of PGV and the highest amplitude magnetic low anomalies coincide with mapped craters (Figure 5b).

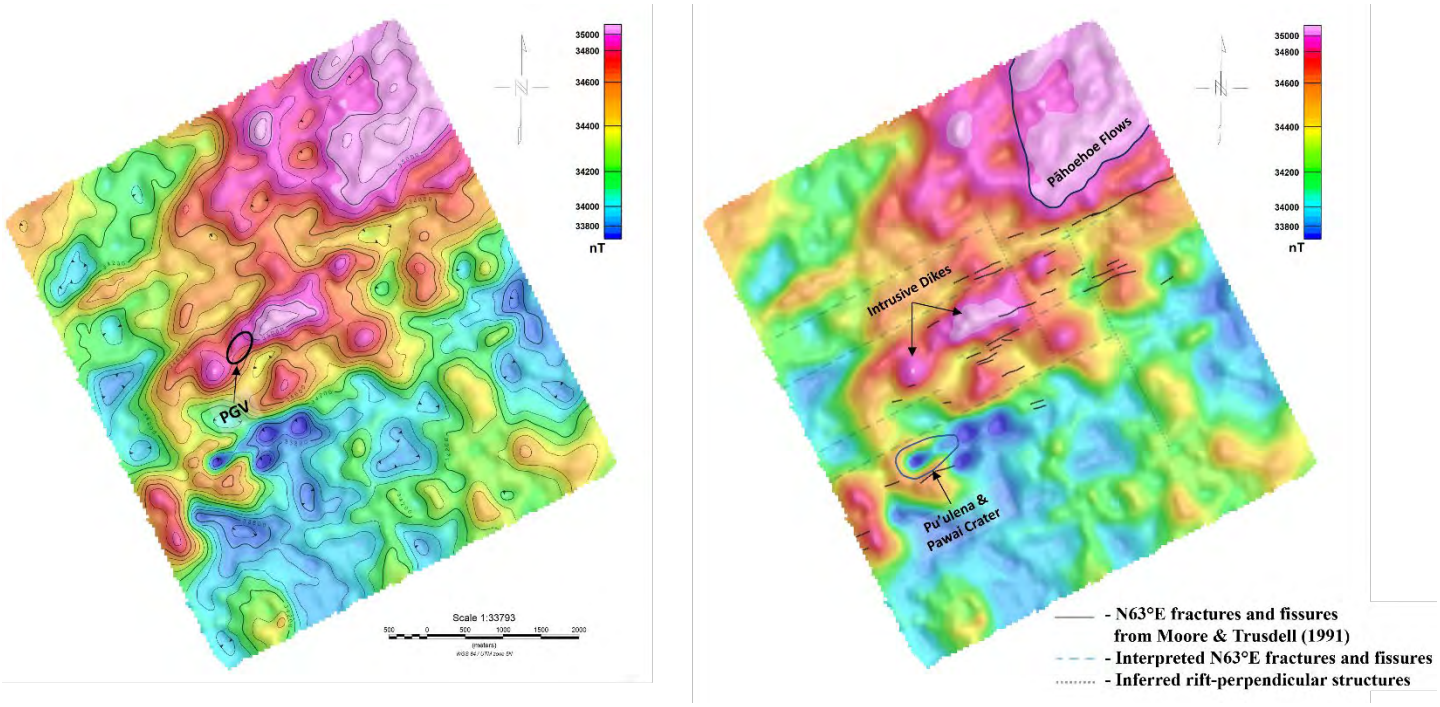

Figure 5: a.) Reduced-to-Pole (RTP) magnetic data with contours every 200 nT. b.) RTP magnetics with interpreted and inferred fissures and fractures based on Moore & Trundell (1991). Both figures have been color shaded to enhance structure.

There are areas in the dataset that may have a positive correlation with topographic relief. In some regions, a positive magnetic anomaly is observed near or over an area with elevated topography. Two strong, spherical magnetic low anomalies are imaged to the southwest of PGV and appear to correlate with the Pu‘ulena and Pawai craters. These magnetic low anomalies may be due to terrain effects, as flying an accurate flight drape over such steep gradients would be challenging. These anomalies may also be the result of alteration occurring in an area of increased permeability or may be areas of lowered magnetic intensity derived from complicated depositional processes.

The 1978 USGS survey and the 2024 Ormat survey show good agreement when sampled over a profile. To facilitate this comparison, the 2024 RTP data were upward continued to a height of 300 m and plotted against the more regional survey. The magnetic intensity profiles are in good agreement, showing the two datasets are generally consistent with each other.

6. Discussion

A key objective of this survey was to capture images of buried structures perpendicular to the LERZ. The apparent offset in the magnetic signature suggests that we may have effectively imaged such rift-perpendicular structures. It is also plausible that magnetic discontinuities in the datasets may be imaging subsurface heterogeneity, variations in dike structure and deposition. Alternatively, we may be measuring highly magnetic intrusive dike complexes that have formed along the rift trend, flanked by relatively lower magnetic intensity material. This juxtaposition in intensity may be creating lineaments that closely correlate with mapped fractures and fissures.

Intermediate to low magnetic lineaments align with mapped fissures and fractures. These geologic features may project into the deep reservoir and are interpreted as potential influencing structures within the geothermal system. However, it is unlikely that the magnetic lows observed in this data set can be directly attributed to hydrothermal alteration from the geothermal system. The geothermal reservoir is overlain by a clay cap, ~1000 m of subaerial basalt and hyaloclastite sequences and a pervasive cold-water aquifer. These are all factors likely to limit hydrothermal alteration near the surface. Given the uncertainty in the depth of investigation, it is highly unlikely that airborne magnetics can image the deep hydrothermal alteration occurring within the reservoir at depths of 1000 m and below. The anomalous magnetic lineaments imaged by this survey correspond with mapped geologic features (Hoversten et al., 2022). Apparent offset in rift-parallel magnetic highs may indicate a NW/SE trending structural fabric, manifesting as a localized left-step structure near PGV (Figure 6). NW/SE-trending structures likely intersect the main N63°E fissures and fractures, potentially acting as additional geothermal fluid pathways and enhancing reservoir connectivity at PGV (Kenedi, 2010).

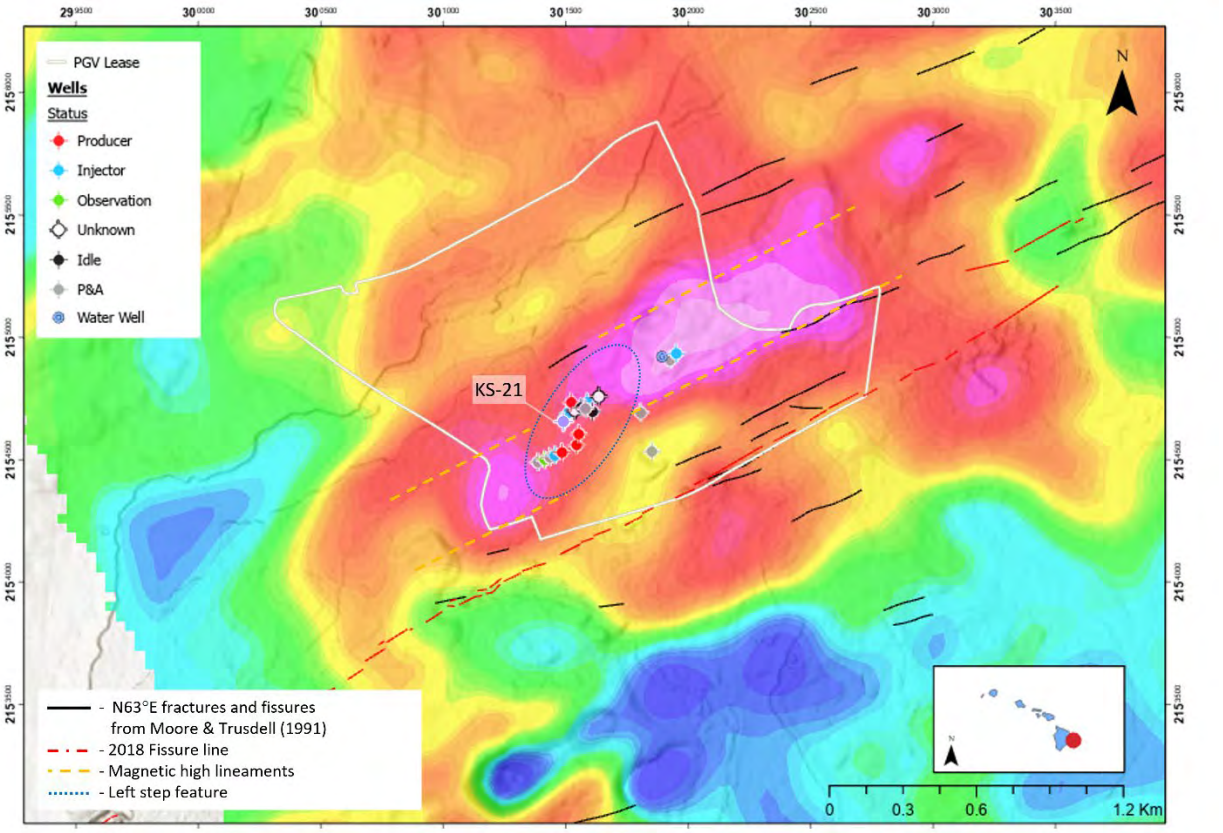

Figure 6: RTP magnetic map highlighting the left-step feature along with interpreted and inferred fractures and fissures.

Strong magnetic high anomalies have been interpreted to result from slower cooling, often associated with in-situ deposition. Intrusive dike complexes and inflated sheet flows share similar mechanisms of emplacement where lava has more time to cool, allowing ferromagnetic minerals to align more effectively with the ambient magnetic field (Audunsson et al., 1992). In contrast, broad intermediate to low magnetic anomalies may be caused by terrestrial flows like ‘a’ā or by weathering alteration processes. The rapid cooling and varying orientation of clasts in ‘a’ā flows do not allow magnetic crystals to align as consistently with the magnetic field, yielding an intermediate to anomalously low response (Harris et al., 2016; Bücker et al., 1999).

The likelihood of encountering reversely magnetized rocks on the Island of Hawai’i is low, and the probability is even lower in the Lower East Rift Zone (LERZ). The oldest rocks on the island have been dated to approximately 0.70 ma, which is younger than the last geomagnetic field reversal that occurred around 0.78 ma. All radiometric ages for rocks in the LERZ are significantly younger than the last geomagnetic reversal, and no reversely magnetized rocks have been documented on the Big Island (Langenheim and Clague, 1987; Doell and Cox, 1965).

Paleomagnetic data collected by Rosenbaum et al. (2009) from boreholes SOH1 and SOH4 (Figure 2) help us understand the magnetic properties of the geology in the LERZ and PGV. Measurements show that shallow dikes have the highest total magnetization compared to other rock types encountered (Table 1). This suggests that shallow dikes are significant sources of short-wavelength magnetic high anomalies associated with the LERZ, while deep dikes likely present as longer wavelength, intermediate magnetic values. These results are consistent with the finding

of this study, that high-amplitude magnetic anomalies are often flanked by broader magnetic low anomalies, likely representing mixed domain terrestrial flows or rock may have been altered in the LERZ (Rosenbuam et al., 2009). Over time, weathering or other forms of alteration may reduce the magnetization of these rocks, explaining the lack of magnetic high anomalies in older areas of the rift zone and in exposed terrestrial flows (Garnier et al., 1996).

Rock Type	**Total Magnetization (Am^{-1})**
Terrestrial flow	5.4 ± 0.6
Hyaloclastites	3.7 ± 2.1
Pillow basalt	9.4 ± 2.8
Shallow dikes (<800 m)	12.6 ± 2.5
Deep dikes	8.4 ± 1.4

Table 1: Total Magnetization values measured by Rosenbaum et al. (2009)

An acoustic borehole image log and Pressure/Temperature/Spinner (PTS) data were collected and analyzed from well KS-21. Despite overall low image log quality, 248 fractures were picked over the 3,266 ft log interval. Most fractures identified are sub-vertically dipping and NE-SW striking, consistent with the trend of the LERZ (Figure 7), and combined analysis of image and PTS surveys supports rift-parallel fractures controlling permeability over imaged feedzones. In addition to the NE-SW striking fractures, there is a minor, but significant, population of WNW- to NNW-trending features distributed throughout the image log. These features are broadly consistent with the attitude of rift-cutting fractures expected from interpretation of magnetic lineaments, however, they do not appear to be major contributors to permeability in the imaged interval and evidence for large, throughgoing NW-trending fractures has so far not been encountered.

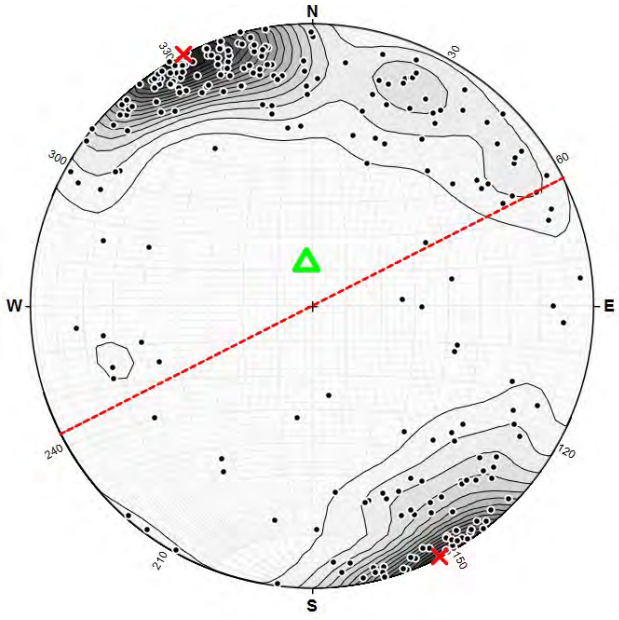

Figure 7: Lower hemisphere stereonet with all fractures identified in the image log (n=248) plotted as black dots representing poles to planes. The trend of the LERZ (063°/243°) is represented by the dashed red great circle, with poles to that vertically dipping plane indicated by red X's. The average attitude of the borehole through the logged interval is plotted as a bold green triangle.

Several tracer studies both pre- and post-eruption have been conducted within the PGV resource to gain a better understanding of potential fluid pathways and the connectivity between production and injection wells. Most notably, tracer studies show a high degree of connectivity within the N63°E-trending rift parallel structures which are well characterized by downhole data including fluid losses during drilling, image logs, and pressure and temperature (PT) surveys.

However, results from multiple tracer studies have also suggested that injection into the northern rift-parallel fractures return to production wells in the southern portion of the reservoir. A cross-cutting structure may explain the connected pathway to allow for the tracer returns. With more recent drilling, additional tracer studies are required to further investigate these potential pathways.

6. Conclusion

The 2024 airborne magnetic survey of the Puna Geothermal Venture within the LERZ has provided a new perspective into the area's magnetic characteristics and structural complexities and has provided a solid foundation for future geophysical interpretation. This survey has identified high magnetic anomalies interpreted as intrusive dikes and thick inflated sheet pāhoehoe flows. In contrast, intermediate and low magnetic anomalies in some areas may be the result of alteration or weathering along mapped fissures and fractures.

Utilizing a multi-disciplinary approach to incorporate the interpretations from this airborne magnetic survey has proven valuable to understanding the geologic structure at PGV. Pairing interpretations from paleointensity data, image logs, and reservoir tracer tests bolsters the interpretation that there are rift-perpendicular structures may exist in the geothermal reservoir and could be conduits for fluid flow. Further integration of these data with existing datasets will improve the geologic conceptual model and inform future resource management decisions.

Further investigation may include additional geophysical investigations, additional injection testing through tracer studies and production data, and geologic mapping. Ground-based electromagnetic geophysics, particularly magnetotellurics (MT), may be helpful in mapping subsurface alteration and understanding the structural controls of the geothermal system, including the geometry clay cap overlying the geothermal reservoir.

Acknowledgement

The authors would like to express our gratitude to our colleagues at Ormat Technologies for their support and encouragement throughout this project. We would like to thank the MWH team for executing this survey in a safe, efficient manner while collecting excellent data. Special thanks to the PGV on-site operational team for their assistance and commitment to safety throughout the duration of the survey. We are very appreciative of our fellow scientists Robin Zuza and Simon Webbison for their insightful feedback and valuable contributions to this study. I would like to express my heartfelt gratitude to my father, John Reynolds, whose passion for geophysics and support have inspired my career path.

Magnetotellurics, 3D inversion, volcanic geothermal systems, deep conductors

ABSTRACT

Elevated temperatures in volcanic geothermal systems result from high heat flow caused by shallow intrusion of magma, driving hydrothermal convection. Understanding the nature and location of magmatic heat sources is therefore relevant for characterizing the geothermal system. Magnetotelluric studies around the world have revealed numerous occurrences of deep electrical conductors below volcanic geothermal prospects. Interpretations of such deep conductors often invoke the presence of magmatic melt and magma derived fluids. However, the architecture of magmatic systems is rather complex and strongly depends on the degree of solidification, residual melt, and volatile content. We describe a selection of scenarios and their impact on geothermal reservoir formation: Under favorable conditions magmatic mush reservoirs in the upper crust can remain stable over long geological timescales thereby providing a constant heat supply for a geothermal system. Undesirable situations are encountered when H_2S from degassing magma combines with water to form sulfuric acid brine, a fluid with exceptional high electrical conductivities. Such acidic hydrothermal plumes can form above largely cooled intrusions and make geothermal drilling unattractive. In cases where volcanic eruption happened through sedimentary overburden, deep conductors may also represent buried fluid-bearing sediments, hence being unrelated to magmatic systems and potential heat sources. Therefore, conclusive interpretations of deep conductors require a comprehensive geoscientific approach. First, a detailed understanding of the geological setting, eruptive history and magma evolution is required and, second, integration of various types of geophysical observables is key to understand the internal structure and fundamental petrophysical properties of deep electrical conductors under volcanic geothermal prospects. Here we present a surface to depth hypothetical model of a volcanic high-temperature geothermal system and a classification or grouping for deep conductors based on the geological setting, volcanic history and experience from well data. As representative examples we

show seven case studies from geothermal prospects in East Africa and Indonesia where deep conductors have been encountered in 3D models.

1. Introduction

Since the beginnings of industrial-scale development of geothermal resources, electrical sounding methods have played an important role in geothermal exploration and for siting drilling targets (Wright et al., 1985). It was recognized early that high-temperature volcanic geothermal reservoirs are often overlain by a pronounced low resistivity layer that is composed of electrically conducting clay minerals, which are produced through hydrothermal alteration (Moskowitz and Norton, 1977). Consequently, electrical resistivity methods became popular in geothermal exploration due to their capability to identify and map the extent of the electrically conductive clay "cap". The clay cap is not only a product of hydrothermal processes and hence a strong indicator for geothermal activity, but it also seals the reservoir top, due to the properties of clays, which swell when in contact with water and form an impermeable layer (Gunderson et al., 2000).

Amongst a variety of active and passive geophysical electromagnetic (EM) sounding techniques, the magnetotelluric (MT) method established itself as a widely used tool in geothermal exploration. MT relies on natural electric and magnetic field variations that originate from global lightning activity and the interaction of the Earth's geomagnetic field with the solar wind (e.g. Vozoff, 1991). The EM source fields are always present, allowing a short deployment time of measurement systems in the field, and MT covers penetration depths relevant for clay cap imaging, reservoir characterization and beyond (e.g. Berktold, 1983; Cumming, 2016; Muñoz, 2013).

In early applications of the MT method in geothermal exploration MT data were generally interpreted using 1D modeling and focused on delineating the clay cap atop the geothermal reservoir (Pellerin et al. 1992, Anderson et al., 2000). 1D imaging of the clay cap is an established application and remains a common method (e.g. Árnason et al. 2010) even after 3D interpretations became feasible with increasing computational capacities. The reason why 1D modelling of MT responses to image the clay cap produces valuable models can be attributed to the strong electrical conductivity signature of the clay cap, which is essentially 1D. Therefore, cross-sections stitched from 1D inversions of the MT responses are still common in geothermal exploration and often used as an initial quality assurance check. Anderson et al. (2000) pointed out that clay cap topography delineated by 1D MT modelling enables the reliable location of geothermal reservoirs, which are encountered under regions of clay cap updoming. 1D models of geothermal areas and prospects often imaged deep electrical conductors below the clay that typically extend from below the clay cap and the geothermal reservoir to greater depths. These deep conductors have been found as early as in studies by Hermance et al. (1976), who interpreted a deep low-resistivity zone beneath Icelandic volcanic prospects as small fractions of basaltic melt. However, quantitative interpretations of deep conductors were hampered by limitations of 1D interpretations of MT data, which provide only a valid approximation for the shallow part near the surface of a volcanic geothermal system. Only in rare cases do MT data obey 1D or even 2D conditions down to larger depths. Owing to their geological nature, volcanic geothermal prospects exhibit strong 3D features that extend from the surface to the lower crust. Deep seated magmatic melt sources feed vertically extensive magmatic pathways that crosscut geological strata and feed shallow melt reservoirs that drive localized hydrothermal fluid flow often hidden under heavily faulted terrain with strong surface topography and steep slopes.

The 3D nature of volcanic geothermal prospects became apparent when 3D MT interpretations of volcanic geothermal prospects provided full-featured 3D images that revealed lateral resistivity variations below the clay cap with vertically extensive transcrustal anomalies raising question about their nature (e.g. Newman et al. 2008, Heise et al. 2015, Hill et al. 2015).

2. Methods

The MT method is an inductive EM sounding technique especially sensitive to electrical conductors (e.g. Vozoff, 1992). MT relies on measuring time series of the natural electric (**E**) and magnetic (**H**) field variations at a specific location (**r**) at the Earth's surface. In the frequency domain (ω) the electric and magnetic field are related through a complex-valued second-rank tensor Z:

$$\boldsymbol{E}(\boldsymbol{r},\omega) = \begin{pmatrix} C_{11}(\boldsymbol{r}) & C_{12}(\boldsymbol{r}) \\ C_{21}(\boldsymbol{r}) & C_{22}(\boldsymbol{r}) \end{pmatrix} \begin{pmatrix} Z_{xx}(\boldsymbol{r},\omega) & Z_{xy}(\boldsymbol{r},\omega) \\ Z_{yx}(\boldsymbol{r},\omega) & Z_{yy}(\boldsymbol{r},\omega) \end{pmatrix} \boldsymbol{H}(\boldsymbol{r},\omega) \quad (1)$$

The impedance Z contains the full 3D information about the electrical resistivity distribution of the subsurface, and is a function of the location (**r**) and frequency ω, which relates to depth. MT electric field data are commonly subject to frequency-independent amplitude changes known as galvanic distortions (e.g. Jiracek, 1990). Distortion is described by a real-valued frequency-independent distortion matrix C. In the ideal case of no distortion present C has the form of the identity matrix and can be omitted from eq. (1).

3D interpretation of MT data requires 3D inverse modelling of the full impedance tensor. In contrast, 1D interpretations of the impedance tensors typically interpret a rotationally invariant of the tensor such as the determinant (Berdichevsky, 1999). For 2D interpretations the impedance tensor is rotated into the direction of geoelectrical strike and only the two modes TE (Z_{xy}) and TM (Z_{yx}) are interpreted. The impedance tensor (eq. 1) can also be affected by galvanic and inductive distortions, which are either caused by small-scale near surface electrical scatterers below the resolution of the data, by pronounced topography (Stark et al., 2013; Käufl et al. 2018), or by a superimposition of both. Concepts to correct for distortions exist for underlying 1D and 2D assumptions (Groom and Bailey, 1989), however, they are strictly speaking not valid for 3D data.

3D inversions can be performed inverting simultaneously for 3D resistivity structure and distortion matrices, with a control parameter that suppresses deviations from the identity matrix, which represents the a priori condition of no distortion (Soyer, 2020). Topographic distortions are addressed by the accurate implementation of topography in the 3D resistivity model (Käufl et al. 2018; Soyer at al., 2019). Another method to bypass distortions is to invert for magnetotelluric phase tensors (e.g. Samrock et al. 2018), a quantity that is unaffected by distortions (Caldwell et al., 2004). 3D inversion of MT data and concepts to address distortion without simplifying assumptions have led to an increasing number of 3D electrical resistivity models of volcanic geothermal prospects that allow for interpretations consistent with theoretical concepts of the architecture of volcanic geothermal systems and geological models. In the following we present a surface to depth hypothetical model of a volcanic hydrothermal system that builds upon existing models with a stronger focus on deep electrical conductors.

Besides geological causes for deep conductors, non-geological sources must be considered as a possible reason. Data distortion, cultural noise and systematic bias in the MT dead band can lead

to geological misinterpretations (Miensopust, 2017; Sato et al. 2017; Hennessy and Macnae, 2018).

3. Comprehensive hypothetical model of volcanic high-temperature geothermal systems

Magma is primarily generated through partial melting processes in the Earth's mantle (Grove and Till, 2015). Melt is generated through two main processes: First, by decompression melting at extensional settings such as continental rifts, in the backarc of subduction zones, at midoceanic ridges and by mantle plume activity. The second melt generation process is through a change of composition in the Earth's mantle that lowers its solidus temperature.

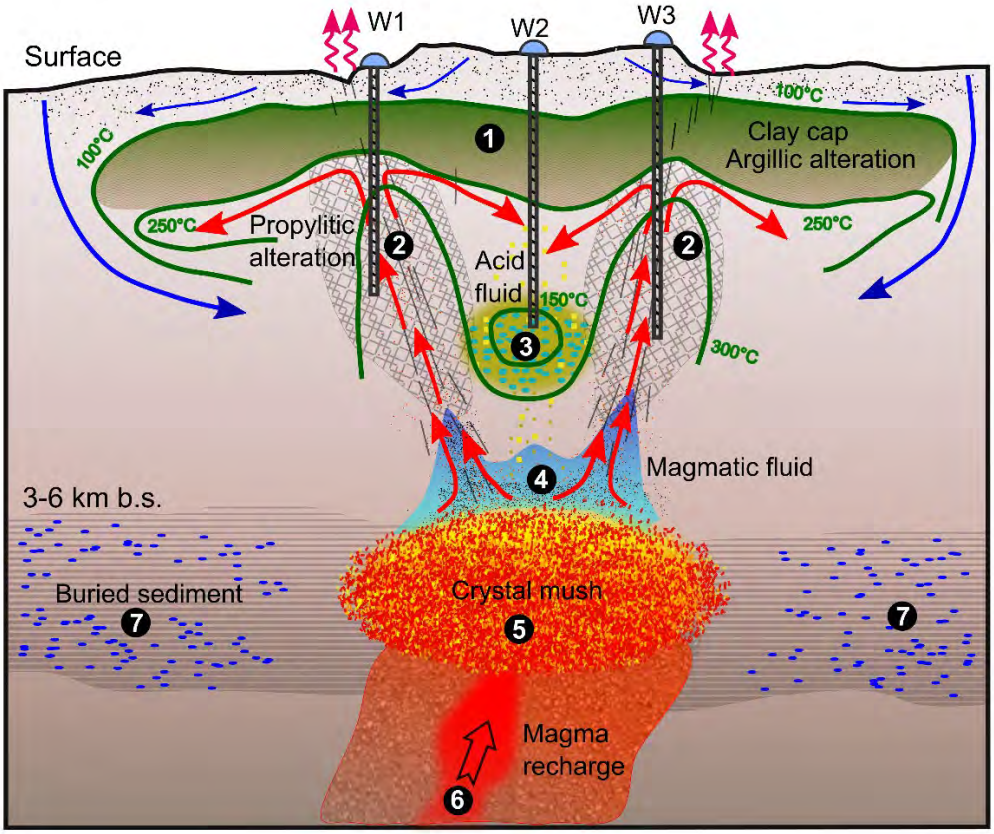

Figure 1: Surface to depth hypothetical model of a volcanic high-temperature geothermal system. The sketch shows the main features of a geothermal system and possible causes for conductive zones below the clay cap. 1) Clay cap: Argillic hydrothermal alteration zone with sealing function atop the reservoir. 2) Propylitic alteration zone below the clay cap, major target for drilling. 3) Acidic hydrothermal plume and formation of pyrite, both form through reaction of sulfur from magmatic degassing with fluids and host rock. 4) Liquid magmatic brine lens with high concentration of dissolved solids. 5) Magmatic reservoir with well interconnected partial melt fraction. 6) Magmatic recharge channel. 7) Buried sedimentary layer.

This process happens e.g. in subduction zones. Magmatic systems are dynamic transcrustal features (Cashman et al., 2017) with a highly complex architecture (Edmonds et al. 2019). Melt eventually reaches the Earth's surface where it erupts in volcanoes or is stored at mid-crustal depths in highly crystalline magmatic mush reservoirs.

Crystal mush reservoirs have relatively small melt fractions and can be in a rheologically locked-up rigid state forming ephemeral systems that undergo increasing solidification through fractional crystallization and degassing (Sparks et al. 2019). Re-melting of crystal mush can be initiated through emplacement of new magma from below at the base of the crystal mush reservoir (Huber at al. 2011). Magma storage in the upper crust drives hydrothermal convection, ultimately leading to the formation of a high-temperature geothermal system (Scott et al. 2015). The architecture of such a system is shown in Figure 1. In the following we will describe the individual geological features and their electrical characteristics. The hypothetical model (Fig.1) builds up and expands work by Berktold (1983), Pellerin et al. (1992), Ussher et al. (2000), Andersson et al. (2000), Cumming (2016) and Samrock et al. (2023) amongst others.

Starting from the surface, the shallow depths of volcanic geothermal prospects are typically composed of fresh volcanic material including pumice, ash, and lava flows. This material is mostly dry and characterized by high resistivity. Going deeper, circulating geothermal fluids lead to the formation of the clay cap (feature 1 in Fig. 1). The clay cap forms through alteration along the flow paths of hot circulating fluids that hydrothermally alter the volcanic host rock producing clay minerals such as smectite (Ussher et al. 2000). These clays are characterized by very low electrical resistivities leading to a pronounced electrically conductive layer atop the geothermal reservoir. The clay cap has also a sealing function due to the tendency of clay minerals to hydrate and swell forming an impermeable layer when exposed to water. Hydrothermal alteration is temperature dependent and with increasing temperature clays produced in the argillic alteration regime become hydrothermally unstable. At higher temperatures propylitic alteration takes place with different alteration products such as chlorite and epidote. These minerals are characterized by much higher resistivities leading to an increase in bulk resistivity in the hotter propylitic alteration zone (feature 2 in Fig. 1) below the clay cap. Its bottom is therefore marked by a pronounced gradient to higher resistivity. Whereas absolute resistivities at the clay cap bottom may vary from place to place, Gíslason et al. (2015) suggest the 10Ωm isoline as a proxy. Observed temperatures at the clay cap bottom vary substantially from prospect to prospect. Ardid et al. (2021) analyzed numerous prospects and inferred an average formation temperature of 198°C at the bottom of the clay cap with a broad range of +48 and -69°C. For the illustration in Figure 2 we use the values reported in Gíslason et al. (2015). Temperatures are hotter in the propylitic alteration zone and in upflow zones that form preferably along geological discontinuities such as faults (Wallis et al. 2017). Since the temperature pattern follows the upflow zones, temperature isosurfaces and hence the argillic alteration front are pushed closer to the land surface leading to the characteristic clay cap updoming above upflow zones (Fig.1; Anderson et al. 2000, Samrock et al. 2023). For a comprehensive database with petrophysical properties, including electrical resistivity of rocks from volcanic geothermal systems, see e.g. Scott et al. (2023).

In the following, low resistivity features below the clay cap and below or within the propylitic alteration zone are referred to as *deep conductors*. Deep conductors can have various origins of which several are described here:

- One reason can be the formation of an acidic hydrothermal plume and a high pyrite concentration. Hydrothermal acid plumes (feature 3 in Fig. 1) form through chemical reactions of sulfur-rich volcanic degassing and water (Byrdina et al. 2018). Byrdina et al. (2018) observed resistivities of acid fluids from Indonesian volcanoes below 0.1Ωm and decreasing resistivities with decreasing pH. Low pH environments also promote the

formation of electrically conductive pyrite (FeS_2) by reaction between H_2S-rich fluids and Fe-rich volcanic rock (Levy et al. 2020).

- Magma-derived fluids that are exsolved from crystallizing melt tend to migrate upwards due to buoyancy forces and may accumulate in the upper part of an active or cooled magmatic intrusion (feature 4 in Fig. 1). Such magmatic brine lenses can be composed of vapor and brine or even supercritical fluids. Romero-Mujalli et al. (2022) analyzed dissolved solutes in hydrothermal end-member fluids from Aso volcano, Japan, and report fluid resistivites as low as 2Ωm. Watanabe et al. (2021) presented an empirical model to calculate the electrical conductivity of H_2O-NaCl fluids for pressures up to 200 MPa and temperatures up to 525°C. Their model shows that magmatic brine lenses have low electrical resistivities at the expected temperature and pressure conditions of a high-temperature geothermal system. Tseng et al. (2020) interpreted a deep conductor with resistivities less than 1Ωm below Kusatsu–Shirane volcano, Japan, as pressurized magmatic brine lens, sealed by an impermeable layer of precipitated silica and halite above.

- Magmatic brine lenses are sourced from deeper magma reservoirs that may exist in form of crystal mush reservoirs (feature 5 in Fig. 1). Crystal mushes have a crystal fraction of minimum 50 to 60 vol.% which is the mechanical threshold when crystals start touching each other and the melt crystal mixture becomes too viscous to flow and erupt (Bachmann and Bergantz, 2008). Samrock et al. (2021) coupled laboratory inferred melt electrical conductivity models and thermodynamic modelling of melt evolution and crystal fractionation to constrain electrical conductivities within crystal mush reservoirs. Their models provide interpretations of deep conductors under volcanic geothermal prospects in the Ethiopian rift that agree with thermodynamic equilibrium conditions and consider crystal mush reservoirs as three phase systems that consist of melt, crystals, and a fluid phase. Cordell et al. (2022) used a similar approach to interpret deep conductors and to constrain magma reservoir conditions by integrating thermodynamic petrological models and resistivities within deep conductors.

- The upper crustal melt reservoir is fed from deeper parental melt sources. Recharge of melt might have ceased or still be ongoing if active magmatic melt channels between the upper crustal melt reservoir and the deeper source region of the melt exist (feature 6 in Fig. 1). Active magmatic pathways will appear as deep rooted conductors below the volcanic geothermal prospect. As an example, Dambly et al. (2023) presented a multiscale magnetotelluric model of a section in the Ethiopian Rift that shows melt generation and transport from the lower crust up to the near surface below the producing Aluto-Langano geothermal field.

- In cases where volcanic eruption happens through deep buried sedimentary layers, deep conductors can be related to fluid bearing sediments under volcanic cover having no volcanic origin (feature 7 in Fig. 1). This situation is encountered in Sumatra where Tertiary transgressive sediments are embedded between older Mesozoic volcanic units and younger Quaternary volcanic overburden (Barber et al., 2005; Mussofan et al., 2016). Despite not having a volcanic origin, deep sedimentary conductors might be falsely interpreted as magmatic heat source. However, if the geological context is known, deep

sedimentary conductors under volcanic prospects might be target zones for drilling since they are often characterized by high permeabilities and provide good reservoir conditions (Ikhwan et al., 2023).

Figure 1 shows a simplified surface to depth sketch of a volcanic geothermal system including its magmatic heat source and shallow clay cap, which is one of the key components of a geothermal system that appears as pronounced shallow low resistivity zone in geophysical models. However, a common mistake is to generally interpret shallow low resistivity zones at volcanic geothermal prospects as clay cap of an active geothermal system. Shallow conductors can also represent clay caps of formerly active geothermal systems, palaeo-outflow zones or sediment basins with smectite-rich volcaniclastics surrounding volcanoes (see e.g. history of exploration at Aluto volcano by Hochstein et al. (2017) and recent geophysical model by Samrock et al. (2023)). The reliable identification of potential target zones for drilling requires holistic conceptual geothermal models that integrate geophysics, geology, geochemistry, and petrology.

4. Examples of deep conductors imaged under geothermal prospects

In our long experience in the field of 3-D MT imaging of volcanic high-temperature geothermal systems, deep conductors appear under about half of volcanic geothermal prospects, whereas other geothermal fields show no indications for deep conductors (e.g. Soyer at al., 2018). In the following we present vertical sections of 3-D magnetotelluric models from volcanic geothermal fields, where deep conductors have been encountered. Note, all presented models have a very good data fit and a small rms misfit value. In addition, multiple modelling and inversion tests demonstrated the sensitivity of the data to the deep conductors.

Figs. 2 to 4 show three examples of deep conductors encountered below volcanic geothermal prospects in Indonesia. A detailed interpretation is beyond the task of this work and data availability is limited; however, all three prospects have a long eruptive history and active geothermal surface manifestations. The conductor below Sibayak (Fig. 2) is clearly deep rooted, which is indicative of an intrusive origin.

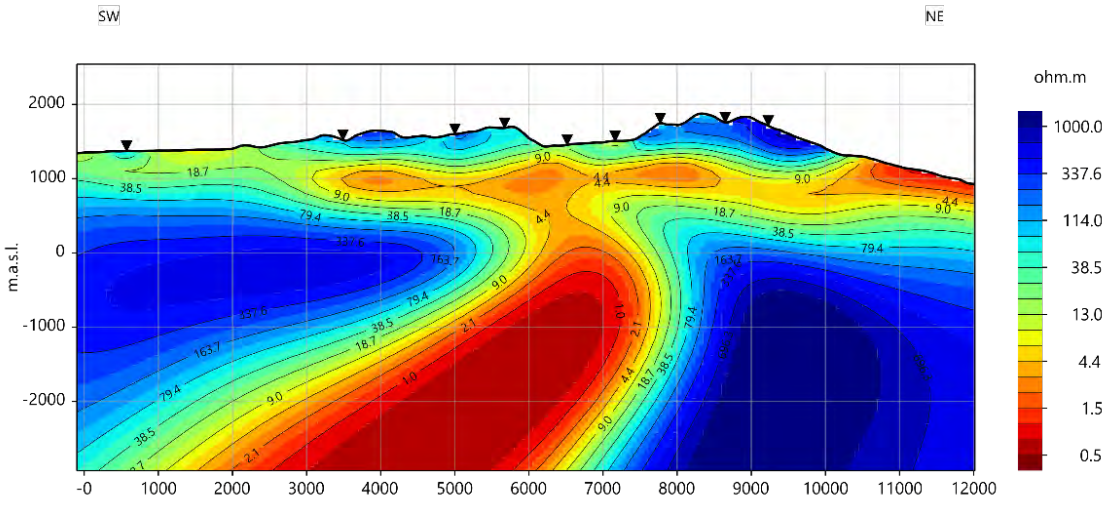

Figure 2: Deep conductor imaged below Sibayak, Indonesia.

Geochemical analyses of aqueous fluids from Sibayak reveal a dominant magmatic volatile contribution and components of quenched magmatic gases (Fahmi et al., 2020). Sibayak belongs to the Singkut caldera from which Forni et al. (2024) report eruption of crystal-rich magmas and geochemical evidence for long-lived large cumulate crystal mushes.

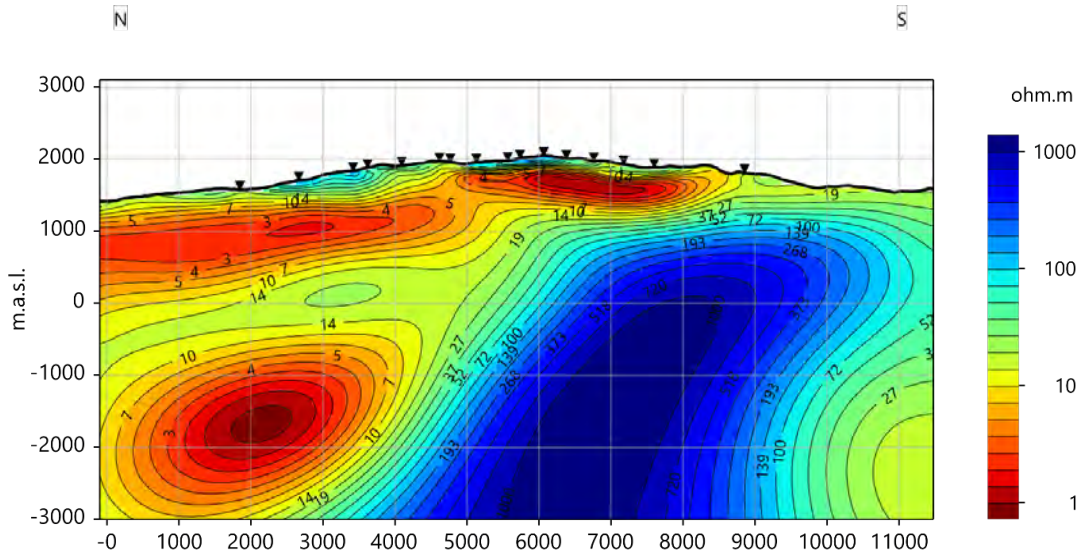

Figure 3: Deep conductor imaged below Patuha, Indonesia.

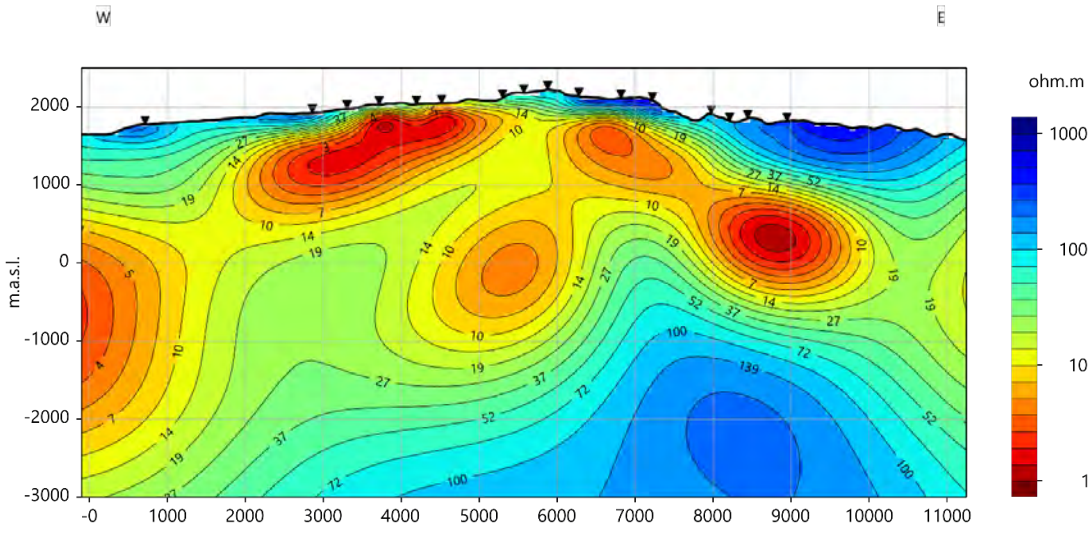

Figure 4: Deep conductor imaged below Dieng, Indonesia

Not enough data are available from Patuha (Fig. 3) and Dieng (Fig. 4) to provide a conclusive interpretation of the deep conductors. In view of the absence of deep roots and considering the isolated shapes of the deep conductors it could be argued that they represent fluid-rich zones, magmatic brine lenses, or hydrothermal fluid plumes with end-member compositions.

Figures 5 to 7 show cross-sections through 3-D MT models from geothermal prospects in the East African Rift. Corbetti (Fig. 5) is a volcanic geothermal prospect in the Main Ethiopian Rift. Geodetic and gravimetric studies proposed ongoing magmatic intrusion below Corbetti (Gottsmann et al. 2020). The location of the deep conductor agrees well with the location of the intrusion proposed by Gottsmann et al. (2020) and was confirmed in an independent MT study by Dambly et al. (2024). Dambly et al. (2024) interpreted the deep conductor in Fig. 5 as crystal mush and inferred 20 to 35 vol. % rhyolite melt in its upper part. Their melt estimates are based on empirical conductivity models for melt and consider temperature and melt composition consistent with thermodynamic equilibrium conditions of rhyolite melt (Cordell et al. 2022).

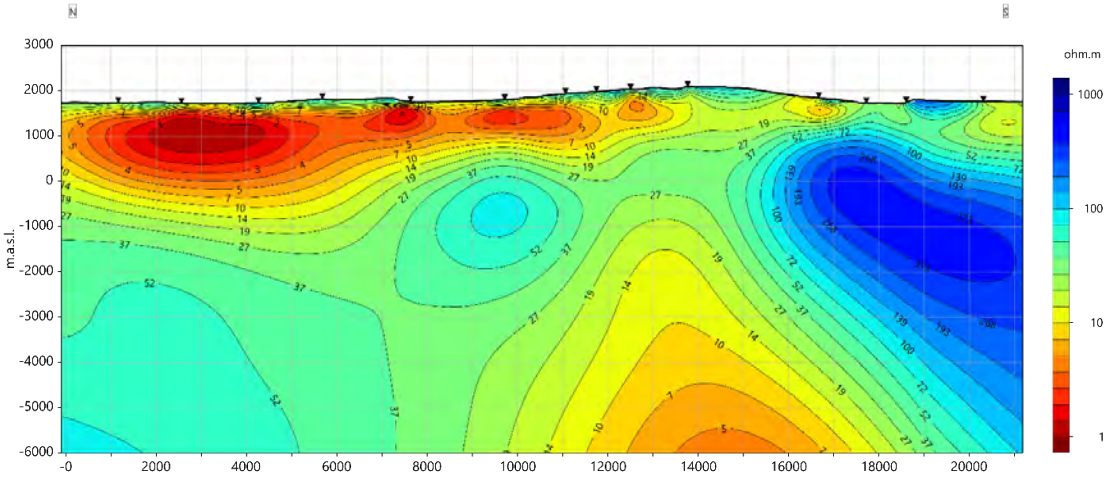

Figure 5: Deep conductor imaged below Corbetti, Ethiopia.

Samrock et al. (2021) presented models from the Aluto and Tulu Moye geothermal prospects in the Ethiopian rift (Fig. 6). They invoke magmatic causes for imaged deep conductors and the presence of upper crustal crystal mush reservoirs with deep-routed magmatic recharge channels. In their studies they combine modelling of phase equilibria in cooling magma and laboratory measurements of electrical properties of melt to derive the evolution of electrical conductivity in a crystallizing silicic magmatic system. Their study considers magma reservoirs as three-phase systems composed of crystals, melt and fluids and shows that different resistivities in the interpreted deep conductors can be interpreted to reflect different stages of melt evolution, temperature, and composition. A detailed discussion of the electrical resistivity model of Aluto and well data can be found in Samrock et al. (2023). The existence of the imaged deep conductor was confirmed by Dambly et al. (2023), who presented a multi-scale cross-rift model of the area that images the extend of the deep conductor down to a magma ponding zone at the base of the crust in agreement with other geoscientific models and the conceptual understanding of magma-assisted rifting in the Ethiopian Rift.

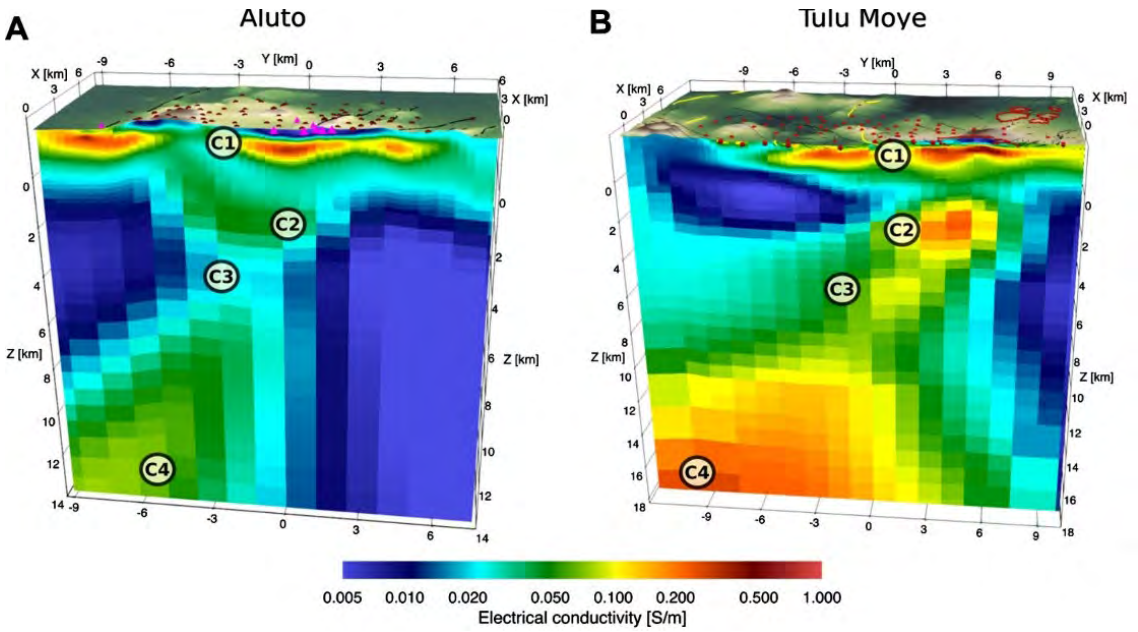

Figure 6: Deep conductors imaged below Aluto (A) and Tulu Moye (B) geothermal prospects in the Ethiopian Rift. Figure taken from Samrock et al. (2021). The two volcanoes are about 50km apart. The authors interpret C1 as clay cap, C2 as gas-rich crystal mush reservoir, C3 as magmatic recharge channel and C4 as deep parental melt region. The differences in electrical resistivity are interpreted in terms of different stages of melt evolution. For details see Samrock et al. (2021) and Dambly et al. (2023).

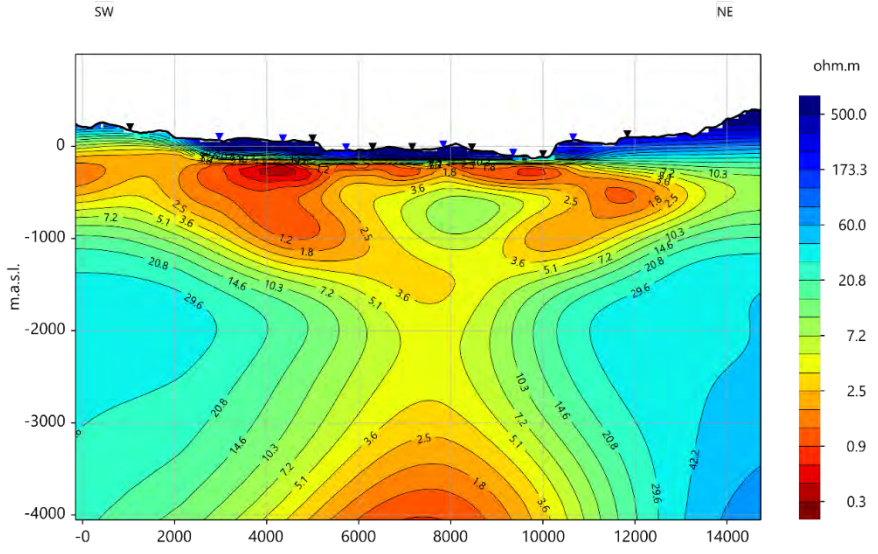

Figure 7: Deep conductor imaged below Asal Fiale, Djibouti.

Asal (Fig. 7) is a geothermal field in Djibouti and lies at the northern end of the East African Rift where continental rifting is in its final stages. The volcanic geothermal prospect is located between the bay of Ghoubbet and Lake Asal and it is characterized by seafloor type hydrothermal activity. The last volcanic eruption occurred in 1978 (e.g. Sakindi, 2015). Varet et al. (2014) report several

events of abrupt heating of the geothermal reservoir that occurred between 1991 and 2001 subsequent to magma injection. The MT model of Asal shows a pronounced deep conductor at depths below 3km b.s.l. (Fig. 7). A magmatic origin of the deep conductor is likely considering ongoing volcanic activity in the area. The interpretation of low electrical resistivities being related to presence of melt at depths below 3km b.sl. agrees with studies by Pasquet et al. (2023) and their presented geological model of the area.

5. Conclusions

Deep conductors under volcanic high-temperature geothermal systems can have many origins that range from magma-related processes and favorable conditions like stable crystal mush reservoirs that represent powerful heat sources, to unfavorable conditions like acidic hydrothermal plumes that cause corrosion of geothermal wells and facilities. Even amagmatic causes are possible in cases where volcanic eruption happens through sediments. The described causes for deep conductors provide only a selection, and thus, an incomplete overview. Interpretation of deep conductors requires detailed knowledge of the geological context and eruptive history of the volcanic geothermal prospect. More work is required in the field of melt electrical conductivity models to provide more complete models for composition-dependent melt resistivities. More research is also required to understand bulk resistivities of reactive multiphase magmatic systems that consist of melt, solid, and fluids in different states from liquid to vapor and supercritical. In reactive systems traditional multi-phase mixing laws to derive bulk resistivities do not apply. Finally, yet importantly, the quality of MT data used to derive 3D resistivity models must be critically evaluated and the robustness of imaged deep conductors must be tested. It must be considered and investigated whether deep conductors might be artifacts with no geological explanation caused by poor data quality and systematic data bias. Currently, there is a lack of examples where deep conductors under volcanic geothermal prospects were identified as false structure and evidently caused by noise, data gaps or inversion limitations. Future studies should also present such cases and address the identification of corrupted data, statistical biases and resulting artifacts in 3D models.

Acknowledgement

The authors would like to express their gratitude to PT Geo Dipa Energi, Pertamina Geothermal Energy, Reykjavik Geothermal, ODDEG and Jacobs for the permission to publish results from the 3D inversion modeling of MT data from Patuha and Dieng (PT Geo Dipa Energi), Sibayak (Pertamina Geothermal Energy), Corbetti (Reykjavik Geothermal) and Asal Fiale (ODDEG, Jacobs). We thank the two reviewers Karen Christopherson and William Cumming for their valuable comments, which helped to improve the manuscript. FS thanks Reykjavik Geothermal, the Geological Survey of Ethiopia and colleagues from Addis Ababa University and ETH Zurich for their essential contributions to the Ethiopian studies.

Heat Flow, Thermal Infrared, Calorimetry, Taupo Volcanic Zone,

ABSTRACT

Assessing the surface heat loss in geothermal areas can provide information and insight into the size and character of underlying geothermal resources. It also provides a means to monitor changes at the surface of a geothermal system and assess geothermal hazards in response to natural and/or development of the geothermal system over time.

Aerial thermal infrared methods provide a quick, easy and safe means to identify heated areas (including water bodies and steaming ground). Over the last decade we have developed methods which relate ground-based measured heat flow to aerial thermal infrared measurements. Empirical relationships are derived which relate thermal infrared measurements to ground-based calorimetry measurements. These are then used to calculated heat loss from thermal infrared data for field-wide heat-loss assessments.

This method has been developed and applied to several geothermal fields within the Taupō Volcanic Zone, located in the central North Island, New Zealand. Each geothermal field has its own unique characteristics which need to be taken into consideration when assessing heat loss. The Karapiti area, part of the Wairakei Geothermal Field, is dominated by steam heated ground while Waiotapu Geothermal Field has a lot of water features and very little heat loss through the ground. These areas require slightly modified approaches to estimate heat loss. For fields with springs and/or thermal streams, ground-based assessments of flow rate and water temperature are also needed to assess the convective heat loss through mass flow.

This paper will overview the approach taken in developing the method, and comparisons between aerial and terrestrial based heat loss assessment at different geothermal fields in the Taupō Volcanic Zone. The true benefit of this method is that field-scale heat flow assessments can be made relatively rapidly with reduced uncertainties compared to ground-based estimates. The techniques also remove a high level of health and safety concerns associated with conducting fieldwork within active geothermal areas.

1. Introduction

Geothermal pools, springs and areas of steaming ground originate from discharges of geothermal fluids and vapour through the subsurface (Figure 1). Accurately quantifying and monitoring surface heat-loss is difficult and can be time-consuming and expensive. However, heat-loss data is becoming ever more important for calibrating and informing geothermal reservoir models and understanding geothermal heat use potential. This paper describes research undertaken over the last decade to improve the quantification of heat-loss assessments using remote TIR techniques and ground-based temperature and calorimetry measurements.

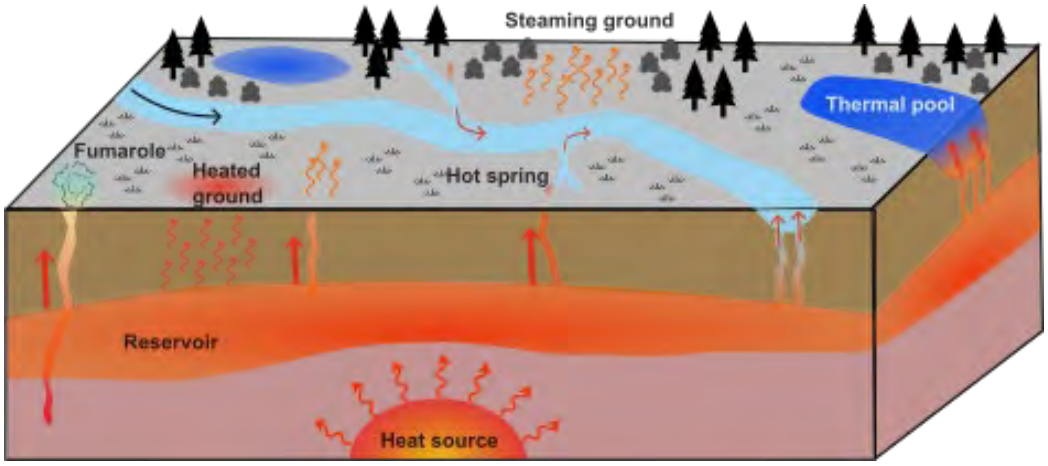

Figure 1: Typical setting of the geothermal area, adapted from Wang and Pang 2023

Investigations into heat flux from geothermal and volcanic areas can be traced back to 1950s (e.g. Bensemen, 1959), with improvements in techniques, approaches and technologies developed over the years (Wang and Pang, 2023; Hochstein and Bromley, 2005; Seward et al, 2023). Documented methods include: calorimeter measurements to determine the total heat flux through the surface of the ground (e.g., Benseman, 1959; Hochstein and Bromley, 2005); the ground temperature-depth profile method (e.g., Hurwitz et al., 2012; Wang et al., 2019); the thermal infrared remote sensing (TIR) method based on the radiative heat loss (e.g., Allis et al., 1999; Eneva et al., 2006; Vaughan et al., 2012; Bromley et al., 2015; Seward et al, 2018a); Satellite infrared (e.g. Andres and Rose, 1995; Mia et al, 2012; 2013; Vaughan et al, 2012; Ramirez-Gonzalez et al., 2019); the chloride content balance method using the concentration of chloride in run off and streams (e.g., Ellis and Wilson, 1955; Ingebritsen et al., 2001); CO_2 surface emissions (e.g., Fridricksson et al, 2006; Yang et al, 2023), and a combinations of two or more approaches (e.g., Bouligand et al., 2019; Favorito et al., 2021; Seward et al, 2018a).

Early assessments of heat loss in New Zealand focused on the heat output of individual surface features, however, this assessment can be unreliable as natural fluctuation and changes in subsurface flow paths can result in cyclic or changing behavior of springs and flowing fluids (e.g., Fisher, 1964; Thompson et al., 1961). Other methods have included chloride flux analysis of discharging fluids (e.g. Nairn and Findlayson, 1981; Bibby et al., 1995; Glover, 1992; Seward and Kerrick, 1996), relationships between the measured ground temperature at 15 cm depth and surface

heat flux (Dawson 1964; Allis, 1981; Fridriksson et al., 2006), surface heat flux based on shallow (1 m deep) temperature-depth profiles (Bromley and Hochstein, 2000; 2005; Hochstein and Bromley, 2001, 2005; Bromley et al., 2011), and aerial and/or satellite thermal infrared (TIR) imagery (e.g. Mongillo and Bromley, 1990; Mongillo, 1994; Mongillo et al., 1995; Mia et al., 2013; Reeves and Rae, 2016; Seward et al., 2018a).

1.1 New Zealand Geothermal setting

New Zealand's land mass lies on the plate boundary between the Pacific and the Australian Plates. Beneath the North Island, the Pacific Plate subducts under the Australian Plate, resulting in a rift system, known as the Taupō Volcanic Zone (TVZ). Twenty-two active high temperature (> 225°C / 435°F) geothermal systems are present within the TVZ, of which seven generate electricity from the resource (Figure 2). Other geothermal fields have varying amounts of utilization, with others having little or no utilization because they are classified as protected.

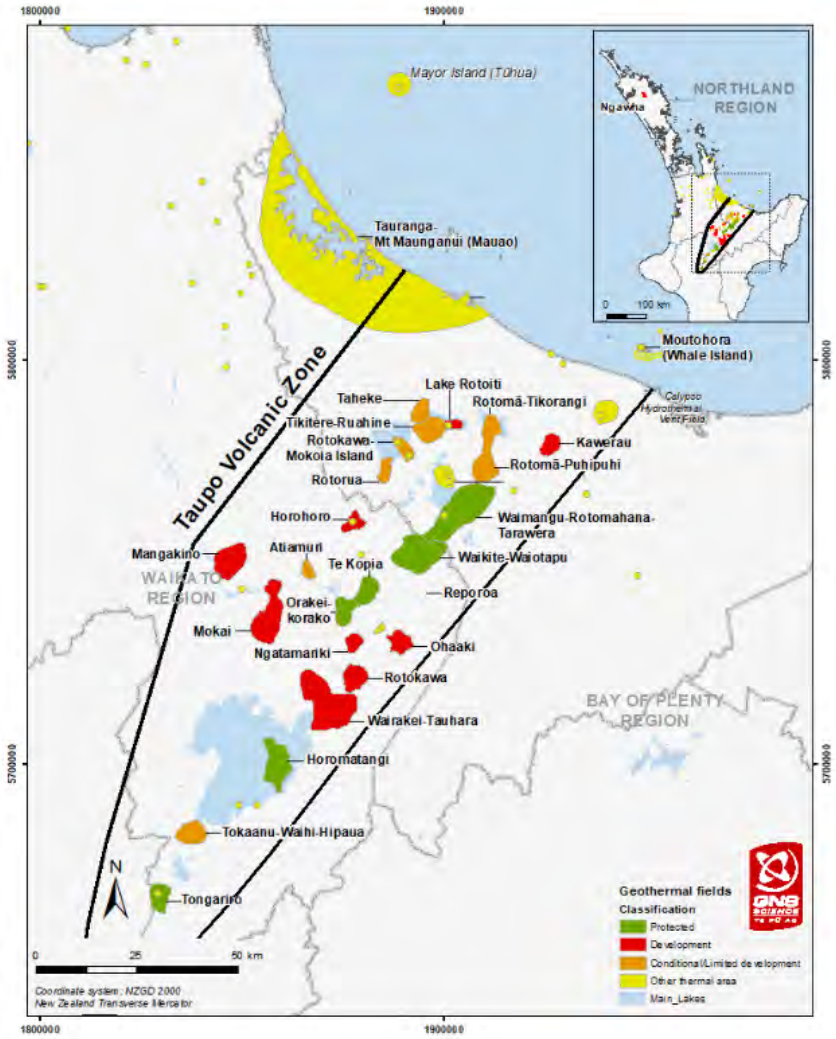

Figure 2: High temperature geothermal fields in the Taupo Volcanic Zone, North Island, New Zealand. Insert shows the location of Ngawha high temperature field, outside of the Taupo Volcanic Zone.

Many of the geothermal systems contain geothermal surface features, including, areas of heated or steaming ground, hot pools, springs and seeps, and fumaroles. The heat lost through these features provide insight into the geothermal resource and can provide a means to identifying changes to the geothermal system. Additionally, these features are of great cultural and economic importance. Geothermal waters are considered Taonga (treasure) by New Zealand's indigenous Māori, with many early settlements located in the proximity of natural geothermal surface features. The protection of these surface features is not only culturally important but also provide a great source of income to local communities with geothermal recreation in the Bay of Plenty estimated to be valued between NZ$90-120M per annum (Bay of Plenty Regional Council, 2018), and Waikato estimating geothermal tourism providing between NZ$63-120M per annum (Barns and Luketina, 2011). These published figures are both out of date, however numbers are thought to be similar today (*pers comm* WRC & BOPRC). It is therefore vital that the use of the geothermal resources is done so in a sustainable and environmentally friendly way so that cultural values and community values are maintained.

2. Methods:

The objective of this study is to assess surface heat loss using remote sensing methodologies. We explore and compare heat loss assessments from both terrestrial based datasets and methodologies, with aircraft collected TIR data.

Heat is lost to the atmosphere within geothermal environments through varying surface manifestations, including hot springs, geysers, hot pools, mud pools, heated and steaming ground, and fumaroles (Figure 1). The heat output from these surface phenomena is often difficult and hazardous to measure.

2.1 Terrestrial based methods

There are several components to consider in determining heat loss for a geothermal area. They include heat loss to the atmosphere from heat transferred through heated ground (section 2.1.1), and from geothermal water bodies, including surface hot pools, and springs (section 2.1.2), and also heat transferred into streams through subsurface seeps, and springs, and also surface flows accumulated in streams (section 2.1.3). The follow sections describe methods for data collection and analysis for each component.

2.1.1 Heat loss through the ground

Two methods have been used to calculate a surface heat flux from the ground, one using a water-based calorimeter, and the other using temperature depth profiles. To get a total heat loss for a geothermal area, sites are selected to represent a predefined ground-cover type, following the assumption that different vegetation types grow in different shallow subsurface thermal regimes (Dawson and Dickenson, 1970; Allis, 1981; Smith, 2013). An average heat flux for each ground-cover class is determined and assigned to the area of like groundcover to determine a surface heat loss for a field.

2.1.1.1 Calorimeter method

One technique for determining surface heat flux is using a water-based calorimeter (Hochstein and Bromley, 2005; Seward et al 2018a). The calorimeter records linear increases in temperature of water (starting from near-ambient conditions), caused by steady ground heat transfer over a set amount of time (e.g. 5 minutes), while covered by the calorimeter. This allows a total heat flux from the surface to be determined. Increase in water temperature while the calorimeter is slightly elevated (on a 2 cm ring) over a similar period of time (e.g., 5 minutes) allows the radiation and convection heat flux from the surface to be determined. Before, after, and in-between ground and elevated measurements, the calorimeter is insulated from the ground to measure "background" atmospheric influences (e.g. air temperatures). Figure 3 shows an example of the recorded temperature in the water-filled calorimeter over a total site occupation period of about 30 minutes.

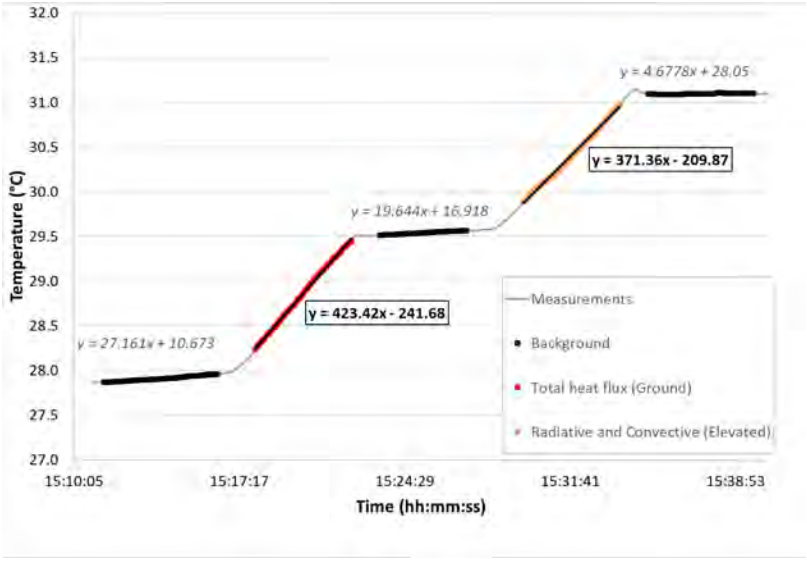

Figure 3: Example of calorimeter data measurements used to calculate heat flux at a measurement site.

The total heat flux is determined using EQ 1:

$$q_{tot} = \frac{mc\left(\frac{\Delta T_g}{\Delta t} - \frac{\Delta T_{lid}}{\Delta t}\right)}{A} \quad \textbf{(EQ 1)}$$

Where, $\frac{\Delta T_g}{\Delta t}$, is the temperature gradient determined while the calorimeter is placed on the ground, $\frac{\Delta T_{lid}}{\Delta t}$, is the change in atmospheric temperature (lid sensor), *m* is the mass of the water within the calorimeter, *c* is the specific heat capacity of water and *A* is the footprint area of the calorimeter. This equation can also be used to determine the radiative and convective heat flux components by substituting $\frac{\Delta T_E}{\Delta t}$ (thermal gradient measured when the calorimeter is elevated) for $\frac{\Delta T_g}{\Delta t}$ into the equation.

2.1.1.2 Temperature-depth Profiles

An alternative approach to determine ground heat flux is from ground temperature-depth profiles (e.g. Hochstein and Bromley 2005; Seward et al., 2018a), where the depth (Z_{BP}) at which boiling temperatures are reached are determined (EQ 2) and converted into heat flux (EQ 3). The depths to boiling points are either measured directly when Z_{BP} is less than 1 m or inferred from extrapolating a fitted exponential function to the temperature-depth data.

$$Z_{BP} = exp[c_1(T_{BP} - T_z)] \quad \textbf{(EQ 2)}$$

Where T_z is the temperature at depth z, T_{BP} is the temperature at which boiling occurs (i.e. T = 98.8°C in the Taupo area), and c_1 is a constant derived by Hochstein and Bromley (2005) at the Karapiti geothermal area (–0.025).

Heat flux is then calculated from the boiling point depth using the following power-law relationship (Hochstein and Bromley 2005).

$$q_{ZB} = a\left[\frac{Z_{BP}}{Z_0}\right]^{-b} \quad \textbf{(EQ 3)}$$

Where a and b are empirically derived constants determined through comparisons of temperature-depth profiles with calorimeter measurements at the same locations. For the Taupo area, a = 148 Wm^{-2} and b = 0.84 (Seward et al. 2018a), and Z_0 is a normalised depth (1 m).

2.1.2 Heat loss from water features (pools and streams)

We use the methods developed by Dawson (1964) and converted to SI units by Sorey and Colvard (1994), to calculate a heat loss from water bodies. Although other methods for deriving heat loss from heated pools have been developed by many (e.g. Lund 2000; Ryan et al, 1974; Shanahan, 1984), Bloomer (2012) suggests Dawsons (1964) method is the most applicable for a variety of temperatures and pool sizes. There are four key mechanisms for heat loss from water bodies to consider when assessing total heat loss. They are evaporation (Q_E), conduction (Q_C), radiation (Q_R) and direct mass flow (Q_S). Dawson (1964) developed the following set of empirical equations to determine each component (in kW).

$$Q_E = 0.001 * A\left(h_{s,Tp} - h_{w,Tp}\right)(0.0065 + 0.0029w)\frac{\left(P_{H2O,tp} - P_{H2O,atm}\right)}{P_{atm}} \quad \textbf{(EQ 4)}$$

Where A is the surface area of the pool (m^2), $h_{s,Tp}$ is the enthalpy of the steam at pool temperature (T_p) (Jkg^{-1}), $h_{w,Tp}$ is the enthalpy of water at pool temperature (Jkg^{-1}), w is the wind speed (ms^{-1}), $P_{H2O,tp}$ is the vapour pressure of water at T_p (bar), $P_{H2O,atm}$ is the atmospheric vapour pressure (bar) and P_{atm} is the average annual atmospheric pressure in bar.

The heat loss by conduction and molecular diffusion, Q_C, is related to Q_E by the Bowen ratio, RB (Sutton 1953).

$$RB = \frac{Q_C}{Q_E} = 6.1 \times 10^{-4} P_{atm}\frac{\left(T_p - T_{atm}\right)}{\left(P_{w,tp} - P_{w,atm}\right)} \quad \textbf{(EQ 5)}$$

where T_{atm} is the atmospheric temperature (°C).

$$Q_R = 0.001 * A\varepsilon\sigma(T_P^4 - T_{atm}^4) \quad \textbf{(EQ 6)}$$

where ε is emissivity (0.955 for water), σ is the Stefan-Boltzmann constant (5.67 x 10^{-8} $Wm^{-2}K^{-4}$), and T_P and T_{amt} refer to the temperature of the pool (*P*) and ambient air (*amt*) temperature (°K).

Heat loss through mass discharge of flowing springs and overflow of pools can be determined by:

$$Q_S = M_w(h_w - h_{atm}) \quad \textbf{(EQ 7)}$$

where M_w is the mass flow of heated water in kgs^{-1}, h_w is the enthalpy of the discharging water in $KJkg^{-1}$ and h_{atm} is the enthalpy of water at the atmospheric temperature in $KJkg^{-1}$ (Sorey and Colvard 1994).

Therefore, the total heat loss (Q_{WB} (MW)) is represented by:

$$Q_{WB} = 0.001 \times (Q_E + Q_C + Q_R + Q_S) \quad \textbf{(EQ 8)}$$

2.1.3 Assessment of geothermal heat loss into streams

Two methods for determining the heat flow within a stream are compared to determine heat loss through surface discharges into streams. The first method below is a similar approach to that described above (EQ 7), where heat loss (MW) is determined from the enthalpy of stream water (calculated from stream temperatures) and flow rate (*V*)

$$Q_T = 0.001 \times H_T V \quad \textbf{(EQ 9)}$$

Where H_T is the enthalpy of the stream at measured temperature (*T*) (KJ/kg) and *V* is the measure flow rate of the stream (kg/s).

In the second approach, heat loss (MW) is calculated from chloride flux (F_{Cl}) and the enthalpy of the deep geothermal water associated with chloride (Glover 1992; Bibby et al 1995).

$$Q_{Cl} = 0.001 \times F_{Cl}H_{Cl} \quad \textbf{(EQ 10)}$$

This second method assumes that the chloride content of surface water provides a direct measure of amount of deep geothermal fluid reaching the surface (Ellis and Wilson, 1955; Hochstein, 1988; Giggenbach et al 1994). The chloride flux method assumes that the ratio of enthalpy to chloride concentration from deep reservoir fluid is constant and that all chloride in the up flowing geothermal water is discharged at the surface (Bibby et al, 1995).

2.2 Aerial Thermal Infrared

Thermal Infrared data are collected by mounting a TIR camera to an aircraft (either a helicopter or a fixed wing plane), and flying survey lines at a known elevation over a survey area. The collected images are mosaicked and geo-registered to aerial photography. Inferred surface temperatures are

calculated per pixel by applying a calibration equation derived from measured water temperatures at known locations collected at the time of the flight. Heat loss through the ground and through water bodies are determined separately, as the emissivity's of the surfaces are different (Seward et al 2018a).

Heat loss (q (m^2)) through ground surfaces is determined using a direct empirical relationship between TIR inferred surface temperatures ($T_{(inferred)}$) and measured heat flux, and is given in EQ 11:

$$q_{TIR} = 50.3 \times \left(T_{(inferred)} - T_{(ambient)}\right) - 148 \quad \textbf{(EQ 11)}$$

Where $T_{(ambient)}$ is the measured ambient air temperature at the time of the TIR data collection, and a is the pixel area (m^2). The empirical equation was determined by Bromley et al (2011), from 8 years of measurement at the Tauhara Geothermal Field and was further tested at the Wairakei Geothermal Field (Bromley et al., 2015).

An average heat flux per image pixel is calculated from the inferred surface temperatures and summed to get a fieldwide heat loss value.

$$Q_{totTIR} = \sum q_{TIR} \times a \quad \textbf{(EQ12)}$$

Equations EQ4 - EQ8 are used, to determine the heat loss from non-flowing water bodies (i.e. pools and lakes). The surface areas (A) of the features are determined from the TIR image, and inferred surface temperatures per pixel are used for T_w. While enthalpy (H), and vapour pressure (P) are determined from the inferred surface temperatures.

3. Results and discussion:

This approach has been tested and developed over several different active geothermal fields, with the initial investigation being undertaken in areas within the Wairakei and Tauhara Geothermal Fields (Figure 2; Hochstein and Bromley, 2005; Bromley et al, 2011; Seward et al., 2018a). These thermal areas are now largely steam driven features, consisting predominately of heated and steaming ground. Seward et al. (2018a) applied the relationship (EQ3) developed by Hochstein and Bromley (2005) and revised the empirically derived constants using 85 Q_{tot} and Z_{BP} data collected between 2001 and 2014 at the Karapiti geothermal site, within the Wairakei Geothermal Field. Results using the revised values showed close correlation between the two terrestrial heat loss methods and the aerial TIR assessment (Table 1).

Table 1: Results from heat loss assessments at Karapiti (Seward et al 2018a). The 18°C cut off for Q_{TIR} reflects the ambient temperature at the time of the TIR survey.

	Heat loss (MW)
TIR Results	
Q_{TIR} for land pixels T>18°C only	49
Terrestrial Results	
Q_{tot}	47.6
Q_{ZB}	58.2

This method was further developed at Rotorua (Seward et al., 2018b), Waimangu (Seward et al, 2023) and Waiotapu Geothermal Fields (Seward et al., 2024), where pools, lakes and flowing streams also contribute to the surface heat loss from these geothermal systems.

At the Waimangu Geothermal Field, comparisons between using the terrestrial based measurements and aerial TIR inferred temperatures to calculate evaporative surface heat loss from large lake surfaces show that the methods provided very different results (Seward et al 2023; Table 2).

Table 2: Comparisons between heat loss values determined from terrestrial measurement and remote TIR data (Seward et al 2023).

Lake	Measured temperature at outlet (°C)	Q_E (MW)	Inferred pixel temperatures (°C)	$Q_{E\text{-}TIR}$ (MW)
Frying Pan Lake (surface area = 35800m^2)	48.7	49.5	23-85	83.8
Inferno Crater Lake (surface area = 6650m^2)	51.3	10.6	20-78	22.3

The key observations from the comparison in Table 2, is that the temperature measured at the outflow or edge of a large water body is not representative of the whole lake (Figure 3). Using terrestrial based measurements alone results in an underestimated heat loss over large surface areas of geothermal lakes, were evaporation and cooling of lake fluids occur between the source and outflow.

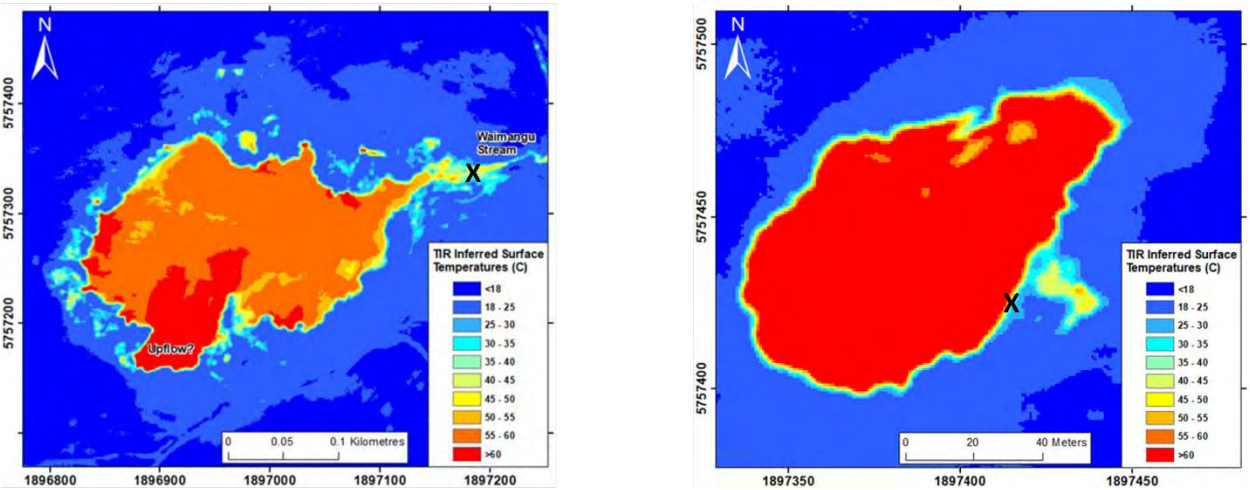

Figure 3: TIR image of (a) Frying Pan Lake and (b) Inferno crater Lake. "X" mark the indicative location of terrestrial based measurement (Seward et al, 2023).

Additionally, further considerations into the effects of varying wind speeds across the surface of large water bodies needs to be considered. For all field assessments, we have assumed an average windspeed of 1ms^{-1}. We are aware that this is likely to result in an underestimation of heat loss in exposed areas and water bodies with large surface areas. Using the TIR data may reduce this effect, by detecting the resulting changes in water surface temperatures (Seward et al, 2018a).

For smaller water bodies, we believe that terrestrial based water temperatures combined with surface areas derived from visual or thermal aerial images provide the best estimations, particularly, for those features with water temperatures > 60°C (Seward et al, 2022). At these elevated temperatures steam is often produced which can mask the thermal signature of the water body, often resulting in cooler than measured inferred surface temperatures (derived from TIR data; e.g Figure 4). As steam is often transient, it is very hard to quantify and account for this effect.

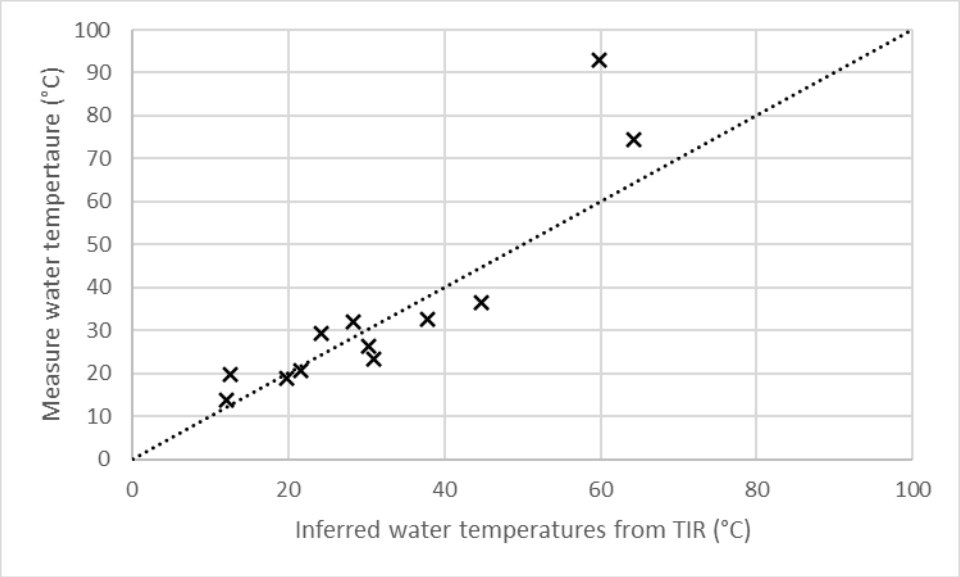

Figure 4: Comparisons of measured water temperatures and inferred surface temperatures from water features located at the Waiotapu Geothermal Field (Reeves and Sanders, 2019).

The effect of steam and evaporation can also affect the results of heat loss from mass discharge to streams. Equations 7 and 9, use the measured water temperature to determine an enthalpy of the flowing water. At higher temperatures, evaporation can result in cooler surface water temperatures, and this suggests that the chloride flux method may be more accurate for estimating advective heat loss from a geothermal system, provided a chloride content of the deep geothermal parent water is known and the chloride concentration in the discharge waters can be measured with sufficient accuracy.

Further complexities were identified at the Waiotapu Geothermal Field, where large difference between heat losses calculated from calorimeter measurements (q_{tot}) and depth-to-boiling point (q_{ZBP}) were measured. Seward et al, (*under review*) discussed the possible causes of these results and concludes potentially two key reasons for the differences. The first of which was related to the measurements made by the calorimeter. At the time of data collection, air temperatures were high (28-40°C) resulting in little temperature change measured during the measurement as the air temperature was very close to the ground surface temperature. The second potential cause is related to the structure of the subsurface. Temperature-depth profiles indicated elevated heat flux compared to the surface measurements, suggesting that there is high heat in the shallow subsurface (< 1m) that is not reaching the surface. Seward et al (*submitted*) suggest that it could potentially be caused by a small scale “heat pipe”-like mechanism, where heat in the form of steam is rising from depth but reaches an impermeable structure (e.g. clay or sinter), resulting in condensation of

steam, which then descends, due to gravity, back to depth. This interpretation of the differences between the terrestrial measurements is supported with TIR data (Figure 5), that identifies very little heat loss from the ground surface. The majority of heat loss at the Waiotapu Geothermal Field appears to be reaching the surface through the water features (Seward et al, 2024; Rodrigues-Gomez et al., 2023).

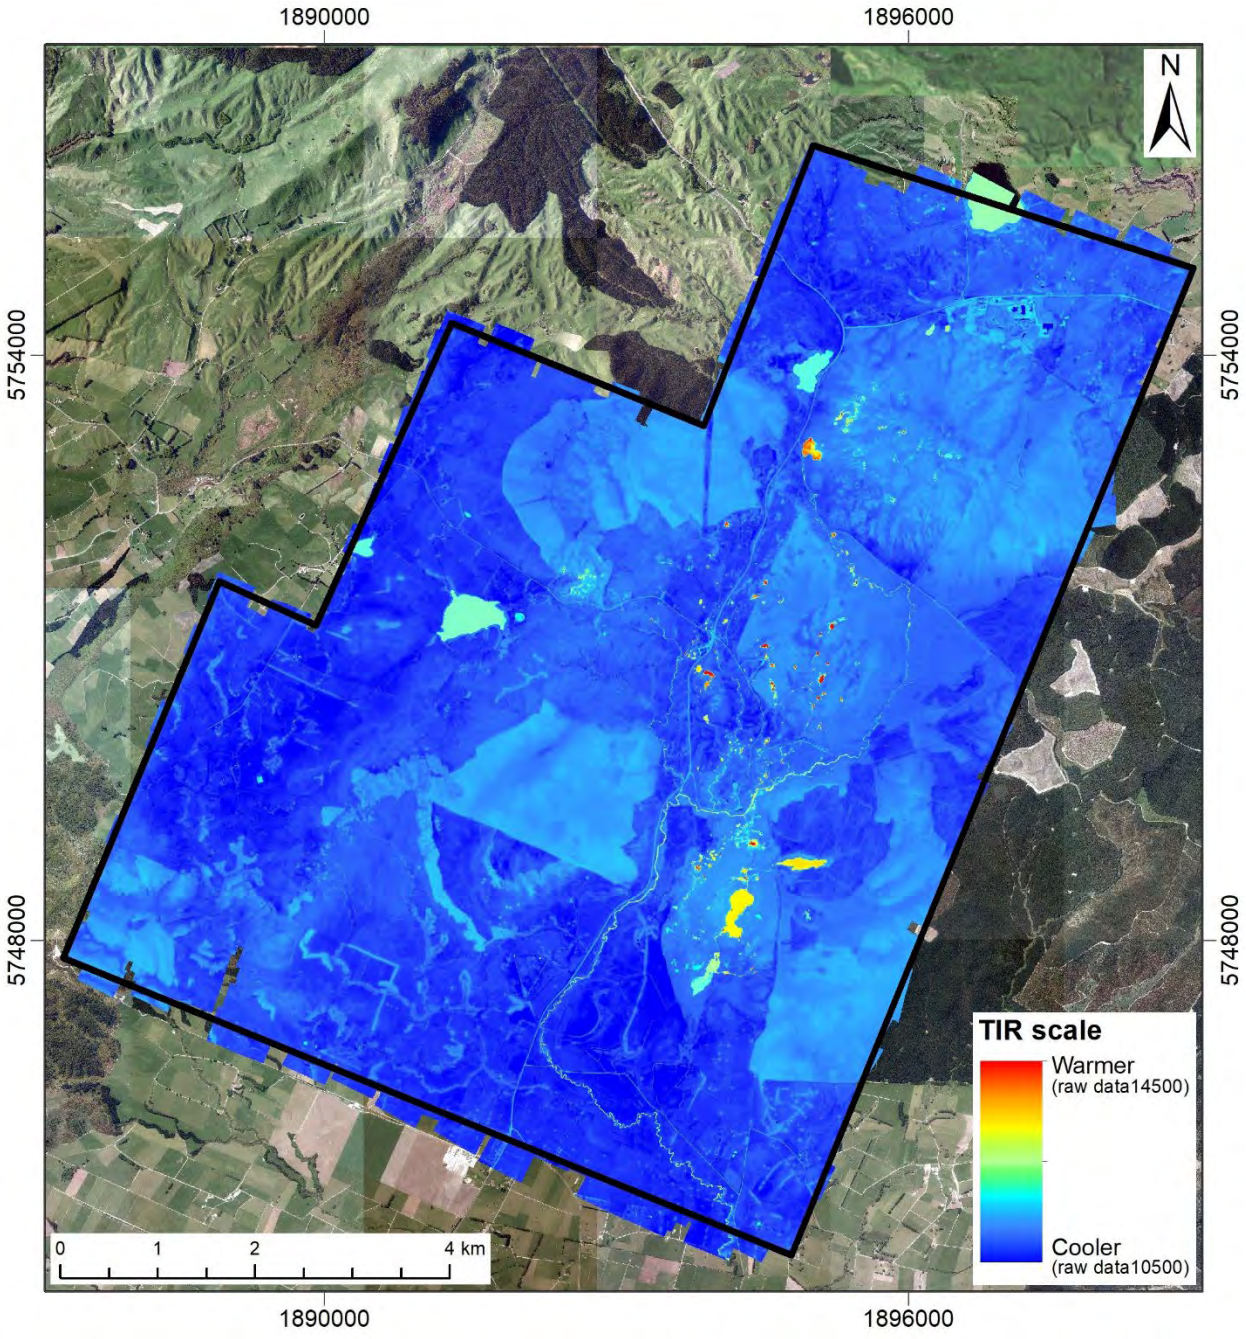

Figure 5: Thermal infrared image over the Waiotapu Geothermal Field. Blue colours show the ambient cooler surface temperatures, while yellows and reds show the area of high surface temperatures. These higher temperatures are generally associated with geothermal water bodies at Waiotapu (Reeves and Sanders, 2019; Seward et al., *2024*).

There are clear benefits to using aerial thermal infrared to determine surface heat loss from a geothermal field. The largest of which is the ability to gather a large amount of data relatively quickly. Remote data collection also allows data to be collected in areas that are not accessible on the ground, it also can be easily replicated, with flight plans, and data collection points set. However, care needs to be taken when interpreting heat loss results, as illustrated above. There are several key components of heat loss that can not be collected remotely, and need terrestrial measurements to be made, namely, mass discharge into streams. Additionally, ground-based measurements of ground temperatures at the time of aerial data collection, allows for inferred surface temperatures to be calculated which are crucial for determining heat loss.

Although there are many sources of uncertainties and errors associated with measuring heat loss, through using a combination of approaches, interpretation of data can be made easier, providing gains on historic approaches.

4. Summary and Conclusions:

This paper has presented methods developed over the last decade to improve estimations of surface heat losses at several New Zealand geothermal fields. It has compared remote sensing techniques with labor-intensive ground-based data collections. Derived empirical relationships to infer heat flux from subsurface temperature gradients, and inferred surface temperatures from TIR data are presented.

The approaches have been applied to several geothermal fields across the Taupō Volcanic Zone, New Zealand. Initial investigations compared two terrestrial approaches and aerial TIR data in a steam-dominated setting (Bromley et al., 2015; Seward et al, 2018a). Results showed close correlations between the 3 methods. Then, the approaches were applied and developed further in mixed- and fluid-dominated geothermal fields (Seward et al., 2023; 2024). In these settings, methods for interpreting and comparing heat loss from water bodies were developed. Although there are benefits for using inferred surface temperatures from aerial data is clear for larger water bodies, the interpretation of results was more complicated for smaller water bodies and stream flows. These geothermal settings emphasized the importance of having terrestrial based measurements for streams and outflow channel, as remote sensing methods cannot capture these mass heat flows.

Discrete terrestrial direct measurements of heat flux (using a calorimeter) are complicated and time-consuming. Time can be reduced through temperature-depth measurements at each site, however, as results collected at Waiotapu Geothermal Field have shown, heat transfer in the shallow subsurface (<1m) does not necessarily result in anomalous convective heat loss at the surface (Seward et al, 2024). Therefore, care must be taken when interpreting these results.

Discrete terrestrial measurements are amalgamated to estimate a field-wide total heat loss through the use of ground-cover classifications. Unquantifiable uncertainties are introduced through this method. This is where the benefits of using aerial TIR data greatly reduce uncertainties.

Conclusions from, particularly, Seward et al. (2024) suggest that the best approach for determining the most accurate surface heat loss for mixed- or water-dominated geothermal systems is through using aerial TIR data, combined with spot terrestrial heat-flux (calorimeter) measurements, and

surface temperatures. For streams and outflow channels, terrestrial measurements of flowrates, water temperatures and chloride concentrations are necessary.

Acknowledgement

The data presented in this paper were collected as part of the 'New Zealand Geothermal Futures' research programme (C05X1702), with additional support from the Waikato Regional Council, the Bay of Plenty Regional Council, and Contact Energy. We would like to acknowledge Ngati Tahu - Ngati Whoa Runanga Trust, Wai-O-Tapu Geothermal Wonderland (WGW), Craters of the Moon trust, Te Puia, Whakarewarewa, Waimangu Geothermal Valley, Department of Conservation, and the other landowners for permission to access land for the surveys, and Chris Bromley for his insight and foundational work.

ABSTRACT

Community Geothermal Coalitions across the United States are nearing completion of their first phase of work focused on expanding community-scale geothermal systems. The work began on October 1, 2023, and is funded through U.S. Department of Energy (DOE), Geothermal Technologies Office (GTO) Community Geothermal Heating and Cooling Design and Deployment Initiative Cooperative Agreements.

A main goal of the initiative is to support the formation of U.S.-based community coalitions that will develop, design, and install community geothermal heating and cooling systems that supply at least 25% of the heating and cooling load in communities. The coalitions describe how switching to a geothermal district heating and cooling system would result in greenhouse gas emission reductions for the community where the system is installed.

In total, the selected coalitions comprise more than 60 partners across the U.S. and include one or more partners that: represent the community, are expert geothermal designers, focus on geothermal workforce development and training needs and include a deployment focused coalition partner such as a gas utility.

The eleven coalitions are designing their heating and cooling systems in close partnership with, and many led by, the communities in which the geothermal projects would be deployed. The

coalitions are based in urban, suburban, rural, and remote communities each developing innovative community scale systems.

Anticipated community benefits include addressing: environmental justice conditions, such as cumulative environmental pollution and other hazards; underserved and disadvantaged communities; and community members who have historically experienced vulnerability due to climate change impacts.

Preliminary case studies developed in the first phase will help illustrate how Community Geothermal Coalitions can be replicated throughout the U.S. followed by the development of more complete case studies by coalitions whose projects move to the deployment phase.

1. Introduction

On July 12, 2022, the U.S. Department of Energy (DOE) announced the Community Geothermal Heating and Cooling Design and Deployment Funding Opportunity Announcement (FOA), for projects that will help communities design and deploy geothermal district heating and cooling systems, create related workforce training, and identify and address environmental justice concerns. Widespread adoption of geothermal heating and cooling systems will help decarbonize the building and electricity sectors, reduce energy costs for families, and boost resilience.

The eleven Community Geothermal (ComGeo) Coalitions funded in Phase 1 are helping to expand community-scale geothermal by supporting new systems and developing preliminary case studies to be replicated throughout the country.

1.1 U.S. DOE Community Geothermal Heating and Cooling Initiative Background

On April 25, 2023, the U.S. DOE Geothermal Technologies Office (GTO) announced the selection of 11 projects in the first phase (Phase 1) of the ComGeo Heating and Cooling Design and Deployment Initiative. In the second phase, following a down select, GTO will support multiple projects to deploy their systems. Under this initiative, GTO is funding U.S.-based urban/suburban, rural, or remote/islanded ComGeo Coalitions to develop, design, and install ComGeo heating and cooling systems.

1.1.1 Community Geothermal Heating and Cooling Design and Deployment Project Locations

The Phase 1 projects are in Nome, AK; Seward, AK; Carbondale, CO; Shawnee, OK; Hinesburg, VT; Wallingford, CT; Chicago, IL; Framingham, MA; Ann Arbor, MI; Duluth, MN; and New York City; NY

1.1.2 Community Geothermal Coalition Role Definitions

Each ComGeo Coalition features representatives in four key roles (Figure 1) including:

- Community Voice: Understand & communicate community needs
- Analysis & Design: Design geothermal district heating/cooling system
- Deployment: Obtain permits & build
- Workforce: Develop & implement training/apprenticeships

Entities in the "Community Voice" role understand and can communicate the energy, environmental, economic, social, and/or other relevant needs that the proposed system would address, as well as local development and regulatory requirements. ComGeo Workforce entities know the community labor market and can help the coalition with apprenticeship opportunities, job placement, and developing training or lesson plans for the applicable trades. Analysis and design entities have the experience designing geothermal systems as well as analyzing the economic and technical aspects of such systems. Deployment entities, although not developing the community systems in Phase 1, have experience building new or retrofitting existing energy systems and can assist or learn from other ComGeo Coalition partners.

To assist coalition formation, GTO provided a Teaming Partner List where interested parties could provide contact information and areas of expertise and search for other entities interested in partnering on an application.

Figure 1: Graphic describing the four types of partners each ComGeo Coalition is required to include in their project team.

1.1.3 Objectives

GTO set five primary goals for the ComGeo initiative as follows:

- Deploy new or retrofitted geothermal, or geothermal-hybrid, district heating and cooling systems in U.S. districts, neighborhoods, and communities;

- Identify solutions for environmental justice conditions, such as cumulative environmental pollution and other hazards; underserved and disadvantaged communities; and community members who have historically experienced vulnerability due to climate change impacts;
- Assist U.S. communities to develop career and technical education and workforce transition initiatives to design, install, inspect, operate, and maintain new energy systems such as geothermal heating and cooling;
- Develop U.S. case studies about projects, including technical and economic data, to illustrate how projects can be replicated by communities throughout the United States; and
- Publish data and information about U.S. community-scale geothermal heating and cooling system deployment to demonstrate the success of such systems in a range of environments and geographies.

1.2 U.S. DOE Community Geothermal Heating and Cooling Initiative Project Requirements

The 11 ComGeo Coalitions are working in American communities with partners from local and state governments, nonprofits, educational institutions, national labs, tribal government entities, utilities, industry, and unions. While there are more than a few terms and conditions that must be adhered to as part of the ComGeo Coalition Cooperative Agreements with DOE, several important requirements are highlighted below.

1.2.1 Coalition and Resources

Since achieving broad community support for a proposed ComGeo heating and cooling system is key, the entity representing the community where the geothermal system is planned to be located is a critical part of the overall project. Thus, each ComGeo Coalition (the project team) is required to include qualified leaders with appropriate expertise and sufficient time committed to each required role in community representation, workforce planning, geothermal analysis and design, and project deployment.

1.2.2 Project Planning, Community Research, and Data Availability

For the ComGeo systems to produce the desired community benefits, plans for system adoption including workforce training require community research and data gathering. To measure the community benefits and impacts, community baseline conditions are assessed including greenhouse gas emissions reduction or prevention, fuel use, electricity use, and/or environmental contamination that can be reduced or avoided. To prepare for geothermal system deployment, regulations, codes, and standards must be included in a permit plan.

2. ComGeo Project Status as of March 30, 2024

Since the ComGeo projects began on October 1, 2023, all eleven teams shared information with each other pertaining to how their community members are being included and how their workforce training and design plans are proceeding. In the final quarter of Phase 1, teams will meet with DOE to review the data they plan to make public and will discuss sharing important lessons learned in preliminary case studies. A generalized status of the ComGeo team activities during the first two quarters is provided below.

2.1 Community Geothermal Engagement and Workforce Training

The Ann Arbor, MI. ComGeo team engaged more than 50 stakeholders using resident-centered success metrics. The City of Chicago "Blacks in Green" ComGeo team is facilitating community conversations to make decarbonization, electrification, and beneficial electrification meaningful and accessible to Chicago communities in their "Sustainable Square Mile" area. The Duluth, MN. ComGeo team is providing outreach to their top 50 natural gas consumers. The Framingham, MA. ComGeo team is conducting a pilot recruitment and training program for geothermal drillers with planned 4–6-week summer internships. In addition, the team is partnering with the GHP trade associations on curriculum development. Union forums were conducted with electrical, utility, operating engineers, plumbing and pipefitting trades. The New York City ComGeo team scheduled site visit with their community stakeholder organizations and are researching NYC workforce entities including technical and vocational schools and local trade unions. The Wallingford, CT. ComGeo team met with their town government, school board, and residents and surveyed four stakeholder groups about employees, barriers, capacities, and other workforce needs. The Carbondale, CO ComGeo team shared preliminary design and modeling at a community open house. The Hinesburg, VT. ComGeo team obtained community input on priorities, concerns, and perspectives on the feasibility of geothermal projects and met with the non-profit "Habitat for Humanity" regarding housing for under-resourced populations. The Seward, AK. ComGeo team receives strong support from the City Manager. The Seward team is also supporting demonstration-related training where residential CO2 heat pump equipment for hands-on training is being provided. The Shawnee, OK ComGeo team gained approval from their tribal (Potawatomi Nation) partner. The Nome, AK ComGeo team conducted community planning meetings to help inform their design options.

2.2 Community Geothermal Design

Several of the ComGeo Coalitions are designing innovative community-scale geothermal heating and cooling systems (GDHC). These preliminary designs contemplate GDHC systems that flow ambient temperature water through a single distribution pipe, loop, or network to Geothermal Heat Pumps (GHPs). This type of design is also referred to as a Thermal Energy Network (TEN) or one that includes several generations of district heating and cooling technology capable of operating as a modular, installed network.

GDHC systems and TENs are more common outside of the United States, although U.S. interest in such systems is growing. GDHC systems leverage commercially available geothermal direct use and GHPs. Conventional direct use systems take advantage of naturally hot water from deep underground, which is pumped to the surface and through a heat exchanger for heating, while GHPs use the naturally occurring difference between the above-ground air temperature and the shallow subsurface soil temperature to create a heat sink in warmer temperatures and a heat source in cooler temperatures.

Unless innovative engineering techniques are used, direct use systems are limited to regions where naturally occurring, hydrothermal resources can be located and brought to the surface for heating. Innovation is needed to add cooling to a direct use system. In contrast, where there is electricity, GHP technology can be used anywhere in the United States for both heating and cooling. In a GHP-based system, an above-ground electric-powered heat pump moves water or another fluid

through a series of buried pipes or ground loops that are generally located tens to hundreds of feet below the surface, where heat is exchanged with the earth.

When either direct use or GHP systems are used to heat or cool water using common piping (or a district loop), GDHC systems can be efficiently designed to heat and cool multiple buildings. The degree of innovation and planning used in the system design can result in more efficient energy distribution taking advantage of heat sources and sinks to the greatest extent possible. Borehole design and spacing to correctly size a system requires innovation.

Early district energy systems, referred to as "1G" or first-generation systems, shown in Figure 2, mostly required fossil fuels to heat water to high temperatures conducive to making steam. As district energy systems evolved, the required water supply temperature significantly dropped. As such, in "4G" or fourth-generation district energy systems, renewable energy such as GHPs can circulate low-temperature—even ambient temperature—water to heat and cool buildings.

Innovative GDHC systems can be roughly classified as either fourth or fifth generation. Fourth-generation systems contain two separate pipe loops, one that acts as a source of hot or cold water, and a second that acts as a sink. In these systems, hot or cold water is delivered directly to buildings, where it is used for heating or cooling. In a fifth-generation system, pipe loop(s) containing ambient temperature (50–60°F) water can act as a source or sink for multiple buildings. An important innovation is the way heat is used throughout the system. For example, discarded heat from one building can be transported and used in another. Buildings connected to this type of system often contain their own heat pump. GDHC systems may also include non-geothermal components. Supplemental boilers and chillers can provide additional heating and cooling on very hot or cold days. Electricity is needed to operate the heat pump(s), and solar panels or another renewable could provide all or some energy.

	1G	2G	3G	4G	5G
Piping Configuration	Pipe acts only as source Only provides heating	Pipe acts only as source Only provides heating	Pipe acts only as source Only provides heating	Two different pipe loops (one loop as source, other loop as sink) Provides heating and cooling	Single "ambient temperature" pipe loop can simultaneously act as source or sink for various buildings, thus enabling "prosumers" Provides heating and cooling Can take discarded heat from one building and transport it for use in another building
Temperature of Supply Pipe	~400 °F	~250 °F	~190 °F	~140 °F for heating ~45 °F for cooling	~60 °F
Fluid in Supply Pipe	Steam	Pressurized Hot Water	Water	Water	Water

Figure 2: District Energy Technology Advancements

GHP systems can use several different ground heat exchanger configurations (e.g., closed-loop horizontal and vertical, standing-column wells, open- and closed-loop pond). The analytical model used in the GeoVision (The Distributed Geothermal Market Demand Model, known as dGeo) considered only the most common and widely applicable of these configurations: closed-loop

horizontal (field loops) and vertical (borehole) systems. Data and information from innovative ComGeo systems will be an important addition to future analysis to estimate the potential for geothermal district heating and cooling systems. Although GHP and GDHC technologies are commercially available, innovation is necessary to develop new systems in regions and communities that have been underserved in this technology space and to transition existing district-scale systems from fossil fuels to geothermal. Successful innovation can be measured by the degree to which a new or an existing system can transition to geothermal heating or heating and cooling.

2.3 Community Geothermal Deployment

Planning for potential system deployment, various ComGeo ownership options are under review by each ComGeo Coalition. The Ann Arbor, MI. team is in conversations with utilities and regulators about municipal ownership. Chicago team ownership options include the City of Chicago as a municipal entity owner or ownership through a private entity. The Duluth, MN. team is assessing business models for construction, ownership, maintenance, and operations. The Framingham, MA. team will decide whether to adopt the ownership model currently in place at an adjacent ComGeo system. The New York City Housing Authority would own their system as would the Wallingford, CT. Housing Authority own theirs. The Carbondale, CO. team is developing a plan that includes project finance, construction, retrofitting, ownership, and operation. The Hinesburg, VT. team is considering a joint development / utility ownership model where all-electric systems are made available to as many utility rate payers as possible and where it is easy for the customer to participate. The City of Seward, AK. would own their system. In Nome, AK. a consortium of five indigenous-led organizations would own their system, and in Shawnee, OK. the Citizen Potawatomi Nation would own theirs.

3. Community Geothermal Data Submissions to the U.S. DOE Geothermal Data Repository

The U.S. DOE Geothermal Data Repository (GDR) is the repository and catalog for data generated by projects funded by GTO (Weers et al., 2022). The GDR provides public access to geothermal datasets, which are increasing in variety, size, and complexity. GTO funds recipients are required to upload their project data to the DOE GDR as the project data is generated in its final form. ComGeo data sets uploaded as of the date of this writing include:

- GDR Submission 1594: “Ann Arbor Electricity and Gas Usage Data” describes hourly electric and gas data for a single-family home type: Worst, Mid, Best. Both the existing system type and replacement geothermal system is simulated.
- GDR Submission 1997: “Connecticut Workforce Needs Assessment Report and Data” provides a geothermal industry workforce needs assessment report for Connecticut.
- GDR Submission 1598: “Final Thermal Conductivity Test Report and Data Logs - Carbondale, CO.” includes the final thermal conductivity test report, a drilling log, and a heat rejection log from Carbondale, CO.
- GDR Submission 1590: “Thermal Conductivity Test and Data Analysis Report” from Wallingford CT. includes a report on a formation thermal conductivity test that was performed on the geothermal test bore at Ulbrich Heights in Wallingford, CT.

Additional details about data uploaded to the GDR is available at GDR: All Submissions (openei.org).

GTO looks forward to sharing additional data helpful to low-temperature geothermal development, including thermal conductivity and drilling datasets, across the country. To facilitate the submission of larger datasets, future ComGeo Coalition project data submissions may utilize a recently developed GDR tool known as an automated data pipeline. The first automated data pipeline implemented within the GDR is for drilling data. This pipeline currently supports and is capable of processing data from Pason (Pason Systems Corp., 2023) and RigCloud (Nabors Industries Ltd., 2021) drilling data platforms in Excel and CSV formats and may in the future be amended to standardize drilling data from other sources and in other formats as well. The pipeline recognizes the platform-specific field names and units and converts them to the standard field names and units in CSV format. The standard additionally includes the RIMBase drilling data platform (Infostat, 2023) field names (Taverna et al., 2023).

4. Community Geothermal Preliminary Case Studies

Case studies of different type of communities (Remote/Islanded, Urban/Suburban, Rural) are an important component of the overall ComGeo initiative. In Phase 1, preliminary case studies are anticipated from ComGeo Coalitions and final case studies at the end of the deployment phase are anticipated from those down selected to continue to Phase 2. During the last quarter of Phase 1 work, ComGeo Coalitions will decide which community, design, workforce or deployment related lessons or best practices to include in their preliminary case studies.

5. Conclusion

While GTO can fund only a subset of the 11 ComGeo Coalition projects to proceed to the deployment stage, the work accomplished by all the teams in Phase 1 is already making an impact on the future of geothermal heating and cooling. The 11 Phase 1 projects are enabling community-scale deployment of GDHC systems in a diverse set of communities by coalitions comprised of technical experts, community leaders, workforce innovators, and deployment professionals. The objective to support the formation of U.S. community coalitions that will develop and design ComGeo heating and cooling systems is more than halfway accomplished. In 2025, ComGeo Coalitions that deploy their systems are poised to supply at least 25% of their overall community heating or heating and cooling demand. Many of the communities are hoping to supply most of their heating or heating and cooling from deployed ComGeo systems.

dual-source heat pumps, integrate air- and ground-source, borehole length, energy efficiency

ABSTRACT

Air source heat pumps (ASHPs) and ground source heat pumps (GSHPs) are the two most common types of electric-driven heat pumps in the marketplace to replace fossil fuel-based heating systems. However, the performance and efficiency of ASHPs depend on the ambient air conditions. Therefore, ASHPs usually are equipped with electric resistance heaters to provide supplemental heating when the ambient temperature is low, and the heating demand is high. The electric resistance heaters could result in high power draws when they are turned on. On the other hand, due to the relatively steady temperature of the ground, GSHPs are more energy efficient than ASHPs when providing space heating and cooling to the buildings. However, the adoption of GSHP is hindered by its high initial cost, mostly due to the cost of drilling boreholes for installing ground heat exchangers (GHE). To solve the above issues, our study investigates the performance of dual-source heat pumps (DSHPs) with respect to that of ASHPs and GSHPs. The DSHP will use ambient air when its temperature is favorable for the efficient operation of the heat pump. When the ambient temperature is too hot or too cold, the ground source will be utilized to retain the high-efficiency operation of the heat pump. Because the cumulative thermal load of the GHE is shared with the ambient air, the size of the GHE could be smaller than those of the conventional GSHPs. The study will model the DSHP and simulate its performance in providing heating and cooling for a typical single-family house in regions with hot, mild, or cold climates. In addition, the required GHE size of the DSHP system will be determined through annual simulations and compared with that of conventional GSHPs.

1. Introduction

In the U.S., residents spend 90% of their time indoors, thereby resulting in a substantial sum of money on building energy costs—upwards of $370 billion annually (Langevin et al., 2024), as heat related mortality is considerably correlated with indoor air temperature (Sailor et al., 2021). Therefore, switching to clean energy sources for buildings and cutting back on total energy use

will not only mitigate climate concerns but also improve everyone in America's health and financial security. Moreover, replacing fossil fuel-based heating systems with electric-driven heating systems can improve indoor air quality (Kelly et al., 2016). The current U.S. administration aims to reduce carbon emissions from U.S. buildings by 65% by 2035 and 90% by 2050 compared with 2005 while enabling net-zero emissions economy-wide (Langevin et al., 2024). Building decarbonization is the key to these targets. Currently, natural gas-based space heating accounts for 52% of the U.S. residential buildings (EIA, 2020). Air source heat pumps (ASHPs) and ground source heat pumps (GSHPs) are the two most common types of electric-driven heat pumps in the marketplace to replace fossil fuel-based heating systems.

A recent modeling study shows that a majority of Americans (at least 62% of households, depending upon the heat pump efficiency) would observe a reduction in their energy bills by upgrading to ASHPs. Moreover, the study shows that ASHP could be cost-effective without subsidies in 59% of households (Wilson et al., 2024). However, another numerical study shows that, whole-house electrification with ASHPs may raise aggregated peak loads in the US by 70% and in 23 US states by more than twice as much (Waite & Modi, 2020). This is mostly because the efficiency and heating/cooling capacity of ASHPs depend on outdoor conditions when they are in use. Therefore, lower outdoor air temperature results in lower efficiency and capacity of ASHPs while heating and vice versa for cooling. As a result, ASHPs are equipped with electric resistance heaters to provide supplemental heating. These electric resistance heaters are turned on when the outdoor temperature is low, and the heating demand is high, thereby resulting in high power draws during peak hours.

Considering the relatively steady temperature of the ground, GSHPs are more energy efficient than ASHPs when providing space heating and cooling to the buildings. Therefore, employing GSHP technology is one workable way to reduce the need for US electric power systems to have their capacity and transmission increased. For instance, GSHPs require 30–50% less than the seasonal average power usage for supplying the same amount of cooling or heating using air-to-air heat pumps, which use the outdoor air as a heat sink/source (Ahmadi et al., 2018). Moreover, mass deployment of GSHP in the U.S. can reduce 26% of carbon emissions from the building sector (Liu et al., 2023). However, the high initial cost of GSHPs is impeding its adoption (Liu et al., 2022). This is primarily because installing GSHP requires drilling boreholes in the ground for installing ground heat exchangers (GHE). The amount of energy released to the ground during cooling and the quantity of energy gained during heating affect a GHE's size and cost. Given the immense thermal storage capacity of the ground, the heat transfer process of a GHE is nearly transient all the time, and thus both the total thermal loads and peak demand of a GHE need to be accounted for when sizing a GHE.

The current numerical study proposes a novel way to use ground and air as heat pump’s source/sink based on the demand. The proposed dual source heat pump (DSHP) will use outdoor air when its temperature is favorable for the efficient operation of the heat pump. When the ambient temperature is too hot or too cold, the ground source will be utilized to retain the high-efficiency operation of the heat pump. The proposed DSHP will have an additional heat exchanger that enables switching between air and ground sources based on the intensity of the energy demand for every timestep. Therefore, DSHP will not potentially raise the regional scale peak demand capacity and transmission needs as that of mass deployment of ASHPs. Since the cumulative thermal load of the GHE is shared by the ambient air, the length of the borehole for the GHE of DSHP can be

smaller than the conventional GSHPs. Thereby, reducing the initial cost of GHE and operational cost by switching between air source and ground source, and possibly shortening the payback period.

The study will model the DSHP using a whole building energy simulation tool coupled with a Python plug-in to enable DSHP simulation and evaluate its performance in providing heating and cooling for a typical single-family home in regions with hot, mild, or cold climates. In addition, the required GHE size of the DSHP system will be determined through annual simulations and compared with that of conventional GSHPs. In the end, a lifecycle cost analysis will be conducted to compare ASHP, GSHP, and the DSHP. The findings from this study can be used as a guideline for homeowners, designers, and builders for new and existing building electrification applications.

2. Methodology

The study uses the whole building energy simulation tool, EnergyPlus v9.5, coupled with a Python plug-in for conducting the numerical analysis. EnergyPlus is a widely used and extensively validated whole building energy analysis software tool. It is an open-source platform developed by the U.S. Department of Energy's Building Technologies Office, as part of their building energy modeling program portfolio. The individual features of the tool and the modeling package as a whole have been validated in several previous studies. Each EnergyPlus simulation requires hourly weather data. The weather files used in this study are typical meteorological year files, which contain data for a specific location, listing hourly values of solar radiation and meteorological elements for one year. These values are obtained by combining previous weather data observations. The latest typical meteorological year (TMY3) weather files. The current study used TMY3 weather files of a hot city, moderate city, and cold city to evaluate the performance and lifecycle cost analysis of DSHP over ASHP and GSHP.

2.1 Single family prototype building models

This study utilizes the U.S. Department of Energy's prototype building models, created following the 2006 edition of IECC, for single-family detached houses (Mendon & Taylor, 2014), which represent a set of identical 221 m^2 two-story houses that use various heating systems and foundation types. ASHP and slab-on-grade foundation are used as the ASHP models for this study, see Figure 1. The prototype building model for ASHP has a nominal heating coefficient of performance of 3.69 and 4.07 that of cooling. The model has supplementary resistance heater which turns on when the temperature is below 7.2°C (45°F) and it works along with the heat pump till the temperature reaches -17.78°C (0°F). Once the temperature goes below -17.78°C (0°F), the compressor of the ASHP is automatically shut off, only electric resistance is the only source for heating. The characteristics of these prototype buildings, such as the insulation level of building envelopes are in compliance with one of the several editions of the International Energy Conservation Code (IECC) for each climate zone (CZ).

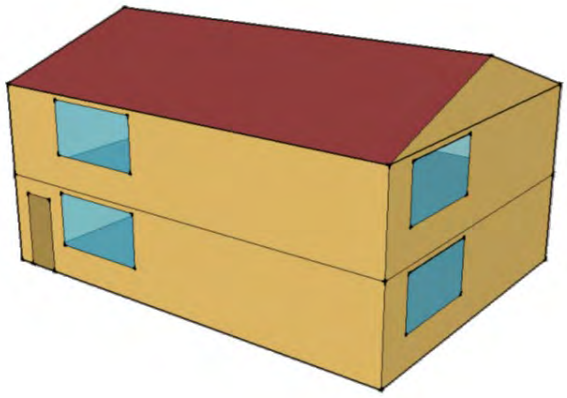

Figure 1. Single family prototype building model used in this study.

2.2 Modeling ground source heat pumps

The original ASHP system of the prototype building model is replaced with a GSHP system. The developed GSHP system includes an extended range water-to-air heat pump, a vertical bore GHE, and a circulation pump. The heating and cooling coefficients of performance of the GSHP system are kept as 4.0 and 6.5, respectively, at the rating conditions for the ground loop application mentioned in the ANSI/AHRI/ASHRAE/ISO Standard 13256-1 Water-to-Air and Brine-to-Air Heat Pumps — Testing and Rating for Performance. The design parameters of the default vertical borehole GHE used in this study can be seen in Table 1. The undisturbed ground temperatures are based on a dataset created by (Xing et al., 2017).

Table 1. Vertical borehole GHE design parameters

Parameter	Default value	Parameter	Default value
Borehole radius (m)	0.0762	Grout heat capacity (kJ/m3-K)	3,900
U-tube pipe thickness (m)	0.0024	Ground conductivity (W/m-k)	1.3
U-tube pipe outer dia. (m)	0.0267	Ground heat capacity (kJ/m3-K)	2,347
U-Tube distance (m)	0.025	Design flow rate (m3/s)	0.000689
Pipe conductivity (W/m-K)	0.3913	Bore spacing (m)	6.5
Pipe heat capacity (kJ/m3-K)	1,770	Maximum GHE supply temp. (°C)	35
Grout conductivity (W/m-k)	1.3	Minimum GHE supply temp. (°C)	-3

The building models used in this study use design day cooling and heating loads to auto-size the capacity of the water-to-air heat pump. This method may not always size the heat pump system with sufficient capacity. In certain cases, the unmet hours (i.e., the hours when the room temperature is not maintained at the set point) could be more than 300 hours, which is the maximum unmet hours recommended by ANSI/ASHRAE/IES Standard 90.1-2010's Performance Rating Method Reference Manual (Goel & Rosenberg, 2016). To ensure the total unmet hours in our study are always less than 300 hours, the auto-sized heat pump capacity is corrected, by increasing heat whenever it is necessary.

The design parameters of the vertical borehole GHE, including the undisturbed ground temperature, and thermal loads of the GHE predicted with an initial simulation of the GSHP

system, which uses a roughly sized GHE, are used to more accurately size the GHE using GHEDesigner (v 1.3). The sized GHE, including the number of boreholes, the layout of the borehole field and the depth of each borehole, and the associated g-functions are used to revise the building energy simulation model to perform the final simulation.

2.3 Modeling dual source heat pumps

The dual source heat pump (DSHP) is modeled by dynamically connecting the EnergyPlus simulation model with Heat Pump Design Model (HPDM) through an EnergyPlus Python plugin as shown in the Figure 2.

Figure 2. Co-simulation using EnergyPlus, Python Plugin, and Heat Pump Design Model

EnergyPlus model includes building information, weather data, schedules, loads, loops, plants, branches, GHE, heat pump, and reports the required outputs. HPDM is a research software designed by Oak Ridge National Laboratory under sponsorship of the U.S. Department of Energy (https://hpdmflex.ornl.gov/hpdm/wizard/welcome.php) for detailed physics-based modeling of various heat pumps. It predicts performance, including heating/cooling capacity and power consumption) of heat pumps in the four different modes (air-source heating, air-source cooling, water-source heating, and water-source cooling) in response to given operating conditions (e.g., ambient air temperature or supply water temperature of the ground heat exchanger). The predicted performance is compared with the performance at reference conditions (i.e., the Air-Conditioning, Heating, and Refrigeration Institute rating conditions for ASHP and GSHP). The calculated ratios at each simulation time step are sent through Python Plugin to the EnergyPlus model to replace the ratios determined using the default performance curves of heat pump in the EnergyPlus model. Python plugin works as a connector between EnergyPlus and HPDM and includes a control strategy to decide the needed operation mode and apply corresponding heat pump mode in HPDM. By coordinating the EnergyPlus model, Python plugin, and HPDM at each simulation time step, the performance of a DSHP is predicted. In this study, a simply control strategy is implemented in the Python plugin to automatically run the DSHP. For cooling operation, if the outdoor air is hotter than 80 °F (26.67°C) and the GHE outlet water is cooler than the outdoor air, then the GSHP system is used to meet the space cooling demands, otherwise, ASHP will meet the space cooling demand. In the case of space heating, the model uses ASHP when the outdoor air temperature is above 42°F (5.5°C), otherwise GSHP is used. Below 42°F (5.5°C), the chance for frosting will be higher (Wang et al., 2018), and therefore, the use of GSHP is more energy efficient than ASHP.

The DSHP simulation is done in the following steps as shown in Figure 3:

1. The initial simulation of DSHP uses the GHE details from the GSHP model.

2. If needed, the DSHP heat pump capacity is adjusted to ensure total unmet hours are less than 300 hours.
3. GHE heat transfer load data is used as input for the GHEDesigner to update the GHE size for the DSHP model.
4. If needed, GHE size is adjusted manually to ensure total unmet hours are less than 300 hours.
5. Conduct the final simulation of DSHP using the updated heat pump size and GHE design details.

2.4 Building Energy Simulations

The simulation is conducted for 3 U.S. climate zones, based on ASHRAE. The study considers one representative city for each climate zone, Minneapolis, MN for a cold climate (ASHRAE climate zone 6A), Albuquerque, NM for a moderate climate (ASHRAE climate zone 4B), and Miami, FL for a hot climate (ASHRAE climate zone 1A). The undisturbed ground temperatures used for DSHP and GSHP building models for 24℃, 16.4℃, and 9.1℃ are Miami, Albuquerque, and Minneapolis, respectively, based on the dataset created by (Xing et al., 2017). The study uses a Python module, Eppy, for conducting the parametric simulation (Glazer, 2016). The default options[1] of the prototype building models are modified slightly to conduct this simulation.

Result and Discussion

3.1 Heat pumps capacities

Table 1 shows the heat pumps capacities for GSHP, DSHP and ASHP systems. GSHP and DSHP capacities are represented in ton refrigeration (ton) while ASHP capacities are represented in (ton) and (kW) for their auxiliary heaters. The table shows that DSHP systems have capacities that are equal or less than those of GSHP systems, as DSHP uses ground source during the peaks hours (when outdoor air condition is extreme). The capacities of ASHP are always lower than DSHP and GSHP, as auxiliary heaters play an important role while meeting peak heating demand.

Table 1. GSHP, DSHP and ASHP capacities

Climate zone	GSHP (ton)	DSHP (ton)	ASHP (ton + kW)
1A	3.13	3.13	3 Ton + 5kW
4B	2.87	2.87	2.5 Ton + 15kW
6A	5.93	5.67	4 Ton +25 kW

[1] The default prototype building models need EnergyPlus preprocessing software to execute "GroundSlabPreprocessorAverage", unfortunately, the current versions of Eppy don't support EnergyPlus preprocessing software while running the simulations, therefore, the outside boundary condition is changed to "Ground". For modeling outdoor infiltration, the prototype building models use the airflow network, which is replaced with an effective leakage area method for this study. The effective leakage area is kept at 0.142 m^2, estimated based on a correlation developed by a previous study (Chan, 2013), to represent 0.8 ACH in the buildings (representing a typical residential construction (Margaret et al., 2022).

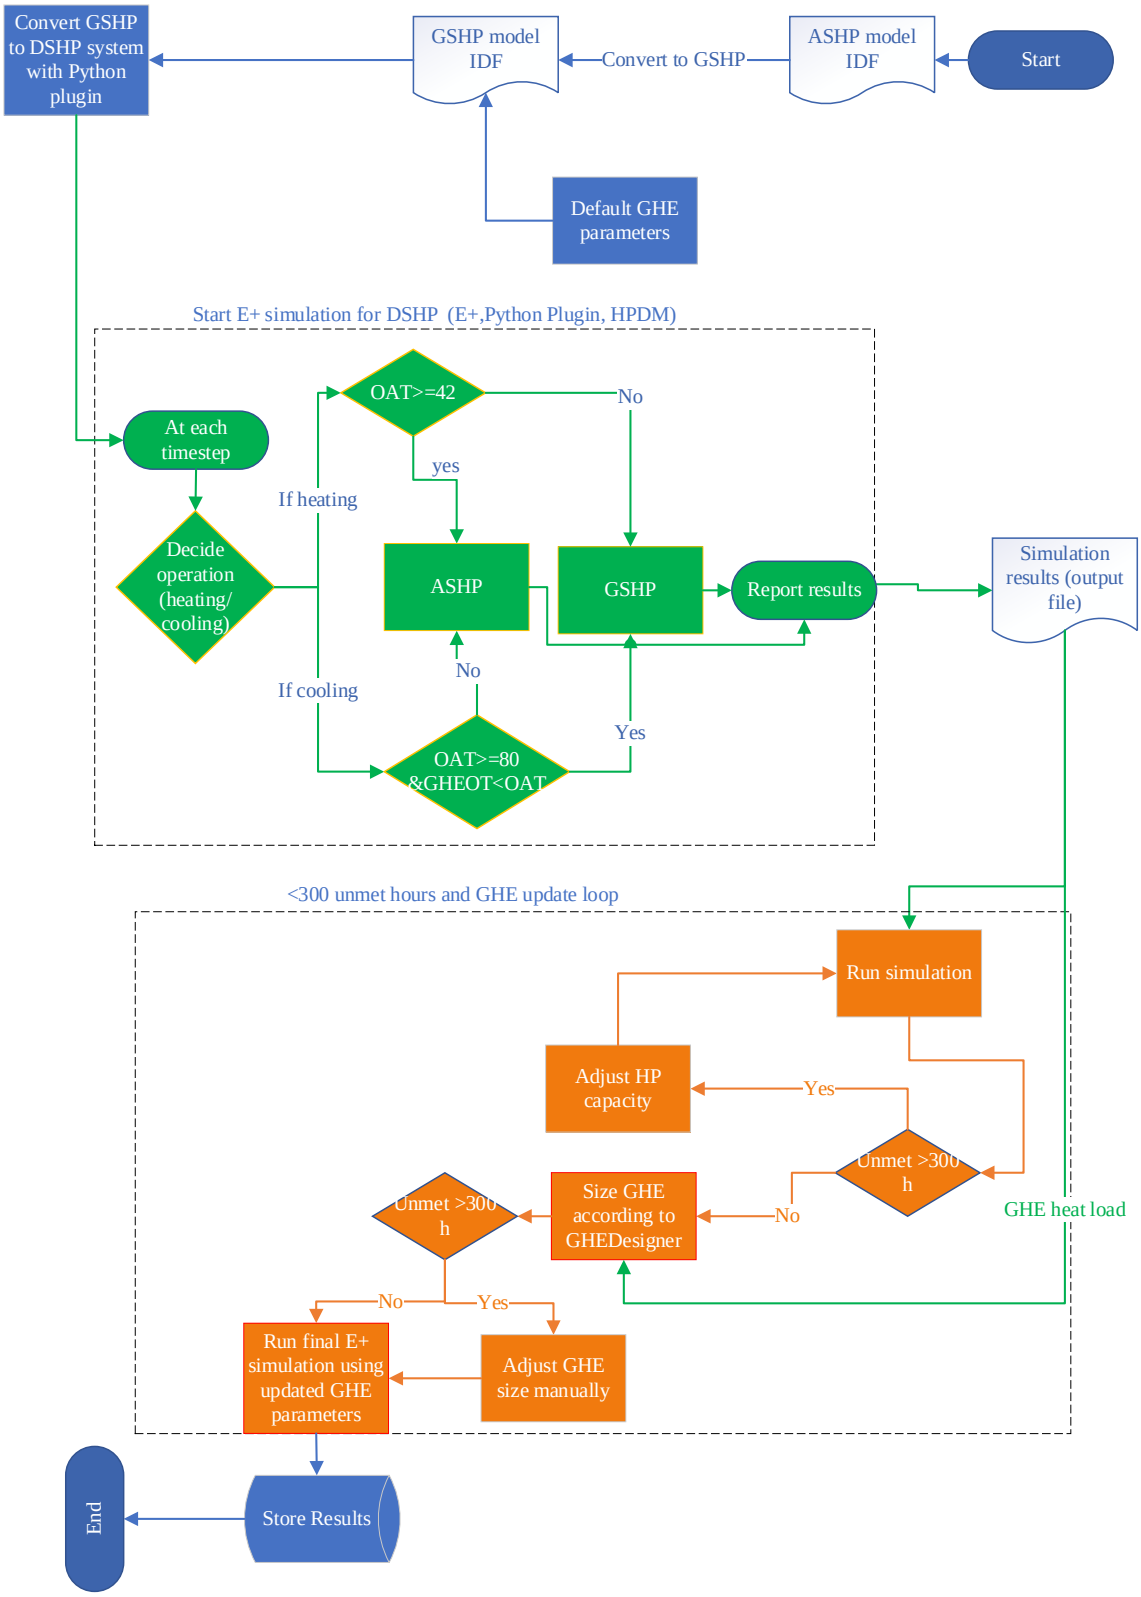

Figure 3. DSHP simulation process

3.2 Cooling and heating energy consumption

Figure 4 compares the cooling and heating electricity consumption for ASHP, GSHP, and DSHP for the three selected regions. The results from the study show that ASHP consumes more electricity than both GSHP and DSHP to meet the same thermal loads for space heating and cooling. For space cooling in Miami (1A), the electricity consumption of GSHP and DSHP is 36% and 7%, respectively, lower than that of ASHP, see Figure 4a. In the case of DSHP, it uses air-source cooling mode more frequently than ground-source cooling mode given the control strategy described before. In Albuquerque (4B), the space cooling electricity consumption is almost similar for the ASHP, DSHP, and GSHP, due to mild summer weather. In Minneapolis (6A), both DSHP and GSHP use less electricity for cooling than the ASHP because of the low ground temperature in this cold climate, see section 2.4.

On the other hand, for space heating, electricity consumption of GSHP and DSHP are ~40% and ~50% lower than ASHP in Albuquerque (4B) and Minneapolis (6A), respectively. Both GSHP and DSHP consumed about the same amount of electricity for meeting the heating demand. It indicates that DSHP runs in ground-source heating mode more frequently than in air-source heating mode. In Miami (1A), electricity consumption is almost the same for all due to warm weather there, even in the winter months.

Figure 5 shows the combined electricity consumption for space heating and cooling in the three locations. The results show that, the combined electricity consumption of DSHP lies between that of ASHP and GSHP. In Miami (1A), the combined electricity consumption of DSHP is closer to that of ASHP due to mild winter weather and the DSHP operates in air-source cooling mode more frequently than ground-source cooling mode. In moderate and cold regions, Albuquerque (4B) and Minneapolis (6A), the combined electricity consumption of DSHP is closer to that of GSHP.

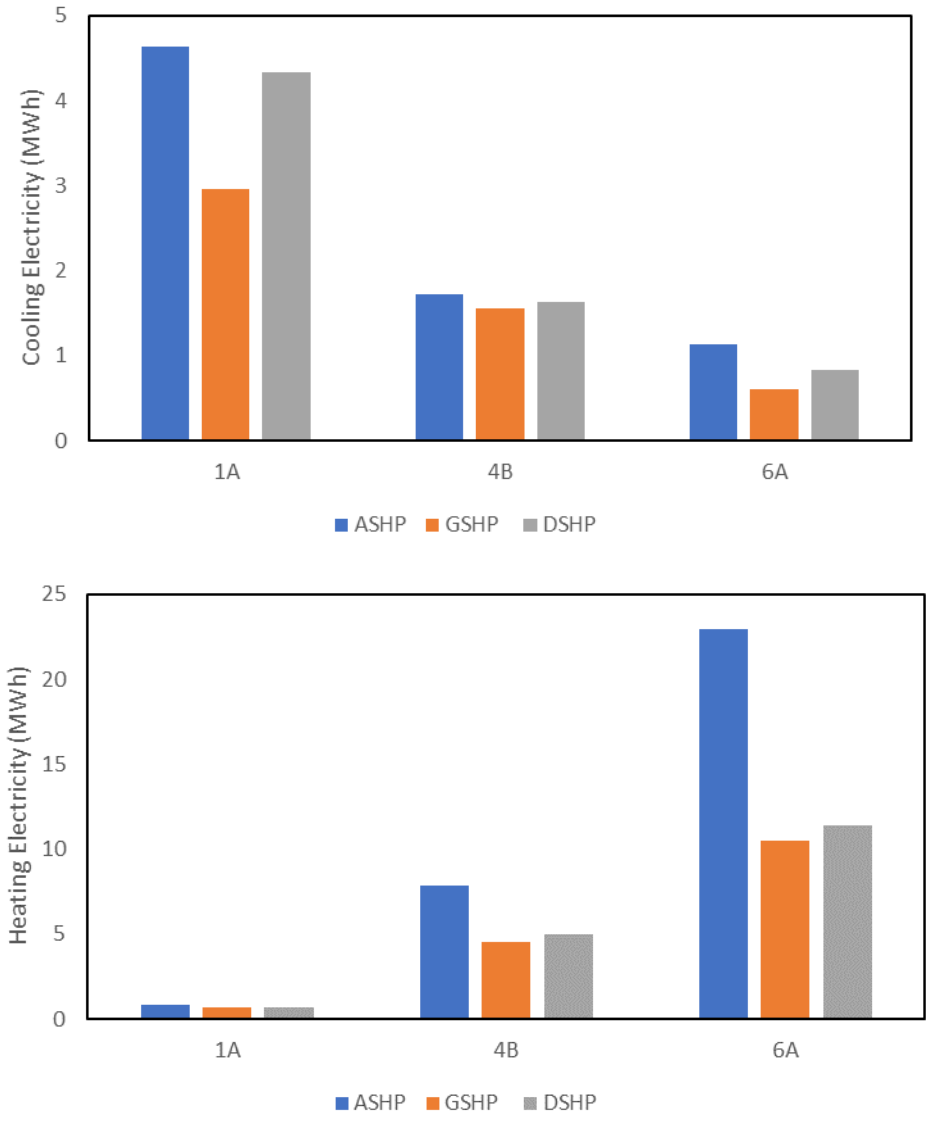

Figure 4. Comparison of a) cooling and b) heating electricity usage for 3 selected regions when electrifying the single-family houses with ASHP, GSHP, and DSHP.

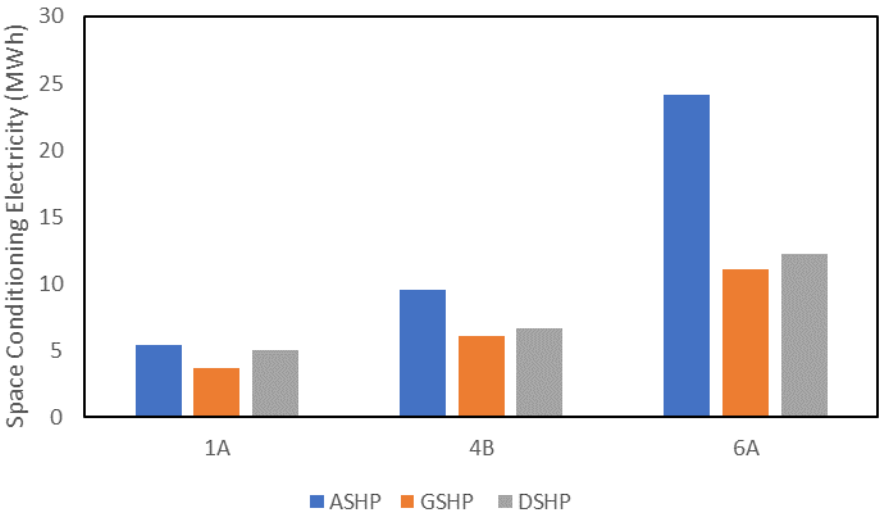

Figure 5. Combined electricity consumption for space heating and cooling in 3 selected cities when electrifying the single-family houses with ASHP, GSHP, and DSHP.

3.3 Borehole length

Figure 6 shows the required borehole length for both GSHP and DSHP in the three locations. The results show that the required total borehole length for DSHP is significantly smaller than that of GSHP. The reason for this reduction is because DSHP does not solely depend on GHE as a heat source/ heat sink. It utilizes air whenever the ambient air temperature is favorable, which reduces the load on the GHE and hence reduces the required borehole length. Interestingly, the reduction in borehole length is significant in extreme climatic locations, therefore it can largely reduce the initial cost for implementing GSHP there. For instance, in Miami (1A), the required total borehole length of DSHP is 325 m shorter than that of GSHP. In Minneapolis (6A), the reduction is 250 m. In Albuquerque (4B), the reduction is 49 m because the required total borehole length of GSHP is low compared with that in the other two cities.

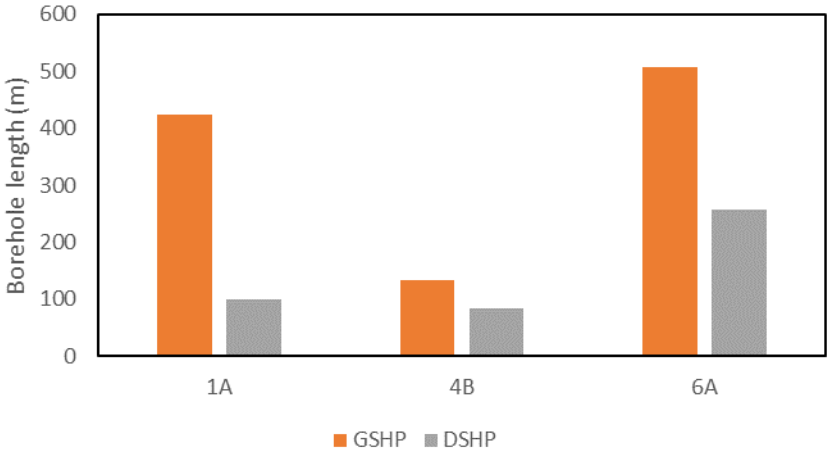

Figure 6. Required borehole length for the selected 3 cities.

3.4 Comparison of DSHP and GSHP

Figure 7 shows the change in the required total borehole length and the combined electricity consumption for space cooling and heating in the three locations when comparing the DSHP system to the GSHP system. The results show that, in Miami (1A), using DSHP instead of GSHP system can cut the required total borehole length by 77%, but it will increase the combined electricity consumption by 38%. In Minneapolis (6A), the required total borehole length is shortened by almost half, and the total electricity consumption is increased only by 10%. Similarly, in Albuquerque (4B), the required total borehole length was reduced by 37% and the total electricity consumption only increases by 8%. In case of hot city, Miami (1A), even though penalty in electricity percentage increase when comparing DSGP system to the GSHP is higher (38%), as shown in Figure 7, their absolute increase in electricity consumption is considerably smaller than moderate or cold regions, as their overall space cooling and heating requirement is lower, see Figure 5.

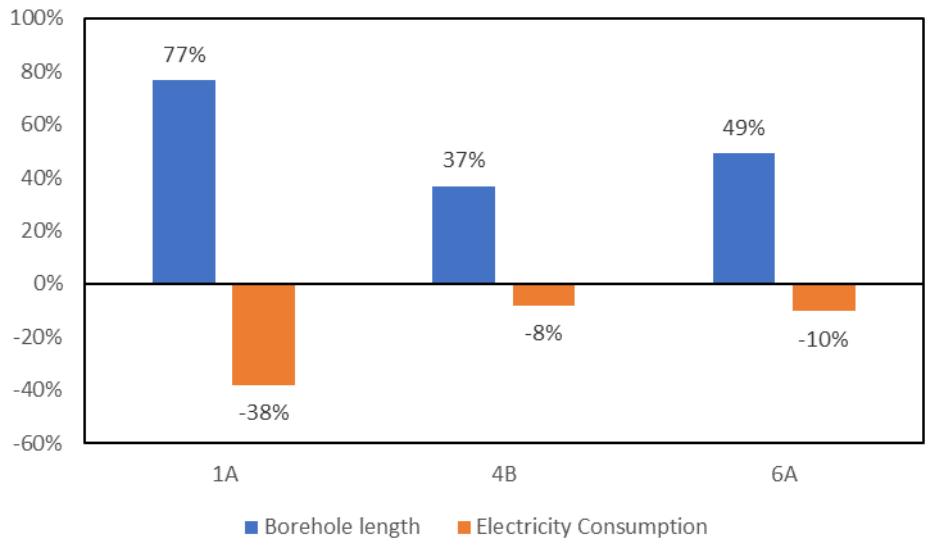

Figure 7. The change in the required borehole length and electricity consumption for meeting the heating and cooling demand of the SHF after converting the GSHP system to the DSHP system.

Conclusions

The results from this study show that deployment of GSHP consumes the lowest electricity for space heating and cooling for single-family houses in hot, moderate, and cold climatic regions. For all the considered regions, DSHP consumes less electricity than ASHP for both space heating and cooling but more electricity than GSHP. However, the borehole length requirement for meeting the thermal demands of DSHP is significantly lower than that of the GSHP, thereby showing the ability to significantly reduce the initial cost for GHE deployments. Therefore, lifecycle cost analysis is to be conducted to compare ASHP, GSHP, and the DSHP to investigate their economic feasibilities. The next step of this study is to conduct an economic analysis accounting for the

added cost of the DSHP unit, reduced cost for GHE, and the lifecycle operating cost. This economic analysis is expected to answer whether the deployment of the DSHP system is more cost-effective than that of GSHP and ASHP for different climates.

ABSTRACT

With the increasing focus on sustainable energy solutions and national net-zero emissions goals, repurposing of abandoned underground mines for thermal energy storage has the potential to make significant impacts. The international Geothermica consortium, Galleries to Calories (G2C), is investigating the potential for storing waste heat from a supercomputing facility in abandoned, flooded coal mines southeast of Edinburgh, Scotland. The system termed the Geobattery or GeoTES involves injecting heat into mine workings, conveying it using regional groundwater flow, and then using the stored thermal energy for district heating and cooling via heat pumps. The Edinburgh site is unique due to the connection of three individual collieries that are linked by underground roadways and hydraulically conductive coal seams, thus enabling heat to be readily stored and transported over several kilometers.

The internal structure of collieries poses challenges due to their partially unknown internal structure, involving fully excavated seams, partially mined pillars, open and collapsed tunnels, and unmined rock formations. To address these uncertainties, we propose to use a multi-level stochastic modeling approach using the open-source Multiphysics Object-Oriented Simulation Environment (MOOSE). Our team has developed a preliminary and geometrically simplified numerical model that focuses on the main coal seams. These seams are further subdivided into multiple subdomains so that they can be discretized individually. Initially, a stochastic analysis involving many thermo-hydraulic simulations is conducted to identify promising bulk parameter combinations that replicate field observations. Once these parameter combinations are determined, the model is extended in a second phase to incorporate the geomechanical effects associated with

various operational conditions of the Geobattery. This extension facilitates the necessary evaluation of heat plume migration and stress field changes, critical for assessing the mechanical stability of the collieries and heat losses that may occur during the operation of the Geobattery.

1. Introduction

The energy transition towards net-zero emissions will require viable long-term energy storage solutions that support communities formerly dependent on fossil fuels. An important application of subsurface energy storage is direct-use heating and cooling. Globally, heating and cooling represents almost half of energy consumption (IRENA, 2023). Repurposing of underground infrastructure including abandoned mines for thermal energy storage and district heating offers a promising avenue to address widespread energy storage challenges. Abandoned flooded coal mines commonly have relatively stable temperatures throughout the year, rendering them ideal candidates for thermal energy storage. The water in the extensive flooded workings is available as a working fluid for thermal energy transport. Moreover, their pre-existing interconnections, often across kilometers of lateral distance, minimize the need for costly drilling, which is a major expense in traditional geothermal energy endeavors involving heat pumps. This system, called the Geobattery or GeoTES, involves injecting heated water into mine workings, conveying it using regional groundwater flow, and then using the stored thermal energy for district heating and cooling via heat pumps as shown in Figure 1.

Internationally, abandoned coal mines have been effectively repurposed into district heating and cooling systems, exemplified by initiatives in Heerlen, the Netherlands (Roijen et al., 2007; Bazargan Sabet et al., 2008; Verhoeven et al., 2014; Adams et al., 2019), Springhill, Canada (Jessop et al., 1995), Asturias, Spain (Jardón et al., 2013; HUNOSA, 2019), and Bochum, Germany (Hahn et al., 2023). In the United Kingdom, ongoing research at the Glasgow Geothermal Energy Research Center (Adams et al., 2019; Monaghan et al., 2022) explores the feasibility of utilizing abandoned Scottish mines for thermal energy storage and district heating applications. Additionally, the utilization of subsurface reservoirs for data center cooling is a current interest of the United States Department of Energy with analyses having been completed in Colorado, Texas, and Virginia (Zhang et al., 2023, Zhang et al., in review).

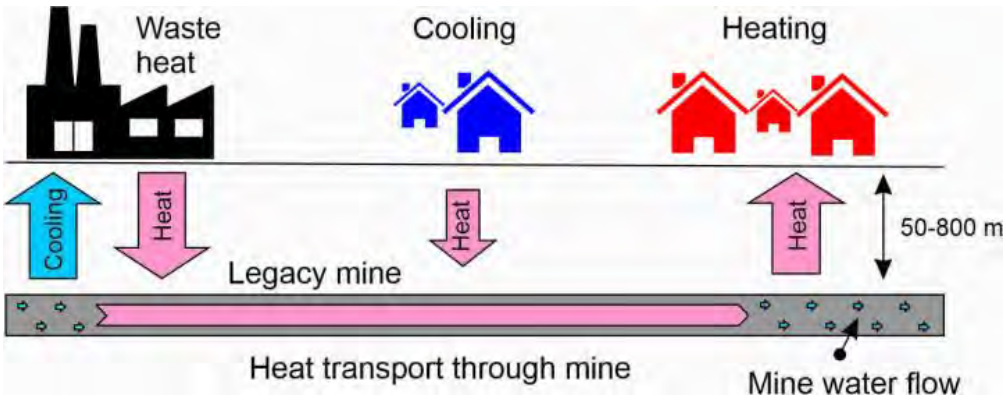

Figure 1: Schematic diagram showing the G2C Geobattery concept with waste heat injected in the mine that is recovered downgradient for heating.

Galleries to Calories (G2C) is an internationally supported Geothermica project led by industry and researchers from the University of Edinburgh and Townrock Energy as well as University of

Strathclyde-Glasgow, University College Dublin, Sandown Ltd, Scene, Idaho National Laboratory, and Lawrence Berkeley National Laboratory. The team aims to demonstrate heat storage and transport in legacy mine workings for recycled heat utilization via heat pump extraction near Edinburgh, Scotland. The specific application is to store waste industrial heat from a university data center in flooded abandoned coal mine workings and use that heat downgradient for community heating during winter months. Repurposing these mines presents technical and commercial challenges due to their intricate and unpredictable nature. We plan to employ advanced modeling methodologies to forecast the system's long-term performance, inform decision making, and conduct risk assessments. Presently, our efforts entail simplified modeling approaches pending the acquisition of more comprehensive field data. This paper provides an overview of the G2C field site, synthesizes pertinent literature, elucidates our initial modeling strategies, and outlines our forthcoming research agenda.

2. Site Description

2.1 Overview

The project site is located approximately 9 km south of Edinburgh, Scotland near the towns of Roslin, Bilston, Straiton, and Loanhead. The abandoned mine workings and their mine water in the Midlothian Coalfield (Figure 2) will serve as both the thermal storage and transport medium. The depth of these mine workings ranges from 50-800 m below the surface, but this project is focused on the upper 150 m to minimize drilling and future operational costs. The heat source for the project is the University of Edinburgh's Advanced Computing Facility (ACF) near the Easter Bush Campus. This facility will provide between 3-9 MW of waste heat to the subsurface. Adjacent communities located approximately 5 km downgradient of groundwater flow will be the main beneficiaries of the heat stored in the mines.

2.2 Geology and Hydrology

Southwest of Edinburgh lies the Pentland Hills rising to an elevation of approximately 578 m above sea level (masl). These hills consist of Devonian and Silurian sedimentary formations of the Old Red Sandstone and North Esk Group as well as extrusive volcanics of the Pentland Hills Volcanic Formation with basaltic and andesitic compositions (Tulloch and Walton, 1958). The Pentland Hills Fault forms the southeast edge of the hills with substantial downthrow to the southeast. Parallel to the Pentland Hills and approximately 13 km to the east of the Pentland Hills lies an unnamed set of hills extending from the coast at Prestonpans stretching towards D'Arcy Farm. Between these two prominent topographic features lies the Midland Valley and the Midlothian Coalfield (Figure 2, British Geological Survey, 2003).

The geology of the Midlothian Coalfield consists of basin-fill sandstones, siltstones, mudstones, ironstones, marine limestones, and coal-bearing units (Figure 3). The main units of interest for this study include the Upper Limestone, Limestone Coal, and Lower Limestone Formations, which contain various coal seams (Figure 4) including the Peacock and Kittlepurse Coals. These coals seams are semi-parallel and highly inclined with thicknesses of approximately 1 m (Figure 5).

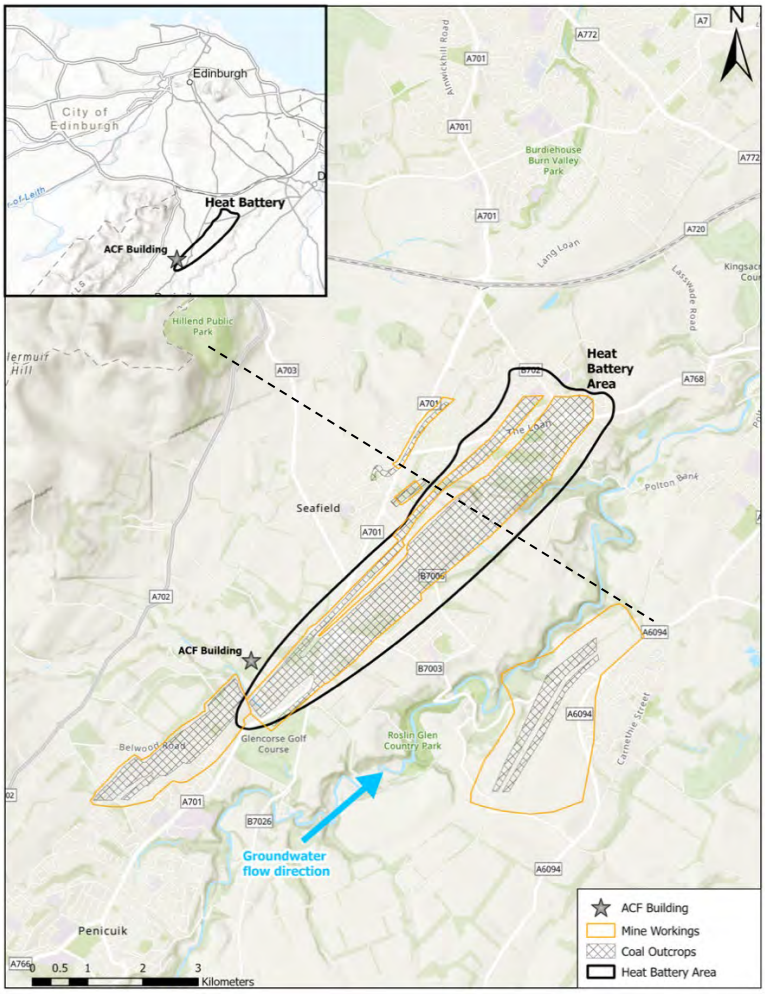

Figure 2: A regional map of the project location south of Edinburgh. Advanced Computing Facility (ACF) is the cooling-waste-heat source indicated by the green star. Hatched pattern represents portions of the legacy mine workings that will be utilized for the Geobattery. Dashed line represents the approximate location of the cross section in Figure 3.

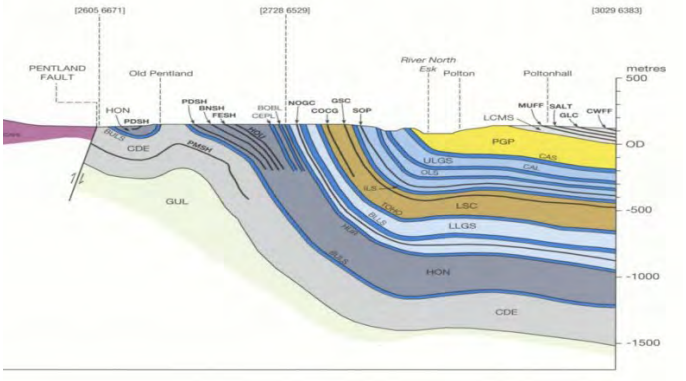

Figure 3: Cross section of the Midlothian Coalfield highlighting the edge and flat coals. Note the Pentland Hills Fault forming the western boundary of the field. Relevant geologic units include Lower Coal Measures (LCMS) Passage Formation (PGP), Upper Limestone Formation (ULGS), Limestone Coal Formation (LSC), and the Lower Limestone Formation (LLGS). (modified after British Geological Survey, 2003)

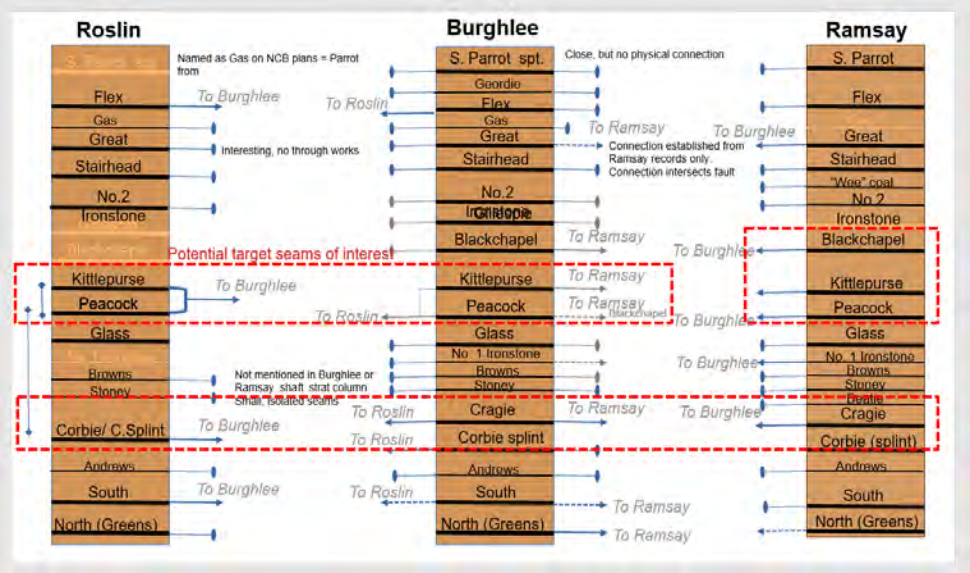

Figure 4. Named coal seams in each of the three collieries. The red dashed lines indicate seams that are hydraulically connected between collieries. Courtesy of Dr. Samuel Graham, University of Edinburgh.

The coalfield area is drained by the North and South Esk Rivers and their tributaries. After coal mining ceased in Scotland in the late 20th century, natural groundwater began filling voids left behind flowing from the southwest to the northeast. Groundwater is recharged by precipitation runoff from the surrounding Pentland Hills. Ambient groundwater temperatures can vary in the mines across Scotland ranging from 12-21° C with a mean of 17° C (Gillespie and Crane, 2013) but measurements from the Bilston Glen Colliery show 15° C. These temperatures can vary due to a variety of factors including the sampling location, the recharging source, the depth of the formation, and the local geothermal gradient, which can range from 17-34 °C/km in similar coal fields in Britain (Farr et al., 2020). Groundwater flow rates can vary widely due to the complex hydrogeological systems created from legacy mine workings and the result of decades of groundwater flow re-entering a system that had been modified for mining for so many years.

2.3 Legacy Mine Workings

For 200+ years coal mining in the UK was performed at differing intensity due to various supply and demand scenarios (Todd, 2023). Older mines utilized manual labor, employing the 'pillar and room' technique. Here, support props sustained the structure while explosives were employed to extract coal manually. Variations of this method were referred to as 'stoop and room' in Scotland (Younger and Adams, 1999). Typically, certain portions of coal, termed stoops or pillars, were intentionally left intact to ensure the stability of the workings (Figure 5). A series of these rooms and pillars would exist and be interconnected with tunnels containing mining rails and other equipment associated with coal extraction. These workings and all associated infrastructure are referred to as a colliery.

Within the proposed Geobattery area, there are three distinct collieries: Roslin, Burghlee, and Ramsay. Groundwater flow and mine water flow from the southwest to the northeast from Roslin to Ramsay, approximately 5 km away (see Figure 5). Vertical shafts at each colliery intersect various coal seams, as depicted in Figure 4. At Roslin, the coal seams are separated by distances ranging from 17 m to 55 m, with an average separation of around 35 m, and the pit bottom reaches

a depth of 280 m. Many of these coal seams are present in all three collieries, and some exhibit hydraulic connectivity, as indicated by the red dashed lines in Figure 4. These connected seams serve as the main pathways for fluid flow within the Geobattery.

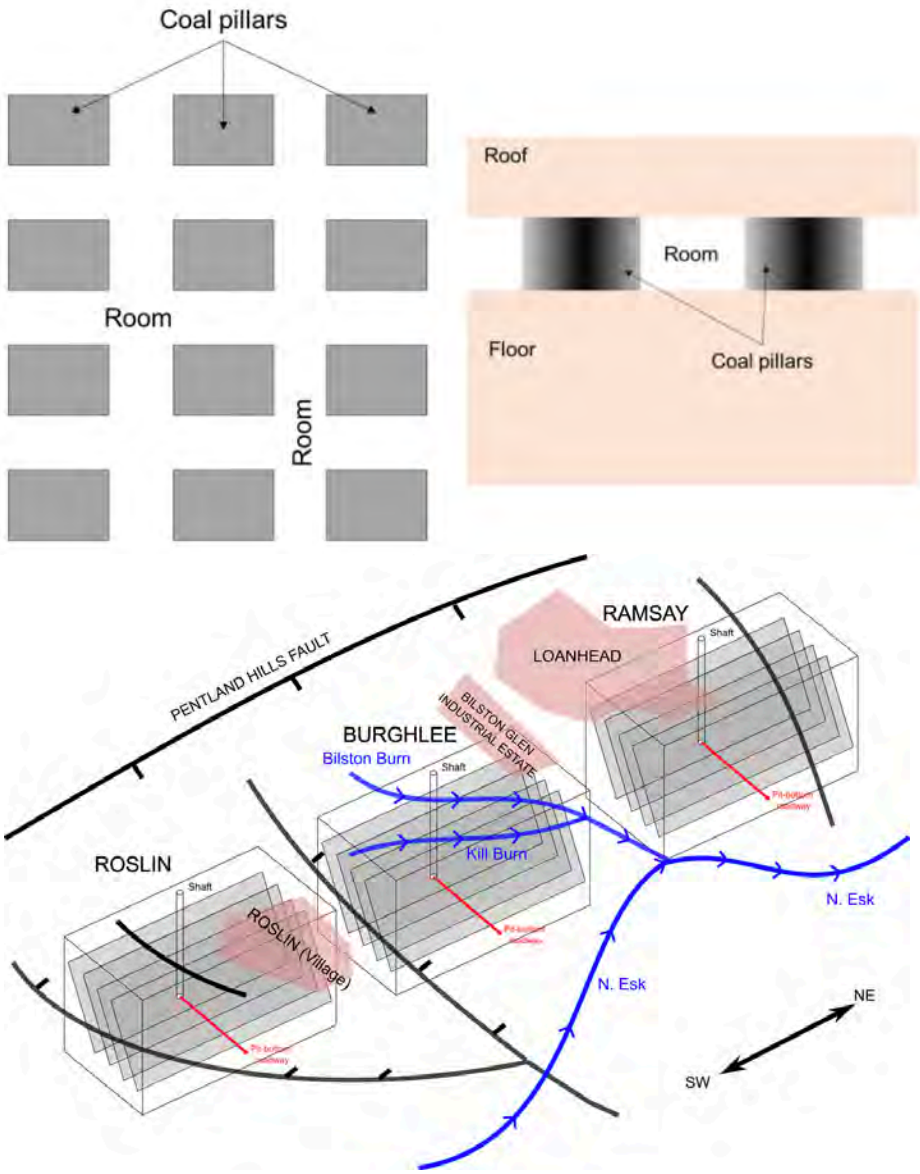

Figure 5: Top-Plan view and cross section view (left) of a simplified layout of a pilar and room working adapted from Younger and Adams (1999). Bottom-Schematic diagram of the tilted planar mined-out coal seams separated by low-permeability rock in the three collieries making up the Geobattery. The pit-bottom roadway connecting the coal seams at the bottom of the mine workings (~300 m deep) is also shown in red (Todd, 2023). Black curves are fault surface traces and blue lines are surface water courses.

3. Preliminary Modeling

Based on the geology described in Section 2, the project team has built a geological model with details on faults, fractures, and formation layers (Figure 6a). It is challenging to create a robust mesh considering all these features for multiphysics coupled simulation. The uncertainties related

to formation parameters (e.g., hydraulic conductivity) as well as the legacy mine working (i.e., pillar versus room) may lead to misinformed predictions of the system. Consequently, we focus on a simplified subset of the original large-scale structural mode while preserving essential geometric information concerning the extent of three collieries, the identified primary conduits for heat storage and transfer (i.e., the Kittlepurse and Peacock coal seams), the primary fault zone between the Roslin and Burghlee collieries, and the associated dip and thickness for each feature as shown in Figure 6b. Note that the team is using two distinct modeling approaches to represent the mine system: one involves a deterministic model implemented in the TOUGH code (Doughty et al., 2024), and the second employs a stochastic approach, using the MOOSE simulator. The initial results of the MOOSE simulations are described below.

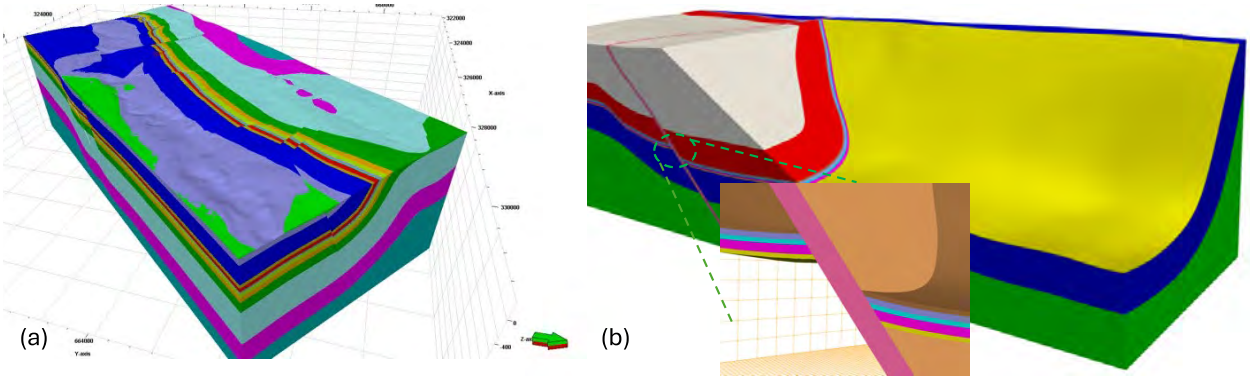

Figure 6. (a) A geological model with detailed structural features. (b) A simplified geological model with key features (i.e., heat transfer conduit – the Kittlepurse and Peacock coal seams and the fault between the Roslin and Burghlee collieries).

The site-specific initial distribution of temperature, effective stress, as well as pore pressure are all unknown at this stage. A 2D regional groundwater flow model at steady-state is used to approximate the pore pressure distribution. We used the open-source Multiphysics Object-Oriented Simulation Environment (MOOSE, Giudicelli et al. 2024) and performed hydraulic simulations using the parameters in Table 1. For boundary conditions, we applied no-flux boundaries for the two sides perpendicular to the ground water flow directions, while a hydraulic static pore pressure is applied at the downgradient surface. A ground water flow flux of 10^{-4} m/s is applied to the upgradient surface based on work done by Doughty et al. (2024). 15 L/s of water is injected into each of the targeted three coal seams (i.e., 45 L/s total water injection). Within this simulation, we used tracers to show the convective thermal plume distribution, excluding heat conduction. Figure 7 shows the tracer plume that reaches the fault and then continuously travels through the conductive coal seams to the downstream Burghlee and Ramsay collieries. The modeled tracer plumes show that the ground water flow difference across different coal seams within the Roslin colliery affects the tracer distribution. However, this impact is negligible once the plume passes through the fault.

Table 1: Parameters of coal seams and limestone bedrock used in initial modeling simulations.

Model component	Permeability (m^2)	Porosity
Coal Seam	10^{-12}	0.20
Fault	10^{-13}	0.05
Limestone bedrock	10^{-18}	0.01

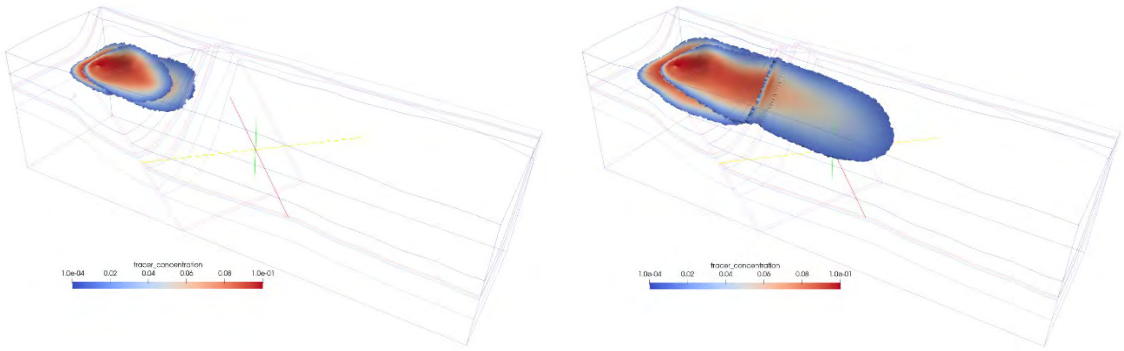

Figure 7. Tracer plume evolution after ½ year (left) and two years (right) of continuous water injection into the targeted Kittlepurse and Peacock coal seams.

The above hydraulic simulation will be expanded into thermo-hydraulic (TH) and thermo-hydro-mechanical (THM) coupled simulations with more *in-situ* data of effective stress and thermal gradient to constrain the model. In addition, we will subdivide the three coal seams into a suite of blocks and statistically assign material properties (e.g., Young's modulus, porosity, permeability) for those blocks so the pillars and rooms shown in Figure 5 can be represented. These statistical simulations will be used to reduce uncertainty by comparing and matching against future *in-situ* testing and monitoring data. Eventually, the THM models with reduced uncertainty will be used to predict performance, design operation, and quantify impacts of the Geobattery.

5. Conclusions and Future Work

The overall concept of storing waste heat in abandoned mine workings for seasonal district heating and cooling is of interest on the domestic and international scale. The mines beneath Edinburgh offer great a opportunity to explore the feasibility of mine thermal energy storage because of established flow paths, favorable groundwater flow magnitude, direction, and temperature, and interconnected mine workings. Initial modeling efforts show that flow is impacted by the fault separating the Roslin and Burghlee collieries. The plume of heated water then travels through the fault downstream, passing through the Kittlepurse and Peacock coal seams.

Over the next year, drilling will commence leading to data collection of key information to better constrain TH and THM simulation efforts. Once data are obtained on the various formations, the team will conduct more sophisticated modeling to ensure safe and efficient operations can be planned and executed for the project. The work being undertaken by the G2C consortium will be instrumental in evaluating this technology and in offering a solution for waste heat storage in mine workings and downstream utilization in community heating and cooling systems.

Technical Feasibility of a Novel Geothermal-Solar Thermal Hybrid Plant

Carl Belmonte

Mapúa University

Keywords

Single-flash geothermal power plant, Solar parabolic dish, Hybrid power generation, Thermodynamic analysis, HelioFocus

ABSTRACT

Coal plants are more efficient than geothermal plants since thermal efficiency is proportional to temperature. When geothermal steam comes out of the well, the temperature is around 180°C compared to coal plants with steam temperatures greater than 500°C. This is why typical coal plants have a thermal efficiency of 36%, whereas geothermal has about 18%. In this work, a novel hybrid system was designed to control the temperature and pressure of geothermal steam to approximate the steam conditions and thermal efficiency of coal plants using solar thermal technology. The thermodynamic model of the hybrid system was developed wherein heat transfer was modified by directly using steam as the heat transfer fluid instead of air to eliminate heat loss in the heat exchanger resulting in more efficient use of solar energy. The results showed that the hybrid plant produced a net additional power output of 26% compared to a standalone geothermal plant due to increased thermal efficiency from 17% to 34%. The hybrid plant also performed better than geothermal and solar thermal plants operating separately. The novel design proved technically feasible and more efficient than all current hybrid designs. Detailed engineering design and economic feasibility of the proposed system are recommended for future studies.

1. Introduction

Geothermal energy is a renewable resource that is virtually unlimited much like solar and wind energy. However, its advantage over the latter is that it provides sustained thermal energy 24 hours a day and 7 days a week. Geothermal wells continuously produce steam because the Earth's magma will remain hot for billions of years. The disadvantage of geothermal energy is the geographic limitation. It is found in the boundaries of tectonic plates such as the Circum-Pacific Belt. The Philippines has access to geothermal steam resources because it is a part of this region. Another disadvantage is that the quality of geothermal steam is beyond the control of engineers. Steam

quality can be controlled in a coal power plant because it is produced in the boiler. In contrast, in a geothermal power plant, the quality of the steam depends on the characteristics of the geothermal reservoir. Geothermal steam loses energy as it goes up the well due to pressure loss, friction, and turbulence. In power generation, the temperature is above 150°C (Li et al., 2020) when the steam comes out of the well compared to the steam in coal plants which is superheated at much higher temperatures. This is why coal power plants are more efficient than geothermal power plants because thermal efficiency is proportional to temperature. Generally, the higher the temperature, the higher the efficiency. If the temperature and pressure of geothermal steam can be controlled in such a way that it approximates the steam in coal power plants, then the thermal efficiency of geothermal power plants will significantly increase. Solar thermal energy systems, particularly concentrated solar power (CSP), can be utilized to achieve this improvement in power plant performance. If the two systems are combined in such a way that they produce a common steam output, then the hybrid system will be more efficient than the two separate systems. In solar energy, CSP is falling behind solar photovoltaic (PV). As of 2020, the global installed capacity of solar PV and CSP is 707 and 6 GW, respectively, according to the International Renewable Energy Agency (*Renewable Capacity Statistics*, 2021). One reason for this large gap in installed capacity is that PV is a simpler system with no moving parts. It directly converts solar energy to electricity without needing conversion to mechanical energy such as a rotating turbine and electric generator. Solar thermal energy plants need a thermodynamic cycle to convert heat to electricity. It also requires more equipment and has a higher capital cost than PV. Another reason is that PV costs have dropped due to economies of scale in manufacturing and low production costs in China. Despite the disadvantages, solar thermal energy systems have one important advantage. Combined with a geothermal power plant, it can improve the overall thermal efficiency of the combined Rankine cycle. It has a synergy with geothermal energy that PV cannot offer.

Several hybrid designs for geothermal-solar thermal systems have been proposed in the literature. Cardemil et al. (2016) analyzed the performance of single and double-flash geothermal power plants integrated with parabolic trough collectors (PTC) for various reservoir conditions. The results showed that a greater increase in power output was observed when solar thermal energy was used in superheating the steam compared to evaporating the brine for both single and double-flash hybrid plants. The 2nd law efficiency also increased by at least 3% when the steam temperature increased. Similarly, Assad et al. (2021) investigated the hybridization of a single-flash geothermal power plant and a PTC system. The steam temperature increased by 50°C due to the additional heat provided by the PTC, effectively increasing the steam temperature from 200°C to 250°C and improving the power output and efficiency of the system. McTigue et al. (2018) evaluated different methods for adding solar heat to a double-flash geothermal power plant. It was found that reheating the brine was the best approach to reduce the risk of scaling and the cost of retrofitting. Bonyadi et al. (2018) proposed a novel hybrid solar geothermal power plant by adding a solar topping steam Rankine cycle to a binary geothermal power plant and assessed its performance. The hybridization scheme led to a higher solar-to-electricity conversion efficiency without affecting the binary bottoming cycle. The power output also increased during the summer days and consumed fewer geothermal resources than a stand-alone binary geothermal power plant.

This paper presents some key differences in the design of the proposed hybrid geothermal-solar thermal system compared to other hybrid systems in the literature. The main difference lies in the type of solar collectors used in the solar thermal system. Solar parabolic HelioFocus dishes are selected in this work because they can produce higher heat transfer fluid temperatures, higher

topping cycle steam temperatures, and higher thermal efficiencies than PTCs or other CSP technologies (Keck et al., 2015). The innovation in the novel hybrid system is implementing all these improvements in a single system. The study is needed to prove in principle that the proposed geothermal-solar thermal hybrid plant is different from and superior in some measures to other hybrid systems found in the literature.

This study aims to design a system to control the temperature and pressure of geothermal steam to approximate the steam conditions in coal power plants using HelioFocus or similar technology. The objectives are: (1) to develop a thermodynamic model of the proposed hybrid geothermal-solar thermal system; (2) to modify the heat transfer between the geothermal steam and the hot air; and (3) to evaluate the performance of the proposed hybrid system.

The long-term plan is to develop this novel technology by conducting further research, building a small prototype plant, and eventually commercializing the technology. Only after making the technology available to the industrial market will society benefit from it. Geothermal power producers will benefit from increased thermal efficiency and power output if the commercialization is successful. The benefits will reach consumers through lower electric costs and less carbon dioxide emission than fossil fuel plants. This will also mitigate the public's grave concern about climate change.

This study covers the basic design, specifications, and thermodynamic model of a hybrid single-flash geothermal-solar thermal power plant. It aims to demonstrate the technical feasibility and increase in thermal efficiency and electrical energy output of the proposed hybrid geothermal-solar thermal system. The data in this paper are gathered from technical literature on hybrid geothermal-solar thermal systems and interviews with an engineer with working experience in geothermal power plant operations. The thermodynamic and heat transfer model is theoretical. It is based on specialized software modeling and manual computations. Assumptions in the model are based on either data gathered or extrapolation of data. The solar thermal system is based on HelioFocus solar dish technology. Data from HelioFocus is used when available. This study does not cover the detailed engineering design of the equipment and components of the proposed hybrid geothermal-solar thermal system. It is limited to available technical data from HelioFocus. Since the thermodynamic and heat transfer model is theoretical, it does not include experimental testing or empirical and operational data. This paper aims for technical feasibility by demonstrating consistency with thermodynamic and physical laws. It does not include economic feasibility because this would require cost data and price quotations from HelioFocus and other equipment suppliers. Since the proposed hybrid plant is not yet in existence, equipment with matching specifications may not be available in the market. In such cases, the equipment suppliers must conduct internal studies before providing cost estimates and price quotations.

2. Review of Related Literature

This paper proposes a novel hybrid geothermal-solar thermal power plant by combining a single-flash steam geothermal power plant with a solar thermal system based on HelioFocus technology to improve plant thermal efficiency and power output. The HelioFocus system uses large solar parabolic dishes to transfer solar thermal energy to the steam to increase its temperature and pressure and attain similar steam conditions found in coal power plants.

2.1 Geothermal Energy

Geothermal energy is the thermal energy produced within the earth used for either electric power generation or heat generation depending on the enthalpy of the resource (Li et al., 2020). The former employs equipment akin to coal power plants including steam generators, steam turbines, and condensers in a thermodynamic Rankine cycle (Martín-Gamboa et al., 2015). However, instead of a steam generator, production wells drilled into the geothermal reservoir supply the steam, which powers a turbine and generator set to produce electricity (*GeoVision*, 2019). Then the energy-depleted fluids are injected back into the earth to recover heat for continuous energy extraction.

2.2 Types of Geothermal Power Plants

The three basic types of geothermal power plants are dry steam, flash steam, and binary cycle as shown in Fig. 1. Low-temperature resources are used in binary cycle power plants (*Geothermal Rising*, 2016). Conversely, high-temperature resources are used in dry steam and flash steam power plants. Binary cycle systems can operate at temperatures as low as 85°C (Barbier, 2002). However, conventional electric power generation is restricted to fluid temperatures above 150°C, as for dry and flash steam systems. In flash steam power plants, the brine is flashed and throttled, and the steam is extracted from the brine. In contrast, dry steam power plants do not need a flashing process because the resource is already steam. Binary cycle power plants employ an organic Rankine cycle (Greenhut, 2010), wherein the brine supplies heat to an organic working fluid through a heat exchanger.

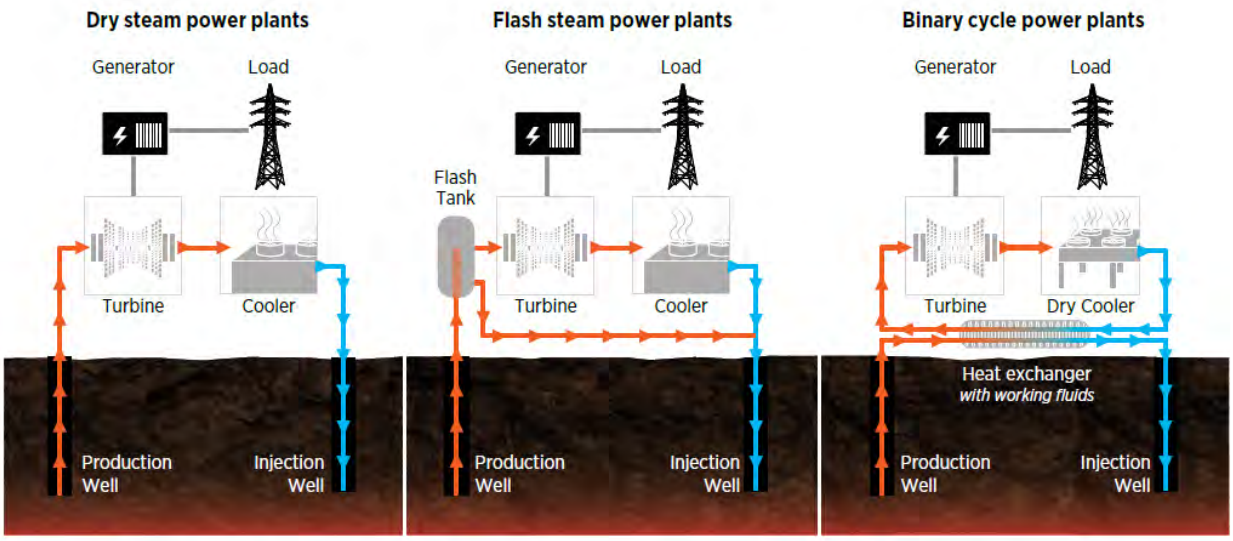

Figure 1: Geothermal power plant technologies (*GeoVision*, 2019).

2.3 Efficiency of Geothermal Power Plants

According to Barbier (2002), geothermal power plants only achieve about a third of the electricity generation efficiency of coal power plants due to the low temperatures of geothermal steam. The

efficiency of geothermal power plants ranged from 10% to 17% with steam temperatures of less than 250°C. Zarrouk and Moon (2014) conducted a worldwide review to determine the conversion efficiencies of geothermal power plants based on the reservoir enthalpy. The results showed that the average conversion efficiency of geothermal power plants was around 12%. The efficiencies were as low as 1% in binary power plants and as high as 21% in dry steam power plants. Fig. 2 shows the geothermal power plant efficiency as a function of the reservoir enthalpy. Dry and flash steam power plants are more efficient than binary plants because they utilize higher working fluid temperatures corresponding to higher enthalpies. Besides plant design, many other factors affect the efficiency of geothermal power plants such as energy losses from the well, non-condensable gas content, parasitic load, heat losses, and turbine and generator efficiency (Zarrouk and Moon, 2014).

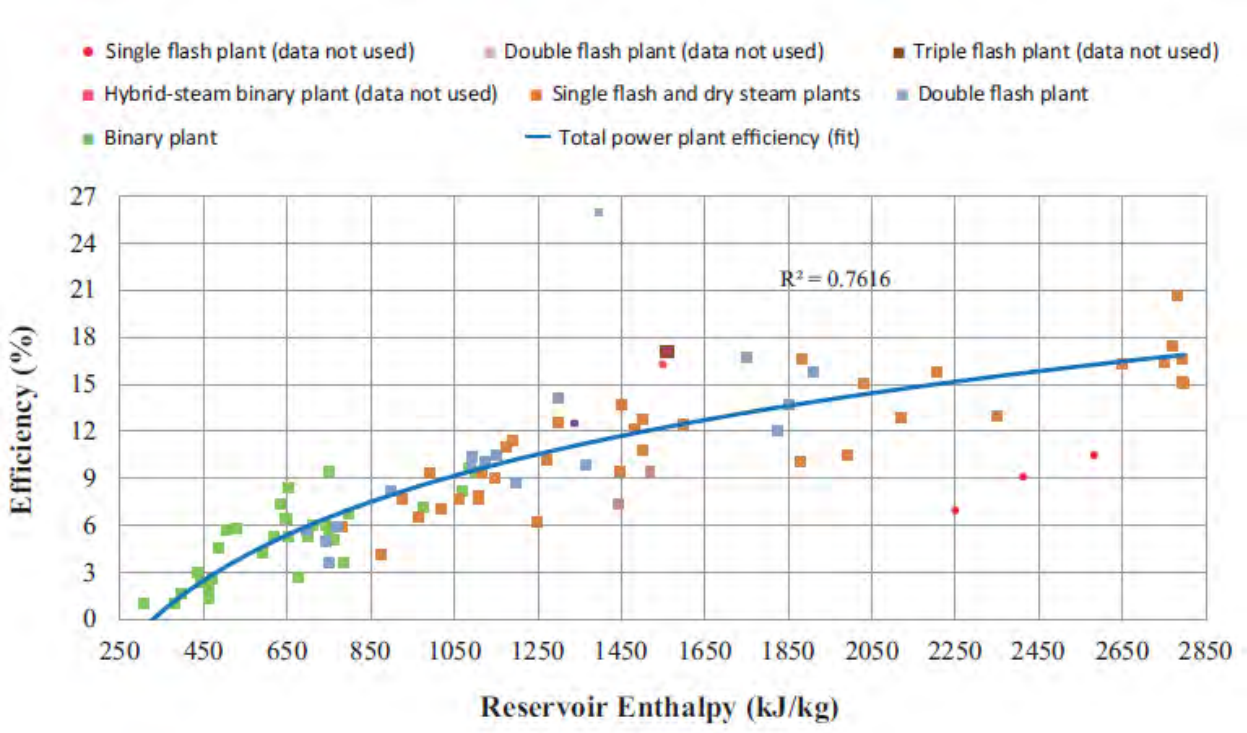

Figure 2: Geothermal power plant efficiency (Zarrouk and Moon, 2014).

2.4 Solar Thermal Energy

Solar thermal technology indirectly converts solar energy into electrical energy using a thermodynamic cycle (Desideri et al., 2013). In high-temperature applications, CSP plants focus solar energy onto special receiving surfaces using reflecting mirrors to achieve the necessary temperatures for electric power generation. Solar energy is captured by the solar field and converted into thermal energy which can be stored (Li et al., 2020). The power block then uses mechanical work to convert heat into electricity.

2.5 Types of Solar Thermal Power Plants

The four main types of concentrated solar power plants are parabolic trough collectors, solar power towers, linear Fresnel reflectors, and solar parabolic dishes as shown in Fig. 3. Parabolic trough collector plants use parabolic reflectors that direct sunlight onto an absorber tube positioned in the parabola's focal line, moving in tandem with the sun (Zhang et al., 2013). Power tower plants consist of distributed mirrors that track the sun independently and direct its rays onto the tower top (Müller-Steinhagen and Trieb, 2004). Similarly, linear Fresnel reflector plants consist of linear mirror strips that reflect and focus the sun rays onto a cylindrical receiver on a linear tower (Islam et al., 2018). Lastly, solar parabolic dish plants consist of parabolic point-focus concentrator dishes that track the sun on two axes and reflect solar radiation onto a Stirling engine receiver at its focus to generate electricity.

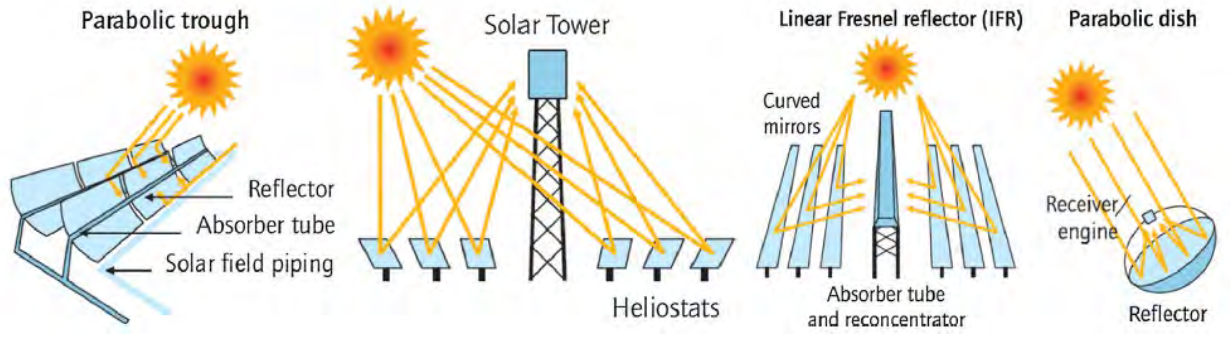

Figure 3: Concentrated solar power technologies (Gonzalo et al., 2019).

3. Methodology

This study demonstrates the technical feasibility of a novel hybrid geothermal-solar thermal power plant by developing a thermodynamic model and conducting a thermodynamic analysis to determine the increase in thermal efficiency and power output of the system compared to (1) a standalone geothermal power plant and (2) a geothermal and solar thermal power plant operating separately. The proposed hybrid system consists of a single-flash steam geothermal power plant and a solar thermal dish system based on HelioFocus technology. The thermodynamic model of the hybrid system is developed in the Engineering Equation Solver software. Manual calculations are also done to highlight important results.

3.1 Hybrid Geothermal-Solar Thermal System

The hybrid plant employs a single-flash steam Rankine cycle integrated with solar thermal energy. The schematic diagram in Fig. 4 shows the components of the hybrid plant. The geothermal fluid from the production well undergoes flashing through the expansion valve and then enters the separator where the saturated vapor and liquid are separated from the mixture. Before reaching the steam turbine, the saturated vapor is directed to the solar field, receiving heat from the solar dishes to superheat the steam. Then it expands in the steam turbine and travels to the condenser where the steam condenses into saturated liquid. Next, another separator removes the non-condensable gases from the saturated liquid and releases them into the atmosphere. Finally, the saturated liquid is pumped back into the reinjection well and the cycle repeats.

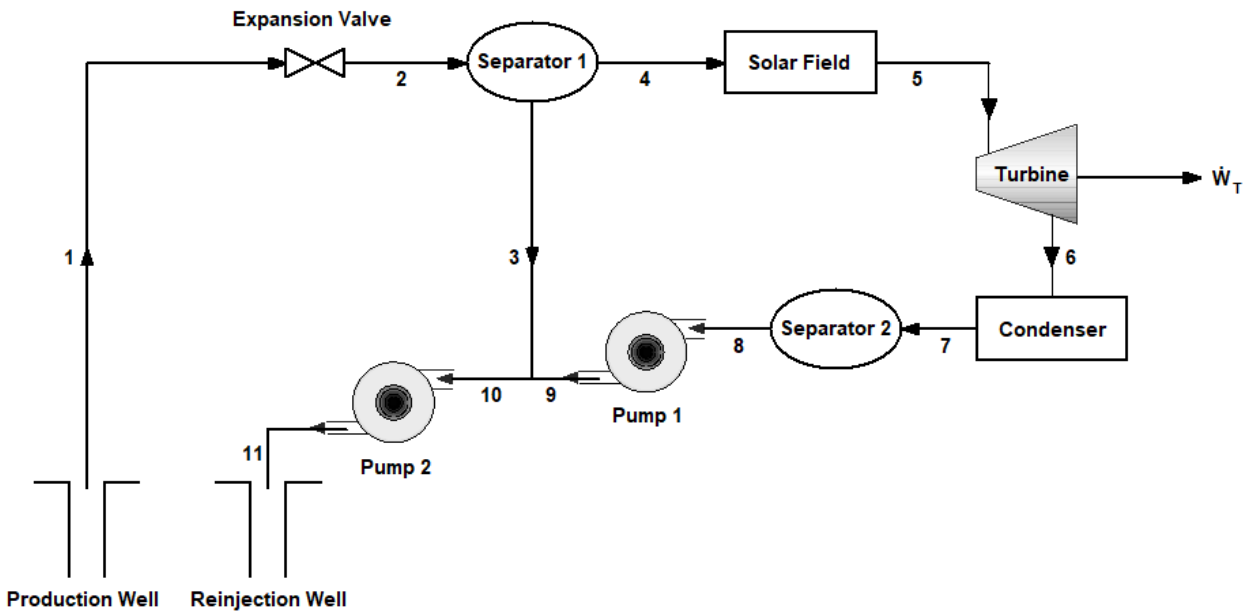

Figure 4: Schematic diagram of the hybrid geothermal-solar thermal power plant.

3.2 Solar Thermal System

The HelioFocus solar thermal system consists of a solar field of parabolic dishes, a heat transmission system, and a heat exchanger (Keck et al., 2015). A volumetric receiver is mounted at the focal point of each dish. It absorbs solar radiation reflected by parabolic mirrors and heats the air to 1000°C. Heat transfer between the hot air and geothermal steam is modified by using geothermal steam directly as the heat transfer fluid instead of air to eliminate the need for a heat exchanger. Heat transfer occurs directly at the receiver of the solar dishes. This reduces the equipment cost and eliminates the heat loss in the heat exchanger resulting in more efficient use of solar energy. From the steam pipe, geothermal steam is distributed to multiple pipes going to the solar dishes. After the solar dishes heat the steam, the steam pipes converge into a single pipe going to the turbine.

The HelioFocus system is selected as the solar thermal system to be integrated with geothermal energy because it has the highest steam temperature and solar efficiency among all CSP technologies. Table 1 shows some of the differences between CSP technologies. The dual axis tracking mechanism of parabolic dishes allows the curved mirrors to always point directly at the sun (Islam et al., 2018). This makes them more efficient than parabolic trough collectors and solar power towers, which have smaller receiving areas for sunlight. Each dish has a receiver installed near the mirrors, resulting in more efficient heat collection, higher concentration ratios, and minimal land use. The modular design also gives flexible installation capacities.

Parameter	Parabolic Trough Collector	Linear Fresnel Reflector	Solar Power Tower	Solar Parabolic Dish	HelioFocus Dish
Capacity (MWe)	10-200	10-200	10-150	0.01-0.4	10-100
Concentration ratio	25-100	70-80	300-1000	1000-3000	2000
Solar efficiency max. (%)	20	21	20	29	30
Land requirement	Large	Medium	Medium	Small	Small
Operating temperature of the solar field (°C)	290-550	250-390	250-650	800	1000
Heat transfer fluid	Synthetic oil, water/steam	Water/steam	Water/steam, molten salt	Air, hydrogen, helium	Air
Steam conditions (°C/bar)	380-540/100	260/50	540/100-160	Not applicable	620/160

Table 1: Comparison of CSP technologies (Keck et al., 2012, 2015, Shi, 2015, Islam et al., 2018).

3.3 Model Assumptions

In this study, the solar dishes in the hybrid system heat the geothermal steam directly to increase its temperature and pressure from 180°C to 500°C and 7 bars to 160 bars, respectively. Steam conditions are typical for coal plants. Consequently, the hybrid plant is expected to achieve the same thermal efficiency. Unless otherwise stated, the solar dishes are assumed to operate based on the available design parameters provided by the manufacturer. The pump work is assumed to be negligible, and the condenser temperature is set to 40°C. The following are the assumptions for each plant model:

3.3.1 Hybrid Model

- The steam quality at the turbine exhaust is 0.85.
- The steam temperature at the turbine inlet is 500°C.
- The steam pressure at the turbine inlet is 160 bars.

- The thermal efficiency of the steam turbine is 35%.
- The heat loss in the solar receiver is 10%.

3.3.2 Geothermal Model

- The steam quality at the turbine exhaust is 0.9.
- The steam temperature at the turbine inlet is 180°C.
- The steam pressure at the turbine inlet is 7 bars.
- The thermal efficiency of the steam turbine is 18%.

3.3.3 Solar Thermal Model

- The steam temperature at the turbine inlet is 500°C.
- The steam pressure at the turbine inlet is 160 bars.
- The thermal efficiency of the steam turbine is 36%.
- The water temperature at the heat exchanger inlet is 40°C.
- The water pressure at the heat exchanger inlet is 1 bar.

3.4 Thermodynamic Model

The thermodynamic model of the proposed hybrid system is developed using mass and energy balance equations based on the laws of thermodynamics to determine the thermal efficiency and power output.

3.4.1 Mass Balance

The following equations give the mass flow rates for each state in the hybrid system (Assad and Rosen, 2021):

$$\dot{m}_1 = \dot{m}_2 = \dot{m}_{10} = \dot{m}_{11} \quad (1)$$

$$\dot{m}_2 = \dot{m}_3 + \dot{m}_4 \quad (2)$$

$$\dot{m}_4 = x_2\dot{m}_2 = \dot{m}_5 = \dot{m}_6 = \dot{m}_7 = \dot{m}_8 = \dot{m}_9 \quad (3)$$

$$\dot{m}_{10} = \dot{m}_3 + \dot{m}_9 \quad (4)$$

where ṁ and x are the mass flow rate and the steam quality of the geothermal fluid, respectively.

3.4.2 Energy Balance

The following equations give the energy rate balance for each state and component in the hybrid system (Assad, 2021, Assad and Rosen, 2021):

State 1: Saturated Liquid

$$h_1 = h_f \quad (5)$$

where h and h_f are the specific enthalpy of the geothermal fluid and the saturated liquid, respectively.

Expansion Valve:

$$h_1 = h_2 \tag{6}$$

State 2: Two-Phase

$$h_2 = h_f + x_2 h_{fg} \tag{7}$$

where h_{fg} is the phase change-specific enthalpy of the geothermal fluid.

Separator 1:

$$\dot{m}_2 h_2 = \dot{m}_3 h_3 + \dot{m}_4 h_4 \tag{8}$$

State 3: Saturated Liquid

$$h_3 = h_f \tag{9}$$

State 4: Saturated Vapor

$$h_4 = h_g \tag{10}$$

Solar Field and State 5: Superheated Vapor

$$Q_{solar} = \dot{m}_4 (h_5 - h_4) \tag{11}$$

where $\dot{Q}_{solar}$ is the solar heat addition rate.

Steam Turbine:

$$W_T = \dot{m}_5 (h_5 - h_6) \tag{12}$$

where $\dot{W}_T$ is the steam turbine power output.

State 6: Two-Phase

$$h_6 = h_f + x_6 h_{fg} \tag{13}$$

Condenser:

$$Q_{cond} = \dot{m}_6 (h_6 - h_7) \tag{14}$$

where $\dot{Q}_{cond}$ is the condenser heat rejection rate.

State 7: Saturated Liquid

$$h_7 = h_f \tag{15}$$

Separator 2 and State 8: Saturated Liquid

$$\dot{m}_8 h_8 = \dot{m}_7 h_7 \tag{16}$$

Pump 1:

$$W_{P1} = \dot{m}_8 (h_9 - h_8) \tag{17}$$

where $\dot{W}_P$ is the pump power.

State 9: Sub-Cooled Liquid

$$h_9 - h_8 = v_8(P_9 - P_8) \quad (18)$$

where v and P are the specific volume and pressure of the geothermal fluid, respectively.

State 10: Sub-Cooled Liquid

$$\dot{m}_{10}h_{10} = \dot{m}_3h_3 + \dot{m}_9h_9 \quad (19)$$

Pump 2:

$$W_{P2} = \dot{m}_{10}(h_{11} - h_{10}) \quad (20)$$

State 11: Sub-Cooled Liquid

$$h_{11} - h_{10} = v_{10}(P_{11} - P_{10}) \quad (21)$$

3.4.3 Net Power Output

$$W_{net} = W_T - (W_{P1} + W_{P2}) \quad (22)$$

3.4.5 Thermal Efficiency

$$\eta_{th} = \frac{W_{net}}{\dot{m}_1(h_1 - h_{ref}) + Q_{solar}} \quad (23)$$

where h_{ref} is the specific enthalpy of the geothermal fluid at the reference temperature (25°C).

3.5 Theoretical Calculation of Heat Loss

The HelioFocus parabolic dish uses a volumetric solar receiver. Solar radiation passes through a transparent window to transfer energy to the volumetric solar receiver inside a pipe where the heat transfer fluid flows. The transparent window allows solar radiation to come in and light and infrared radiation from the solar receiver to come out. Hence, radiation travels both ways: in and out of the pipe through the transparent window. The outgoing radiation is a heat loss because it exits to the atmosphere outside the thermodynamic system of the hybrid plant. The heat loss can be theoretically estimated using the Stefan-Boltzmann law. The HelioFocus solar receiver can heat air to 1000°C. This is assumed to be the equilibrium temperature.

Assuming that the incoming solar irradiance is equal to the outgoing radiant emittance of the solar receiver,

$$E = M \quad (24)$$

where E and M are the incoming solar irradiance and outgoing radiant emittance, respectively.

From the Stefan-Boltzmann law,

$$M = eoT_e{}^4 \quad (25)$$

where e, o, and T_e are the emissivity of the solar receiver, the Stefan-Boltzmann constant, and the equilibrium temperature, respectively.

Combining Equations (24) and (25),

$$E = eoT_e{}^4 \tag{26}$$

In the proposed hybrid plant, geothermal steam is heated to 500°C by the incoming solar irradiance. The outgoing radiation is heat loss. Again, this can be calculated from the Stefan-Boltzmann law:

$$J = eoT^4 \tag{27}$$

where J is the radiant emittance of the solar receiver at T = 500°C.

The heat loss is given by:

$$q = \frac{J}{E} = \frac{e\,o\,T^4}{e\,o\,T_e{}^4} \tag{28}$$

where q is the heat loss percentage.

Simplifying Equation (28),

$$q = \left(\frac{T}{T_e}\right)^4 \tag{29}$$

However, this assumes that the incoming solar irradiance equals the outgoing radiant emittance. In reality, the incoming solar irradiance is greater than the outgoing radiant emittance because not all the heat energy is radiated out. Some heat energy is used to heat the air to 1000°C. Hence, the equilibrium temperature must be higher than 1000°C and the true value of the heat loss must be less than the upper bound of the heat loss.

The lower bound of the heat loss can be obtained by calculating a higher equilibrium temperature:

$$E_h = eoT_h{}^4 \tag{30}$$

where E_h and T_h are the higher incoming solar irradiance and higher equilibrium temperature, respectively.

Since the heat loss is equal to the radiant emittance of the solar receiver at T_e = 1000°C,

$$qE_h = M \tag{31}$$

Substituting the Stefan-Boltzmann formula and simplifying,

$$qeoT_h{}^4 = eoT_e{}^4 \tag{32}$$

$$T_h = \frac{T_e}{\sqrt[4]{q}} \tag{33}$$

Let the lower bound of the heat loss = q'

q' is obtained by substituting T_h for T_e in Equation (29),

$$q' = \left(\frac{T}{T_h}\right)^4 \tag{34}$$

4. Results and Discussion

4.1 Thermal Efficiency

4.1.1 Hybrid Geothermal-Solar Thermal Plant vs. Standalone Geothermal Plant

Thermal efficiency increases from 17% to 34% when a geothermal power plant is converted into a hybrid geothermal-solar thermal system. The calculation of thermal efficiency is based on specific enthalpy. The analysis starts at the steam turbine instead of the production well to obtain the useful energy input of the geothermal plant. This is the thermal energy of the extracted steam per unit mass. In the case of the hybrid plant, an additional solar energy input is added to the total energy input to account for the solar energy provided by the solar dishes. The useful energy output is expressed as the specific work of the turbine on a unit mass basis. Thermal efficiency is simply the ratio of the total energy output to the total energy input. The results agree with the thermal efficiencies typically found in coal plants.

4.1.2 Hybrid Geothermal-Solar Thermal Plant vs. Separate Geothermal and Solar Thermal Plants

Thermal efficiency increases from 24% to 34% when a separate geothermal and solar thermal plant is converted into a hybrid geothermal-solar thermal system The separate geothermal and solar thermal plants each produce their own steam to generate electricity. Consequently, they have different steam turbines and thermal efficiencies because of the differences in steam temperatures and pressures. The thermal efficiency of the solar thermal plant is 30%, whereas the geothermal plant is 18%. Thus, the average efficiency of the two plants is 24%. However, the hybrid system combines the two plants to produce a common steam output. As a result, the thermal efficiency of the hybrid plant is 34% which is higher than the two plants.

4.2 Power Output

4.2.1 Hybrid Geothermal-Solar Thermal Plant vs. Standalone Geothermal Plant

Power output increases by 136% when a geothermal power plant is converted into a hybrid geothermal-solar thermal system. The power output is expected to improve significantly because the energy input has increased with the addition of the solar thermal system that collects solar energy. However, overall thermal efficiency has also increased, contributing to a higher power output. The solar energy input is deducted from the total power output to quantify the incremental power output due to the improved efficiency. The increase in power output due to improved thermal efficiency is 26%. Additionally, the calculated lower and upper bounds of the heat loss in the solar receiver are 2% and 13%, respectively. The assumed heat loss value in the hybrid model is within the computed range.

4.2.2 Hybrid Geothermal-Solar Thermal Plant vs. Separate Geothermal and Solar Thermal Plants

The power output has increased by 261% when a separate geothermal and solar thermal plant is converted into a hybrid geothermal-solar thermal system. The solar thermal plant is given the same solar energy input used in the hybrid plant to determine the energy output of the solar thermal plant compared to the additional energy output of the hybrid plant. The big advantage of the hybrid plant over a solar thermal plant is that the former applies solar energy to heat geothermal steam further which is already in a gaseous state. The latter uses solar energy to turn water into steam. The latent heat of vaporization is much higher than the specific heat of steam. Thus, the hybrid plant can produce a greater steam mass than a solar thermal plant given the same solar energy input. The results are summarized in Table 2.

Parameter	Geothermal	Geothermal & Solar Thermal	Hybrid
Thermal Efficiency (%)	17	24	34
Increase in Power Output with Hybrid (%)	136	261	-
Net Increase in Power Output with Hybrid (%)	26	-	-
Steam Temperature (°C)	180	180/500	500
Steam Pressure (bar)	7	7/160	160

Table 2: Power Plant Performance.

5. Conclusion

A novel hybrid system was designed to control the temperature and pressure of geothermal steam to approximate the steam conditions and thermal efficiency of coal power plants by integrating solar thermal energy with geothermal energy. The thermodynamic model was developed for the hybrid system wherein the heat transfer process was modified by directly heating the geothermal steam with solar dishes instead of using the air-to-steam heat exchanger to reduce equipment costs and eliminate heat loss in the heat exchanger. The hybrid system was analyzed to evaluate its performance compared to a standalone geothermal plant and separate geothermal and solar thermal plants. The novel design is technically feasible and capable of generating an additional 136% power output compared to a standalone geothermal plant due to additional solar energy input and increased thermal efficiency from 17% to 34%. It is also superior to a separate geothermal and solar thermal system as it can generate 261% more power output given equal solar energy inputs. Moreover, it achieves a higher thermal efficiency than all current hybrid designs in the literature. Further studies may be done on the detailed engineering design of the equipment and components of the proposed hybrid geothermal-solar thermal system. An economic feasibility study may also be recommended when the required equipment with matching specifications becomes available in the market.

Denver Basin, Play Fairway Analysis, Geothermal Direct Use, Combined Heat and Power, Sedimentary Basin Geothermal Play Type, Python Code, Favorability Map

ABSTRACT

This project is part of a national initiative to showcase the benefits of incorporating low-temperature geothermal resource assessment into the deployment of geothermal heating, combined heat and power (CHP), and geothermal direct-use (GDU) technologies. The initiative was established to accelerate the country's decarbonization efforts by identifying potential for low-temperature geothermal resource utilization (<150°C, e.g., CHP and GDU) in selected sedimentary basins with numerous population centers.

The play fairway analysis (PFA) methodologies in this study were adapted from previous PFA investigations of sedimentary basin geothermal play types (SBGPTs) that evaluated the potential for low-temperature resources (<150°C). Workflows, relevant datasets, a new Python library, and common and composite geological criteria maps are utilized to develop low-temperature geothermal resource favorability maps for the Denver Basin, a sedimentary basin spanning Colorado, Nebraska, and Wyoming. The replication of these methodologies in other SBGPTs can evaluate potential for low-temperature resources. To facilitate future assessment of low-temperature geothermal resources in SBGPTs, this project provides PFA workflows, data, tools, and favorability maps that will ultimately support the utilization of low-temperature geothermal resources in sedimentary basins.

1. Introduction

Sedimentary basins often have numerous layers of highly porous rocks and can have elevated fracture permeability, depending on the stress regimes affecting each basin. Candidate fluids for low-temperature geothermal utilization (<150°C) readily accumulate in these naturally porous, fractured rocks at depth. Nearly half of the United States is underlain by sedimentary basins that have been widely uninvestigated for low-temperature geothermal resource potential (USGS 2022).

A sedimentary basin geothermal play type (SBGPT) is influenced by its historical development and current tectonic and geological conditions. Crucial elements of an SBGPT include heat sources, the presence of circulating fluids (either natural or injected) for heat transport, reservoir porosity and permeability as well as storage attributes (both natural and induced), and reservoir

seals. These characteristics differ from hydrocarbon play systems, which are characterized by their source rock, reservoir traps, and trapping mechanisms (Doughty et al. 2018).

Most hydrothermal plays dominated by conduction in sedimentary basins occur in deep aquifers with a nearly normal thermal gradient (Moeck 2014). Variations in porosity and permeability are dictated by lithology, faulting, diagenetic patterns, and stress fields (Wolfgramm et al. 2009; Hartmann and Beaumont 2000), all of which are significantly shaped by the evolution, subsidence rates, and contemporary tectonics. Previous research focusing on geothermal resources in sedimentary formations emphasized those with high porosity/high permeability (~100 mD) for effective convection (Augustine 2014) or high porosity/low permeability at elevated temperature gradients, typically found at depths greater than 3 km (Moeck 2014). SBGPTs with low permeability may harbor petrothermal resources, which can be accessed by enhancing permeability through various reservoir stimulation techniques (Zimmermann et al. 2007). The storage capacity related to the host rock's porosity could critically affect the performance of Enhanced Geothermal Systems (EGS) in hot sedimentary aquifers (Rybach 1981).

It is imperative that more research be conducted to evaluate the potential for low-temperature geothermal resources in highly permeable and porous rocks of sedimentary basin geothermal play types (SBGPTs). This study centers on implementing a geothermal play fairway analysis (PFA), adapted from the hydrocarbon industry for low-temperature resources in SBGPTs, with a specific focus on the Denver Basin. The workflow is based on the forthcoming Geothermal Play Fairway Analysis Best Practices report (Pauling et al. 2023) and the Low-Temperature Geothermal Play Types assessment (Davalos-Elizondo et al. 2023), which identified a general geothermal PFA process (Figure 1).

PFA methodologies should be adapted to each geothermal play type individually. To classify this SBGPT, we used the scheme suggested by Coleman and Cahan (2012) based on a simple geological setting (Figure 2): (1) intracratonic basins created within the boundaries of a craton; (2) pericratonic basins formed near or accreted to the margins of the craton; (3) intercratonic basins formed between cratons and extend onto oceanic crust; and (4) oceanic basins that developed independently of cratons, primarily on oceanic crust.

Identification of areas with low-temperature geothermal potential in SBGPTs is a multicriteria geospatial decision problem. We suggested three essential criteria for the evaluation of low-temperature resources (Figure 1):

- Geologic criteria (e.g., heat, accessible fluid, permeability, and seal).
- Economic criteria (e.g., population, infrastructure, heating and cooling demand, levelized cost of heat).
- Risk criteria (e.g., exclusion areas, and environmental/natural disaster regions).

The focus of this paper is exclusively on the geological criteria, our goal is to identify potential locations for more detailed geological data collection. Further work has been conducted to effectively integrate other criteria in the future.

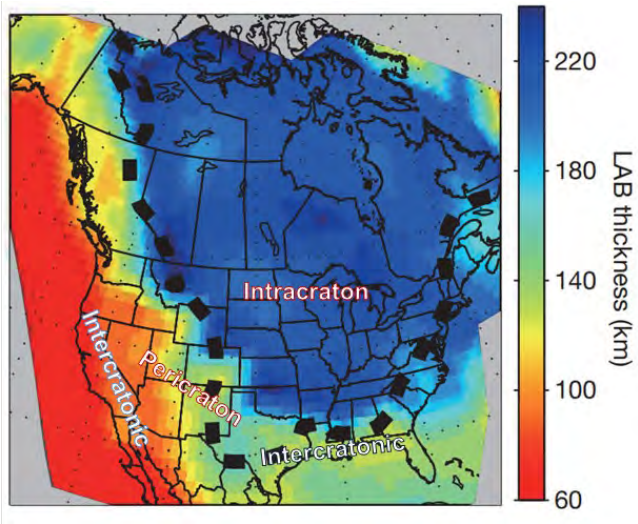

Figure 2: Present lithospheric-asthenospheric boundary thickness of North American continent from Yuan and Romanowicz (2010). A thick black dashed line indicates the borders of the craton

2. Background

The Denver Basin is characterized as a geothermal sedimentary foreland basin play type (Figure 3). This foreland basin is located on the eastern side of the Rocky Mountain orogenic belt in a pericratonic setting. Foreland basins are sedimentary basins that form between an orogenic belt and a craton, characterized by thick sedimentary deposits and asymmetric shape (Allen et al. 1986). They develop due to the weight of thickened crust and deposited sediments, causing the lithosphere to bend downward and create zones of extension and normal faulting. The formation of foreland basins is driven by factors such as horizontal compression, slab pull, lateral asthenospheric push, and delamination of the retreating mantle lithosphere (Garcia-Castellano and Cloetingh 2011). The rigidity of the plates also plays a key role in controlling the geometry and drainage history of foreland basins.

The Denver Basin is asymmetric, with suspected granite basement rocks underneath the sedimentary cover. It becomes much deeper as it stretches towards the Front Range in the western direction, reaching depths of around 3.5 km, while it is approximately 1.6 km deep in the eastern part (Dixon 2002). It spreads across more than 82,000-km^2 area, primarily in Colorado, followed by smaller portions in Wyoming and Nebraska (Fishman 2005). This basin is renowned for its petroleum extraction, with thousands of wells drilled for oil and gas production in various reservoir formations, providing data that describes the subsurface conditions.

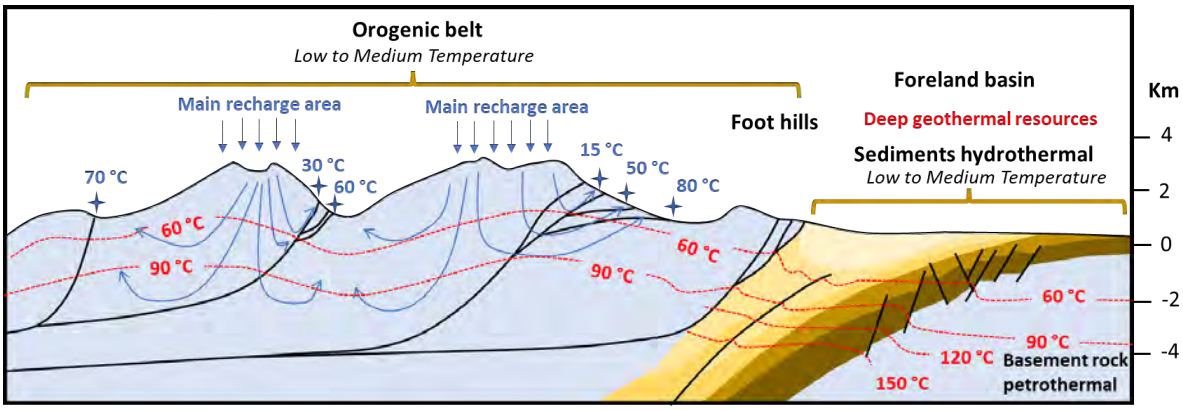

Figure 3: Orogenic Belt Geothermal Play Type and related SBGPT foreland basin. Modified from Moeck (2014)

3. Methodology

A classification of the Denver Basin geothermal play type as a foreland basin was established to outline the specific scope of work. Our approach includes: 1) identifying relevant data; 2) developing python code to combine multiple relevant data into PFA for geological criteria; and 3) rendering favorability or common criteria maps for low-temperature geothermal resources.

The PFA workflow was adapted accordingly (Figure 2) allowing overlaying of multiple geological criteria layers (see Table 1) to evaluate resource potential. We created favorability maps to identify suitable regions for CHP and GDU technologies. Moreover, the Python library titled “geoPFA” was developed and utilized to generate a workflow for producing common and composite maps

(Section 5). This Python library and its implementation are updated as the project and related work evolve, and it is expected to be released as an open-source toolset when it is robust enough.

QGIS, an open-source geographic information system from OSGeo, was used in combination with the geoPFA Python library to combine and process (e.g., interpolate, standardize, transform) different sets of geographic data related to the geological criteria from the raw data layers (e.g., heat, fluid, permeability).

The relevant data for this PFA workflow is outlined in Table 1, but may vary depending on data availability, region, and new discoveries.

Table 1. Relevant data suggested for PFA of low-temperature geothermal resources in the Denver Basin

GPT and Combination Method	Criteria	Component	Data
Pericratonic Foreland basin Modified Voter Veto	Geological	Heat	Bottom-Hole Temperatures
			Gradient Temperatures
			Thermal Conductivity
			Heat Flow
		Accessible Fluid	Hot Springs
			Co-production Water (BBL) Per Year
			Groundwater Wells
		Permeability	Faults and Shear Zone
			Earthquake Data

4. Relevant Data

4.1 Geological Criteria

Choosing optimal locations for low-temperature GHC and GDU opportunities involves the consideration of multiple factors. Suitability of sites is determined, in-part, based on geological criteria, such as heat, fluid, and permeability components (Section 3, Table 1). Combining these criteria into favorability maps suggests viable domains for low temperature geothermal resource utilization, without consideration for other important factors like risk and economic criteria.

4.1.1 Heat Component Analysis

Analyzing the temperature at the bottom of oil and gas wells, along with navigating limited certainty of reported bottom-hole temperature (BHT) accuracies, forms the basis for evaluating geothermal resources, according to Spicer (1964) and Whealton (2015, 2016). The end goal of our assessment is to determine the heat flow throughout the Denver Basin, suggesting areas of high heat flow that may be suitable for low-temperature geothermal resource utilization. There is a wealth of temperature data Python from oil and gas wells in the Denver Basin; decades of historic oil and gas production has provided many datapoints in the western and central regions of the Denver Basin. The basis for our heat component evaluation relies on BHT datasets as reference points for temperature at depth.

We identified three BHT datasets (Figure 4A): (1) Southern Methodist University (SMU); (2) Association of American State Geologists (AASG); and (3) Colorado Geological Survey (CGS). BHT data from Wyoming, Nebraska, and Colorado was gathered and narrowed down to focus specifically on the Denver Basin region. Despite abundance of BHT data, measurements can be distorted by heat changes caused by drilling and errors during data collection; for instance, if BHT data comes from a survey conducted a week after drilling, mud circulation could cause the BHT measurement to be falsely lower than if the data point were collected from a thermally stable shut-in well. Several correction methods have been created to estimate equilibrium conditions for BHTs in sedimentary basins (e.g., Harrison et al. 1983; Förster & Merriam 1995; Blackwell & Richards 2004).

To estimate heat flow and temperature distribution at depth, understanding the thermal conductivity of thousands of boreholes was necessary. It involves assigning lithologic units, unit thicknesses, and thermal conductivities from the surface to the basement for each borehole that had BHT data in the analysis. We utilized the lithology charts and thermal conductivity values used by the SMU data from AAPG COSUNA in the Denver Basin. To complete this assessment, an interpolation was performed, which estimated the likely distribution of thermal conductivity throughout the basin (Figure 4B). Higher thermal conductivities are associated with the southwest Denver Basin, while a nearly static thermal conductivity of 1.6 W/m/K is consistent in the northeast.

This project generated a uniformly corrected set of BHT datapoints from the SMU, AASG, and CGS datasets. Applying a generalized correction scheme was required. If a prior BHT correction scheme had been applied to the constituent datasets, that correction was reversed to obtain the original uncorrected BHT datapoints (i.e., AASG). We used the Förster correction to unify the datasets. The Förster correction has been suggested as the best correction scheme tailored for Denver Basin based on equilibrium data by Crowell et al. (2012; Equation 1):

$$Tcf = 0.0124\,x + 7.8825 \quad (1)$$

where Tcf is the temperature correction factor, and x is the depth at which the BHT measurement was reported. It is important to mention that this correction formula is only suitable for the Denver Basin and potentially other basins that have comparable stratigraphy (Crowell et al. 2012). For this reason, the Förster equation was applied to the Wyoming portion of the Denver Basin to the limited BHT datapoints in that region, as the stratigraphy is not drastically different from the Colorado and Nebraska portions (which the Förster correction scheme had been applied to previously in Crowell et al. 2012). The BHT data of SMU, AASGS, and CGS were corrected with the Förster equilibrium factor (Figure 5). Overall, the improved unified BHT dataset offered a more thorough evaluation of BHTs, reducing uncertainty and navigating potential errors in the datasets via tailored correction scheme for the Denver Basin. This unified BHT data will be available in the Geothermal Data Repository.

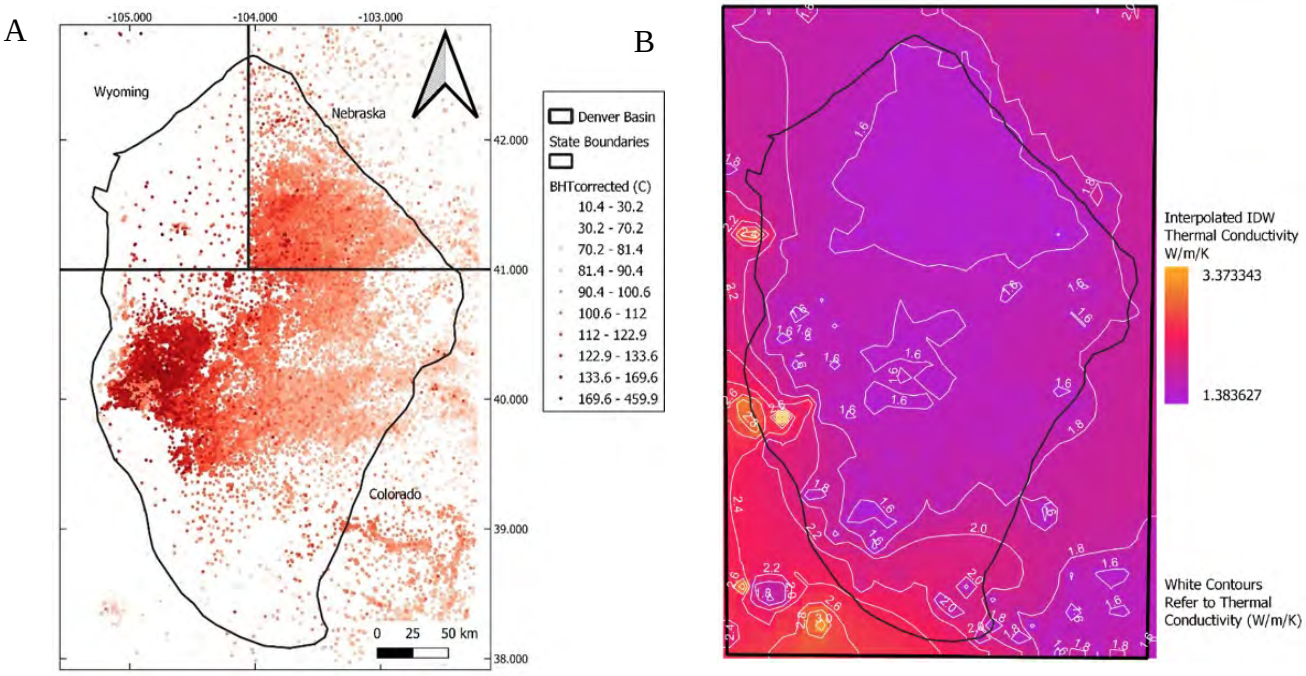

Figure 4: A. Bottom-hole temperatures of oil and gas wells in the Denver Basin from three different datasets: SMU, AASG, and CGS. Depth increases to the western side and decreases towards the eastern side of the basin. B. Thermal conductivities interpolation of rock across the Denver Basin

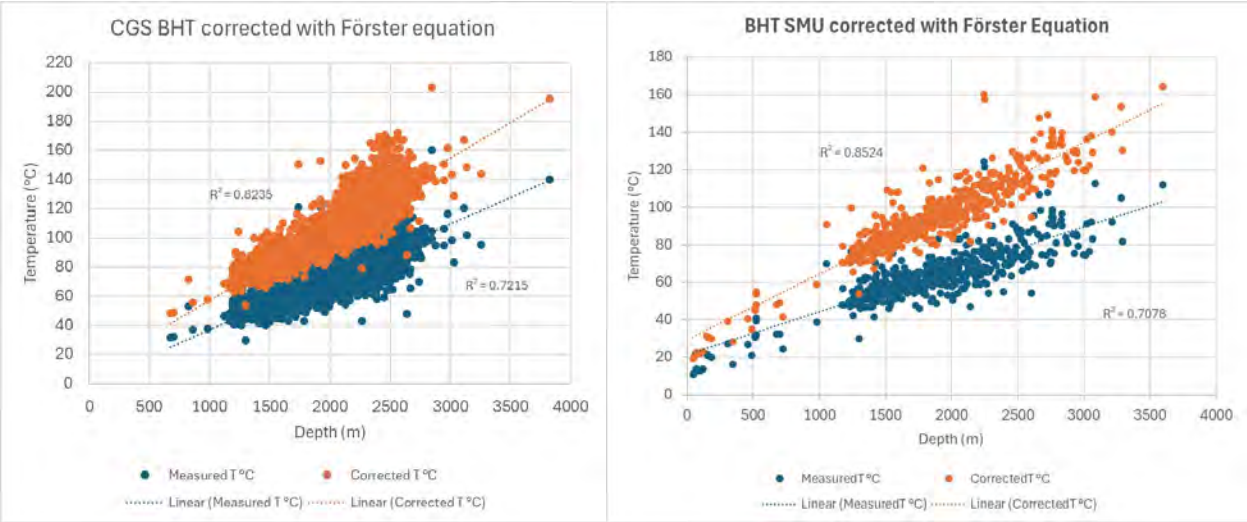

Figure 5: Bottom-hole temperature data of SMU and CGS corrected with the Förster equilibrium factor suggested by Crowell et al. (2012)

Heat transfer is also an essential factor in assessing the potential of geothermal resources, as the heat discharge data linked to Earth's heat flow is a vital indicator of potential. Heat flow maps are valuable tools for pinpointing regions of high geothermal resource potential in a specific area or country (Blackwell et al. 2007). The geothermal gradient plays a vital role in determining heat flow. Therefore, the uniformly corrected BHT dataset was used to estimate a temperature-depth profile (Figure 6A) in equilibrium developed by Crowell et al. (2012). We estimated the geothermal gradient as follows (Equation 2):

$$dT/dZ = [\text{corrected BHT datapoint} - \text{Surface temperature (°C)}]/ \text{depth (m)} \quad (2)$$

where dT/dz is the geothermal gradient (°C/Km).

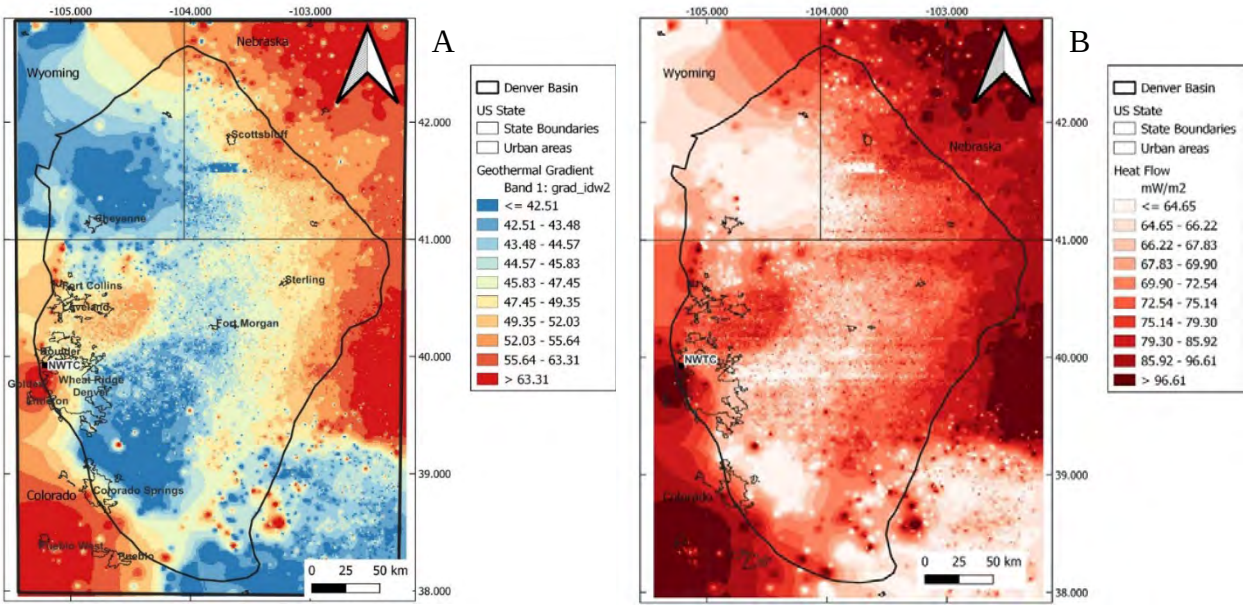

Figure 6: A. Geothermal gradient estimated from BHT data at 1 km. The average gradient temperature in the Denver Basin ranges around 42°C/km to 63°C/km. B. Heat Flow map of the Denver Basin calculated from geothermal gradient and thermal conductivities from SMU data. The heat flow map shows ranges around 64 to 96 mW/m^2. NWTC: National Wind Technology Center facility

We calculated heat flow as a function of depth (mW/m^2; Figure 6B). The uniform BHT dataset is required to estimate a geothermal gradient in conjunction with the lithology-dependent thermal conductivity. The following equation was used to estimate the heat flow:

$$Q = dT/dz * K \quad (3)$$

where Q is the heat flow (mW/m^2), dT/dz is the geothermal gradient (°C/Km), and K is thermal conductivity (W/m/ K), see Figure 4B.

The 1D heat flow model contains the following input assumptions and simplifications:

1. The model assumes that the generation of radiogenic heat is consistent and evenly spread throughout sedimentary rocks.
2. Input data was spatially interpolated to estimate the average and standard error of the average data values for the resource, producing maps depicting thermal quality in a GeoTIFF format (Figure 6).

In the Denver Basin, BHT data are concentrated in regions containing oil and gas reserves, such as central Colorado, while data are scattered in areas lacking exploration, such as southeastern Wyoming and southern Colorado. Sparsity of data in areas of the basin necessitates interpolation algorithms that can accurately predict nonexistent datapoints in both sparse and clustered datasets.

The intended application of the heat component is to suggest areas with a high geothermal resource potential based on temperature gradient as a proxy of heat flow, with high-temperature resources above 150°C typically used for generating electricity, while lower-temperature resources (<150°C) can be utilized for various direct applications such as heating buildings, industrial processes, agriculture, and recreational purposes.

4.1.2 Fluid Component Analysis

This first analysis was focused on the presence of coproduction water in oil and gas wells. Water production data can be used to provide information about where flowing water exists in the basin. It also indirectly provides a proxy for permeability aquifers and/or geothermal reservoirs, which is a key factor in hydrothermal resource and direct-use assessment. This type of data indicates reservoir quality of rocks by showcasing their capacity to uphold fluid flow rates needed for extracting heat from the rocks.

The main source for this water coproduction data from O&G wells in the Denver Basin is the USGS database that collates drilling and production records in the United States. The USGS dataset offers a comprehensive summary of the production records of U.S. wells spanning from 1817 to 2020. It was constructed using information gathered by IHS Markit, a commercial database provider. The production figures are consolidated in increments ranging from 2 to 10 square miles, detailing the cumulative output of oil, gas, and water volumes. In this study we used water production aggregated in 2 miles square that sum production per year in Barrels (BBL; Figure 7A).

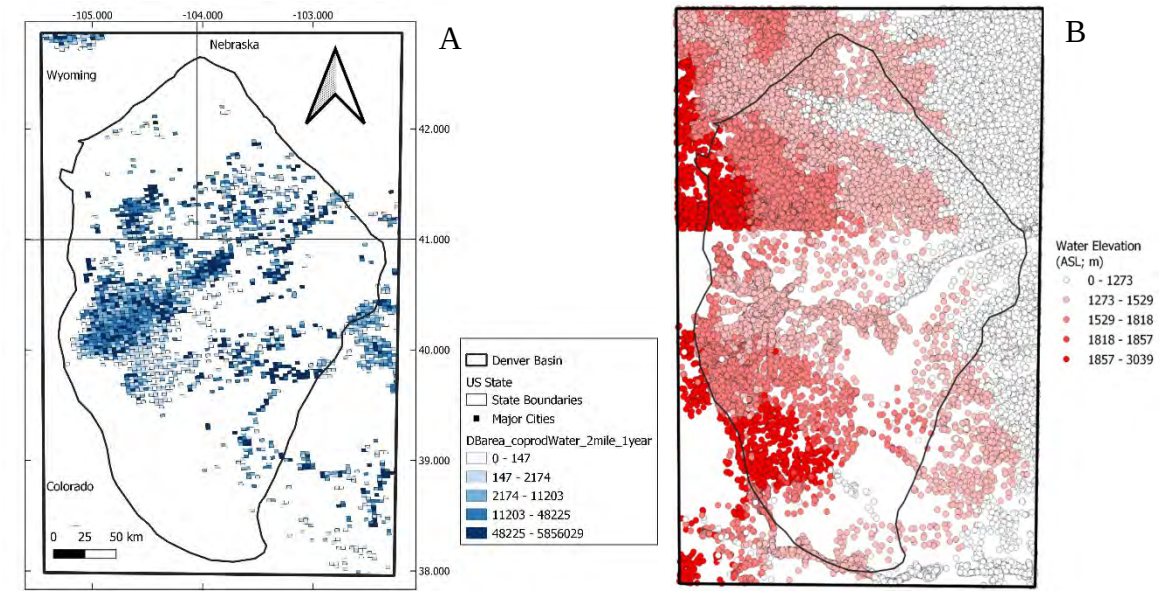

Figure 7: A. Water coproduction volumes (BBL) per year from oil and gas wells in the Denver Basin. B. Well water levels for Colorado, Nebraska, and Wyoming

The data quality information mentioned that comparing the annual production numbers with the total production figures revealed a discrepancy likely stemming from wells with unspecified production years. To ensure accuracy, the consistency between the original and processed total production values was verified. Moreover, a cross-check of well counts in various categories was

performed to confirm alignment, with the disparity between annual and total figures attributed to wells lacking spud dates.

Deeper reservoirs in the Denver Basin are well explored; for instance, over 8,000 wells have been drilled across the basin into the top of the Terry ("Sussex") sandstone alone (Fishman 2005). When investigating potential for direct-use geothermal energy (range of 50 m to 1,000 m vertical depth; minimum 80°C), grasping the potential volume of fluid available in shallower reservoirs is crucial. To achieve an estimation of shallow fluid availability, the elevation of static water level for all available groundwater wells in the Denver Basin area was calculated in Equation 4:

$$WL=GL-SWL \quad (4)$$

where WL (ft) is the water elevation in the well above sea level, GL (ft) is the ground surface elevation, and SWL (ft) is the reported static water level measured in the well. The datasets used to create an estimated water elevation in the Denver Basin were: SEO groundwater wells, where the depth to water (static water level) and well depth was reported in feet (WWDC 2024) and the ground elevation was obtained from USGS DEM files and converted to feet; CDSS wells, where the water elevation was reported as field 'WLElevation' in feet; and DNR for Nebraska, where Static Level was reported in feet. Well water elevation availability is visualized in Figure 7B.

4.1.3 Permeability Component Analysis

The permeability component analysis was simplified using structural geology data (e.g., faults and shear zones) and earthquake data due to a lack of accessibly data and short time frame to find, collect, and organize porosity, thickness, and other permeability data of reservoirs rock in the Denver Basin.

Most of the structural data in the region (Figure 8A) is inferred from surface fault features predominantly located in the western and southwestern parts of the Denver Basin. In the western section, the prevailing fault structures are primarily high-angle reverse faults that trend northwest and dip northeast, as documented by Erslev and Selvig in 1997. On a more specific level within the Wattenberg area, north of Denver, smaller but important structural characteristics are evident. These include ENE-trending wrench strike-slip faults and related listric normal faults with NNE, N, and NNW trends, as highlighted in works by Fishman (2005), Weimer (1996), and Weimer & Davis (1996). Research from multiple sources, such as Fishman (2005) and Weimer (1996), suggests the existence of five significant wrench faults in the Denver Basin within right-lateral movement along vertical planes, extending from the basement to the sedimentary cover (Weimer 1996). The intricate patterns of faulting indicate that the region is predominantly experiencing compressive stress, with the highest horizontal stress oriented towards the NNW, as noted by Heidbach et al. (2018).

Secondary permeability in the Denver Basin was assessed by distance from geologic structures in the Denver Basin. In a study conducted by Filina et al., structures in Nebraska were interpreted from a filtered magnetic field (2018). The structures identified in the study were digitized and included in the assessment of Denver Basin secondary permeability. Colorado structures were obtained from the USGS Geologic Map Database, and Wyoming structures were obtained from the Wyoming State Geological Survey. Primary permeability data of aquifers and rock formations were not accessible.

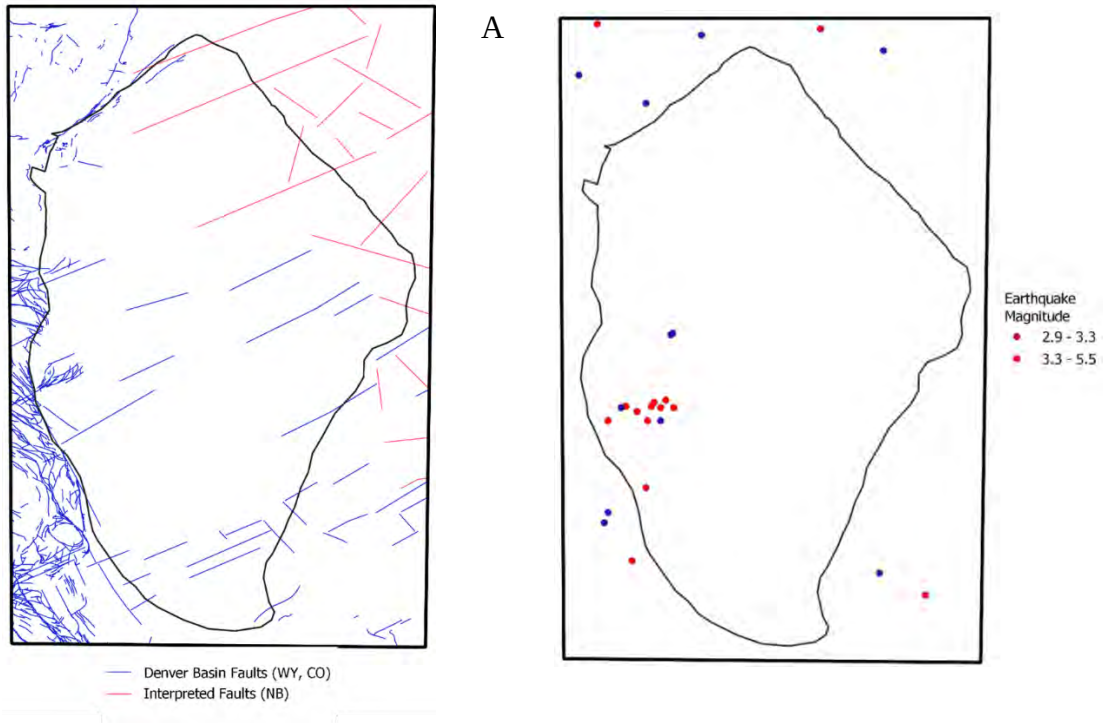

Figure 8: A. Faults and filtered magnetic lineaments and structures in the Great Basin area. B. Earthquakes greater than 2.9 magnitude in the Denver Basin from USGS earthquake catalog

To project secondary permeability of active faults, earthquake data from the 1950s to present day that was equivalent to or exceeded 2.9 magnitude was obtained from the USGS earthquake database presented in Figure 8B to identify Quaternary Faults and permeability of fluid pathways.

5. PFA Methodology

The Python library geoPFA was built with extensibility and reusability in mind, in the hopes that it may eventually be developed further and released as an open-source Python library. It is technologically agnostic and is modelled after the workflows described in the PFA Best Practices report. The library includes tools for:

- Reading in geospatial data in various formats (i.e., shapefile, TIFF, CSV).
- Cleaning the data (i.e., projecting onto the same CRS and grid, changing geometry type).
- Processing the data (i.e., distance function, various interpolation methods).
- Transforming the data (i.e., standardization, various methods for going from data values/data layers to favorability values/evidence layers).
- Weighting and combining the evidence layers (i.e., Voter-Veto method).
- Plotting the data and ouputs.

Throughout this section, examples of how the geoPFA Python library can be used to conduct PFA will be provided. The geoPFA is expected to be released as an open-source toolset in the future.

5.1 Configuration

There are several required inputs for each criterion and each component in the PFA process. These include component weights, component prior probabilities, evidence layer weights, and data layer transformation methods. In the full PFA, we will also add in criteria weights since there will be multiple criteria.

Component weights and component prior probabilities were assigned using expert opinion. Transformation methods were assigned based on a simple understanding of which relative relationship between data values and favorability (e.g., high values are more favorable = No transformation, or vice-versa = Negate). This could also be done more intelligently in the next PFA iteration. Evidence layer weights were also assigned using expert opinion and are set to 1.0 when there is only one evidence layer within a component (i.e., heat). Below are these parameters in tabular format for the geologic criteria only (Table 2).

geoPFA is built to be extensible to any possible combination of criteria, associated components, and data layers. It does so through requiring a configuration file that specifies the relationship between the data layers, respective components, and respective criteria. It also specifies the weights, units, data column names, and required transformation method for each data layer, and the prior probabilities associated with each component. Figure A.1 in the Appendix shows the configuration file for the geologic criteria only, in json format, compiling the information from Table 2 into a machine-readable format. Note that additional criteria may be added to the configuration file and formatted in a similar way.

Table 2: Table of component weights, component prior probabilities, evidence layers, evidence layer weights, and transformation methods applied. This table provides the basis for the configuration file shown in Figure A.1 in the Appendix.

Criteria	Component	Component weight*	Component Prior Probability	Evidence Layer Name	Evidence Layer Weight**	Transformation method
Geologic	Heat	0.40	0.65	Temperature Gradient	1.0	None
Geologic	Permeability	0.30	0.50	Structures (Faults)	0.50	Negate
Geologic	Permeability	0.30	0.50	Earthquakes	0.50	None
Geologic	Fluid	0.30	0.50	Hot Springs	0.5	Negate
Geologic	Fluid	0.30	0.50	Groundwater	0.2	Negate
Geologic	Fluid	0.30	0.50	Coproduced Fluid	0.3	None

*Note that the Voter-Veto method, as published in Ito et al. 2017, does not allow use of component weights. We have created a modified version of the Veto equation for combining component and criteria probabilities using weights.
**Note that the data layer weights are set to 1 when there is only one layer associated with a component.

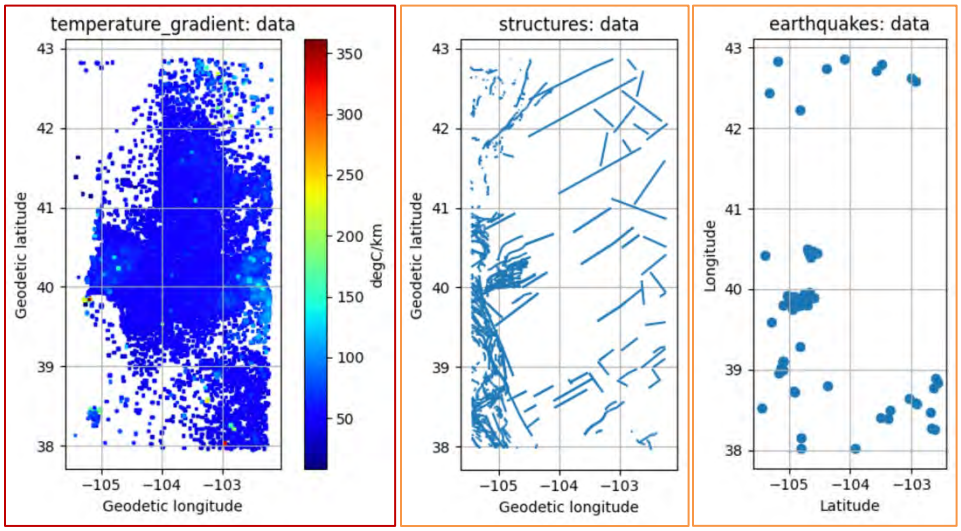
It is also important that the data directory follows this same structure: there is a directory for each criteria, which contains subdirectories for each component, which each contain their respective data layers. The temperature gradient shapefile is named as described in the configuration file. Everything is also named as it is in the configuration file. This structure is demonstrated in Figure A.2 in the Appendix.

The configuration file is read into a Jupyter Notebook and stored as a Python dictionary named ‘pfa.’ This ‘pfa’ dictionary is updated throughout the process so that the entire PFA process is stored in a single data structure. This allows users to reference different parts of the PFA process throughout the workflow, for example, by comparing the original data layer to the final resulting favorability map or comparing the component favorability maps to the criteria favorability map.

5.2 Read in Data

The configuration and setup make it straightforward to read in the data (see Appendix: Figure A.3). Figure A.3 in the Appendix is a screenshot of the code which uses the ‘gather_data’ function from the ‘GeospatialData’ class in the geoPFA Python library. In this code snippet, we limit the data gathering only to shapefiles, but this can be adjusted to other formats, or all compatible geospatial data formats (currently shapefile, TIFF, and CSV). You can see from the text output that three data layers were read in–one for each component of the geologic criteria.

We can plot the raw data layers and see that they include various geometries (from left to right: point, line, and polygon), different CRSs, and different data spacing. The data need to be converted into point geometries, interpolated and/or processed to represent a feature of interest (e.g., distance from faults instead of fault traces), and projected onto the same CRS and the same grid (Figure 9). They also require some cleaning of outliers to show the trends more clearly in the data. These raw data layers are stored in Pandas GeoDataFrames (a type of dataframe that stores geospatial metadata and geometry) and added to 'data’ keys within their associated layer/component/criteria path within the ‘pfa’ dictionary so that they can be plotted at any point throughout the process.



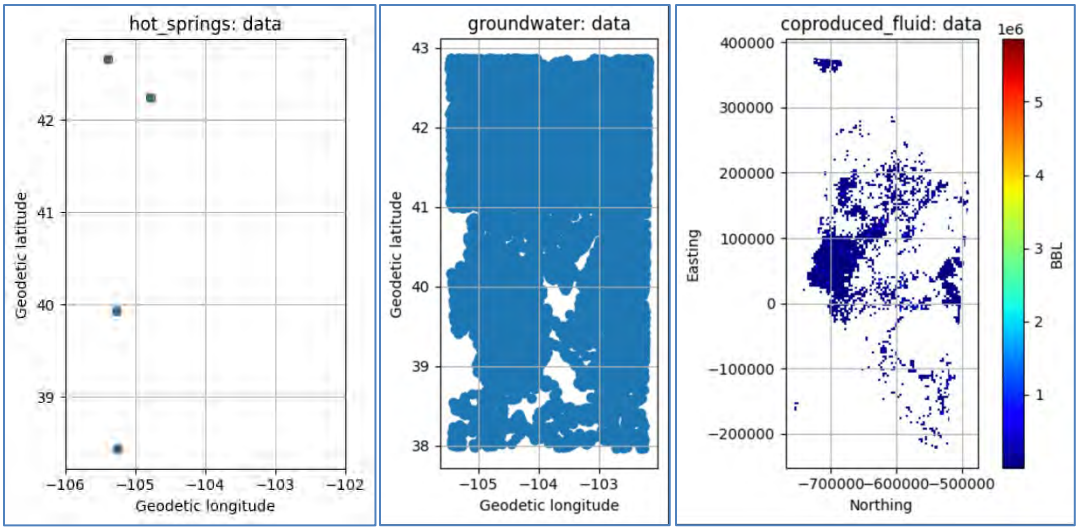


Figure 9: Raw data layers input into geoPFA for geologic criteria favorability mapping, including layers associated with the heat (red border), permeability (orange border), and fluid (blue border) components

5.3 Cleaning and Processing

Cleaning is done in just a few lines of code (Appendix: Figure A.4). This includes projecting everything onto the same CRS and filtering out outliers in some datasets by setting everything above the 0.9 quantile to the value associated with the 0.9 quantile. Particularly, the coproduced fluid and temperature gradient datasets included anomalously high values that masked the trends in the data. Outliers above the 90th percentile were filtered out and set to the value at the 90th percentile. Next, all the datasets were projected onto the same CRS. WGS 84 (EPSG:3857) was used because it is a common projected coordinate system. A projected coordinate system is a requirement for the interpolation and distance function to be accurate.

Linear interpolation is applied to temperature gradient and coproduced fluid data to produce 2D maps from these point datasets. A Euclidean distance function is used to calculate distance from faults, converting this line dataset into a 2D map. All three of the resulting 2D maps are on the same grid with the same CRS.

This is done using functions built into the ‘Cleaners’ class in the geoPFA. Currently the code requires somewhat manual cleaning of the data, but this could be automated in the future through allowing the user to specify cleaning methods for each layer within the configuration file.

Next, the data layers are interpolated/processed into maps (Appendix: Figure A.5). This process also puts all the layers onto the same grid through setting the ‘nx,’ ‘ny,’ and ‘extent’ variables. In addition, since the ‘interpolate_points’ function in the ‘Processing’ class of geoPFA requires point geometry, the polygon geometry of the produced fluid data layer is converted to point geometry by calculating the centroid of each grid square and applying the values for each grid square to its associated centroid. We have built this functionality into the ‘interpolate_points’ function. Currently, this function includes options for linear, cubic, or nearest-neighbor interpolation, and the linear option is selected.

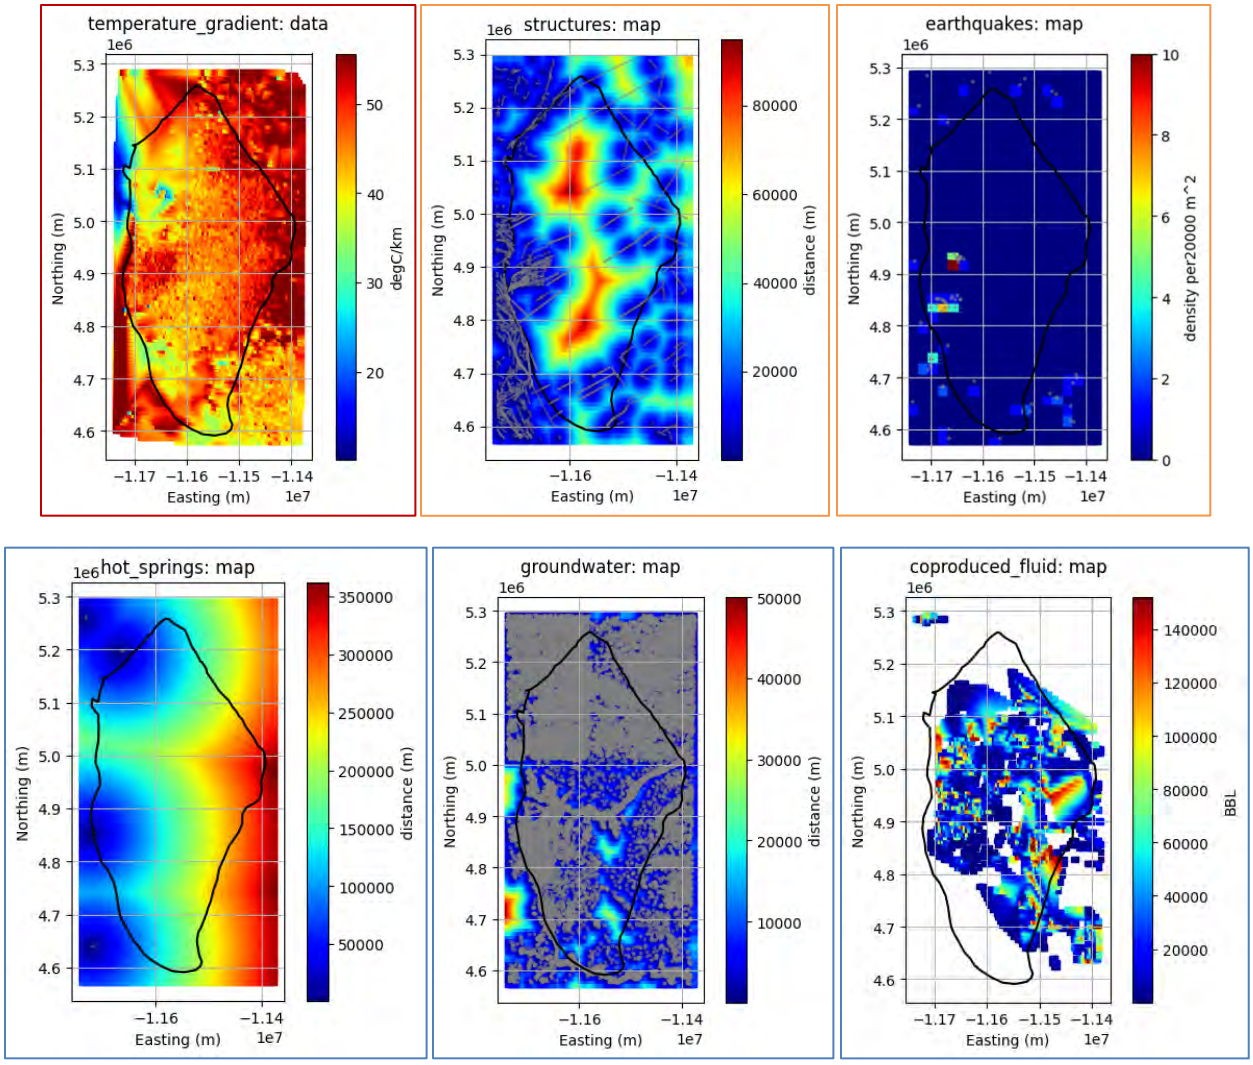

Figure 10: Processed data layers (or maps) input into geoPFA for geologic criteria favorability mapping, including layers associated with the heat (red border), permeability (orange border), and fluid (blue border) components Note that gray lines and dots represent data locations. Data locations are not labelled in the temperature gradient and coproduced fluid maps because the data points are dense and hide the trend in the interpolation

The fault location data is easily converted into a 'distance from faults' map using the 'distance_from_lines' function, and the hot springs and groundwater datasets are converted into 'distance from hot springs' and 'distance from groundwater observations' maps using the 'distance from points' function. The earthquake location data is converted into an 'earthquake density map' using the 'point_density' function. All three of these functions are in the 'Processing' class of the geoPFA. Similar to the cleaning functionality, geoPFA requires somewhat manual processing of the data, but this could also be automated in the future through allowing the user to specify processing methods for each layer within the configuration file.

The resulting maps are added to 'map' keys within their associated layer/component/criteria path within the 'pfa' dictionary so that they can be plotted at any point throughout the process. Above are the resulting maps produced from the processed data layers (Figure 10).

5.4 Transformation and Layer Combination

Next, all the data layers need to be converted into evidence layers. This involves normalizing and transforming (mapping data values to favorability values) each of the data layers. The evidence layers are then weighted and combined using the Voter-Veto method (Ito et al. 2017).

These steps are all built into the 'do_voter_veto' function in the VoterVeto class because transformation methods are specific to a given layer combination method. Transformation methods are additionally specific to a given data layer and are therefore specified in the configuration file for each data layer (Appendix: Figure A.6). For example, lower distance from faults is more favorable than higher distance from faults, so the evidence layer is produced by multiplying the fault distance map by –1 ('negate' method). No transformation methods are applied to the temperature gradient and coproduced fluids data layers because higher values are more favorable. In the future, transformation methods will be improved to better represent probability distributions associated with data layers as they pertain to their respective components and criteria. This will enable mapping of probabilities rather than just relative favorability.

Each data layer is normalized using min-max normalization. This puts all datasets on the same, positive, scale so that datasets with higher magnitudes do not dominate the results. Normalization may be done using either 'min-max' or mean absolute deviation ('mad').

Figure A.6 in the Appendix shows that we are able to normalize, transform, weight, and combine all of the data layers using just one line of code and the information (i.e., prior probabilities, transformation methods) stored in the configuration file. This uses the 'do_voter_veto' function from the 'VoterVeto' class in the geoPFA.

The 'do_voter_veto' function is written to complete the following steps:

1. Converts the data from a Pandas GeoDataFrame into a rasterized array to allow linear algebra/matrix math.
2. Transforms the data layers ('map') into evidence layers ('pr') using the transformation method specified for each data layer in the configuration file (if any) and then normalizing.
3. Weights and combines evidence layers into component favorability maps using the 'voter' method with the evidence layer weights in the configuration file.
4. Combines component favorability maps using the 'veto' method.
5. Combines criteria favorability maps using the 'veto' method.
6. Converts the rasterized favorability maps back into Pandas GeoDataFrames with the original geometry.

In other words, the weights and prior probabilities described in Table 2 are used in a modified version of the Voter-Veto equation (Ito et al., 2017). Within the Voter-veto method proposed by Ito et al, the Voter method (generalized linear model) is used to combine data layers into component favorability maps. Then, the modified Veto equation (element-wise multiplication) is used to combine component favorability maps into a geologic criteria favorability map, and to combine criteria maps into combined overall favorability maps, vetoing areas where any component criteria have a favorability value of 0. The original equations for this methodology are

described in Section 2.1 of Ito et al., 2017, and our modified version of the Veto equation is as follows:

$$\Pr(R) = \frac{\sum^c w_c \Pr(X_c)}{\max[\sum^c w_c \Pr(X_c)]} \times \max[\prod^c \Pr(X_c)] \quad (5)$$

where PrR is the probability of a resource, w_c is the weight of a given component or criteria, and Pr(X_c) is the probability of a given component or criteria. In written language, the equation produces a weighted some of the components or criteria, depending on which level the probability mapping is occurring on, normalizes by dividing by the maximum value, and scales using the product of the individual component or criteria probability maps to ensure that the resulting probability map represents a valid probability distribution. The veto portion of the equation is optional, but when desired, resulting indices in Pr(R) are set to zero if the associated indices in any Pr(X_c) are zero. In the methodology presented here, the veto option is used when combining criteria, but not when combining components.

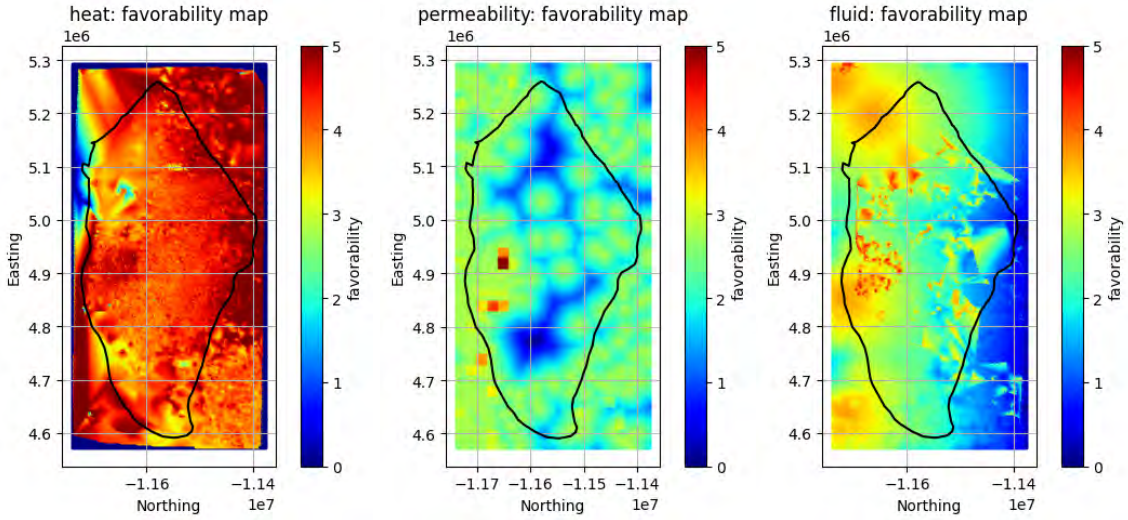

Figure 11: Geologic criteria component favorability maps, including heat, permeability, and fluid components, produced using geoPFA

The resulting evidence layers and component favorability maps are added to 'fav' keys within their associated criteria/component/layer and criteria/component paths, respectively, within the 'pfa' dictionary so that they can be plotted at any point throughout the process. The resulting component favorability maps are shown in Figure 11. Note that since we only are inputting one data layer to map the heat component, the temperature gradient evidence layer is equivalent to heat component favorability map, but typically this is not the case. The resulting criteria favorability maps are added to 'fav' keys within their associated criteria paths (in this case 'geologic') within the 'pfa' dictionary, and the resulting combined favorability map (not yet generated) is stored under a 'fav' key at the top level of the 'pfa' dictionary. The draft geologic criteria favorability map produced by geoPFA is shown in Figure 12.

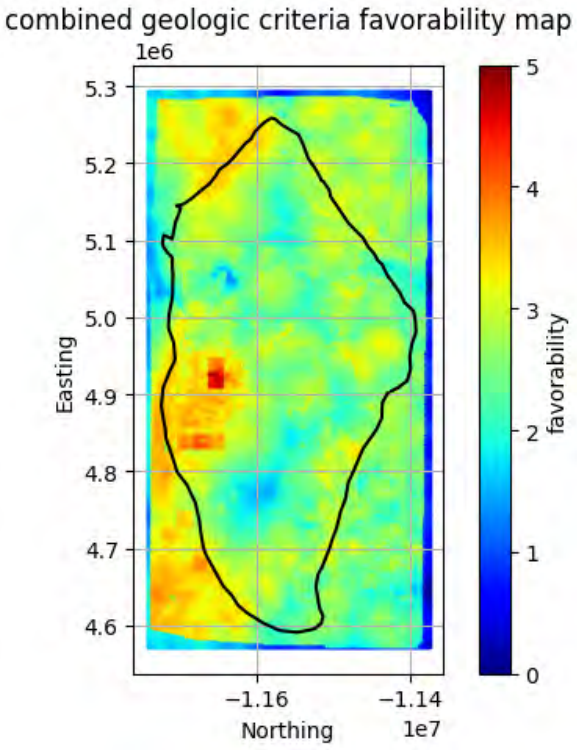

Figure 12: Combined geologic criteria favorability map of the Denver Basin, produced using geoPFA

6. Geological Criteria Favorability Map

The resulting favorability map is shown below in Figure 13. In the future, more robust data transformation methods will be implemented to more realistically map data values to probability values.

The map appears to validate the methodology thus far. The map highlights the area to the west end of the Denver Basin (e.g., Wattenberg area) where there appears to be intersection between faults, some seismic activity, elevated temperature gradient values, ground water presence, a hot spring, and relatively high volumes of coproduced fluids. It also highlights some other smaller areas that are not as obvious to the human eye, within the northwest (in southeast Wyoming) and southwest areas (near Colorado Springs) of the Denver Basin.

However, the significant reliance on earthquake density as a component of permeability in the geothermal favorability map raises concerns about potential artifacts, as the highest probability area coincides with multiple back-to-back earthquakes in very close proximity to each other. This suggests that the earthquake component may need to be weighted lower in our future analyses to avoid artifacts in the resulting favorability maps.

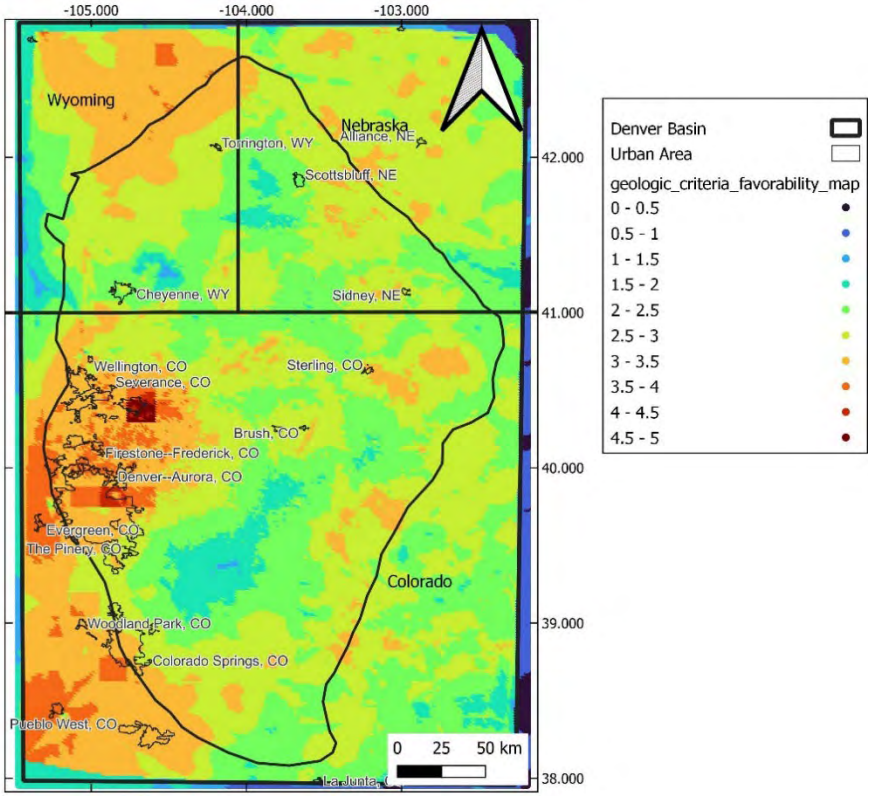

Figure 13: Geological Criteria Favorability Map for the Denver Basin

7. Conclusions

The study adapted PFA methodologies from previous studies to SBGPT to assess the potential of low-temperature resources in the Denver Basin. The resulting favorability map highlights areas with high potential for geothermal technology opportunities. While the map is still uncertain, it suggests promising areas, particularly in the western part of the Denver Basin.

To improve the accuracy and uncertainty quantification of the geological resource maps, future steps include: (1) incorporating additional high-quality data that provide enough information to create confidence layers; (2) adding more layers to the permeability component, particularly those that provide information about primary permeability in the geological formations rather than only secondary permeability; (3) improving interpolations and implementing more intelligent transformation methods; (4) refining prior probabilities and weights for each component (e.g., earthquakes will be weighted lower); and (5) building other layer combination methods into the geoPFA library, such as weights of evidence. The geoPFA Python library is expected to be released as an open-source tool in the future to enable others to use this code for their own PFA studies.

Furthermore, identifying potential areas for geothermal direct uses, and combined heat and power is a complex geospatial decision-making problem that requires consideration of multiple criteria. This paper was focused on the geological criteria, including heat, accessible fluid, and permeability, as essential factors for evaluating low-temperature resources. However, it is recognized that other critical criteria such as risk (seismicity, exclusion areas, and environmental/natural disaster) and economic factors (population, infrastructure, heating and

cooling demand, and levelized cost of heat) must also be considered in the evaluation process in this project. Future work will integrate these additional criteria to provide a comprehensive assessment of potential areas for geothermal applications.

In conclusion, this project aims to accelerate the country's decarbonization efforts by identifying opportunities for utilizing low-temperature geothermal resources (<150°C) in sedimentary basins with numerous population centers geothermal direct uses, and combined heat and power applications. The project has provided PFA workflows, data, tools, and favorability maps to support the utilization of low-temperature geothermal resources in the Denver Basin. Future improvements will focus on refining the methodology to ensure accurate and reliable results, ultimately facilitating future assessment of low-temperature geothermal resources in sedimentary basins and supporting the country's transition to a low-carbon economy.

Geothermal heat exchanger, building cooling, Hawai‘i, favorability map, numerical modeling

ABSTRACT

Scientists at Berkeley Lab have teamed up with The University of Hawai‘i at Manoa (UH Manoa) through the U.S. Department of Energy’s (DOE’s) Energy Transitions Initiative Partnership Project (ETIPP) to evaluate the technological and market feasibility of shallow geothermal heat exchanger (GHE) technology for building cooling, energy efficiency, and emissions reduction applications in Hawai’i. The team is assessing the data necessary to model the feasibility of deploying this technology, the actual models that will be used, and what hurdles need to be overcome to install a demonstration case. UH has an abundance of geologic and geothermal data and is looking to the national labs’ expertise to execute this analysis. UH is also interested in investigating policy, regulatory, and business conditions advantageous for implementation of a pilot project, and more broad deployment of this technology in Hawai‘i.

In many locations around the world, the demands for heating and cooling are roughly balanced over the course of the year, so GHEs do not cause significant long-term changes in subsurface temperature. This is not the case in Hawai’i, where the demand for heating is very small, meaning that over time, GHEs will add heat to the subsurface. If temperatures increase significantly, GHE systems will not work as designed. Regional groundwater flow has the potential to sweep heated water away from boreholes, thereby maintaining the functionality of the GHE system. Significant regional groundwater flow requires two things: a sufficiently large driving hydraulic head gradient

(usually closely related to surface topography), and sufficient porosity and permeability to enable groundwater to flow in large enough quantities to enable near-borehole temperatures to be maintained at ambient values. Hawai‘i’s volcanic terrain offers ample surface topographic variation. The lava itself shows an extremely large range of porosity and permeability, making it crucial to select sites with large enough values of these properties. Numerical modeling of coupled groundwater and heat flow can be used to determine how large is large enough. Both closed-loop and open-loop systems are being investigated. Another option being considered is using cool seawater as the source of chill.

Currently work is progressing on two fronts. A hydrogeologic model for a closed-loop system is being developed for the Stan Sheriff Center at the UH Manoa campus, where a subsurface karst system immediately downgradient of the borefield may provide efficient removal of heated groundwater. The team will also develop a technoeconomic model for this site to compare the cost of cooling using a GHE system with the costs of operating the current air conditioning system. At the state scale, geographic information system (GIS) layers of various attributes relevant for GHE are being combined to develop an overall favorability map for employing GHE in Hawai‘i.

1. Introduction

This study is a DOE Energy Transitions Initiative Partnership Project (ETIPP), which seeks to partner DOE national laboratory scientists with remote, coastal, and island communities looking to transform their energy systems and increase energy resilience. The overall goals of this project with the University of Hawai‘i include analyzing the potential for geothermal cooling in buildings across its 10 campuses by modeling shallow geologic conditions and building heating and cooling loads and evaluating potential geothermal technologies that could improve energy efficiency and significantly increase sustainability for these communities. This could contribute to decarbonizing building energy requirements throughout the United States (e.g., Liu et al., 2023).

This project builds upon an earlier assessment by Dores and Lautze (2020), who evaluated a variety of scenarios relating to the applicability of ground source heat exchangers for space cooling in Hawai‘i. They examined a number of important parameters for six of the Hawaiian Islands, such as shallow geology, depth to water table, and groundwater and measured air temperatures. These datasets were then projected onto GIS maps of each of the studied islands. For effective cooling to occur using GHE technology, a threshold maximum water table depth of 80 m was assigned. The groundwater temperature was used as a proxy for subsurface ground temperature at the same depth as the groundwater measurement, and a comparison was made between air and subsurface temperatures throughout the year for the major population areas on the four most populated islands. Using literature values for the thermal conductivities of the four main rock types—alluvium and fill, basalts and other volcanic rocks, sand and dune deposits, and limestone and reef deposits—the basalts and limestones were identified as having the most prospective thermal properties for deploying GHE systems. Both seasonal and yearly operational scenarios were evaluated. The study concluded that space cooling would be feasible using GHE systems in Hawai‘i, and that more detailed modeling would be needed to assess the impacts of advective heat transfer.

The current project has two primary objectives: 1) expanding the GIS-based screening methodology of Dores and Lautze (2020) to further assess the feasibility of deploying GHE

technology in Hawai‘i, and 2) conducting a more detailed technical and economic assessment of the potential for developing such a system for cooling of the Stan Sheriff Center athletic complex at the UH Manoa campus. This involves developing a detailed 3-D geologic model of the area that can be used to create a hydrogeologic framework for numerical modeling. One of the key concerns for applying GHE in tropical environments is that heat is continually added to the subsurface with only cooling being used, and that lateral flow of groundwater is required to sweep the heat away so that the system can continue to operate.

2. GIS-based Screening Criteria for GHE in Hawai‘i

As noted earlier, Dores and Lautze (2020) used the shallow geology, depth to water table, and groundwater and air temperatures to help identify prospective areas within six of the Hawaiian Islands where GHE might be feasible. Our team expanded this list of parameters to include additional screening criteria that would be useful in evaluating the suitability of a particular location for installing a closed-loop GHE system. We also looked at the potential of using open-loop systems as well as seawater cooling systems (e.g., Leraand and Van Ryzin, 1995), but this evaluation is confined to closed-loop GHE applications. The criteria consist of a variety of physical (i.e., geographic, geologic, hydrologic), ecological/environmental, and cultural factors that would influence the viability of deploying a GHE system. Two examples of these GIS screening criteria (soil permeability and the locations of schools and Department of Defense (DOD) land) on O‘ahu are displayed in Figure 1. Table 1 summarizes these features and provides some suggestions as to what might constitute favorable versus unfavorable conditions for each of these parameters. Many of these parameters can be mapped using corresponding GIS layers, so that multiple factors can be examined and areas that have favorable or unfavorable conditions can be easily identified using this approach.

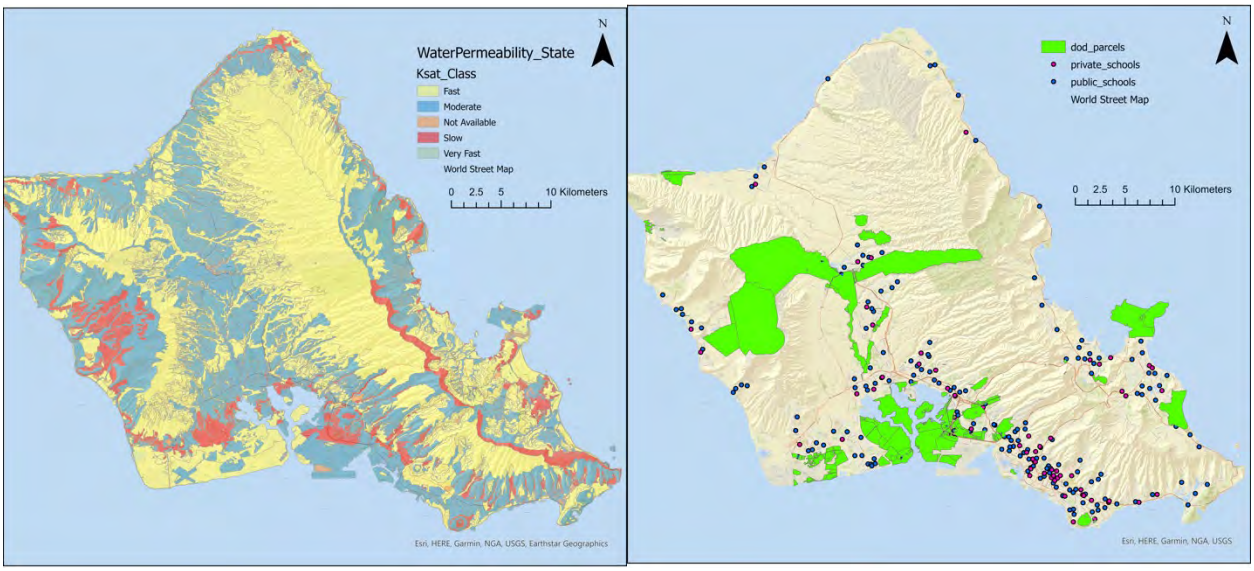

Figure 1: Left – GIS map of O‘ahu depicting different soil permeability zones: slow = <3μm/s; moderate = 3 – <10 μm/s; fast = 10 – <100 μm/s; very fast = ≥100 μm/s. Right – Locations of DOD lands and public and private schools on O‘ahu. See Table 1 for data sources.

2.1 Key Physical Parameters

A number of physical parameters are important for GHE installations. To meet the needs of cooling, the groundwater temperature needs to be low enough to be able to effectively cool buildings. Given that the GHE system will not be balanced between heating and cooling, there needs to be sufficient groundwater flow so that heat can be swept away from the boreholes. Having a sufficiently sloped piezometric surface and hydraulic head will promote higher lateral water flow rates needed to remove the heat, but it's also important to consider the ground surface slope (i.e. from the Digital Elevation Model), as it will add complexity to siting the GHE. The subsurface geology needs to have high enough permeability to facilitate a high flux of groundwater flow through the area where the borefield will be situated. Finally, the boreholes need to be located in an area with a fairly shallow water table, as the bulk of the boreholes need to be located in the saturated zone to allow for effective heat transfer between the closed-loop boreholes and the surroundings.

2.2 Key Ecological and Environmental Parameters

The siting of a GHE will require drilling numerous boreholes. This may not be possible in densely vegetated and forested lands, and in areas that have endangered species. There are areas with restricted watersheds that might not permit GHE deployment. There may be conflicts with existing use of the subsurface for freshwater production or water injection. The use of a closed-loop system may minimize such conflicts. Areas with existing wells will be better characterized with respect to their hydrogeology, which can help develop better constrained models that can be used to predict long-term GHE performance and estimate the cost effectiveness of such systems.

2.3 Key Cultural Parameters

There are a variety of cultural factors that may promote or restrict the deployment of GHE systems. Areas with an elevated community heat index and high cooling needs may be good candidates for such a system. Disadvantaged communities often lack access to housing with resilient and inexpensive cooling systems, so developing such systems within those neighborhoods could have very beneficial impacts. Some organizations, such as schools and the U.S. military, have prioritized decarbonizing their facilities and making them more climate resilient, so they may be good candidates for GHE cooling systems. There are some locations, such as national parks and sites of cultural and archeological sensitivity, where such systems cannot be deployed.

Table 1: Summary of key screening parameters for siting GHE installations

Parameter	Importance	Data range	Favorable	Acceptable	Unfavorable	Comments	GIS data source
Physical parameters							
Elevation	Useful	0 to >3,000 m	0-20 m	20-100 m	> 100 m	Proxy for depth to water table	https://planning.hawaii.gov/gis/download-gis-data-expanded/
Slope	Useful	0 to 90°	2-5°	0-2°, 5-10°	>10°	Higher slope harder to build on, but provides steeper hydrologic gradient	Calculated from Elevation model
Depth to water table	Critical	0 to >100 m	0-10 m	10-80 m	> 80 m	GHE needs to be deployed within saturated zone for heat to be dissipated effectively via advection	Dores and Lautze, 2020 https://waterdata.usgs.gov/hi/nwis/gw/
Geology	Critical	Basalt lava flows, breccia, tuff, limestone, alluvium	Fractured basalt, limestone		Unfractured basalt (dike-rich zones)	Fractured basalts typically have good horizontal permeability. Caverns in limestone may be problematic for drilling and well completion.	https://ngmdb.usgs.gov/Prodesc/proddesc_111883.htm
Soil moisture	Useful	Arid to very wet (7 classes)	Wet zones	Intermediate zones	Arid zones	Wet zones likely have higher subsurface flow, arid zones may have deeper water table	https://www.sciencebase.gov/catalog/item/57a902e8e4b05e859bdf3c83

Permeability	Critical	Ksat classes (fast, moderate, slow, very fast)	High permeability	Intermediate permeability	Low permeability	High permeability zones more likely to effectively dissipate heat	http://gis.ctahr.hawaii.edu/SoilAtlas
Groundwater temperature	Critical		< 20°C	20-25°C	>25°C	Warm water less favorable for cooling applications	https://www.higp.hawaii.edu/hggrc/projects/hi-play-fairway/pf-project-data/
Tsunami zone	Useful		outside		inside	Borehole installations are below ground surface, so this should be less critical	https://www.honolulugis.org/apps/39a9e07068a14d01a85b437adcf50beb/explore
Ecological and environmental parameters							
Vegetation cover	Useful	Bare ground, sparse vegetation, forested	Bare ground	Sparse vegetation	Forested	Densely forested areas would be impacted by developing a GHE borefield	https://planning.hawaii.gov/gis/download-gis-data-expanded/
Critical species habitat	Critical		No critical species present		Critical species present	It may be possible to install a GHE system and not disturb critical species habitat	https://planning.hawaii.gov/gis/download-gis-data-expanded/
Restricted watersheds	Useful/Critical		Unrestricted		Restricted	With a closed-loop system, deployment of a GHE system might be permitted in a restricted watershed	https://planning.hawaii.gov/gis/download-gis-data-expanded/
Underground injection zones	Useful		Distant		Proximal	There may be competing uses to the subsurface, injection may perturb	https://planning.hawaii.gov/gis/download-gis-data-expanded/

						subsurface temperatures; these areas may have better subsurface characterization	
Recycled water management zones	Useful		Unrestricted	Conditional	Restricted	There may be competing uses to the subsurface, water recycling may perturb subsurface temperatures; these areas may have better subsurface characterization	https://planning.hawaii.gov/gis/download-gis-data-expanded/
Water quality	Useful	Water to be left in natural state, discharge allowed, water known to be toxic/corrosive	Discharge allowed	Water to be left in natural state	Water known to be toxic/corrosive	For closed-loop system, main concern would be corrosion to underground installation. Heating of subsurface over time would perturb natural state conditions.	https://planning.hawaii.gov/gis/download-gis-data-expanded/
Existing wells	Useful					Existing wells may provide useful information regarding subsurface conditions, but may also indicate competing uses of the subsurface	https://www.higp.hawaii.edu/hggrc/projects/geothermal-digital-collection/groundwater-collections/

Cultural parameters							
Land ownership	Useful	Private and public lands	DOD, UH lands		Some private land, protected land	Landowner needs to provide access to site, some landowners are motivated to decarbonize operations	https://planning.hawaii.gov/gis/download-gis-data-expanded/
Schools	Useful	Public and private	School sites			Schools often have significant cooling load, interest in developing renewable energy resources, GHE system provides educational opportunities	https://planning.hawaii.gov/gis/download-gis-data-expanded/
Parks	Useful		No parks	Urban, multi-use parks	National parks and preserves	Parks often restrict or prohibit development. Also, parks may not have a need for cooling nearby.	https://planning.hawaii.gov/gis/download-gis-data-expanded/
Archeology/cultural site	Critical		No identified sites		Identified sites	Presence of archeological or cultural features would likely preclude GHE deployment	https://planning.hawaii.gov/gis/download-gis-data-expanded/
Community heat index	Useful		High heat index – greater need for resilient cooling		Low heat index – lesser need for resilient cooling	Linked to cooling demand	https://www.arcgis.com/apps/View/index.html?appid=ff1b73d836074cf6b2aca420fffbd930 (for O‘ahu)
Population density	Useful		High density	Intermediate density	Low density	Greater cooling demand with more concentrated	https://files.hawaii.gov/dbedt/op/gis/maps/

						population density, impact of urban heat island effect	2010_pop_density.pdf
Cooling demand	Critical		High cooling demand		Low cooling demand	GHE systems in greater need where cooling demand is higher	https://www.honolulugis.org/
Disadvantaged communities			Areas with disadvantaged communities		Areas with affluent communities	Deployment of GHE in disadvantaged communities can address energy poverty	https://screeningtool.geoplatform.gov/en/#6.3/20.657/-157.697

3. Evaluation of the Stan Sheriff Center at UH Manoa

The UH team members identified the Stan Sheriff Center at the UH Manoa campus as an ideal candidate to evaluate for cooling using GHE technology. It has a very high cooling load and is surrounded by open space and athletic fields where GHEs could be deployed. The following sections describe our efforts to characterize the local geology, develop a 3-D hydrogeologic model, create a numerical grid, and conduct some scoping simulations with different lateral groundwater flows to evaluate the potential for this area to sustainably provide cooling using GHE.

3.1 Geologic Model of the Stan Sheriff Center Site

A variety of data sources were used to create a 3-D geologic model of the area surrounding the Stan Sheriff Center at the UH Manoa campus (Wolf, 1975; Finstick, 1996; Holliday, 1998; Clague et al., 2016; Okuhata, 2017; Sherrod et al., 2021). The campus is partially located in an old quarry within the 76 ka Sugarloaf melilite nephelinite flow, which is reported to have a thickness of 15 m (Clague et al., 2016), and a series of limestone underground caves have also been reported in the area (Halliday, 1998); limestone reef deposits outcrop just seaward of the campus, on south side of H1 (Figure 2). Just to the north is Waʻahila Ridge, representing a series of older lava flows from the Koʻolau volcano. A number of engineering geology borings in the area help constrain the shallow subsurface geology as well as the depth to the water table, which is generally around 2.4 m to 3 m (8 ft to 10 ft) depth below ground surface. All of this information was georectified and imported into the Leapfrog 3-D geologic modeling tool. Figure 3 displays the plan view image of the study site, as well as a cross-sectional view of the area. For simplicity, six geologic units were identified: the older Koʻolau basalt (which forms the basement rock of this area), the younger Sugarloaf lava flow, limestone, coralline sand, alluvium, and fill. The locations of identified shallow limestone caves are also represented in this geologic model.

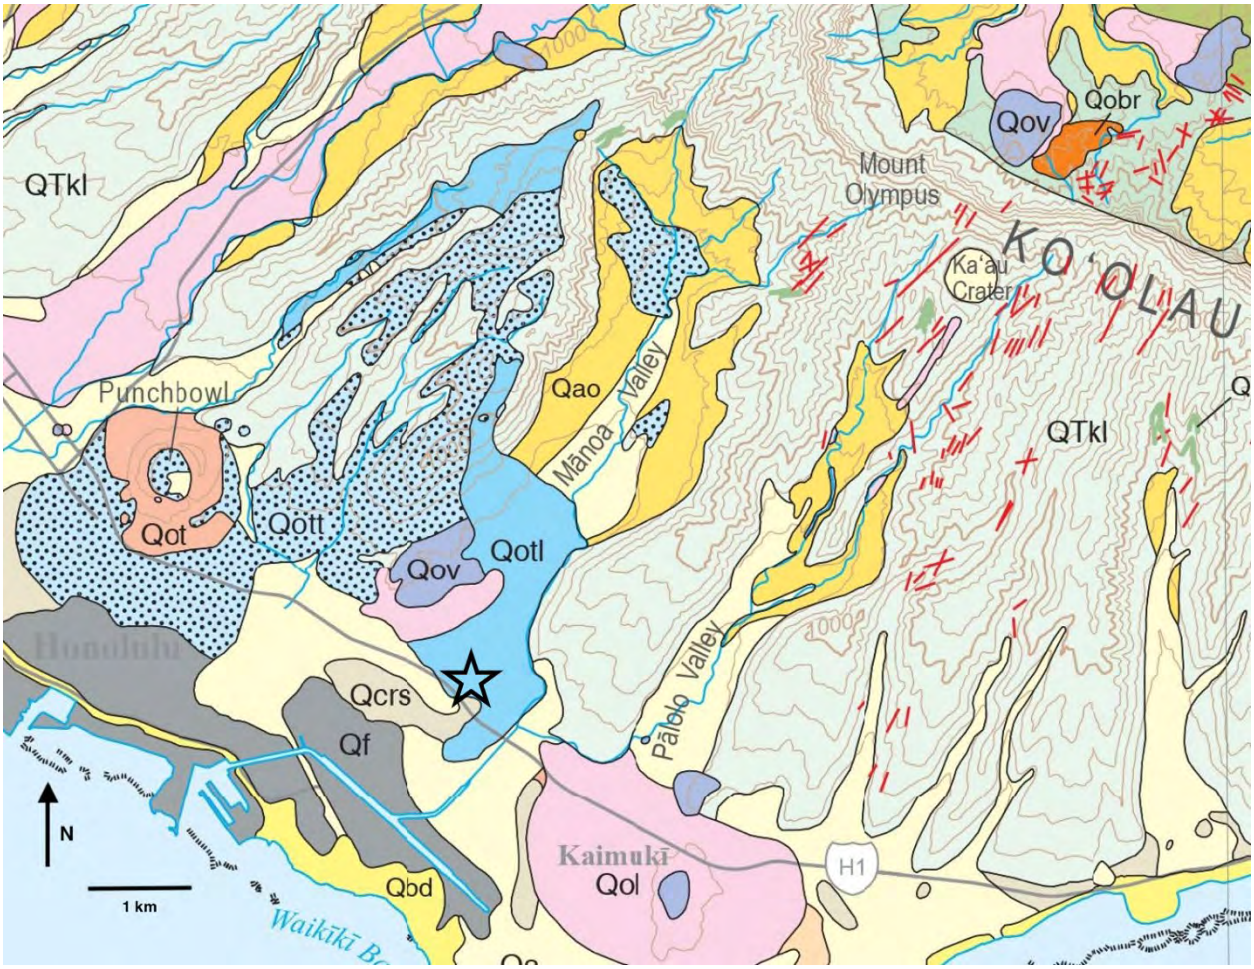

Figure 2: Portion of the geologic map featuring southern Oʻahu, from Sherrod et al. (2021). Depicted geologic units are as follows: Qf - Fill (Holocene); Qa - Alluvium (Holocene and Pleistocene); Qao - Older alluvium (Pleistocene); Qbd - Beach deposits (Holocene); Qcrs - Calcareous reef rock and marine sediment (Pleistocene); Qol - Lava flows, Honolulu Volcanics (Pleistocene); Qov - Cinder vent deposits, Honolulu Volcanics (Pleistocene); Qot - Tuff cone deposits, Honolulu Volcanics (Pleistocene) Qotl - Lava flows from Tantalus Peak and Sugarloaf vents, Honolulu Volcanics (Pleistocene); Qott - Tuff from Tantalus Peak and Sugarloaf vents, Honolulu Volcanics (Pleistocene); QTkl - Lava flows from Koʻolau Basalt (Pleistocene and Pliocene). The star denotes the location of the Stan Sheriff Center at the UH Manoa campus.

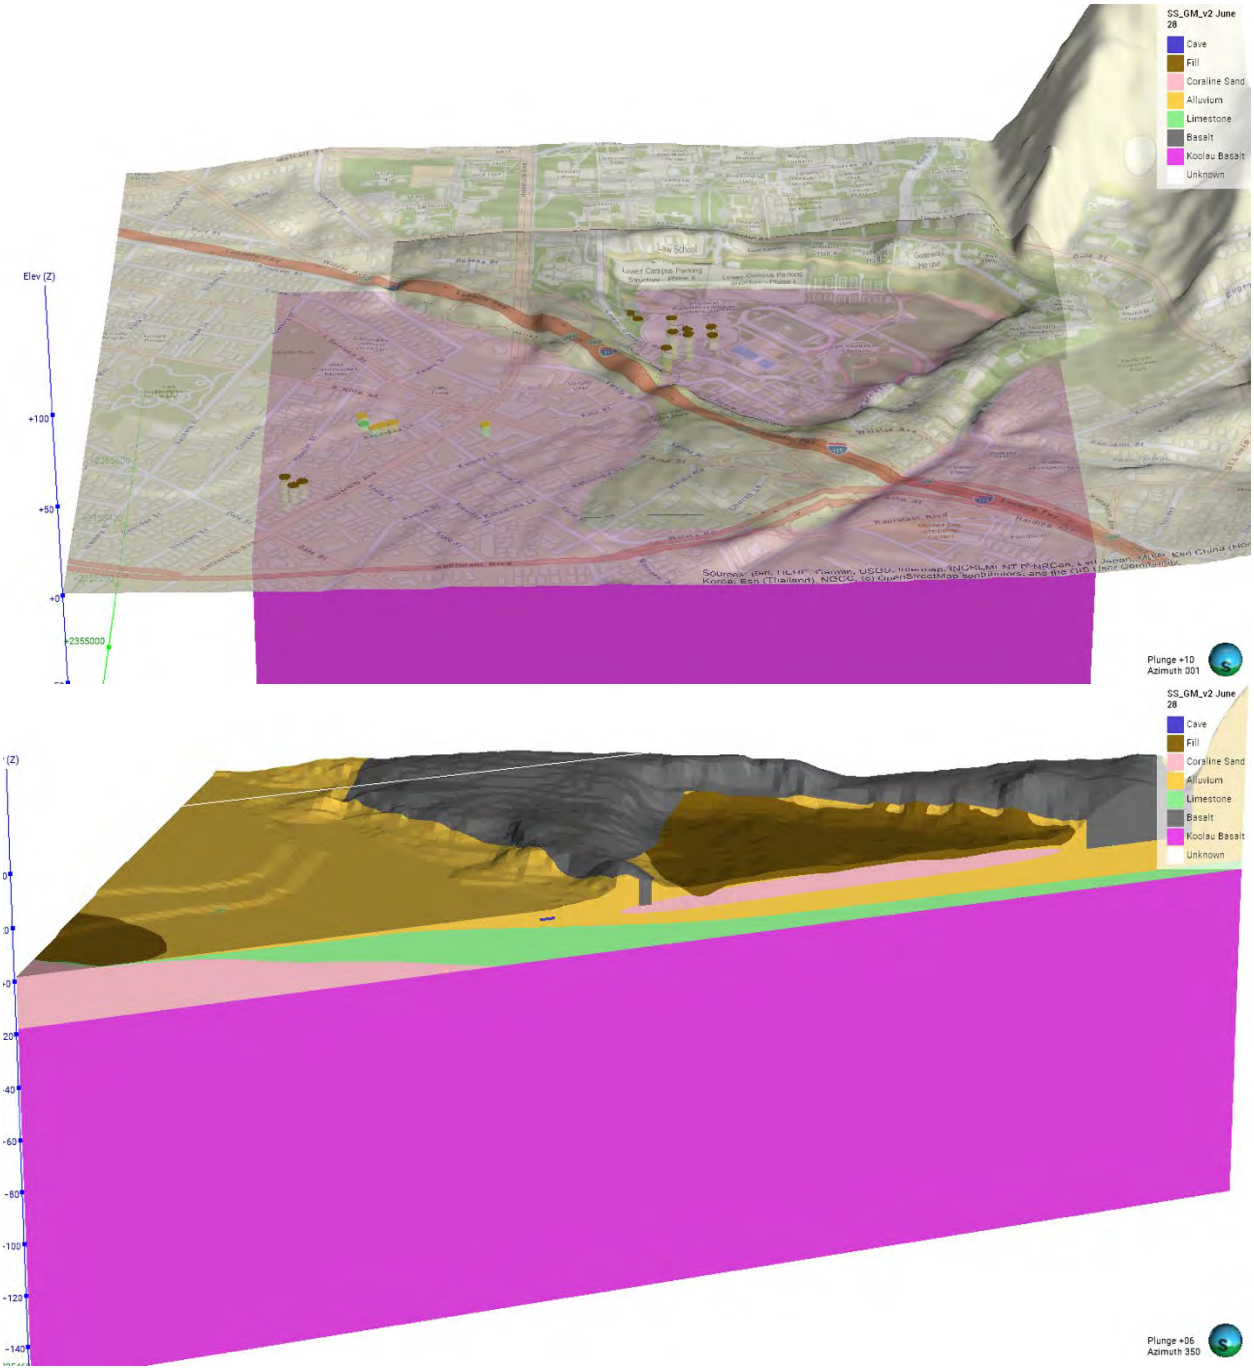

Figure 3: Three-dimensional images from the geologic model of the UH Manoa Stan Sheriff Center. Upper figure shows the excavated quarry in the Sugarloaf lava flow where the athletic complex is located, along with locations of engineering boreholes. The lower figure depicts a cut section through the 3-D geologic model, with the exposed cross section parallel to the main hydrologic flow direction (from right to left). Note that the majority of the geologic section is comprised by the older Ko'olau basalt flows.

3.2 Hydrogeologic Model and Heat Exchange Model of the Stan Sheriff Center Site

One of Leapfrog's capabilities is to convert the 3-D geologic model into a grid for the numerical simulations, where the grid blocks are assigned the appropriate petrophysical, thermal, and hydrologic properties corresponding to those pertaining to the units in the geologic model (e.g., Milicich et al., 2015). The grid was oriented so that the grid blocks would be parallel to the primary groundwater flow direction, which flows down from the crest of the Ko'olau Range towards the coastline in a southwesterly direction (Nichols et al., 1996) (Figure 4).

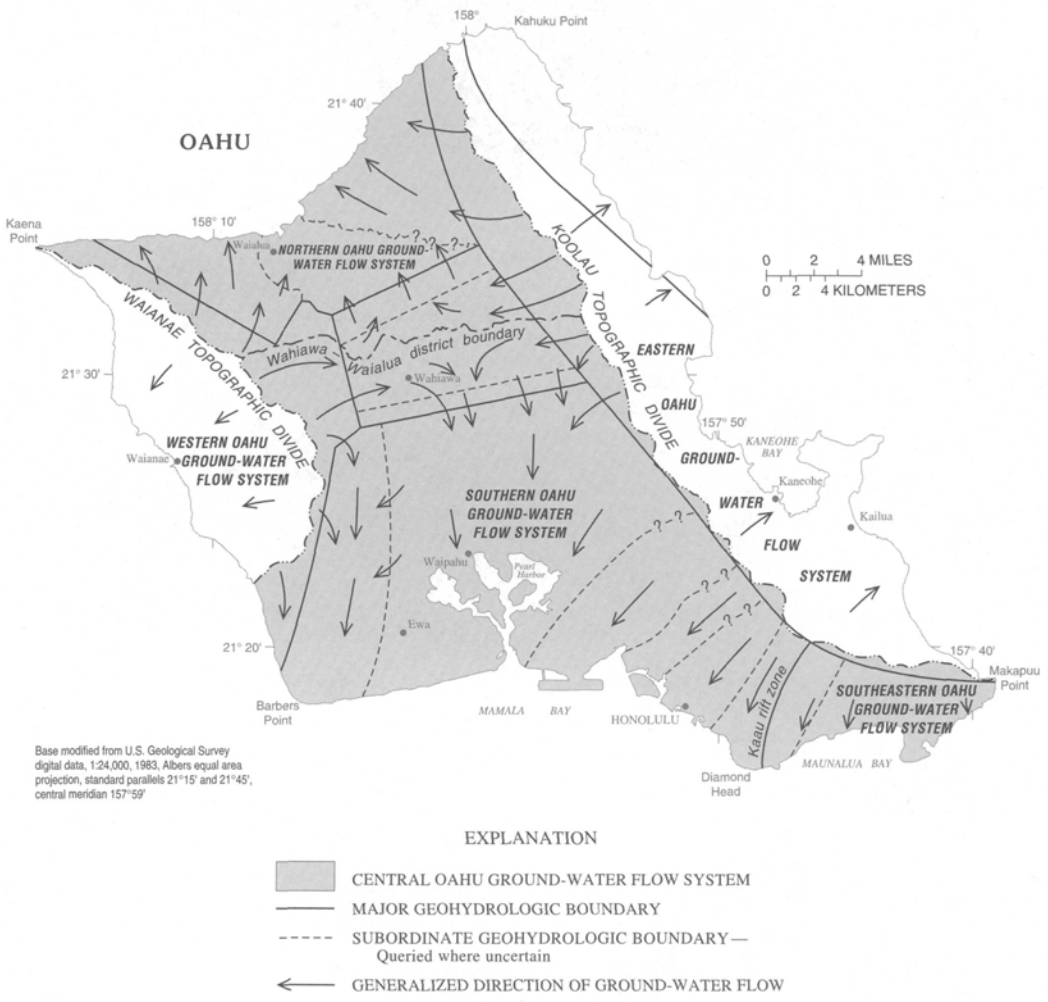

Figure 4: Groundwater flow systems for O'ahu (Nichols et al., 1996). The UH Manoa campus is located within the southern O'ahu groundwater flow system, just west of the Kaau rift zone.

The grid extent and thickness were designed to contain the potential region where a GHE system would be potentially deployed for cooling the Stan Sheriff Center. The grid extends from the ground surface to a depth of about 150 m. It contains 21 layers, with each layer thickness about 10 m. The upper five layers are incomplete, representing the variable surface elevation. The lower 16 layers all contain 2771 grid blocks. The total number of grid blocks in the model is about 46,000. Lateral grid spacing is 25 m, but the central portion of the grid is refined to 12.5 m, to better resolve

caves and the borefield. The lateral extent of the model is about 1.3 km in the east-west direction and 1 km in the north-south direction. Although the model itself is oriented east-west/north-south, the grid is rotated laterally to align with the regional groundwater flow direction. Figure 5 shows the grid. The numerical simulator being used is Transport of Unsaturated Groundwater and Heat (TOUGH) (Jung et al., 2018), a multi-phase, multi-component simulator for fluid flow and heat transport through porous or fractured geologic media.

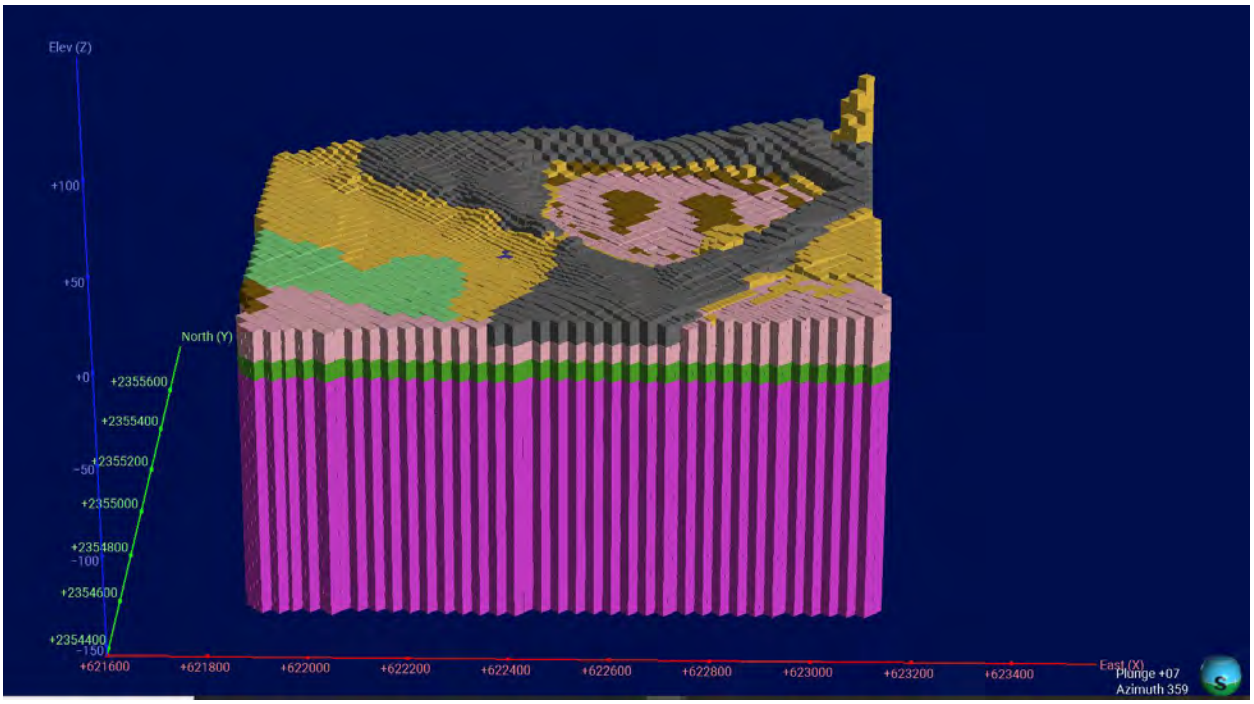

Figure 5: TOUGH grid used for the preliminary simulations.

There have been a number of hydrogeologic studies that have modeled groundwater flow in southern O‘ahu (e.g., Finstick, 1996; Nichols et al., 1996; Hunt, 1996; Lau and Mink, 2006; Rotzoll and El-Kadi, 2008; Okuhata, 2017; Izuka et al., 2018; Izuka and Rotzoll, 2023); they have summarized the hydrologic properties of the main geologic units of this area. In addition, Dores and Lautze (2020) have reported representative thermal conductivity values of the main lithologic units; these have been supplemented by data from Clark (1966) and Robertson (1988). Tables 2 and 3 present a summary of these properties, which are needed to properly simulate the groundwater flow and heat exchange of a GHE system. It is important to note that if 100 m closed loop borehole heat exchangers are to be used, then the Ko‘olau basalt unit will be the primary hydrogeologic unit controlling the heat exchange (the geologic model depicted in Figure 3 suggests that this unit will be present at depths greater than 20 m).

Table 2: Summary of key hydrologic properties of primary geologic units

Rock type	Hydraulic conductivity (m/d)	Effective porosity (%)	Comments	Sources
Koʻolau basalt (dike-free lava)	600 (horizontal – longitudinal); 150 (horizontal – transverse); 0.75 (vertical)		HC values used in our simulations	Okuhata (2017)
	152-1524			Hunt (1996)
	457, 305-1524	5	Porosity value used in our simulations. Vertical permeability estimated to be much lower than horizontal	Lau & Mink (2006)
	401-550		Based on Fig. 8a for study area	Rotzoll & El-Kadi (2010)
Honolulu volcanics	3 (horizontal – longitudinal); 1 (horizontal – transverse); 0.05 (vertical)		HC values used in our simulations	Okuhata (2017)
	0.3-152			Hunt (1996)
Limestone	100 (horizontal – longitudinal); 100 (horizontal – transverse); 0.5 (vertical)		HC values used in our simulations	Okuhata (2017)
	30-6096			Hunt (1996)
	0.43-53 (13)	15-45 (35)	Used average porosity value in our simulation. Coral ledge	Finstick (1996)
Alluvium	0.05 (horizontal – longitudinal); 0.05 (horizontal – transverse); 0.05 (vertical)		HC values used in our simulations	Okuhata (2017)
	0.0009-2.9 (0.9)	38-71 (54)	Used average porosity value in our simulations	Finstick (1996)
	0.006 – 0.113	46.4-62.4	Values for older alluvium	Lau & Mink (2006)

	0.3-152			Hunt (1996)
Fill	0.015-86 (43)	28-69 (46)	Used average HC and porosity values in our simulations	Finstick (1996)

Average values shown in parentheses

Table 3: Summary of thermal properties of primary geologic units

Rock type	**Thermal conductivity (W m^{-1} K^{-1})**	**Specific heat (10^3 J/kg K)**	**Comments**	**Sources**
Basalt	2.0		TC value used in our simulations	Dores & Lautze (2020)
	2.1-3.1		TC mean values for 2 different lavas measured at 20°C	Clark (1966)
	2.1	1.03	TC determined for non-porous rock with 10% mafic phenocryst content at 300 K; SH value for Dresser basalt at 20°C	Robertson (1988)
Limestone	3.1		TC value of 3.0 used in our simulations	Dores & Lautze (2020)
	2.18-3.05		TC mean values for 3 different limestones measured at 20°C	Clark (1966)
	2.7	1.01	TC determined for non-porous rock at 300 K; SH value for Bedford limestone at 20°C	Robertson (1988)
Alluvium	0.8		TC value used in our simulations	Dores & Lautze (2020)

As noted in Table 2, permeability in the basalt is anisotropic, with horizontal permeability much greater than vertical permeability, and longitudinal permeability (i.e., in the direction of the lava flow) higher than transverse permeability. In basalts, permeability is dominated by the presence of fractures. The TOUGH code is able to independently model fracture and matrix permeability by employing a dual continua model, where grid blocks are subdivided into fracture and matrix grid blocks by using the multiple interacting continua (MINC) approach (Pruess, 1992). The orientation and spacing of the fracture network can be specified using this approach. For these preliminary simulations, only a single continuum was used, but by orienting the grid with the direction of groundwater flow, we also align it with the orientation of the major fractures, enabling the code to model anisotropic fracture permeability effectively.

Another important input for this model is the initial temperature distribution in the subsurface. There are a number of deep groundwater monitoring wells in southern O‘ahu, including three (Kaimuki High School (HS), Kaimuki Station, and Waahila) that are fairly close to the UH Manoa campus. As part of the groundwater monitoring effort, multi-parameter sensors that measure fluid electrical conductivity, temperature, and pressure are regularly run in these wells to detect changes in the fresh water-brackish water interface (Rotzoll et al., 2010). The temperature information from these wells can be used to constrain the general temperature-depth gradient that can be expected for the Stan Sheriff site. For these preliminary simulations a uniform initial temperature of 21.5°C is used – Dores and Lautze (2020) report an average groundwater temperature of 21.36°C for Honolulu. These temperatures are consistent with the thermal profiles from the nearby monitoring wells mentioned above that were shared by the Honolulu Board of Water Supply.

The details of the vadose zone and heat and moisture transfer to the ground surface are not addressed in these preliminary simulations, but they are within the TOUGH simulator capabilities and will be included in future modeling. Here, the entire model domain is water-saturated and the top model boundary is closed.

Initially, all lateral boundaries of the model are closed, and a gravity-equilibration simulation is done to create a hydrostatic pressure distribution throughout the model. Next, columns at the upgradient and downgradient extremes of the model are held fixed with a given pressure difference, and the model is run to steady state, to create a regional groundwater flow. Finally, heat sources are specified to represent five 100-m long boreholes, with a total heat source strength of 400 kW, roughly comparable to the cooling load for the Stan Sheriff arena, and the model is run for 20 years.

3.3 Preliminary Heat Exchange Simulations of the Stan Sheriff Athletic Complex Site

Where the heating and cooling loads of a geothermal heat exchange system are unbalanced, it is important that heat that is discharged into the subsurface is dissipated through advective flow caused by groundwater flow to the sea so that the GHE system retains its efficiency over time. Such a system operates more like a radiator (such as the Verona ground source heat exchange (GHX) system, which has over 6000 GHX boreholes (Hart et al., 2022)), where heat dissipation is needed to maintain the heat balance of the subsurface reservoir over time. Thus, capturing the impact of lateral groundwater flow and its ability to sweep heat out of the system is critical in developing numerical models to help design and predict the system performance. Most GHE models utilize a simple g-function to represent heat exchange between the closed loop system and the subsurface, which does not capture the thermal impact of lateral groundwater flow, as it only

captures the effects of conductive heat transfer. A more rigorous representation of subsurface heat and flow processes can be realized using the TOUGH simulator, which can accurately model the effects of both advective and conductive heat flow. This simulator has been used to model geothermal district heating and cooling systems, and has been adapted to connect with the Modelica Buildings library (Wetter et al., 2014) developed by Lawrence Berkeley National Laboratory (LBNL), which includes dynamic simulation models for building and district energy and control systems (e.g., Doughty et al., 2021; Hu et al., 2022). Building upon these past efforts, our initial models examine the heat dissipation that can be achieved using a range of reasonable lateral groundwater flow rates based on reported transmissivity values.

Figure 6 shows some results of the preliminary modeling. Three cases were considered: no regional groundwater flow, small regional groundwater flow, and large regional groundwater flow. The plots show plan views of the temperature field at the top of the central portion of the model surrounding the borefield, after 20 years of heat injection. It is clear that the magnitude of regional groundwater flow has a significant effect on the long-term temperature in the borefield, with the maximum temperature decreasing as the magnitude of groundwater flow increases. The five injection boreholes are each separated by 12.5 m, and are arranged in a square.

Figure 7 shows an alternative suite of cases where the same load is distributed between 25 boreholes, also with 12.5 m separation, arranged in a square. It is apparent that the maximum temperature is much smaller in this case.

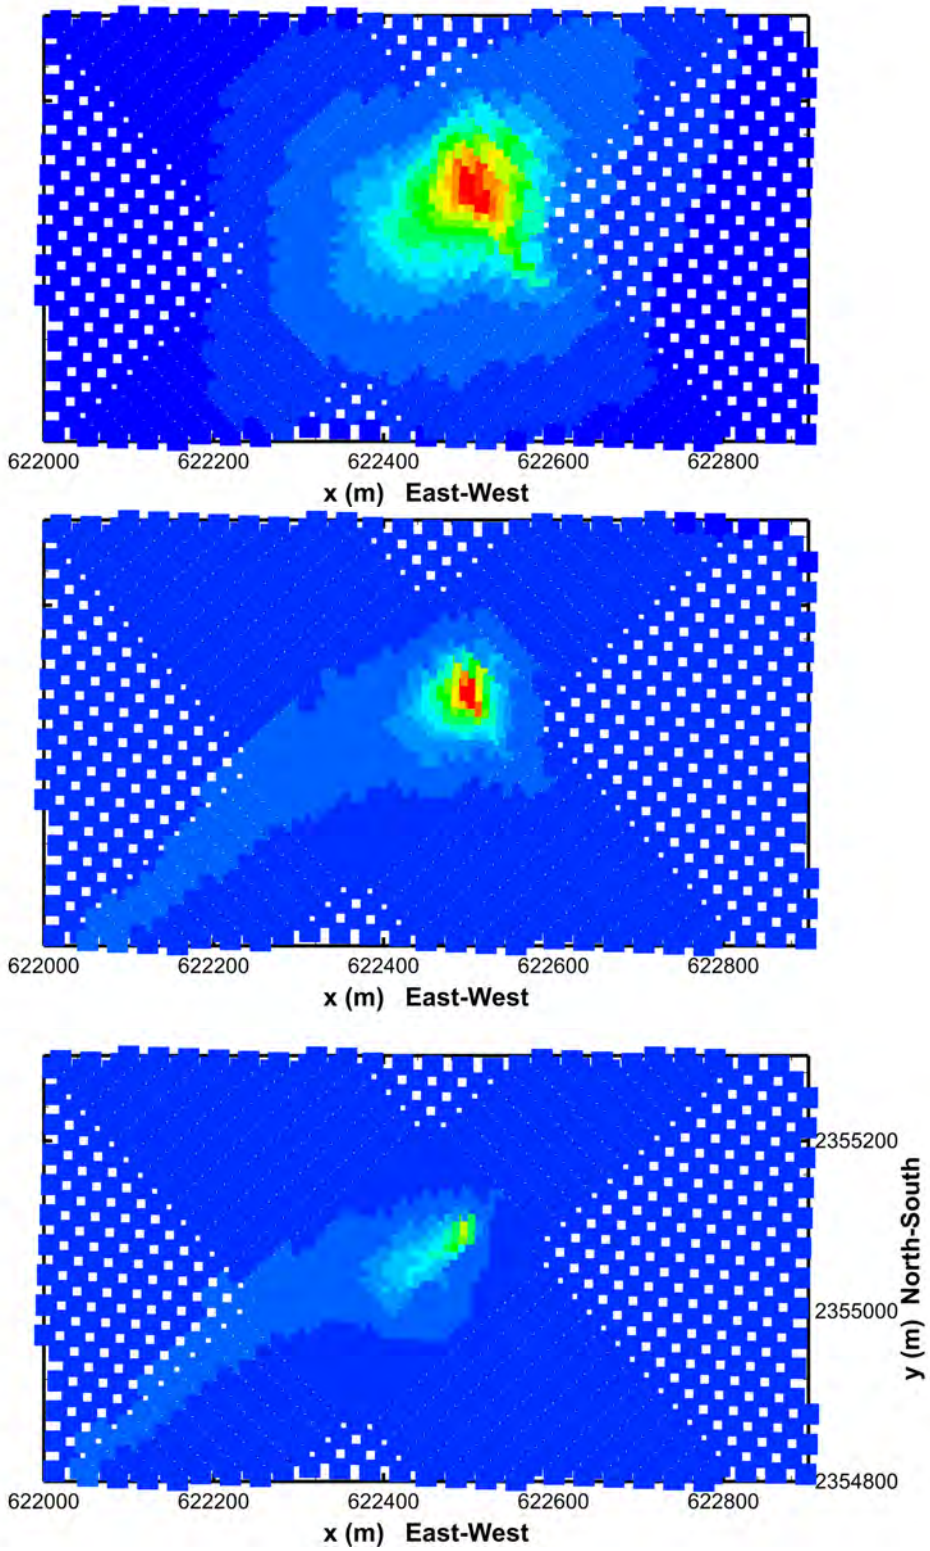

Figure 6: Preliminary TOUGH simulation results for a borefield with five boreholes. Temperature distributions at the top of the model after 20 years of heat injection. Top to bottom: increasing groundwater flow. Warmer colors indicate higher temperatures.

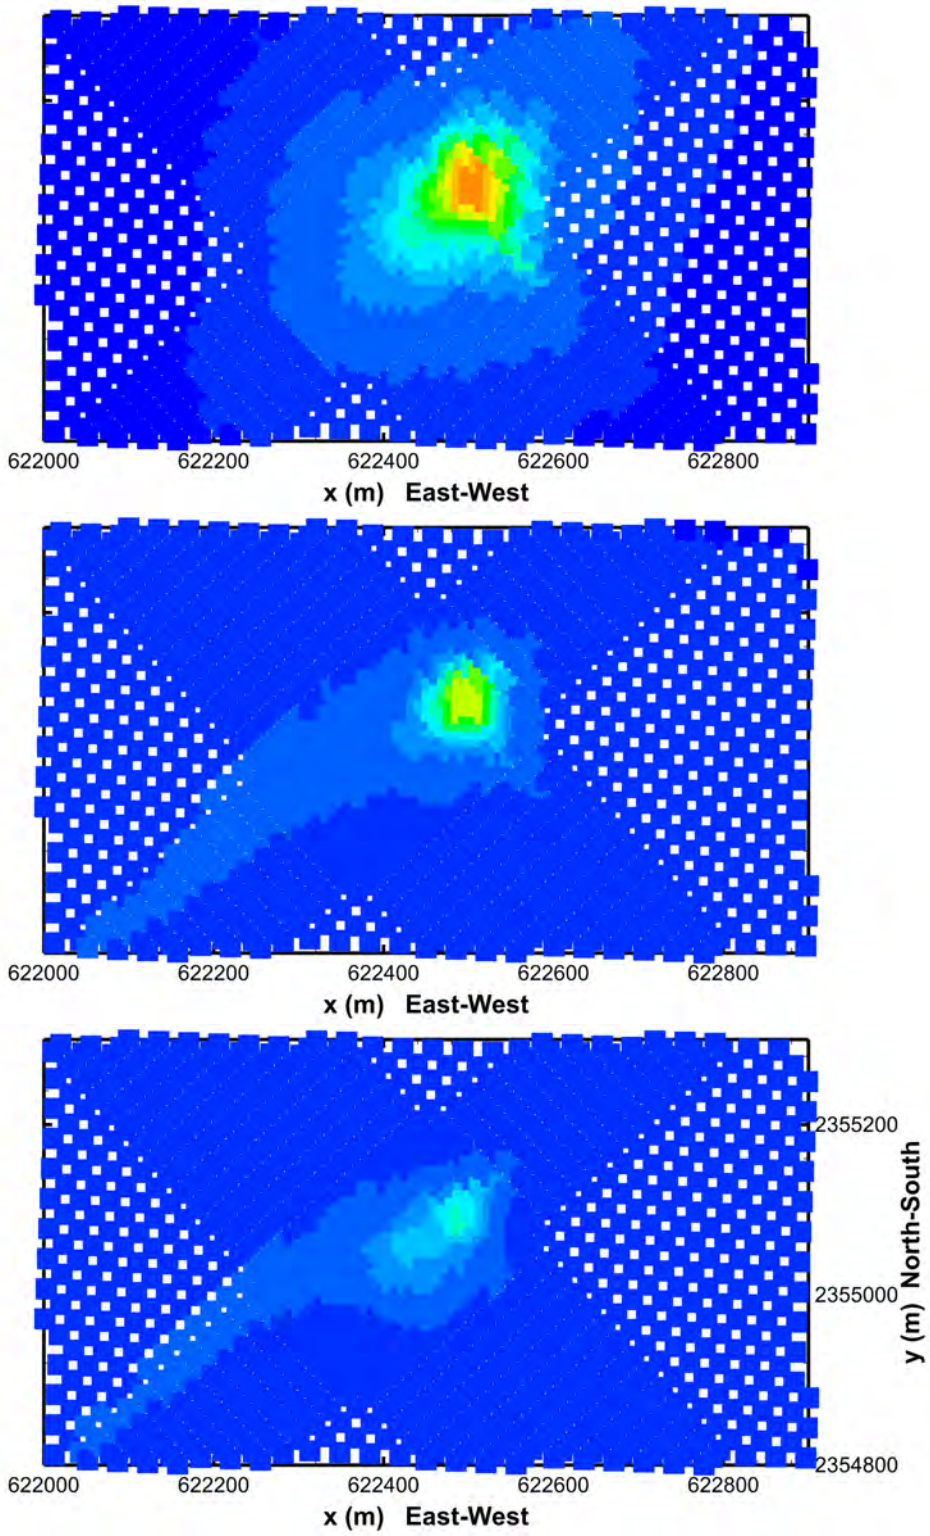

Figure 7: Preliminary TOUGH simulation results for a borefield with 25 boreholes. Temperature distributions at the top of the model after 20 years of heat injection. Top to bottom: increasing groundwater flow. Warmer colors indicate higher temperatures.

4. Next Steps

The preliminary TOUGH model can be improved in several ways to improve representation of the hydrogeologic setting: (1) the model can be reoriented in the direction parallel to groundwater flow to allow better assignment of pressure boundary conditions, (2) the vadose zone (with a smaller thermal conductivity due to drier conditions) can be represented, (3) moisture and heat transfer to the atmosphere, including evaporation and infiltration, can be included. Double-porosity or MINC methods can be used to better represent heat transfer in fractured rock. More accurate representation of the borehole heat exchangers can be implemented (e.g., Falta et al., 2023).

The results of the initial TOUGH simulations will then be coupled with Modelica runs to evaluate the effectiveness of a GHE system in providing sustained seasonal cooling to the Stan Sheriff Center. We will build a mechanical and thermal model of the Stan Sheriff Center's heating, ventilation, and air-conditioning (HVAC) system to assess the energy and demand impacts of transferring heat to the geothermal resource. We will then calculate the electricity bill savings associated with those energy and demand impacts. Finally, we will calculate the net present value of the geothermal exchange system, accounting for the capital costs of its installation, the lifecycle electricity bill savings, and tax credits made available in the Inflation Reduction Act (IRA).

There are several key economic incentives that could support the development of a GHE project such as the one described in this paper. The IRA includes the Clean Energy Investment Tax Credit, which applies to geothermal heat pumps, and includes a monetization pathway for non-taxable entities, such as universities. Eligible projects can claim up to 40% of the project cost as a credit. The base credit is 6%, but is increased 5 times to 30% if the system is less than 1 MW, or if the project meets prevailing wage and apprenticeship requirements. An additional 10% credit can be obtained if the project meets domestic content requirements. In addition, Hawaiian Electric Company offers incentives for custom energy efficiency project of up to 50% of incremental project costs–this effort would need to be coordinated with the utility, requiring an application that includes the energy savings calculations.

How 5th Generation Energy Networks Can Be The Source Of Energy To Supply High Temperature Water to Decarbonize Buildings Using High Temperature Distribution Loops

ABSTRACT

A challenge of decarbonization and electrification of buildings has been the expense associated with converting the buildings to 130° piped heating networks for radiators and perimeter induction heating. New technologies in high temperature heat pumps can deliver 180°F plus temperatures to these buildings from 5th generation thermal energy networks.

1. High Temperature Building Heating Loops

Throughout the heating ventilation and air conditioning industry, building loops have Ben designed for perimeter induction heaters and radiators at temperatures from 150 to 200°F or more. This has posed challenges for the conversion to heat pump technologies. Until recent years, heat pumps have been limited to about 140°F delivery temperatures. With more robust technologies being introduced to the industry, we are finding success with high temperature heat pumps delivering hot water at temperatures of up to 240° or more.

This presents a remarkable solution for industry. Previously, groups have had to B retrofitted for lower temperature heating delivery devices. With these new high temperature heat pumps, buildings may be left as is as far as infrastructure, significantly reducing the construction costs for decarbonization and electrification of these buildings using heat pumps.

2. High Temperature Heat Pumps

Heat pumps such as the Oilon ChillHeat are providing solutions that allow building extra fits from combustion boilers that typically deliver 160°F plus temperatures to building systems. With high temperature delivery, building mechanical systems can be left intact.

Figure 1: The Oilon ChillHeat Heat Pump is providing temperature lift of 100F or more (Oilon)

Performance of these heat pumps is remarkable in both the heating and cooling mode. With combustion heat boilers, cooling is not typically possible. This opens another dimension to building decarbonization and electrification. When considering the need for cooling becoming increasingly important to sustain health and safety of building occupants, this provides solution to a growing problem of heat stress in our built environment.

Using Heat Pump and the Stable Earth Temperature (Background taken from GRC Transactions, Vol. 45, 2021)

Ground Source Heat Pumps have been used throughout the world for generations, one example is Tampa's Church of Christ Scientists that was initially installed in 1949 (EggGeo 2014). Combining a ground source heat pump and the stable temperature of the earth is a proven technology that continues to provide the most energy efficient cooling and heating available. This is attributed to the steady temperature of the heat source and heat sink, being the earth and its stable temperatures.

Installation at a building requires excavation and /or drilling to access the earth's ambient temperatures, which drives the cost of the technology. The outside ground source pipe and work can be responsible for 60% or more of the total cost.

The costs for excavation are brought down by creating a geothermal pipeline that is installed in place of or into already existing typical natural gas pipeline, like a water main. Each home and building are connected to the District Geothermal Energy Network, just as they are to City or County Water. They will pay a connection and / or an energy fee just as they would for electricity or water.

3. Ambient Geothermal Distribution Pipelines

Eversource, has applied to do geothermal districts for multifamily buildings, dense urban or mixed-use, and purely residential. (Hasan 2020). The system will use ground-source heat pump technology, which uses electricity to transfer heat from the ambient temperature GeoMicroDistrict

(in the ground) to a network of geothermal heat pumps to provide clean heating and cooling for the buildings within each district.

In this case, the pipelines will be buried in place of or into the existing natural gas pipelines, providing the heat exchange needed for each of the buildings on the circuit. Some buildings need heating, and others need cooling at the same time; normally wasted energy is harvested for use in the pipeline. An example of this is the Stanford Energy System Innovations (SESI). The project illustrates the capability to combine waste heat from cooling operations with the heat needed for heating operations, reducing energy consumption by sharing as much as 80% of the energy moved on campus (Stagner 2015). (See Table 1)

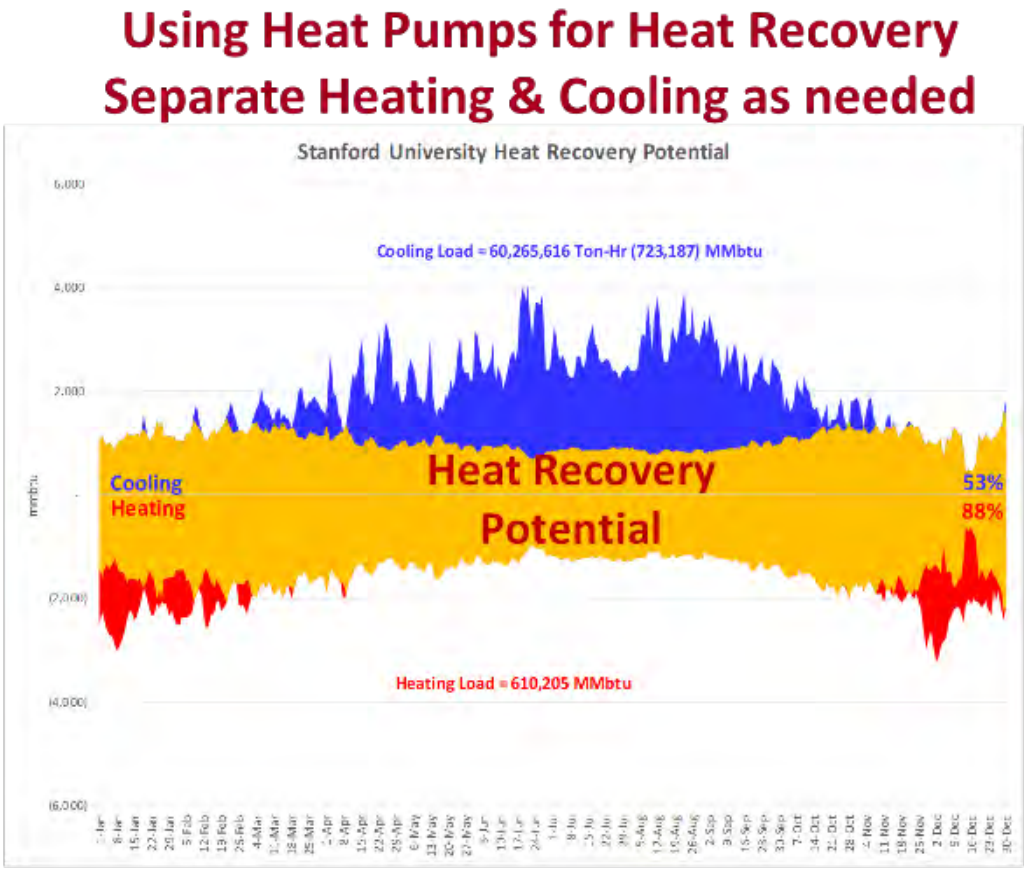

Figure 3: Stanford Energy System Innovations (SESI) shows the shared energy from buildings needing heat, and those rejecting heat.9

Similarly, District Geothermal Energy Networks will enable energy access for all of buildings in a community to tap into one central exchange source, without the added cost of onsite excavation and drilling [Figure 3].

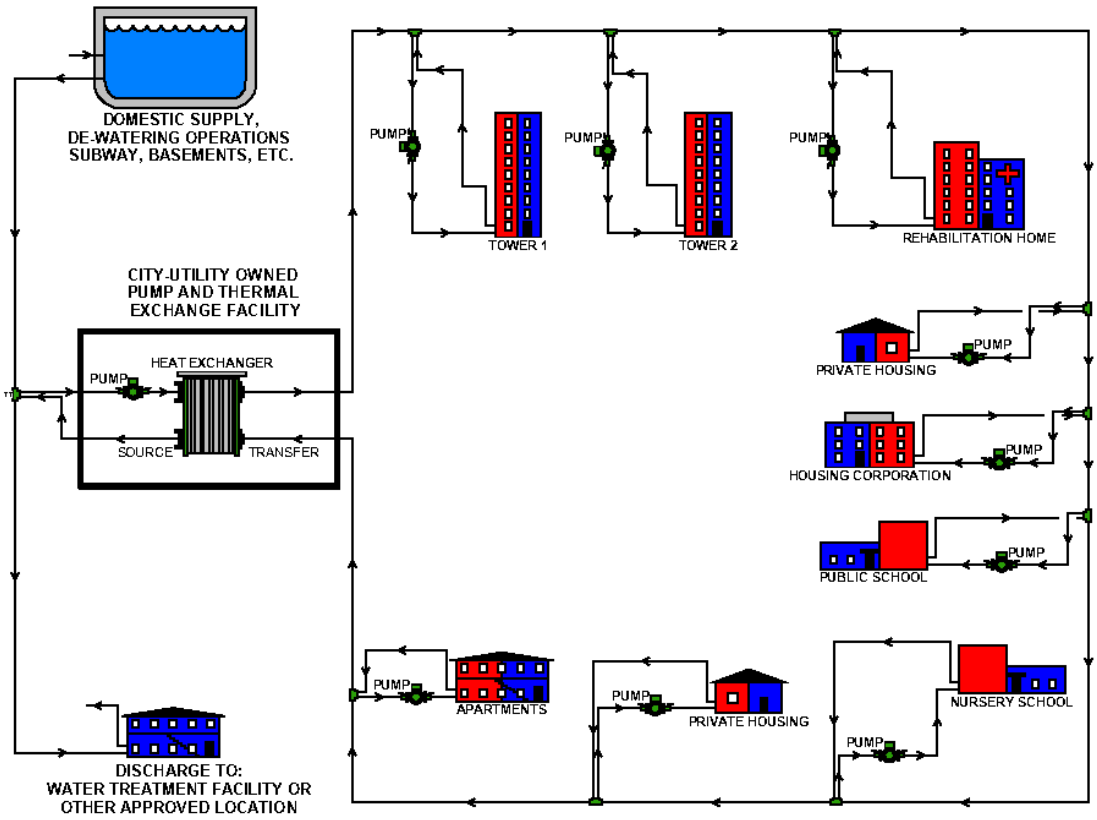

Figure 4: A District Geothermal Energy Network has many different buildings served, and many different heat sources and heat sinks

4. Ambient Temperature Surface Water & Aquifer Exchange

There are dozens of variations for earth-coupled heat exchange. The possibilities are wide and varied. Some of the solutions have a lower first cost than others for a variety of reasons. Some are listed below and depicted in Figure 4.

- **Closed loop vertical exchange:** Can be configured in 2-pipe, 4-pipe, concentric and many more adaptations.
- **Closed loop horizontal exchange:** Can be configured in many various ways to apply open-trench based exchangers.
- **Closed loop pond/lake/ocean:** These can be configured to use fabricated plate exchangers, or polyethylene pipe arranged in the body of water.
- **Closed loop energy piles:** Like closed loop vertical exchange, these can be adapted in many different ways.
- **Open standing column wells:** Primarily allows for reduction in boreholes, allowing for a smaller footprint. Needs specific geology (competent bedrock).

- **Open Class V well doublets:** Primarily allows for reduction in boreholes, allowing also for a smaller footprint. Needs a specific geology (abundant aquifer). Great for large-scale applications in hot and humid climates (cooling dominant).

Figure 5: Some of the variations for heat sources and heat sinks in a District Geothermal Energy Network (Egg 2014)

Efforts are underway to prepare a heat map like that which has been created in the UK for the Department of Energy & Climate Change. Surface water thermal exchange includes rivers, ponds, lakes, aqueducts, and water features. Surface water exchange can consist of plate exchangers or pipe in the water, water extraction and rejection, or any variations of submerged exchangers.

The UK Department of Energy and Climate Change commissioned a study of surface water exchange potential. The study shows 6 GW of thermal capacity, enough to heat and cool 7 million homes (Department of Energy & Climate Change 2015). Though the United States has no such research, it is reasonable to suppose U.S. capacity would be greater.

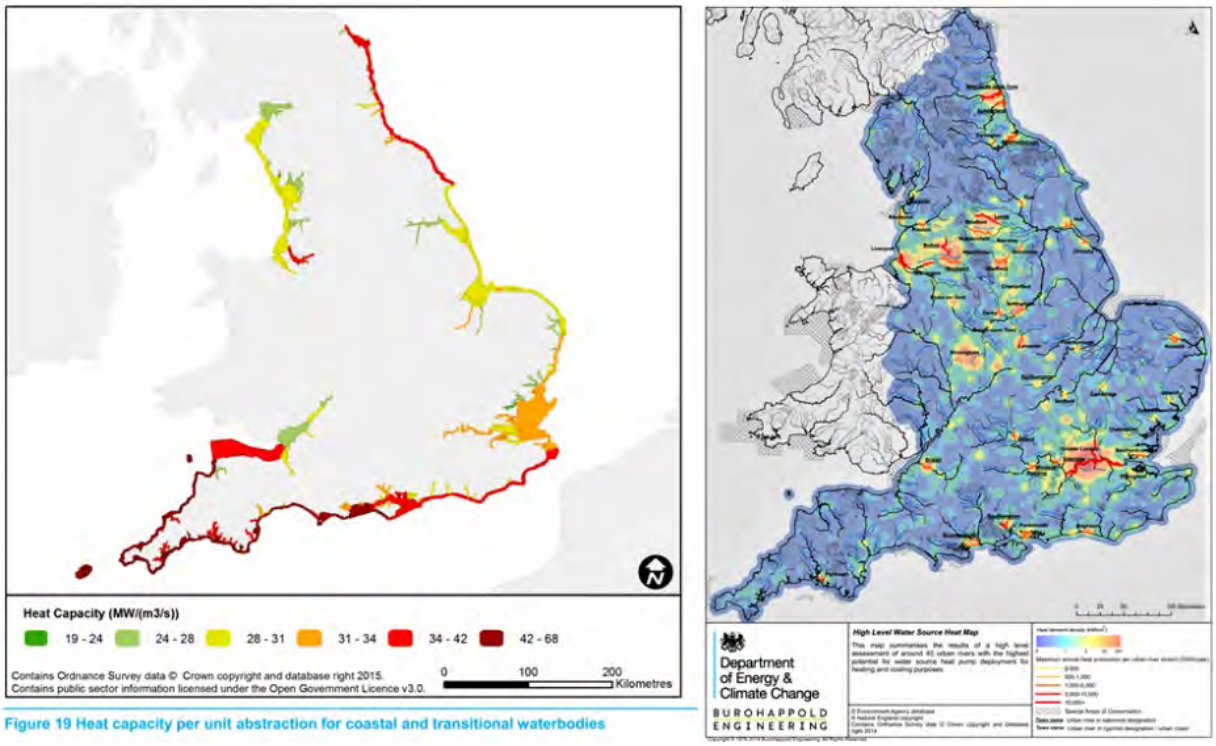

Figure 6: UK National Heat Map for Surface Water (Department of Energy & Climate Change 2015)

Infrastructure dewatering thermal exchange includes ongoing efforts for low-lying cities and infrastructure, subways and conduits that need to be kept dry and, of course, the need for current and future efforts to handle ocean rise. Where relative sea-level rise occurs, it amplifies near-term vulnerability to storm surge and increases long-term flood and inundation risk.

Well Water Thermal Energy Exchange is another of the technologies identified along with surface water energy exchange that can significantly reduce first cost. It is depicted in the Figure 6a and is identified as either “Aquifer or “Well Water” Thermal Energy Exchange. Water is pumped from one well, used for thermal exchange, then injected into another. This method is considered environmentally friendly and a good use of resources.

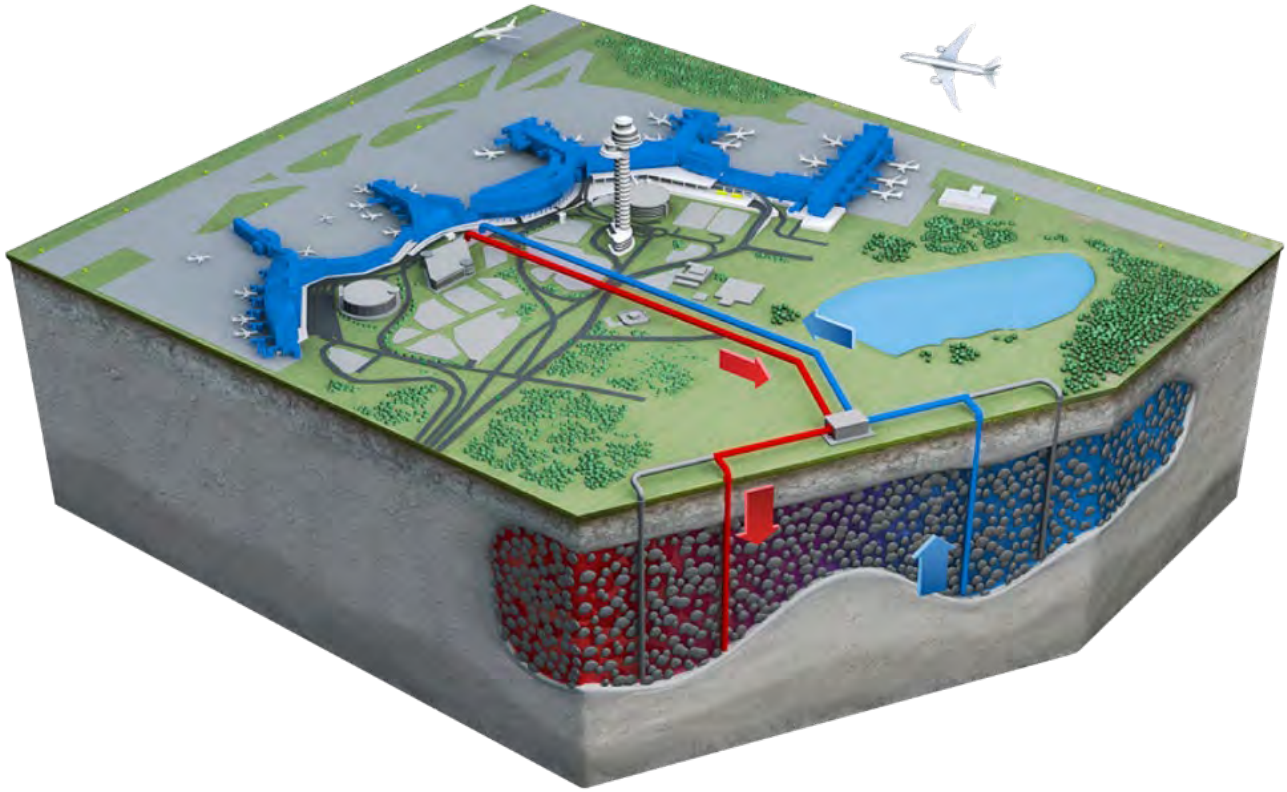

Figure 7a: Depiction of Aquifer Thermal Exchange

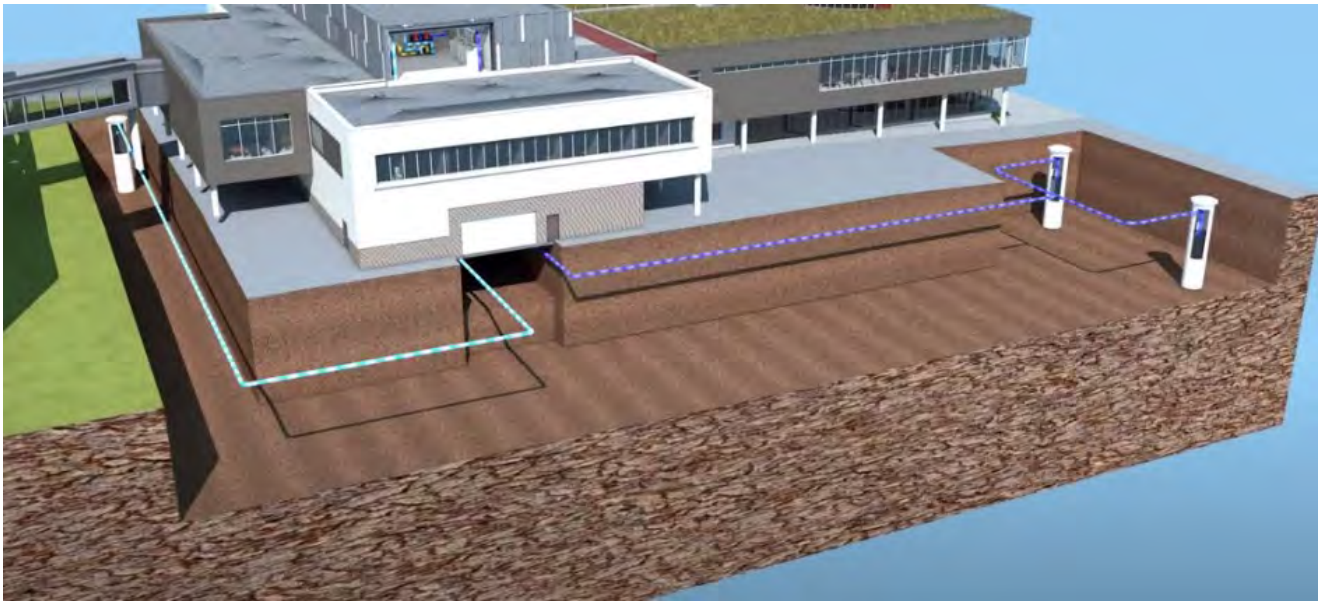

Figure 7b: Another depiction of Well Water Thermal Exchange

We have the means of heat transfer already in the ground, which can eliminate the need for much of loop infrastructure that is normally identified as prescribed by the ground source heat pump

industry. Tapping existing pipe infrastructure for thermal exchange helps to reduce the first cost well below that of single geothermal systems, and adds load sharing and diversity, significantly reducing energy consumption beyond stand-alone systems, once again as in the Stanford example. The water/energy utility can own the exchange facilities and sell the energy.

With the advent of high temperature heat pumps, building retrofits and utility thermal energy networks may be done without re-piping the building hydronic systems. The existing radiators and heat distribution equipment can remain in place.

*Note: The terminology **Thermal Energy Networks**, **GeoMicroDistrict, Ambient Geothermal Networks, Pipelines, or Distribution** as applied to geothermal systems are used interchangeably. These all have the common thread of an ambient, or an earth temperature fluid pipeline used as a utility to provide energy exchange for geothermal heat pump systems in homes and buildings.*

Ground Source Heat Pump (GSHP) and Geothermal Heat Pump (GHP) mean the same thing.

ABSTRACT

Building heating and cooling took center stage in the European Union's 2023 Energy Efficiency Directive update, released in September of the same year. There were more than 350 mentions of heat, largely relating to the decarbonization of current combustion processes, including those in individual building systems. One of the pillars of decarbonizing building stock in the plan calls for a near doubling of existing district heating and cooling networks by 2050. The same calls for building stock decarbonization are being heard in North America, though the organization of regulation is much more disparate. Lessons from similar European initiatives suggest that local utility planning for city-scale projects is an effective way to attract investments in sustainable heat. In the context of geoexchange heating and cooling, that using the earth as a modulating mechanism for stable fluid temperatures, 5th generation district heating and cooling systems are useful in every geologic province of the continent. These 5th generation district heating and cooling systems are more frequently referred to as thermal energy networks (TEN) in North America, with the ability to operate at ambient or near-ambient ground temperatures using a spectrum of centralized through distributed water-source heat pumps (WSHP). While front-end engineering and design of the systems rely on detailed transient simulation, prefeasibility is an important first step in providing sufficient technical and economic data to support the development of networks that may contain a few dozen, or even a few thousand, structures. City-scale sustainable heat planning, therefore, requires city-scale simulation capabilities. In this desktop study, a downtown section of Boulder, Colorado serves as an exploratory example of which metrics are important to consider before proceeding with production level engineering on a TEN. Geographic information system simulation tools enable the designer to quickly iterate through optimal pipe routing pathways, bills of materials, and electrical ramping requirements of heat pumps, among other technical outputs, creating a method of global sensitivity analysis in the earliest stages of design while respecting the variable entering and exiting fluid temperatures of closed loop borehole arrays.

1. Introduction

Over the last year Europe took a strong step towards building stock decarbonization with a revision of the Energy Efficiency Directive (EU/2023/1791). As a result, energy policy from the European Union (EU) now implements a principle of energy efficiency first (Directorate-General for Energy, 2023). Full decarbonization of district energy systems is a 2050 requirement, with public buildings to receive similar envelope renovations no later than 2040. All buildings with floorspace greater than 750 m^2 (>8000 ft^2) must renovate or consider the use of performance-based contracts from energy service companies to decarbonize their heating and cooling systems within the same timeframe (European Commission, 2023).

In the United States the Inflation Reduction Act of 2022 (IRA) offers provisions for home and commercial building energy efficiency tax credits (Internal Revenue Service, 2024a, 2024b). The IRA itself does not codify sustainable heating and cooling like the EU Energy Efficiency Directives do. Instead, the US Department of Energy (US DOE) recently released their first-ever building sector decarbonization blueprint, targeting a national 90% emissions reduction by 2050. The report cites building energy consumption costs of $370 billion dollars, annually (US Department of Energy, 2024a, 2024b).

Both the EU Energy Efficiency Directive and the US DOE building sector decarbonization report suggest such conversions of predominately combustion-driven heating and cooling may put the most vulnerable low-income persons across society at risk of energy cost increases (European Commission, 2023; US Department of Energy, 2024a). These would be the people across society unable to afford individual building system upgrades or building envelope improvements on their own. A community- or city-scale sustainable heating and cooling plan is, therefore, necessary to avoid inequities brought about by the energy transition. One system type that may offer city-scale decarbonization of building stock heating and cooling with the same utility-like economies of scale as gas distribution grids is the thermal energy network (TEN).

The modern TEN is a 4th or 5th generation district heating and cooling system, typified by its ability to perform waste heat recovery, leverage lower-temperature resources, temper hydronic distribution systems with heat pumps or passive heat transfer equipment, and maximize performance by minimizing electricity inputs (Buonocore et al., 2022; Lund et al., 2021; Zeh et al., 2021). During the intervening decades since the 1800's installation of 1st generation of district energy steam distribution, greater efficiencies have been found with decreasing source and sink temperature regimes. Lowering temperature regimes reduces the requirements for zone heating and cooling within a building and mitigates heat losses or gains to the soil along a district distribution network (Collins, 1959; Lund et al., 2014). Some of the sources and sinks that can tie to those distribution networks now include conventional geothermal resources of a relatively high temperature, and closed loop borehole arrays of a near ambient ground temperature (Hirsch & Paepcke, 2022; Wirtz et al., 2022; Zeh et al., 2021).

Regulators across several states are recognizing the importance of finding utility-scale replacement options for gas distribution systems, with many beginning to lean into TEN concepts. The landscape of law requiring gas utilities to implement TEN options across their service territories is growing. As of this writing, laws or proposed bills mentioning TENs exist in Colorado, Illinois, Massachusetts, Maryland, Minnesota, Vermont, Washington, and New York, among others. This

number is likely to grow as policymakers realize the only sustainable heat solution is one accessible to everyone.

Therefore, policymakers, energy service companies, and utilities need designers that offer accessible solutions for city-scale planning and TEN prefeasibility. The remainder of this paper addresses design implementation approaches that apply to TEN implementation studies and their eventual construction. Further, to demonstrate the initial steps a section of the downtown core for Boulder, Colorado serves as a basis for the desktop investigation.

2. Approaches to TEN Design

District heating and cooling design relies on several requirements. These requirements include the available sources and sinks across a community, the initial and projected demand by building, and the intended configuration. As mentioned, sources and sinks for TENs are more efficient at lower temperature regimes. It is also true, however, that the policymakers and designers must take advantage of waste heat resources across their community. These waste heat resources may dictate the eventual system configuration. Building energy modeling is another non-trivial task in the design, representing the initial and projected demand across the system. Some preliminary demand information may be available from gas utility operators, but the operation of the TEN can become sophisticated to the extent that city-scale modeling and simulation becomes a better characterization method. There are many different configurations of a TEN which impact design, performance, ease of installation, and construction risk, among other variables. Generally, the topology of thermal networks is either radial, meshed, or ringed (von Rhein et al., 2019). Radial and ringed topologies are often most appropriate for centralized or hybridized TENs while a mesh represents a complicated hydraulic design with potentials for efficiency gains on a case-by-case basis (Figure 1).

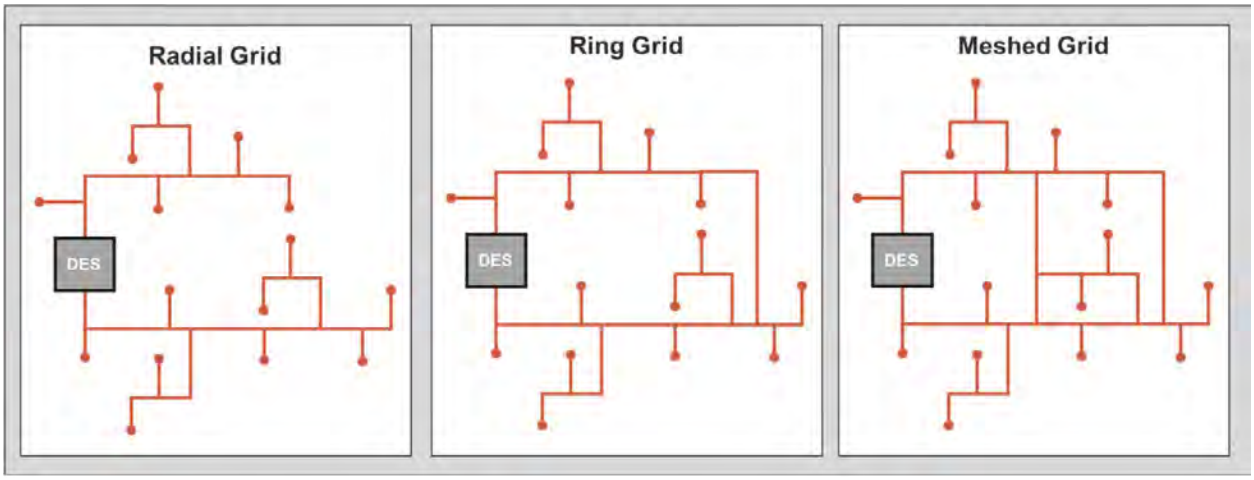

Figure 1 Network topologies for community-scale heating and cooling systems (von Rhein et al., 2019).

Before the advent of most low-temperature networks with heat recovery, district energy relied mostly on steady state calculations to dimension the systems. These dimensioning techniques are still important for transient systems, such as borehole heat exchange supported networks, but they now represent only one of several steps. The system dimensions are assembled in such a way that they can meet the transient operational constraints of maximum and minimum temperature responses. Maximum and minimum temperature responses are a function of design

parameterization – for example, the choice in sizing a closed loop borehole array – and stochastic climatic inputs, waste heat recovery cyclicity, and the incident heat losses or gains.

While many more details exist across other resources on the dimensioning of TEN inputs, such as thermal energy storage (TES) (Jebamalai et al., 2020), pipe configurations (Averfalk & Werner, 2018), supply equipment (Manente et al., 2019; Schifflechner et al., 2023), and primary side equipment (Postnikov et al., 2019), among others, this paper focuses on the new logistics of dynamic design implementation. (IQGeo, 2023) suggests there are three levels of design technique maturity (Figure 2). In the first tier, designers are pushing approximate numbers through spreadsheets that may or may not address the complexities of other subsurface utilities and artifacts that the distribution system installers may encounter during the roll-out. When encountering a tier three design, the integration of geospatial mapping and automation provides the necessary accuracy that would-be TEN providers should expect from their engineering consultancies. Comsof Heat is one such software that enables that automation with pipe routing based on heuristic clustering algorithms, approaching a near cost optimization for right-of-way use cases (Jebamalai et al., 2019).

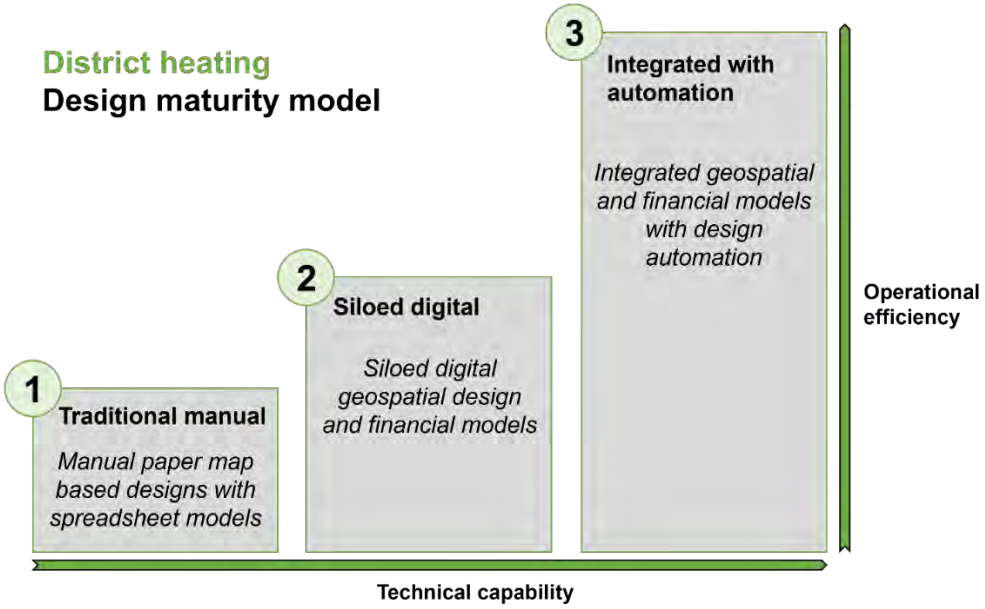

Figure 2 Three design technique maturities for thermal energy networks (IQGeo, 2023).

The following section will explain Comsof Heat as an important steady-state system dimensioning tool which integrates with a transient system ground response on a desktop study of a hybrid TEN for Boulder, Colorado.

3. Case Study Methodology

There are four primary steps to the analysis of a TEN for Boulder, Colorado. They include:

- Geospatial reconstruction of the service area
- Building energy modeling
- Borehole array modeling and simulation
- TEN dimensioning

Geospatial construction of the service area requires building footprints and geometries. Previous analysis from states other than Colorado recommends gathering occupancy, floorspace, and other parameters of the structures from cadastral data (Fry, 2021). After gathering the appropriate building information, each structure undergoes energy modeling to extract annual hourly load profiles for heating, cooling, and domestic hot water (DHW) consumption. These load profiles are fed into thermal response functions with a central heat pump performance curve. Finding the borehole array dimensions to meet the demand using an average, near-ambient, distribution temperature, we use Comsof Heat to dimension the pipe network.

This system prefeasibility demonstration uses a hybrid TEN configuration. Hybrid configurations for the network include a central heat pump at the central utility building with distributed heat pumps across the district. This limits unnecessary heat losses as the fluids make their way to 150 buildings across Boulder, Colorado. Each of the 150 heat pumps range in cost from $15,000 - $90,000, depending on peak demand size. These 150 buildings include retail storefronts, multifamily housing, and offices. Each receives various construction sets typified by US DOE building benchmarks, sorted by climate zone (“Commercial Reference Buildings,” n.d.). The predominate years of construction for the structures are before 2000. These years of construction will dictate the building standards and, therefore, the building envelopes. To minimize computational time, only the building geometries and types for the service area of interest are run through simulation (Figure 3).

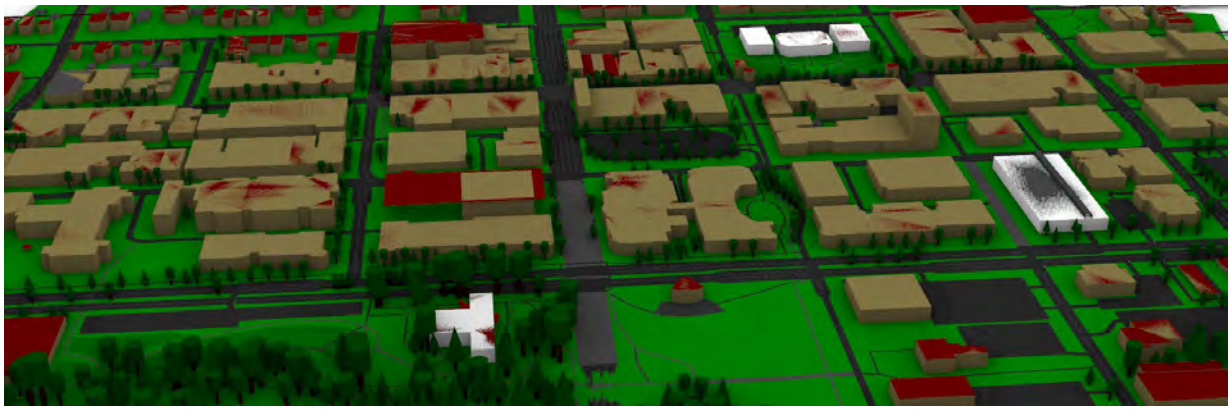

Figure 3 Isolated building geometries for building energy modeling of the Boulder, Colorado downtown district.

System dimensioning of both the borehole array and the pipe distribution grid requires several iterations. These iterations account for the simultaneity of demand (Eq. 1 and Eq. 2), and the incident peak heat transfer necessary across the closed loop borehole array. The simultaneity of demand is a principle advantage of district energy that reduces the average pipe diameters of the network and decreases costs. A coincidence factor is taken which suggests that demand for space heating or DHW across the district heating network does not occur at the same time. For example, as more structures of varying types connect with the network, the simultaneous demand will decrease. The peak of heating or cooling demand is multiplied by the coincidence factor to determine the simultaneous demand. It is generally good practice, even in single-building systems, to remove the simultaneous load when considering sizing of geothermal or geoexchange sources or sinks. This concept is, therefore, extended to the city scale to dimension component parts of a TEN. General engineering parameter assumptions for the pipe network appear in Table 1. A plastic pipe catalog is also part of the simulation, with the material having unique thicknesses, roughness,

maximum pressure gradients, and thermal conductivities. The burial depth is set to a minimum 36 inches (0.91 m), as regulated by Boulder County (Boulder County, 2017).

$$C_{SHC} = x + \frac{(1-x)}{n} \quad \text{Eq. 1}$$

$$C_{DHW} = \frac{1}{\sqrt{n}} \quad \text{Eq. 2}$$

Where:

x is the simultaneity factor[1]

n is the number of consumer nodes

C_{SHC} is the coincidence factor for space heating or cooling

C_{DHW} is the coincidence factor for domestic hot water

Table 1 Engineering parameter assumptions for the distribution system.

Parameter Type	Value
Ground thermal conductivity (W/(m.K))	1.1
Wet ground thermal conductivity (W/(m.K))	2
Near surface ground temperature (ºC)	9.44
Ground-to-air transition insulance (m^2.K/W)	0.0685
Ground water depth (m)	1
Elevation head (m)	2
Working fluid specific heat (kJ/(kg.K))	4.186
Pump efficiency (%)	60
Distribution temperature (ºC)	15
Target differential temperature (ºC)	5
Seasonal coefficient of performance (COP) for DHW, distributed heat pumps	2.8
Seasonal COP for space heating, distributed heat pumps	3.5
Seasonal COP for space cooling, distributed heat pumps	6.1

Closed loop borehole arrays serve as a modulating thermal storage device, where heat can both be extracted or rejected to the borehole array. This study uses software based on the conduction-only

[1] In this study a simultaneity factor of 0.62 is taken, aligning with several European empirical standards.

thermal response from the borehole. This is generally derived or modified from the infinite line source (ILS) method, as originally described by Ingersoll et al., 1954, p. 146. This collection of equations describes the heat released from a point along a continuous line, where the heat released at the point is divided by the thickness to get the heat released per unit length of the line. Ingersoll describes this as appropriate for "subterranean sources and sinks," with an example for closed loop boreholes tied to heat pumps (Ingersoll et al., 1954, p. 151). Several modifications to the Ingersoll work are generally incorporated into modern engineering software, such that the long-response limitation (hours or days for temperatures to change) of the ILS becomes relevant for short-response thermal impacts (minutes for temperatures to change) (Nian & Cheng, 2018). One of the earliest and most well-known modifications to the ILS approach for borehole thermal response is the finite line method, described by Eskilson (1987) – also in use for this case study. The general engineering parameter assumptions for individual boreholes appear in Table 2. In practice, these parameters are refined through the study of well logs, predictive models, and in-situ testing and define the boundary conditions of the borehole thermal response.

Table 2 General engineering parameter assumptions for the closed loop boreholes in simulation.

Parameter Type	Value
Effective borehole thermal conductivity (W/(m.K))	1.7
U-tube diameter (inches)	1.5
Grout thermal conductivity (W/(m.K))	1.5
Borehole separation (m)	7.62
Borehole thermal resistance (m.K/W)	0.16
Initial borehole ground temperature (ºC)	9.44
Peak flow rate ($(m^3/hr)/kW$)	0.195
Borehole depth	183
Propylene Glycol (% by weight)	20

Finally, Comsof Heat features economic parameterization to estimate the costs of the construction roll-out period, revenue during TEN operations, and net present value, among others. The general economic parameters for the techno-economic calculations appear in Table 3.

Table 3 General economic parameter assumptions for the Boulder, Colorado TEN simulations.

Parameter Type	Value
Network lifetime (years)	50
Network deployment time (years)	3
Discount rate (%)	7
Cost of electricity ($/kWh)	0.06
Annual electricity price escalation (%)	1.0
Subsidy for project capital costs (%)	30
Fixed annual O & M costs (% of asset value)	0.75
Variable annual O & M costs ($/MWh$_t$)	1
Borefield capital costs ($)	$30,000 per borehole
Central energy transfer station costs ($)	$500,000
Distributed heat pump costs ($/kW)	225 – 600 depending on unit size
Relative pipe cost ($/(mm.m))	4
Tariff ($/kWh)	0.10
Service connection fee ($)	2,200
Fixed monthly fee per user account ($)	60

4. Results

The load profile of the downtown district will dictate the size of sources and sinks which connect with a thermal energy network. The peak load for heating and DHW is 11,998 kW_t while the peak load for cooling is 7,954 kW_t (Figure 4). There are 556 equivalent full load hours (EFLH) for cooling and 1437 EFLH for heating. The EFLH is a ratio for the annual heat delivery divided by the peak of the hourly demand. This indicates a heating dominant district, based on the non-rigorous building envelope assumptions for simulation inputs.

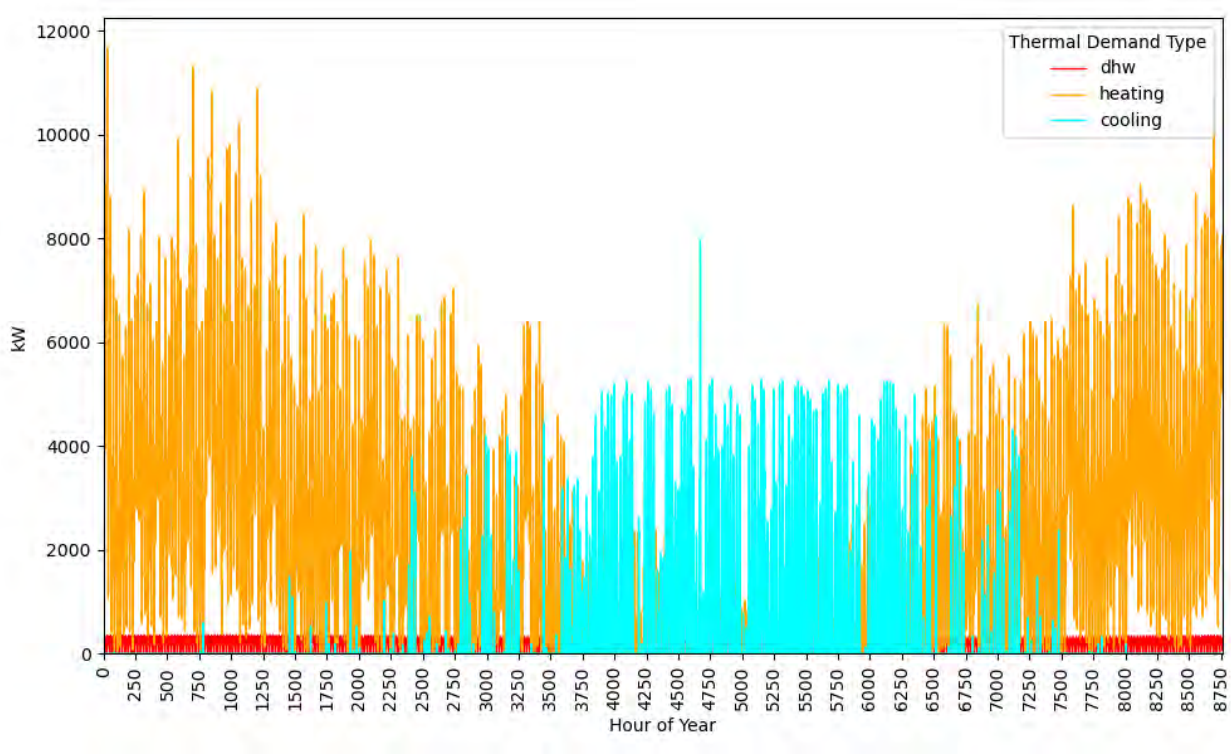

Figure 4 Annual load profile for the simulated downtown district of Boulder, Colorado.

To accommodate the demand for both heating and cooling over a 50-year planning period while also maintaining a minimum entering water temperature (EWT) to heat pump equipment above 0ºC, the ground loop heat exchanger (GLHE) requires more than 5,000 boreholes without hybridization. Such a system would cost more than $150,000,000 before subsidy, for drilling and completions alone.

A hybrid approach using supplemental distributed heat pumps decreases simultaneous demand to 5,505 kW_t. That is 44% of the sum of all peaks for heating. Standardization of the load profile and reiteration of the borehole array simulation indicates the need for 2,500 boreholes. The scale of this system would cost $75,000,000 for drilling and completions.

Since the seasonal heat transfer imbalance from the load profile cannot be resolved through diversity alone, a final iteration assumes a 50-year project lifetime with a run-of-the-river heat exchange with Boulder Creek to pre-charge the borehole array for the heating season. Extracting 37% of the total heating demand from the creek, the borehole array size drops to 1,000 boreholes. The pre-subsidy cost of the drilling and completions would then be $30,000,000. The minimum EWT for the equipment is 0.1ºC across 50 years (Figure 5). The central heat pump seasonal COP for cooling is 6.0 and 3.6 for heating, resulting in a central utility cooling production cost of $10.00/$MWh_t$ and heating production cost of $16.67/$MWh_t$.

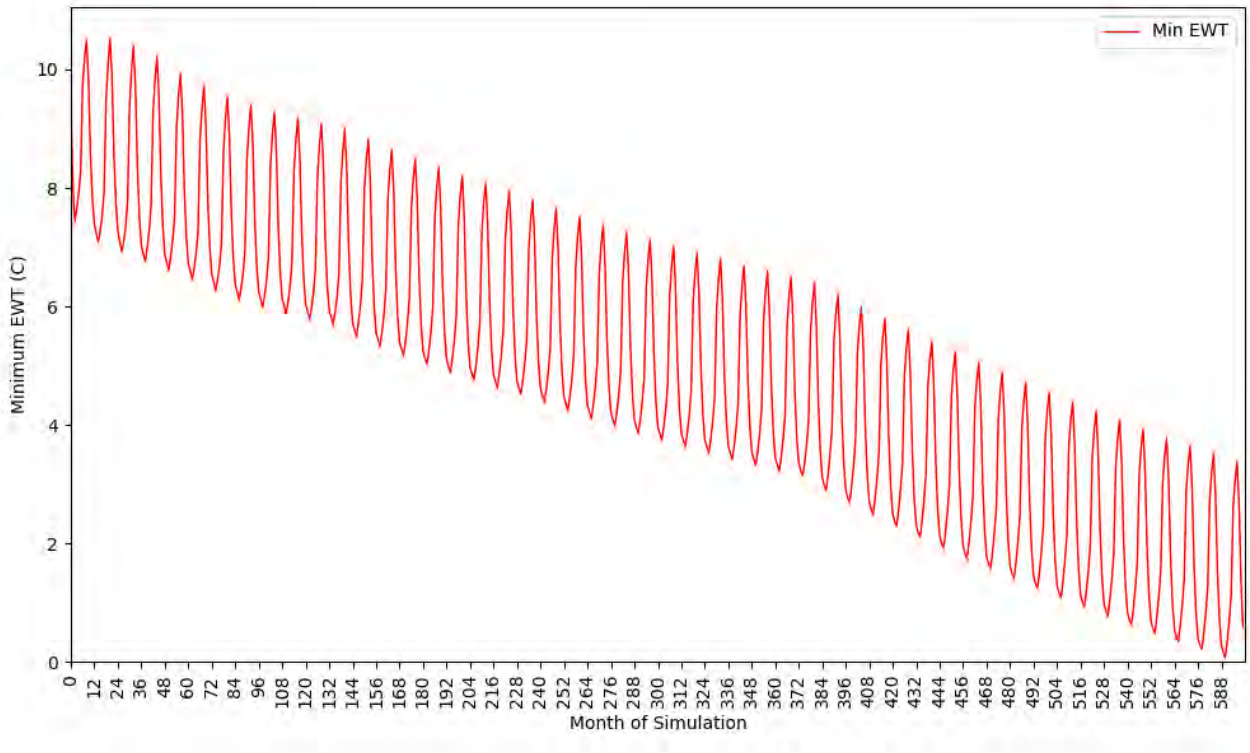

Figure 5 Minimum EWT for central heat pumps from 1000 borehole array, over 50 years. This figure demonstrates that the system meets the minimum temperature constraints over the project lifetime.

Assuming the borehole array position along Boulder Creek, on what is largely public property, a simulation of the thermal energy network routing seeks a near optimum pipe placement (Figure 6). Comsof Heat routing algorithms indicate the need for 8,415m of pipe, ranging in size from a nominal diameter of 100 – 400mm (4 – 16 inch). The peak mass flow rate for the system ranges from 1 – 260 kg/s, depending on zone (Figure 7). For an enhanced dimensioning value in the planning stage, the material selection can be made with the appropriate manufacturer's pipe catalog characteristics as inputs (constraints).

Figure 6 Thermal energy network routing with proposed energy sources in Boulder, Colorado.

Figure 7 Mass flow rate at peak operating conditions for the thermal energy network in Boulder, Colorado.

The unsubsidized total project cost is $40,381,248. That results in a deployment cost per commercial customer in the service area of $237,536. Clustering algorithms for the construction roll-out phasing across a 3-year period suggest 2.5km, 2.3km, and 3.6km of network pipe will be put into operation over year 1, year 2, and year 3, respectively. With the borehole array constructed in year 1, that correlates with a subsidy schedule of $13,565,229, $1,112,586, $1,474,683 for the corresponding years of construction.

Other commercial metrics include the simple payback period, levelized cost of heat, and the internal rate of return. The thermal energy network, in this conceptual design, pays back in 17 years. The internal rate of return is 5.76% and the levelized cost of heat is $0.158/kWh$_t$.

5. Discussion

Thermal energy networks are assemblages of district energy systems. The component parts of these networks can complement each other in a variety of ways. The design in this desktop demonstration uses a radial network pattern to maintain a 15ºC supply temperature from a heat-pump-equipped central energy plant connected to distributed heat pumps. These central-distributed hybrid networks offer the flexibility for expansion and the option to introduce thermal energy storage as a more impactful demand side management tool.

In other configurations of a thermal energy network, the topology may appear as a ring. Those instances can leverage more load sharing, where it is available. The heating dominance from the building energy modeling in Boulder, Colorado makes it challenging to balance a closed loop borehole array or provide load sharing. Hybridization of the sources and sinks is highly advantageous, and the demonstration area is conveniently situated near a creek. This and other sources, such as low flow groundwater doublets or data center waste heat, may condition the borehole array on a seasonal basis, providing a performance boost. Cities themselves could use the potential to attract desirable tenants, such as commercial operators who reject more heat over the year than they consume.

In the context of utility-scale heating and cooling network deployment, an operator having leverage over multiple sources and sinks will maximize their ability to conduct energy arbitrage. Such energy arbitrage can be optimized through time as the behavior of the closed loop borehole array varies. This behavior of the closed loop borehole array is the supply temperature variation across time. While the ILS and finite line methods of conduction-only modeling do provide designers with trends to expect at the decadal scale, operators will find a great deal of difference from these simulations in practice.

Some of the likely reasons to expect variation in the study area include the presence of Boulder Creek, and the accompanying alluvial sediments. These unconsolidated zones, and those lithologies influenced by them, will induce movement of the thermal plume that would otherwise accumulate during a given heating or cooling season. For this reason and others, all commercial systems should be equipped with the appropriate measurement, monitoring, and verification devices.

All the values in this desktop demonstration are fictitious. It is likely with better market survey and building energy modeling practice that more commercially viable scenarios may be found.

This preliminary design methodology would also benefit from a preceding site suitability analysis, for example.

With the completion of these initial plan iterations, the designer now has appropriate starting dimensions for their system. Field testing remains a requirement. These preliminary dimensions undergo even more rigorous modeling and simulation in the detailed design phase to validate the expected transient thermal performance of the borehole array when coupled to the thermal energy network.

6. Conclusion

Thermal energy networks have varying temperature regimes (Hirsch & Paepcke, 2022; Wirtz et al., 2022; Zeh et al., 2021). Those with higher geothermal and geoexchange uptake generally offer greater energy efficiency, resulting in lower electricity consumption. Ambient temperature networks have lower parasitic heat losses or gains than previous generations of district energy systems (Lund et al., 2014; Zeh et al., 2021). In some cases, this makes them a good commercial opportunity for gas and electric utility companies wishing to participate in the energy transition while reducing peak electricity consumption from a community's soon-to-be electrified heating and cooling demand.

This work demonstrates the steps necessary to conduct the initial design of a thermal energy network with an expandable radial topology, using a desktop study of a district in Boulder, Colorado. The preliminary design uses assumptions of ground thermophysical properties to size a borehole array. This borehole array size is then reduced in size with source hybridization and considerations for load diversification. A 1,000-borehole array meets the requirements for 150 commercial and multifamily structures across the service area. Using several iterations to dimension the network, the design is ready for more rigorous analysis. Preliminary techno-economics for the system suggest it has a 17-year simple payback with an internal rate of return of 5.76%.

While the parameters for the system design in this desktop demonstration are fictitious, this paper offers insights that are often not readily available to the would-be utility or municipal planner, entering the thermal energy network business for the first time. There are many ways to design, model, and simulate these systems. While there is no one-size-fits-all approach, the history of district energy operators dating back more than 100 years suggests that multi-scenario planning is a critical first step in designing a system that is modular, expandable, and long lasting.

ABSTRACT

Geothermal district heating (GDH) in North America has a history dating back to the 1800s. Although North American GDH systems have been around almost as long as the steam networks of New York, they have not enjoyed large scale commercial expansion. There are several reasons for this. Low enthalpy geothermal systems historically develop around surface manifestations. Early production from these surface manifestations is often a matter of trial and error. Few low enthalpy geothermal systems undergo rigorous exploration, geologic investigation, or wellfield planning prior to drilling. In many cases, this leads to unnecessary contamination of distribution lines in the GDH, decreases in equipment lifetimes, and overall declines in reservoir temperatures and pressures. Despite the lack of deliberate development procedures for most North American GDH systems, they tend to save communities millions of dollars over the lifetime of operation, decrease the carbon footprints of building space conditioning, and provide jobs in sustainable energy. This paper explores the direct uses of geothermal energy, including GDH, in the Town of Lakeview, Oregon, highlighting early exploration, recent development activity, and recommendations for the future. To other GDH system operators, or those considering development, the case of Lakeview can serve as a lesson, a tale of continuous improvement, and a success story.

1. Introduction

Geothermal resources have been at the heart of the Town of Lakeview since its founding in 1869. The town of 2,326 people sits in a Known Geothermal Resource Area (KGRA), with surface manifestations - hot springs - to the north and south of the downtown core. Commercial development of the geothermal resources began in 1923, with bathing or balneology as the primary application (Coury and Associates, Inc., 1980).

In recent decades, various geothermal exploration programs have taken place in Lakeview, leading to new developments and pilots ranging from greenhouse operations to small modular power

plants. Lakeview's community pool is fed by geothermal waters from a depth of 2300 feet and has been since 1938. The earliest GDH system (no longer operational) supplied 15 single family homes in the Goldmohr Terrace neighborhood. Magma Power began wildcat drilling for geothermal in 1960. The resulting well had an initial production temperature of 217ºF, which later fed greenhouse operations (Sifford, 2010). Between 1982 and 1983, Wood & Associates of California owned and operated modular Ormat Technologies Inc. (Ormat) and Solar Power System (now defunct) organic Rankine cycle (ORC) power plants in a canyon in the adjacent Warner Mountain Range, with a total stamped capacity of 2.1 MW_e (Wood & Ram, 1983).

Today, Lakeview is home to two of North America's 23 operating GDH systems (Lund & Toth, 2021; Robins et al., 2021; Thorsteinsson, 2008). These geothermal heating systems support agencies within the State of Oregon, the regional hospital campus, public schools, and emergency service facilities, among others. Both systems are foundational for the community, serving as critical infrastructure and a consistent draw for businesses throughout the region.

The production well feeding the northern GDH, serving Warner Creek Correctional Facility, began producing from a completion depth of 602 feet in December of 2004. Slotted liners, at a diameter of 10 inches, are in place from 181 – 601 feet. The well itself is capable of producing between 200 – 500 gallons per minute. From a line shaft pump house (Figure 1), the field gathering system arrives at a heat exchange substation, several hundred feet west, where a gauge read 192ºF in December 2023. An initial fluid temperature of 204ºF at the wellhead, has held steady since 2004. All fluids are reinjected.

Figure 1: Production wellhead for the northern GDH in Lakeview, December 2023.

The production well feeding the southern GDH, which serves the remainder of GDH customers across Lakeview, has a completion date of September 2013. The well, having a total depth of 900 feet and liners from 242 – 900 feet, was originally capable of producing 190 gallons per minute with a fluid temperature of 191ºF. During a site visit in December 2023, sustainable flow rates were as low as 80 gallons per minute with a production temperature of 158ºF. All fluids are reinjected.

Maintaining both GDH systems is important to Lakeview for several reasons. The customers subscribing to the heating service from the municipal utility collectively avoid fuel expenditures, saving in the hundreds of thousands of dollars each year. These savings allow more money to stay in the community, contributing to economic growth. Many of the customers are using the heat to support critical infrastructure, including emergency services, living quarters, and medical care departments. The importance of these critical services is emphasized due to the relative remoteness of Lakeview. If local emergency medical services became unavailable, residents in an emergency situation would be left with a choice between an unfeasibly long ground transport or an unfeasibly expensive air transport.

2. Lakeview Geothermal Resource Area Characterization

The Oregon Department of Geology and Mineral Industries (DOGAMI) maintains a well database and geothermal information layer in a web map service. Some of the geothermal data for Lakeview originates from geothermal gradient well surveys that took place in the late 1970s (Brown et al., 1980). These data sources, along with previous consulting engineer reports, served as the basis of desktop review for a more recent geothermal resource characterization in Lakeview, performed by Jacobs (Fry et al., 2024).

There are more than a dozen low enthalpy wells in Lakeview with fluid temperatures above 100ºF. Two predominate surface manifestations in Lakeview include Hunters Hot Springs to the north, and Barry Hot Springs to the south of the downtown district. Of those, the highest temperature wells are in, or west of, Hammersley Canyon, near Hunters Hot Springs. Both GDH production wells are in close proximity to the respective north and south surface manifestations (Figure 1).

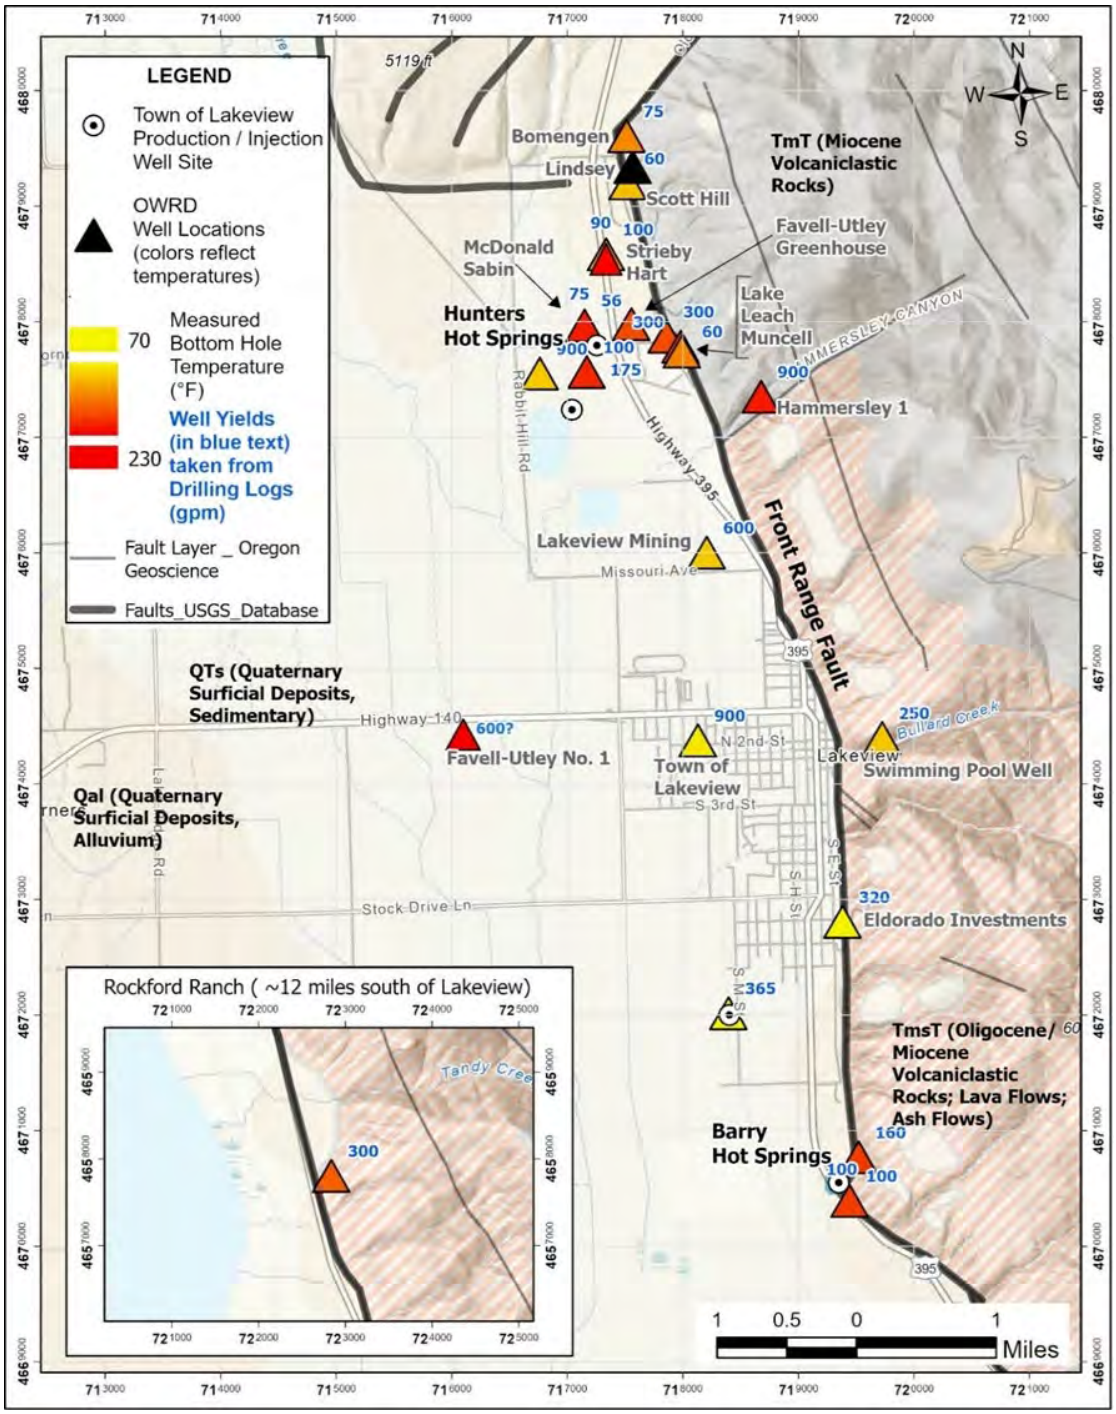

Figure 2: Plan map showing some of the geothermal wells from the Oregon Water Resources Department (OWRD), and other features from DOGAMI databases (Fry et al., 2024).

The surface manifestations coincide with other higher temperature wells and, although there is limited west to east and vertical spread in well and temperature data, this suggests the presence of two distinct upflow zones surrounding Hunters Hot Springs and Barry Hot Springs. These upflow zones occur along the western side of a north-south running front range fault, evident in a cross-

section interpolation from well logs (Figure 2). To the east of the front range fault is the Warner Mountain Range. To the west of the fault are the alluvial plains and the Town of Lakeview.

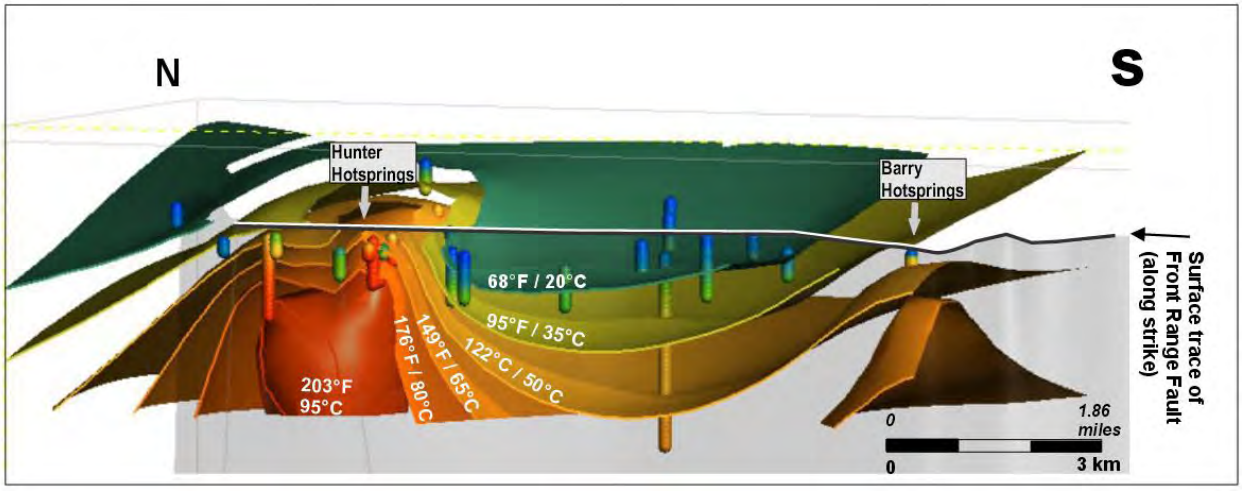

Figure 3: Cross section view of inferred interpolated temperature isotherms (Fry et al., 2024) from well gradient data (Brown et al., 1980).

The upflow zones of Lakeview's geothermal resource lie within a typical Basin and Range geological setting, with characteristic block faulting and deep sediment basin fill – in Goose Valley, a structural basin west of the Warner Range. The dominant influence on upflow and outflow is the front range fault, where lateral migration of hot fluids travels through permeable clastic horizons of the valley basin away from the fault. There is, therefore, interlayering of permeable and low permeability deposits in the plain, variably affecting the geothermal system beneath Lakeview (Figure 3).

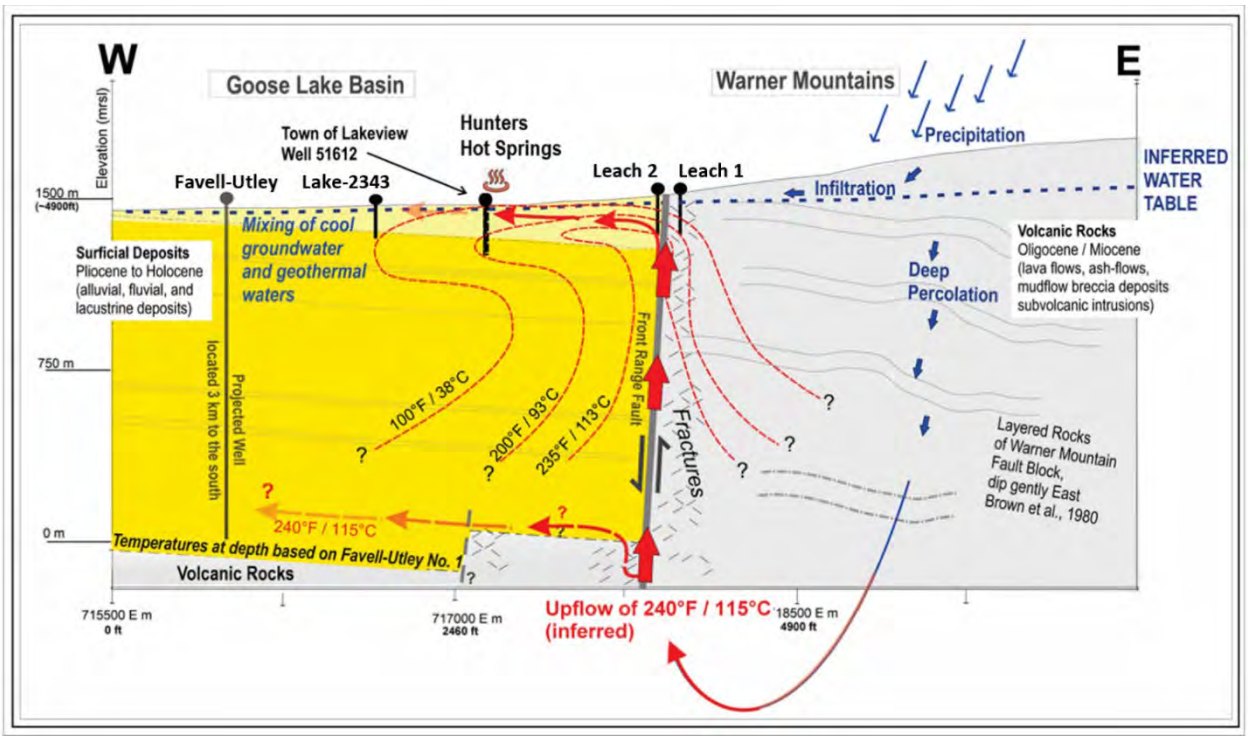

Figure 4: Idealized conceptual cross section of the geothermal area at Lakeview (Fry et al., 2024).

Poor data integrity in the DOGAMI database does not allow for adequate characterization of the geothermal resource in Lakeview. During investigation by Jacobs, it became evident that future iterations of exploration and study must include field surveys to update existing DOGAMI datasets. Some current data only shows well locations by the closest quarter section, with rare descriptions of proximate locations in available well logs and geoscientific reports.

3. Historic Design and Operation of Geothermal Facilities

The US Geological Survey (USGS) put Lakeview on the list of Known Geothermal Resource Areas in 1971, in accordance with the Geothermal Steam Act of 1970 (Godwin et al., 1971). Most of the projects for geothermal power and heating surface facilities in Lakeview included front end engineering design studies. These studies, however, only rarely attempt to characterize the subsurface system. In practice, since 1970 – and throughout the history of geothermal development in Lakeview – it appears most drilling continues to take place near the surface manifestations. Further, for the current GDH systems under ownership by Lakeview, the planning reports for the facilities do not match systems in place.

The mismatch between study and practice in the GDH systems is not exclusive to Lakeview. The 23 operating GDH systems in North America have largely been the result of drilling success by chance, near surface manifestations. When that is the approach taken for GDH implementation for municipal operators, the system sustainability becomes a risk.

During the recent investigation, Lakeview undertook a well remediation effort for the south GDH producer. In February 2024, Blue Spark Energy of Calgary performed hydraulic pulse stimulation to remove scale. As of this writing, the flow rates are back to 2014 volumes, but the temperatures remain the same.

Sustaining design temperatures for GDH systems is important for several reasons, one of which involves end-user equipment. End-user equipment may require a minimum entering fluid temperature to achieve a differential temperature high enough to meet space conditioning (heating) and domestic hot water (DHW) preparation needs. Where this differential temperature becomes insufficient, the end-users may need to supplement the GDH supply with peaker equipment – such as a boiler. This operation becomes costly where, following a production well temperature decline curve, additional fuel purchases become the norm.

Some ways to prevent temperature declines in GDH operations include rigorous hydrogeologic investigations, geothermal resource assessments, and system design that emphasizes energy efficiency. Rigorous hydrogeologic investigation can provide insights into regional groundwater flow directions, and seasonal regimes which might affect shallow production in outflows – like those found in Lakeview. Drilling into the fractured upflow zone – such is the case with the southern GDH production well in Lakeview – may be contraindicated by good geothermal resource assessment before drilling. Fractured upflow zones may result in successful production wells for a short period, but the fluid pathways may change over the life of the operations or new influences from cold feedzone flow may decrease system performance. Designing a GDH for energy efficiency means thinking holistically about the temperature regimes of the end-users, not simply designing to a given peak demand or seeking to develop around the hottest well. In the case of Lakeview, the south GDH has become susceptible to unplanned increases to the end-user demands, creating conditions which require more pumping from the geothermal resource. Accounting for these factors in design and ongoing operations for GDH systems may mitigate resource temperature declines.

In the northern GDH system, serving the Warner Creek Correctional Facility, a review of piping and instrumentation diagrams suggests that the original end-user design temperature for fluids entering the substation is 210ºF. As of February 2024, the entering fluid temperature at the Facility is 160ºF, with the production wellhead temperature at or near 210ºF. The difference between the design temperature and the current entering fluid temperature results in greater boiler cycling and, therefore, additional fuel expenditures. This is particularly costly in a place like Lakeview, where delivery of fuel is expensive, forcing unit rates for gas and fuel oil well above hub averages.

To date, no evidence has been found indicating delivery temperatures from the heat exchange substation (Figure 4) were ever intended to reach 210ºF. There are several reasons why this design flaw might occur in GDH development, and they may serve as lessons for future engineering practice. In discussions with facility operating engineers at Warner Creek Correctional Facility and Lakeview, two or potentially three different engineering firms were designing the whole geothermal well, heat exchange substation, transportation pipelines, and in-facility hot water distribution system at the same time. Heat losses through the system were likely underestimated. Design temperatures for each section of the system, whether it was production, heat exchange, distribution, or in-facility portions, were not communicated correctly.

Figure 5: Heat exchange substation for the northern GDH, taken December 2023, serving the Warner Creek Correctional Facility.

Communication between geothermal system engineering and development firms serving multiple clients across the same GDH network is paramount. The Warner Creek Correctional Facility design flaw is not a problem of GDH operations, rather it is an apparent problem of communication during the design stages. Some ways in which multi-stakeholder GDH developments may unfold with more design risk mitigation includes the use of different contract vehicles, employment of an owner's engineer, or provision of single source engineering design. In GDH, and district heating more broadly, multiple stakeholders may contribute funding to the design of the initial operations. This may mean that multiple procurement systems overlap each other from multiple institutions. To mitigate risk, a standalone operations, development, and design agreement can serve as an important delivery vehicle. Owner's engineers may serve as a single source of truth to review multiple engineering design firm works across the different sections of the GDH system - wellfield, heat exchange substations, transportation pipelines, and in-facility connections, among others. Employing a single design firm for all of the different sections of the GDH system will drastically reduce miscommunication risk. Very few firms, however, have experience in the exploration of geothermal resources, well targeting, wellfield design, surface facilities design, and in-facility mechanical systems, to offer single source options. Some combination of the contract vehicles, owner's engineering services, and design team procurement strategies are likely necessary to implement and efficient GDH while mitigating design risk.

Similar strategies are applicable to the relatively small power generation capacity that may be possible from Lakeview's geothermal resources. In historic review, it appears that the Ormat modular power generation equipment in operation at Lakeview during the early 1980's was

susceptible to very large parasitic loads, waning demand for higher cost electricity sources following the oil crises of the 1970s, and short-term contract vehicles (Sifford, 2010; Wood & Ram, 1983). Modern power generation equipment may offer a more economical model to develop the resource for electricity production. A holistic approach to geothermal systems development, therefore, remains the necessary norm for small operators at the peripheries of the grid – such is the case with Lakeview.

4. Development Opportunities

Lakeview is a place rich in natural resources, while also located to the greater California market. The premiums for sustainable materials and low- or no-emission power and fuels in the California market attract many manufacturers to Lakeview.

Lakeview has a long history in the wood products industry, including milling services, engineered wood, cabinetry, and door manufacturing, among others. Mining operations are ongoing in the nearby Warner Mountain Range. Greenhousing and agriculture are staple industries for the community. Recently, biofuels and low-emission cement production facilities have begun construction in Lakeview. These facilities alone will require more than 30MWe, preferably no-emissions electricity. Limitations in the interconnection of Lakeview to distant electricity generation plants provides a new opportunity for geothermal heat and power development in or around the town. For those developers willing to invest in the proper exploration, design, and construction of geothermal heat and power facilities, adjacent industry presents a primary business development opportunity for heat and power purchase agreements.

5. Recommendations and Findings

In a summary strategy report for Lakeview, Jacobs provides a detailed discussion of recommendations for policymakers and city engineering officials (Fry et al., 2024). In this section we offer some recommendations and findings to private geothermal resource developers and would-be low-enthalpy geothermal system engineers or geoscientists.

- At the outset of a geothermal development project, implement a communications plan for all design teams that is commensurate with experience, past performance, and operational expectations.
- Low-enthalpy system development may not be as attractive as higher margin power systems, but it nonetheless may serve critical infrastructure.
- When developing low-enthalpy geothermal systems, a subsurface sustainability study is just as important at the outset of a project as any medium- or high-enthalpy venture.
- Contract vehicles and rate base agreements are an important component of long-term sustainability of the geothermal resource for GDH and the overall performance of mechanical systems.

6. Conclusion

The Town of Lakeview is a place with abundant natural resources, one of which being geothermal. Geothermal development has been a foundation of the community, dating back to the earliest native American presence in the region. Today, Lakeview is home to 2 of the continent's 23 GDH systems (Lund & Toth, 2021), saving end-users tens of thousands of dollars every year. As new

industries arrive in Lakeview, greater and more sustainable uses of the geothermal resources may reduce combustion fuel consumption, save businesses and homeowners money, and contribute to greater economic growth for the community.

Developing these low-enthalpy geothermal resources for Lakeview in a sustainable manner will require more rigorous exploration of the subsurface, thoughtful design of the surface facilities, and communications. Low-enthalpy geothermal development, including the GDH systems in Lakeview, can and do serve critical infrastructure. This critical infrastructure is vital for life, economy, and community sustainment. These multiple stakeholders across a community like Lakeview are often also the financiers of such systems, and designers must support their needs by clearly communicating what is and is not possible to know at the outset of a geothermal engineering program. Engineering design of low-enthalpy geothermal resources is, therefore, a serious task requiring thoughtful communications plans to mitigate design flaws. A firm supporting these community geothermal system developments should also describe to the stakeholder group the role of contract vehicles and base rate agreements which mitigate unplanned changes to demand and, therefore, risks to geothermal resource and mechanical systems' sustainability.

Acknowledgement

The authors wish to thank the entire Town of Lakeview for embracing geothermal as a viable resource for improving their community. We would like to thank the executive, administrative, and engineering staff of the Town of Lakeview for providing ongoing data updates and an openminded nature during development strategy discussions. We would also like to acknowledge Shiela Strubel – Community and Economic Development – and Scott Langum – Special Projects Manager – for their tireless commitment to understanding the geothermal systems in place and expansion potential.

Advancing District Energy Geoexchange Solutions in Single Family Home and Mixed-Use Communities: Strategies and Real-World Insights

Carson Gemmill, Cameron Leitch, Neeraj Raghuram, and King Tung

Enwave Energy Corporation

Keywords

District Energy, Geoexchange, Ambient Loop, Thermal Energy Network (TEN), Thermal Networks, Geothermal Heat Pumps, Hybrid Geoexchange Systems, 4-Pipe Systems, Ground Source

ABSTRACT

District energy geoexchange systems are emerging as a promising solution for efficient, low-carbon heating and cooling in communities. This paper explores the implementation strategies and real-world applications of these systems, focusing on 4th and 5th generation district energy (DE) configurations. We present a comprehensive comparison of these two generations, highlighting their respective benefits and drawbacks in various contexts.

Two case studies are examined in detail: the Etobicoke Civic Centre Precinct, utilizing a 4th generation DE geoexchange system, and the Springwater Single Family Home community, using a 5th generation system. These cases illustrate the practical considerations and decision-making processes involved in selecting and implementing district energy geoexchange solutions.

Our analysis reveals that the choice between 4th and 5th generation systems depends on factors such as load aggregation benefits, operational complexity, space constraints, and end-user preferences. The 4th generation systems excel in scenarios where centralizing thermal energy generation offers significant advantages, while 5th generation systems prove beneficial in distributed, smaller-scale applications.

This research contributes to the growing interest in sustainable community energy systems and provides valuable insights for planners, developers, and policymakers considering district energy geoexchange solutions.

1. Introduction

Buildings account for 30% of global final energy consumption and 26% of global energy-related emissions(Delmastro & Chen, 2023). Electric heat pumps have become an increasingly effective way for buildings to reduce energy consumption and emissions due to operating, equipment, and installation costs becoming more competitive in certain markets, as well as their high efficiencies relative to other forms of heating production (Bolin, et al., 2022). When applied in a jurisdiction with a low carbon grid (or when leveraging renewable power) this decarbonization benefit can be further enhanced to achieve near zero emissions.

Geothermal heat pumps (or geoexchange systems as referred to in this paper) are regarded as one of the most efficient means of providing heating and cooling energy to buildings (U.S. Energy Information Administration (EIA), 2022). This is due to the relatively stable temperature of the ground used as a heat source and sink driving superior system Coefficients of Performance (COPs) compared to other heating and cooling technologies.

The application of geoexchange has been common for single buildings and is now becoming more popular for communities (Wiltshire, 2015). District energy (DE) is the centralizing of thermal energy production and shared distribution of this thermal energy through a network of buried piping. DE systems have been in use across North America for over a century but have typically been limited to college campuses or central business districts (Fulton & Thomas, 2023). In Europe, their adoption is more widespread. According to a report published in 2021 by the European Union (EU), 12% of heat for space heating and hot water in the EU was supplied through district energy systems (Kranzl, et al., 2022).

The appeal of DE systems is growing, and the role they have to play in the global energy transition has been building momentum. A recent study in Europe singles out district heating and cooling as one of Europe's most efficient measures to reduce fossil fuel imports over the next decade (Mathiesen BV, 2023). The United Nations refers to DE as "a secret weapon for climate action and human health" and DE systems are recognized for their ability to assist in connecting heat pumps to renewable energy sources using thermal grids (UN Environment Programme, 2019). Consistent with this sentiment, geoexchange systems when applied at the DE scale offer a number of benefits to the communities they serve. Recently, the term Thermal Energy Network (TEN) has emerged to describe the next generation of district energy systems that focus on the use of low-carbon energy sources such as geo-exchange (The Building Decarbonization Coalition (BDC), 2024).

2. District Energy Geoexchange Systems Overview

This paper will focus on implementing district energy geoexchange systems in 4th generation and 5th generation DE systems, and the benefits and drawbacks to be considered when evaluating when system to implement. Refer to Figure 1 for an overview of the major development stages in the evolution of district energy systems, including the 4th and 5th generations.

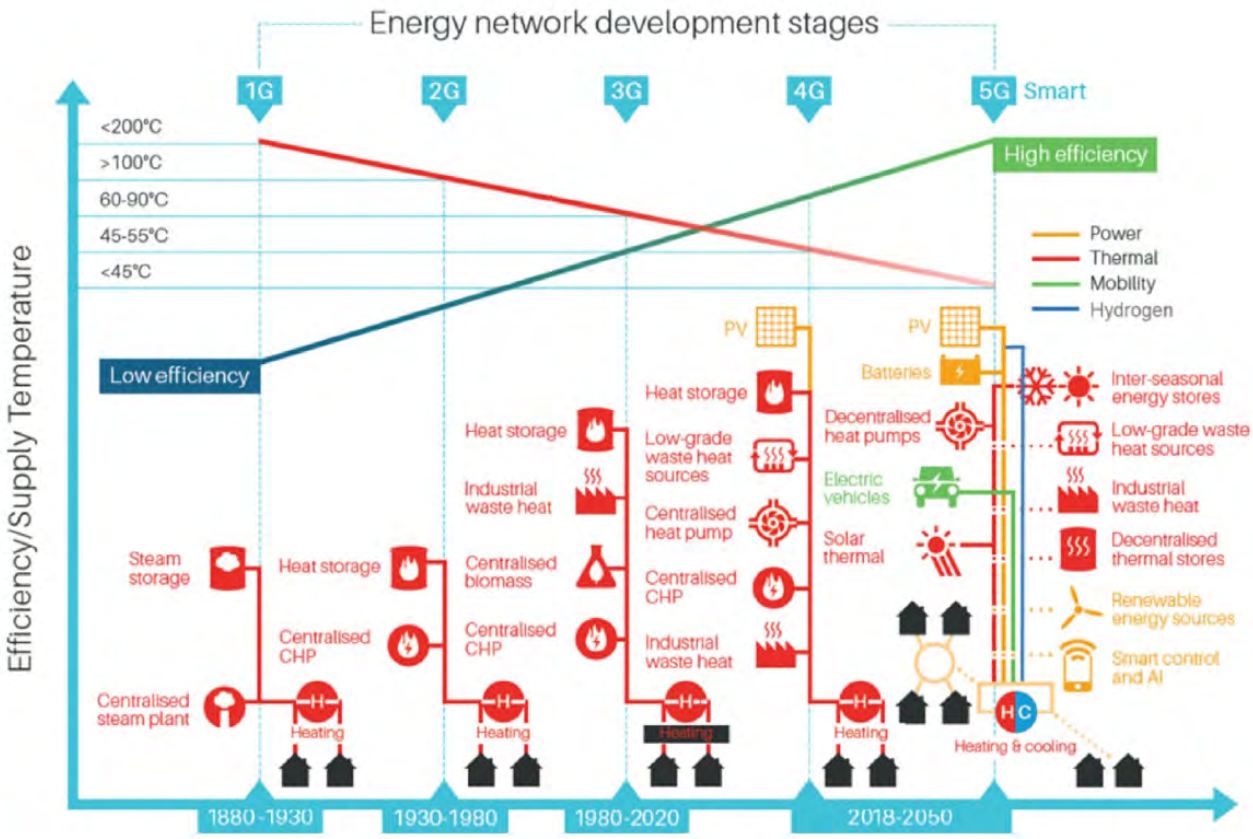

Figure 1: Energy network development stages including 5G concept (Revesz, et al., 2020).

2.1. 4th Generation DE Geoexchange System – 4-Pipe Systems

A 4th Generation DE system, also known as the "modern 4-pipe system", is characterized by low temperature hot water distribution (ranging from 30 – 70ºC) that enables the use of centralized plants featuring heat pumps, as well as other renewable or waste heat resources (Lund H, 2014). These systems deliver hot water and chilled water (4 pipes) at temperatures adequate to provide space heating, space cooling, and domestic hot water, often via a local building heat exchanger system. When integrating geoexchange into a 4th Generation DE system, supplemental heating and cooling sources (such as dry coolers, cooling towers, or supplemental boilers) are usually implemented to improve overall system economics and these systems are often referred to as hybrid geoexchange systems (Gudmundsson, et al., 2022).

2.2. 5th Generation DE Geoexchange System – Ambient Loop Systems

A 5th Generation DE system, also known as an Ambient Loop system, is characterized by maintaining temperature in the loop at near ambient conditions (below 45ºC) to maximize the ability to share energy amongst the network and to maximize the ability to integrate waste heat sources (Revesz, et al., 2020). These systems deliver thermal energy via supply and return pipes (2 pipes) and require the use of distributed heat pumps to "upgrade" the thermal energy from the Ambient Loop to be used for heating and cooling application at each thermal end-user.

Geoexchange systems integrate well with these types of systems as they provide the heat source (or sink) necessary to maintain the Ambient Loop temperatures in the necessary range.

3. Comparing 4th Generation & 5th Generation Systems

The main distinction between 4th and 5th Generation system has to do with where useful thermal energy is generated. In 4th generation systems, this is done at central plants; in 5th generation systems, this is done at the end-user site (Gudmundsson & Thorsen, 2021).

While 5th Generation DE Systems are regarded as having the potential to be the most energy efficient system given their ability to share energy between end-users and to leverage waste heat sources, this may not be the case in every application (Gudmundsson & Thorsen, 2021; Revesz, et al., 2020). Furthermore, 4th Generation systems offer other qualitative benefits that may be desirable to the end user, and therefore in certain applications may be deemed more attractive. Table 1 outlines these key considerations and the potential benefits and drawbacks to be considered.

Table 1: Comparing the Benefits and Drawbacks of 4th and 5th Generation DE Geoexchange Systems

	4th Generation DE Geoexchange System	5th Generation DE Geoexchange System
Generation		
Geoexchange Field		
Benefit		- Allows for simpler integration of geoexchange systems distributed throughout the network (given heat pumps are located at the end-user site)
Drawback	- Typically requires geoexchange to be implemented into the central plant(s), requiring distributed fields to be piped back to this central distribution	
Central Heat Pump Plant		
Benefit	- Aggregating loads into central heat pump plants can allow for the greatest value add in employing operational optimization strategies, driving greater system COPs - Depending on the jurisdiction, central heat pumps can allow for leveraging time-of-use rate or demand management structures for greater economic value	N/A

	4th Generation DE Geoexchange System	5th Generation DE Geoexchange System
	- Diversity of end-user load profiles can permit construction of a smaller overall central plant capacity relative to the sum of the end-user peak demands that are required by a 5th generation system.	
Drawback	- Requires significant space to site a central plant	N/A
Supplemental Systems		
Benefit	- Central plants allow for the greatest value add hybridizing the geoexchange field with supplemental systems given their ability to optimize both installed geo capacity and delivery temperatures	
Drawback		- Challenging to integrate and add value given useful thermal energy production occurs at the customer site

Distribution

Piping System	**4-Pipe Distribution:**	**2 Pipe (or Single Pipe) Distribution:**
Benefit	- Relatively simple and predictable system hydraulics	- Reduced network piping and capital costs - Lower system distribution losses
Drawback	- Increased network piping and capital costs - higher system distribution losses	- Can result in more complicated system hydraulics - Temperature control is not centralized which can add complexity to manage - Smaller system temperature differentials drive significantly larger pipe sizes

	4th Generation DE Geoexchange System	5th Generation DE Geoexchange System
End-Use		
Thermal Exchange	**Energy Transfer Station:**	**Distributed On-Site Heat Pumps:**
Benefit	- End-user benefits from simple, passive on-site heat exchangers to access the thermal energy (highest value thermal product delivered) - Requires no further thermal "upgrade" to deliver heating and cooling energy - Least energy intensive for the end-user on-site - Smallest space requirement for the end-user - Low and infrequent maintenance requirements	- Ability to design the heat pumps to meet the specific temperature needs of each end-user
Drawback		- End-user requires an on-site heat pump to produce useful thermal energy (lowest value thermal product delivered) - Adds operational complexity and maintenance requirements for the end-user - Added space requirement for the end-user

4. Case Studies

To date, Enwave has developed two major geoexchange based district energy systems – each of which employs a different system design approach. This section will provide an overview of each of these projects and explain the rationale behind the design approach that was taken in each case. The case studies include the Etobicoke Civic Centre Precinct and the Springwater Single Family Home Community.

5. Etobicoke Civic Centre Precinct – 4th Generation DE Geoexchange System

5.1.Development Overview

The Etobicoke Civic Centre (ECC) Precinct is a mixed-use redevelopment located in Toronto, Canada. The redevelopment consists of 6 development blocks, with a total floor area approaching 300,000 m^2. The building use types across the precinct include commercial office, community space, retail, and significant residential development. Refer to Figure 2 for a conceptual plan of the redevelopment area.

The ECC Precinct is being master planned by the City of Toronto, and therefore is adhering to ambitious building standards with a heavy focus on low carbon energy systems.

Enwave worked in partnership with the City of Toronto under a Joint Development Agreement (JDA) signed in 2018 to develop a new low carbon district energy system to be built alongside the new ECC development. The precinct is recognized by the City of Toronto as the City's first Net Zero community.

Figure 2: ECC Precinct Conceptual Plan (Mirabelli, 2021)

5.2. Technical Solution Overview

A 4th Generation DE Geoexchange System was selected as the solution of choice to serve the ECC precinct. The ECC District Energy System consists of a central district energy (DE) plant, a connected geoexchange system, distribution piping system (DPS) and energy transfer stations

(ETS) at each end-user site. Refer to Figure 3 for a conceptual diagram of the DE system. Table 2 summarizes the major equipment components and capacities.

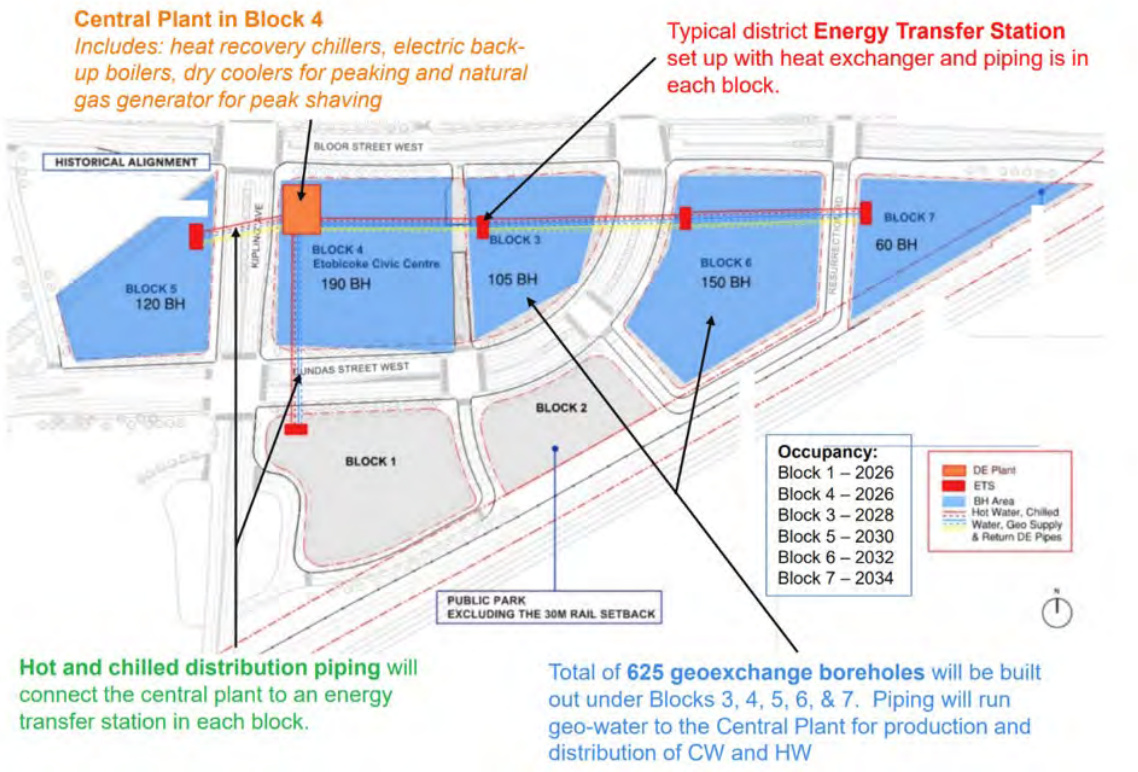

Figure 3: ECC Precinct District Energy Conceptual Plan.

Table 2: ECC Precinct DE System – Component Capacity Summary

Component	**Details**
Geoexchange Boreholes	625 at 244 m
Heat Pump Capacity	11.25 MW(th)
Supplemental Heating Capacity Installed	1.90 MW(th) – Electric Boiler
Supplemental Cooling Capacity Installed	1.40 MW(th) – Dry Cooler
% of Annual Heating Energy Source from Geoexchange	100%
% of Annual Cooling Energy Source from Geoexchange	75%

5.2.0.Generation - Geoexchange & Supplemental Systems

The Central DE plant, located within the ECC “Block 4” building, includes heat pumps integrated with a geoexchange system that will serve the base heating, domestic hot water, and cooling loads and be supplemented with electric boilers and dry coolers for peak heating and cooling loads,

respectively. The system will also consist of natural gas generators to facilitate electrical peak load shedding and enhance system resiliency.

The boreholes of the geoexchange system are located underneath the footprints of each of the buildings. The geoexchange bore field will be phased to meet the demands of the district and installed in alignment with development construction timelines. To date, two buildings in the community have been designed and are under construction, totaling over 100,000 m^2 of floor area. Enwave has built the first phase of the geoexchange system totaling 190 boreholes. At full build-out, the project is expected to require a total of 625 boreholes.

5.2.1.Distribution – 4-Pipe System (5th Generation DE)

The project consists of a 4-pipe DPS comprised of hot water and chilled water supply and return piping. The distribution piping delivers thermal energy to the end-users via an ETS in each building.

The system also has an additional pair of distribution pipes, geoexchange supply and return lines, to connect the geoexchange borefields installed below each building throughout the precinct. This brings the total distribution to 6 pipes – hot water supply/ return, chilled water supply/ return, and geoexchange supply/ return.

5.2.2.End-Use – Energy Transfer Station

Each end-user site interfaces with the DE system through an ETS. The ETS consists of heat exchangers for space heating, space cooling and domestic hot water (DHW), metering, valves, controls and other ancillaries. Each building's space heating and cooling will be served by fan coil systems with larger units serving the corridors and common spaces. The building thermal loads will be connected by a four-pipe system that connects to the ETS, which receives/rejects heat to the central DE plant via the DPS.

5.3. Rationale for a 4th Generation DE System

A 4th Generation DE Geoexchange System was selected for the ECC Precinct for the following reasons:

- The partnership with the City of Toronto motivated a willing host for the central plant. Centralizing thermal energy production at end-use temperatures allowed for thermal energy to be delivered via customer ETSs, driving significant space savings and operational simplicity for the end-user.

- The central plant allowed for the ability to take full advantage of the diversity in loads in selecting equipment sizes, resulting in a ~20% reduction in installed cooling capacity and a ~10% reduction in installed heating capacity based on design loads. This benefit grows further when considering the total heat pump capacity that would be required for the alternative 5th generation solution with in-suite heat pumps installed at each site.

- The central plant facilitated the ability to integrate supplemental capacity (such as dry coolers and electric boilers) to centrally manage any geoexchange load imbalance over the life of the system. This allowed for the geoexchange system to be "right sized" to optimize

energy and emission performance with operating and capital costs, as the supplemental equipment was designed to address the system redundancy needs.

- Economies of scale were realized through purchasing fewer, large capacity units.
- Centralized operations offered increased operational flexibility to optimize system efficiency.
- Reduced operations and maintenance costs by procuring contracts at scale.
- Central plant operation allowed for the ability to integrate generators for electrical load shed. Through this, an operational strategy was developed to participate in demand response programs through the electrical system operator which drove significant operating cost savings for the plant.
- Provides enhanced redundancy to the community as back-up power for the thermal energy system can be provided centrally.

6. Springwater Single Family Home Community – 5th Generation DE Geoexchange System

6.1. Development Overview

The Springwater is a single-family home community located in Markham, Canada. The development consists of 312 single family homes, including townhomes and detached homes and ranging in size from 170 m^2 to 290 m^2. Refer to Figure 4 for a conceptual plan of the Springwater development.

The Springwater geoexchange system was developed collaboratively between Mattamy homes Canada, Enwave Energy Corporation, and the City of Markham. For the City of Markham, the project offered an opportunity to demonstrate that near net-zero emission heating and cooling for single family homes was possible at no additional cost compared with the business-as-usual HVAC.

6.2. Technical Solution Overview

A 5th Generation DE Geoexchange System was selected to serve the Springwater community. The novel system consists of a single-pipe, low-temperature ambient system with distributed vertical geoexchange boreholes and ground-source heat pumps (referred to as in-suite heat pumps) installed at each end-user site, thereby eliminating the need for a central plant. The result is a system that achieves over a 90% reduction in greenhouse gas emissions compared to traditional in-home heating and cooling systems. Refer to Table 3 for a summary of the system component capacity, and Figure 5 for an overview of the system components.

Figure 4: Springwater Community Concept Plan. (CondoNow, 2024)

Table 3: Springwater DE System – Component Capacity Summary

Component	**Details**
Geoexchange Boreholes	144 at 244 m
Heat Pump Capacity	312 in-suite heat pumps ranging from 5kW to 10kW (Estimated total of 2.3MWth)
Supplemental Heating Capacity Installed	In-suite heat pumps include 100% resistance back up
Supplemental Cooling Capacity Installed	N/A
% of Annual Heating Energy Source from Geoexchange	100%
% of Annual Cooling Energy Source from Geoexchange	100%

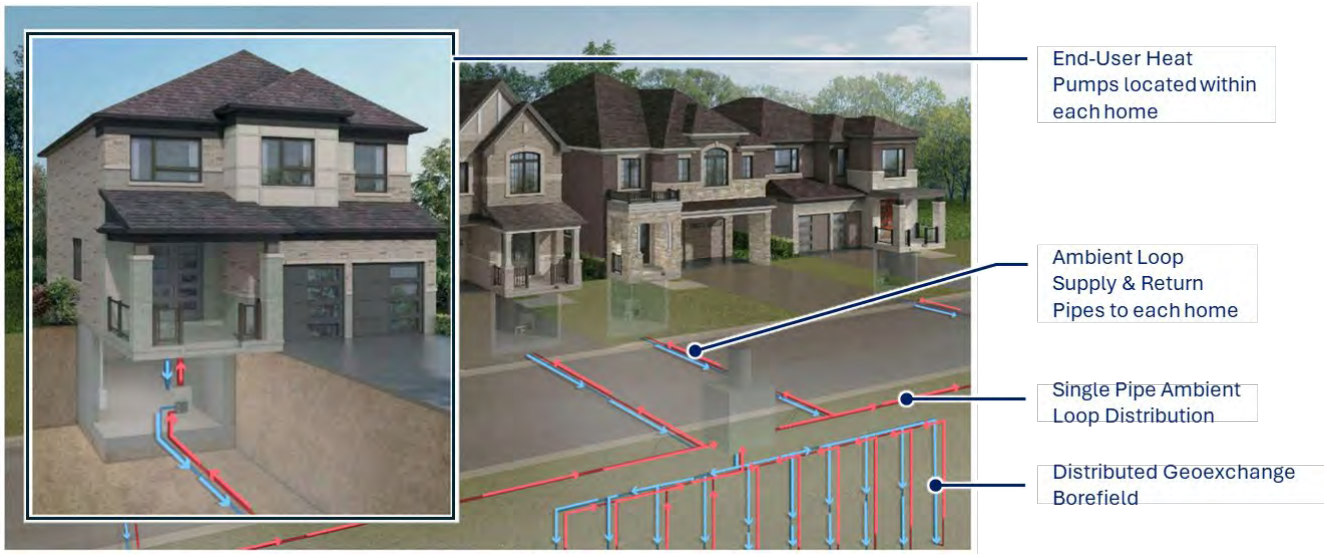

Figure 5: Springwater Geoexchange DE System – Components Diagram

6.2.1. Generation - Geoexchange overview

Heating and cooling energy for the Springwater community is provided exclusively from the distributed geoexchange system. Geoexchange boreholes are installed throughout the public right-of-way, in arrays of 12 boreholes drilled to a depth of 259 m each. Each borehole array collects in a buried vault that houses pumps for circulation within each array. In total, there are 12 borehole arrays and pump vaults, making up a total of 144 boreholes throughout the system. Each borehole array injects/ rejects thermal energy at strategic locations throughout the ambient loop distribution in order to maintain sufficient temperature throughout the loop.

6.2.2.Distribution – Single Pipe Ambient Loop System (5th Generation DE)

The single pipe ambient system runs in a loop throughout the community, spanning over 2.9 km. There are four distribution pumping vaults distributed throughout the system that maintain sufficient flow and pressure throughout. The loop temperatures vary annually between -3 and 32 ºC depending on the time of year. Refer to Figure 6 for the Ambient Loop Distribution diagram.

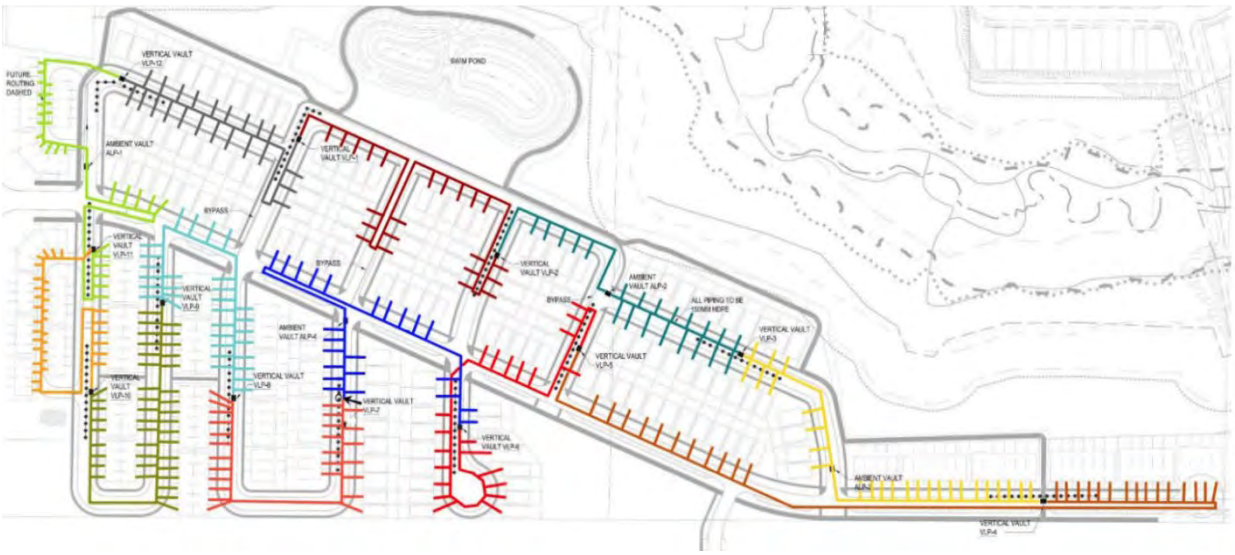

Figure 6: Springwater Geoexchange DE System – Ambient Loop Distribution Diagram

6.2.3.End-Use – Water-to-Air Heat Pumps

Water-to-Air heat pumps located within each home provide space heating and cooling throughout the year. Each home has its own circulation pump to pull in water from the distribution loop as required. This gives each end-user full flexibility to control their own setpoint and operate the system in heating and cooling mode as they see fit.

6.3. Rationale for a 5th Generation DE System

A 5th Generation DE Geoexchange System was selected for the Springwater Community for the following reasons:

- The distributed heat pump system allowed for the elimination of a central plant. The pumping system was installed in buried vaults located in the public right-of-way. This strategy ensured all system infrastructure was installed below grade, allowing the developer to maximize sellable land.

- Partnership with the City of Markham facilitated the coordination of the DE system with other utilities in the public write-of-way. Given the city's support, all system infrastructure was able to be located in the public right-of-way, including distribution, the geoexchange bore field, and pumping vaults. Once again, this maximized the developer value proposition to ensure no sellable land was impacted by the DE system development.

- Geoexchange was used as the only source/ sink of thermal energy for space heating and cooling. This maximized the value associated with an ambient loop system – removing all noisy and visible equipment above grade.

- Given the small size of each end-user served, space savings associated with centralizing thermal energy generation would be immaterial if any. This further supported the case for an ambient loop system.

- The development electrical service was planned at 208V, typical of a residential community. This added further cost and space requirements to aggregating loads into a central plant, once again supporting the case for a distributed ambient loop type system.

- The developer did not want any geoexchange infrastructure located within the private parcels slated for sale. This forced all geoexchange borefield arrays to be located within the public right-of-way. Given this constraint, it naturally led to a distributed system with multiple geoexchange injection points through the ambient loop system compared to "home running" long geoexchange distribution piping back to a central plant for thermal distribution.

- The single-pipe ambient loop system facilitated through the distributed geoexchange concept drove capital cost savings compared to a 4-pipe system required in a 4th generation DE system.

- Given the smaller scale of the system, significant operating and capital cost benefits would not be realized that would justify centralizing thermal energy production.

7. Conclusion

This paper aims to bring to light the practical considerations when considering the use of 4th generation and 5th generation DE systems integrating geoexchange. Much like most of the conversation the exists around the energy transition today, there is no one-size-fits-all approach. Each project context needs to be reviewed and the benefits and drawbacks of each type of system considered to determine the highest value approach. Further, there are more things to consider beyond just the quantifiable techno-economics of each system, but also the often hard to quantify, qualitative aspects of each system such as their impact on space, operational complexity, and resiliency.

In summary, the factors favoring the installation of a 4th Generation DE Geoexchange System over a 5th Generation system are driven primary by the value proposition associated with centralizing thermal energy generation. In our experience, 4th Generation systems win out when realizing high value in aggregating loads to reduce overall system capacity size, achieving scale where operating strategies can be implemented that justify the added cost and complexity, and where providing significant end-user benefits such as space savings and operational simplicity are perceived as high value.

Acknowledgement

The case studies presented in this paper are based on the experience and insights gained by the Enwave team in working with our many developer, municipal, consultant, and contractor partners who supported us in the development of these next generation DE systems. A big thank you to the municipalities whose low carbon ambitions have been the catalyst for the development of these systems, and to the developers who are taking action and leading the way by adopting these systems into the communities they build.

Rangárveita - Small District Heating in the South Part of Iceland - Future Master Plan

Heimir Hjartarson, Egill Maron Thorbergsson and Thráinn Fridriksson

Veitur

Keywords

Heating, Geothermal, Rangarveita, Master Plan, Roadmap, Veitur

ABSTRACT

Rangárveita District Heating Utility (RDHU) harnesses geothermal energy from four main production wells—LL-04 and LL-06 in Laugaland, boasting temperatures around 96°C, alongside KH-36 and KH-37 in Kaldárholt at approximately 67°C. Additionally, GN-01 at Laugaland serves both as a reinjection well and occasionally as a producer. This infrastructure supports heating for homes in Ásahreppur, Hella, Hvolsvöllur, Gunnarsholt, and areas along its 35 km main supply pipeline, delivering about 3 million cubic meters of hot water annually. With demand growing by roughly 1.3% each year the RDHU has a challenge to support regional heating needs.

As communities expand, Veitur is tasked with ensuring the scalability of its district heating systems to meet increasing demands. Accurate forecasting and strategic planning for resource expansion and pipeline enhancements are crucial. To this end, Veitur has launched "Resource for the Future" projects for each of its district heating systems, aiming to assess and plan for future needs effectively.

Investment decisions, particularly those concerning geothermal exploration and capacity expansion, are based on comprehensive analyses of potential hot water sources and their integration into the existing network. These long-term plans, spanning over 50 years, are informed by detailed evaluations, including AHP (Analytic Hierarchy Process) analysis. This process helps pinpoint optimal geothermal resource development opportunities and their alignment with current infrastructure, thereby guiding strategic investments.

The project presents a systematic exploration of geothermal resource development options for Rangárveita, assessed through AHP analysis to ensure their compatibility with existing transport pipelines. The findings serve as a crucial foundation for Veitur's investment strategies, ensuring that the utility's capacity to meet future heating demands remains robust and sustainable.

1. Introduction

Rangárveita District Heating Utility (RDHU) is owned by Veitur ohf., a subsidiary of Reykjavík Energy. The RDHU was established by the municipalities in Rangárvallasysla, South Iceland, in 1981 to serve, mainly the small towns of Hella and Hvolsvöllur and also the rural areas in the vicinity of the main pipeline. Reykjavík Energy acquired the RDHU in 2005 and Veitur has been responsible for the operation of the RDHU since 2014.

Initially, the RDHU was run on a single production well at Laugaland í Holtum, located about 10 km NW of Hella and 22 km NW of Hvolsvöllur. In 2000 a second geothermal resource, at Kaldárholt, was taken into production and connected to the RDHU via a 12 km long pipeline. After the addition of the Kaldárholt field a number of users in the rural areas in Rangárþing ytra and Ásahreppur were connected. As of today, there are two production wells at each geothermal area, LL-04 and LL-06 in Laugaland and KH-36 and KH-37 in Kaldárholt. Overview of the RDHU is shown in Figure 1 (Kristjánsson and Tómasdóttir 2024).

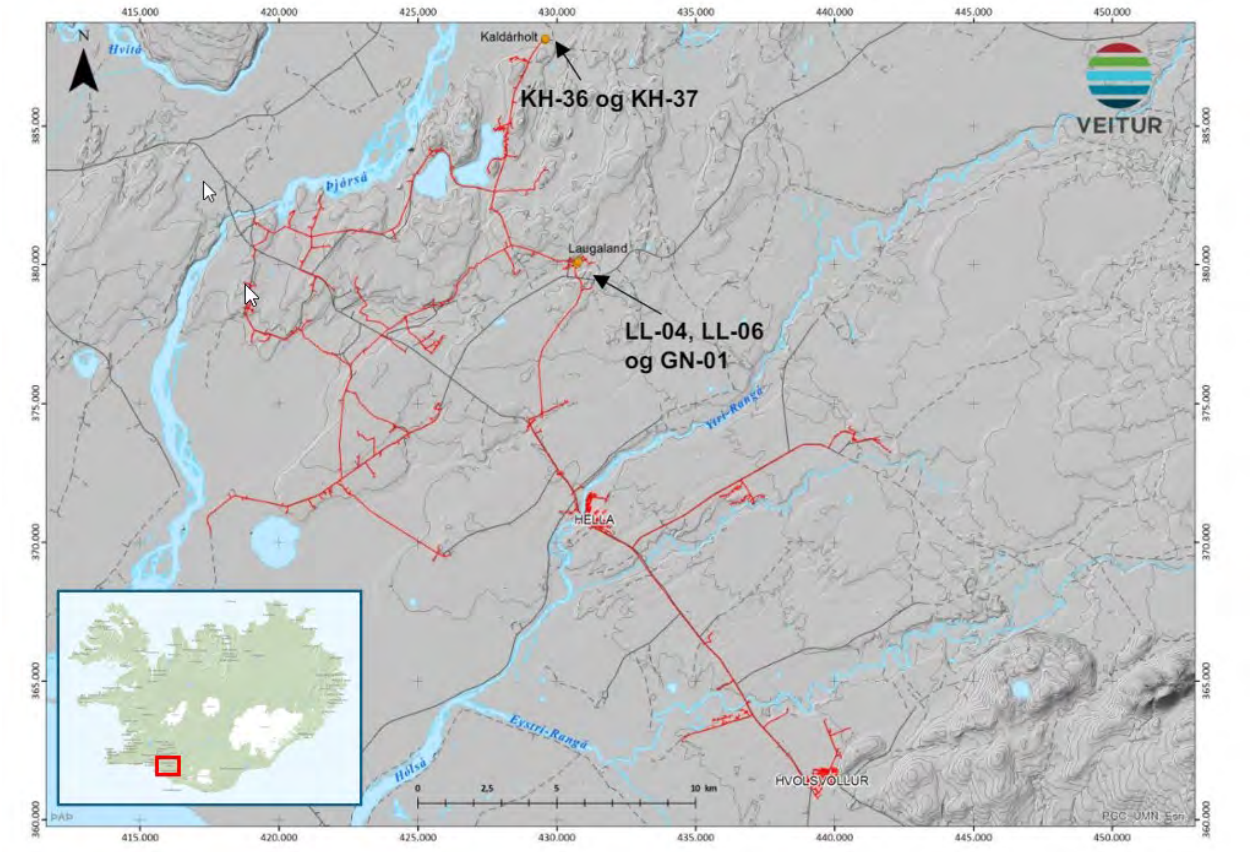

Figure 1: Overview of RDHU network. Red lines are district heating pipes. Grey lines are roads. Wells KH-36 and KH-37 in Kaldárholt are shown as wells LL-04, LL-06 and GN-01 in Laugaland

2. Current status and challenges

One of the main challenges of the RDHU are the relatively long distances between the production areas and the load centers. This was already a challenge in the beginning when production started at Laugaland. The length of the main and secondary transport pipelines further increased when the

Kaldárholt field was connected. Long pipelines pose a challenge for district heating utilities where demand is growing because if the pipes are too large heat loss will be a problem and if the pipes are too small, they will need to be scaled up frequently as demand grows, which is very costly.

To further complicate things for the RDHU, neither of the two geothermal resources used for the system are optimal production fields. While the Laugaland field is hot, 95 to 97°C, the productivity of the field is limited resulting in massive drawdown in response to production and long-term water level drop if annual production exceeds some 15 l/s on average. The Kaldárholt field, on the other hand, is very productive with very little drawdown in the reservoir at annual production levels in excess of 80 l/s but there the problem is relatively low temperature of only ~65°C (Kristjánsson and Tómasdóttir 2024).

The RDHU has been operated at close to full capacity for the last few years. As demand grows in Hella and Hvolsvöllur it is critical to add more capacity in the near future. At this time no additional geothermal resources in the vicinity of the RDHU have been confirmed through deep drilling but several prospective resources have been explored with surface investigations and shallow, temperature gradient drilling. The purpose of this project is to define a road map for the expansion of the RDHU in the next decades. While this project has a strong up-stream focus, i.e. the main objective is to identify the most feasible geothermal resources, it also must consider the necessary expansions of the transport capacity in the system needed for each potential resource.

In Figure 2 is a simplified schematic of RDHU network which show how two production fields and the temperature and transmission capacity restrictions. The western area of the utility in Ásahreppur relies solely on water from Kaldárholt, which is relatively cold (65°C) and cools considerably before reaching customers. Laugaland mixes Kaldárholt water with hotter water from Laugaland (95°C), but due to limited production capacity, the output temperature remains relatively low (73°C). During cold spells, the transmission capacity is fully utilized between Kaldárholt and Laugaland, as well as between Hella and Hvolsvöllur, leading to unmet demand and the closure of swimming pools.

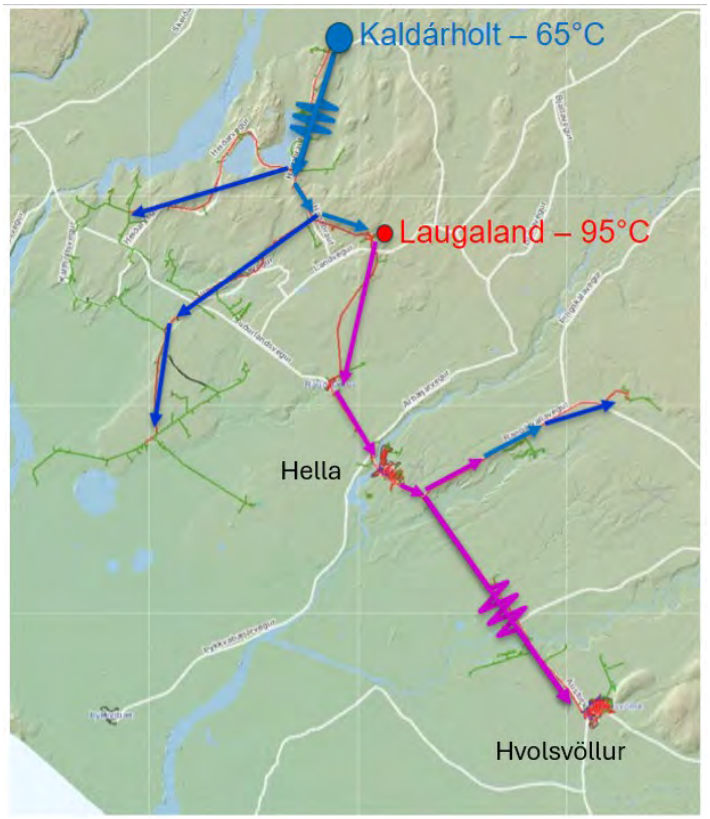

Figure 2: Simplified Schematic of RDHU distribution network, the temperature in the system is indicated with color change and transmission capacity restrictions indicated with zik zak line

3. Purpose and scope

The Rangárveita Future Master Plan (Roadmap) is a strategic initiative aimed at evaluating the current state of resources and predicting future hot water demand for the RDHU from 2023 to 2070. This project aims to prioritize actions to improve the resource status of the utility and provide support for further strategic planning.

The primary goal is to assess the resource status of Rangárveita, estimate future demand for hot water, and identify the most suitable energy supply options. This information will guide the prioritization of actions to enhance the resource status of the utility. The project does not aim to fix decisions or exact timelines but rather to support further strategic planning for the district heating system's infrastructure development.

In order to prioritize the financial resources of the RDHU it is important to compare the potential additional geothermal resources before Veitur invests in costly deep exploration drilling. The most important parameters to consider for that comparison include the expected properties of the geothermal system in terms of temperature and productivity and the location of the geothermal fields with respect to the pipelines of the RDHU. The location will affect the feasibility of utilization in two ways; a) it will have direct bearing on the cost of connection to the RDHU main pipeline and b) the location of the connection point with the main pipeline will determine how the diameter of the main pipeline needs to be scaled up.

The project described in this paper involved the development of a demand forecast for the RDHU and AHP analysis of different additional heat resources for the utility. Below we briefly describe the methodology used for the demand forecast, the AHP analysis of the 12 to 15 options considered and the resulting strategic plan for geothermal exploration, capacity addition and scaling up of transport pipelines for the RDHU.

3.1 Past Strategic Projects

Previous strategic projects identified urgent resource shortages and recommended increasing production capacity. Efforts included installing deep pumps and improving electrical infrastructure for borehole pumps. However, these measures have only temporarily increased production capacity without fully resolving the transportation constraints.

Efforts to secure additional resources for Rangárveita have been ongoing since the utility's inception. Various strategies have been proposed over the years, including deep drilling at Kaldárholt and linking to geothermal fields on Skeið. The most recent strategic project in 2020 suggested several actions, such as utilizing excess water from existing privately owned wells and exploring new geothermal sites. These historical efforts provide a foundation for current and future initiatives aimed at enhancing the utility's resource base.

3. Future Demand Scenarios

Predicting the future is challenging. Demand forecasts estimate potential demand development. Veitur regularly update short- and long-term demand forecasts. This project looks 50 years ahead to ensure sufficient hot water for customers. Since most resource-enhancing actions take many years or even decades, timely forecasts are crucial.

Forecasts for future demand are based on historical data and population growth trends. These projections help identify potential future demand increases, ensuring timely implementation of resource-enhancing actions. The forecasts consider various factors, including historical usage patterns, population growth, and planned development in residential and tourism sectors. Key limitations include:

- High system complexity and missing data in some areas.
- Many meters have only about 5 years of data, too short to analyze trends reliably.
- In areas with longer usage history, population and peak power usage are less stable.
- Population forecasts and municipal scenarios conflict with each other and historical growth.
- Demand exceeds production and transportation capacity during cold spells, meaning historical peaks may not reflect actual demand, potentially leading to underestimated forecasts.

To simplify the problem future demands scenarios where only produced for the RDHU after Laugland where mixed water from Kaldárholt and Laugland is distributed to the larger municipalities of Hella and Hvolsvöllur. In Figure 3 is presented historic demand peaks and predictions for future demands in the RDHU after Laugaland and the result show that the RDHU needs to get more geothermal resources to cover increased demand for hot water in the coming years.

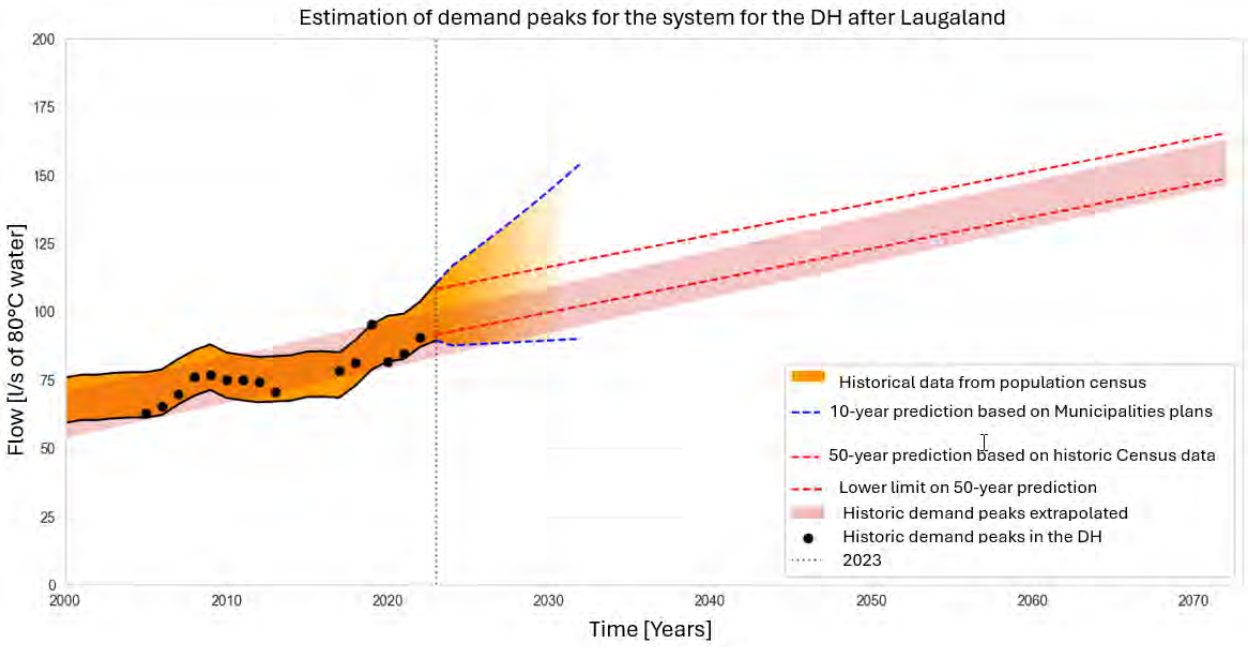

Figure 3: Historic demand peaks and predictions for future demands in the RDHU after Laugaland in standard liters per second. The red shaded area is linear extrapolation prediction based on historic census and demand peaks. The blue dotted lines show possible future utilization based on municipalities plans. The flow of geothermal fluid is standardized to 80°C thermal equivalent of 80°C for easier comparison.

In Figure 3 the flow data is standardized to represent flow of thermally equivalent amount of 80°C hot water, called "standard liters per second" or sl/s. The temperature of the hot water in the RDHU varies by location, day, and season. To standardize the flow time series, the thermal power that users can obtain from the water is calculated, assuming they return it at 30°C. The equation used is following:

$$R_{80°C} = R * \frac{T - T_{\text{return}}}{80 - T_{\text{return}}} \quad (1)$$

were $R_{80°C}$ is the equivalent flow of same thermal power if the actual water temperature were 80°C, R is the measured flow, T is the actual water temperature and T_{return} is the estimated temperature of the return water, or 30°C.

4. Transmission Capacity Issues

Transmission capacity is a critical challenge for Rangárveita. The main bottlenecks are the pipelines between Kaldárholt and Laugaland and between Hella and Hvolsvöllur, as is presented in Figure 2. Simulations indicate that the maximum flow from Kaldárholt is nearing its limit, and similar constraints exist between Hella and Hvolsvöllur. Enhancing transmission capacity involves significant investment, and any increase in resource acquisition must consider these transmission limitations to avoid further bottlenecks.

5. Geothermal Resource Options

The strategic project evaluated 13 potential geothermal/thermal resources for the RDHU shown on Figure 4 and presented in Table 1. These resources were assessed based on cost, resource risk, expected temperature, and potential benefit to users. The analysis aimed to identify the most feasible options for increasing resource availability.

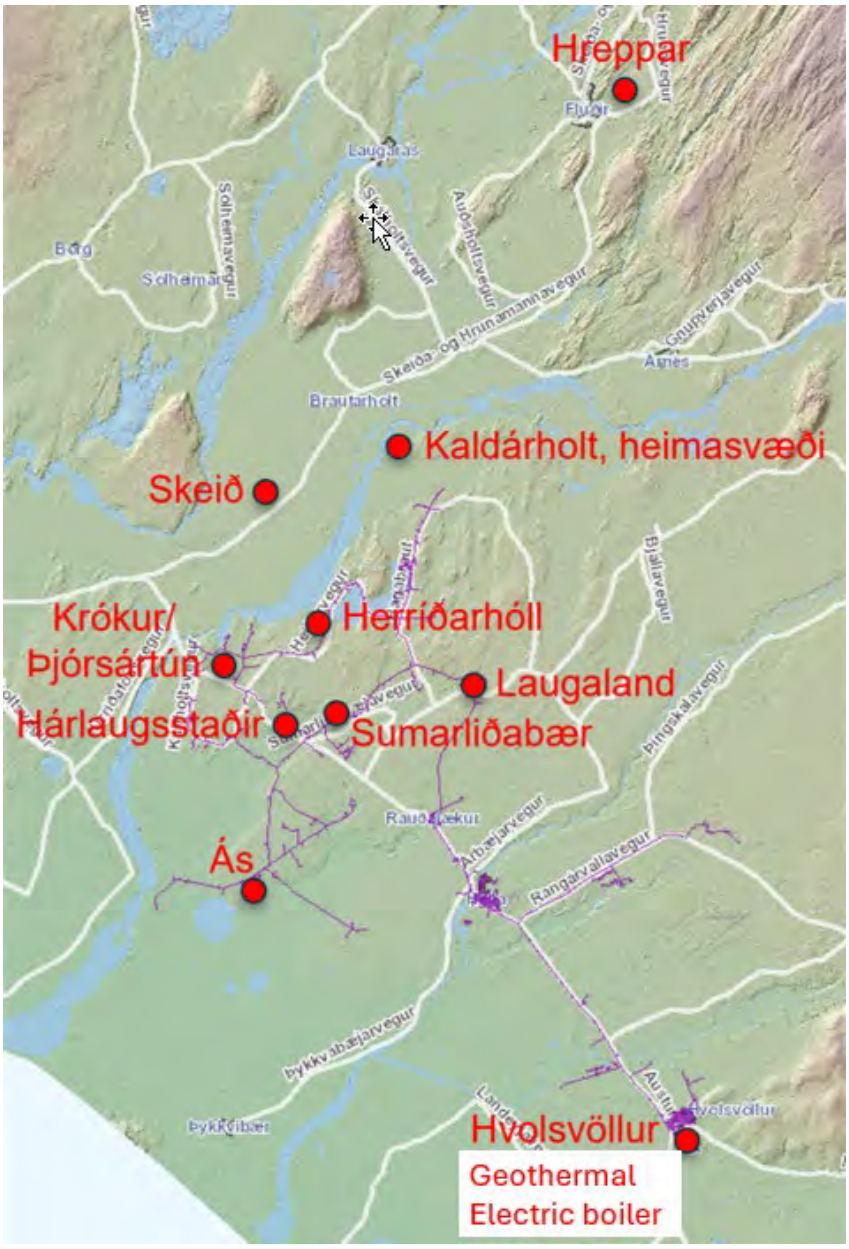

Figure 4: Overview of potential Geothermal options for Rangárveita District Heating Utility (RDHU).

Table 1: Geothermal Resource options that were evaluated and assumptions

Geothermal resource option	Potential capacity (l/s)	Probable temperature (°C)	Distance from DHS (km)	Next steps (excluding Connection to DH)
Hreppar	>50	100	22	Drilling and commissioning
Skeið	25	80	12	Exploration, drilling and commissioning
Kaldárholt, heimasvæði	25	70	3	Drilling and commissioning
Herríðarhóll	25	70	0,2	Exploration, drilling and commissioning
Krókur/Þjórsártún	25	70	1,3	Exploration, drilling and commissioning
Hárlaugsstaðir	25	70	1,8	Exploration, drilling and commissioning
Sumarliðabær and well SB-19	6	72	0,2	Commissioning
Sumarliðabær and new well	20	72	0,2	Exploration, drilling and commissioning
Ás	25	70	1	Exploration, drilling and commissioning
Laugaland, reinjection well	12,5	95	1	Drilling and commissioning
Laugaland, production well	25	95	1	Drilling and commissioning
Hvolsvöllur new geothermal field	25	70	2,5	Extensive exploration, drilling and commissioning
Hvolsvöllur electric boiler	10	80	0	Install electric boiler and connect return water

6. AHP Analysis

The Analytic Hierarchy Process (AHP) was used to rank the geothermal resources and heating options presented in Table 1. This analysis considered cost, resource risk, expected temperature and capacity, user benefit and interest in collaboration. The weight for each factor is presented in table Table 2 and then further explained.

Table 2: The weight for each factor used in the AHP analysis

Factor	Weight
Cost	10
Resource Risk	3
Expected Temperature	2
Estimated Capacity	2
User Benefit	2
Interest in Collaboration	1

6.1 Cost

Highest score (1) for the option with the cheapest cost per liter per second and lowest score (0) for the option with the most expensive cost per liter per second. Linear scaling between highest and lowest scores for all other options. All costs for geothermal exploration, development, and transportation are spread over the depreciation period of investments, with operating costs calculated as a fixed percentage of investment. Additional electricity costs for electric heating options are based on heating 10 l/s for 30 days per year. For a new geothermal field near Hvolsvöllur, the cost of upgrading the transport pipeline needed to handle more flow is deducted. This does not apply to electric heating options, which are considered temporary solutions.

6.2 Resource Risk

Highest score (1) where temperature and capacity are proven by drilling (and for electric heating options). 0.75 if geothermal resources are confirmed by drilling but further drilling is needed to verify additional capacity. 0.5 if surface activity provides strong indications of a usable resource. 0.25 if surface activity provides weak indications of a usable resource. 0 for areas with no surface activity.

6.3 Expected temperature

The score for expected temperature is presented in Table 3.

Table 3: Expected temperature scoring system

Temperature Range	Score
≥90°C	1.0
80-90°C	0.75
70-80°C	0.5
<70°C	0.0

6.4 Estimated Capacity

Highest score (1) for options that cover half of the expected increase in demand for the utility by 2070 (30.5 l/s at 80°C), with linear scaling down to a score of 0 for 0 l/s. All options with expected capacity over 30.5 l/s receive a score of 1.

6.5 User Benefit

The proportion of users benefiting from the thermal option in the utility, multiplied by the difference between the expected temperature and 65°C, multiplied by the expected capacity up to 30.5 l/s. The highest value receives a score of 1, scaled linearly down to 0.

6.6 Interest in Collaboration

Highest score (1) for resources managed by the utility; 0.75 for options where responses have been positive towards RDHU collaboration requests; 0.5 for options where geothermal rights are held by RDHU but the landowner is unwilling to collaborate; 0.25 for options where collaboration has not been sought; 0 for negative responses to RDHU collaboration requests.

6.7 AHP results

The AHP results is presented in Table 4. The most feasible option is to increase production capacity in Laugaland, either through increased sustainable production (ranked 1st) or enhanced reinjection (ranked 3rd). Utilizing excess water from the production well at Sumarliðabær also ranks very high (2nd place) due to the absence of risk and low connection costs, despite the landowner's lack of interest in collaboration. The next ranks include four low-temperature areas in the western part of the service area: Kaldárholt heimasvæði, Herríðarhóll, Sumarliðabær, and Ás. The unknown geothermal potential near Hvolsvöllur ranks 8th, despite complete uncertainty about its existence, primarily because of the significant benefits if the transmission line between Hella and Hvolsvöllur does not need to be upgraded. Following this are the expected low-temperature areas in the western region at Hárlaugsstaðir and Krókur/Þjórsártún, then connections to geothermal areas in Hreppar and Skeiðar, with electric heating options in Hvolsvöllur ranking last.

Table 4: Results from the AHP analysis. Flow data is standardized to represent flow of thermally equivalent amount of 80°C hot water, called "standard liters per second" or sl/s

Geothermal Resource Option	Weighted AHP score	USD/sl/s	KUSD
Laugaland production well	16.0	650	3,065
Sumarliðabær and well SB-19	14.4	200	145
Laugaland reinjection well	14.3	1,000	2,471
Kaldárholt, heimasvæði	12.6	1,170	3,500
Herríðarhóll	10.5	1,050	3,022
Sumarliðabær new well	10.3	1,250	3,022
Ás	10.1	1,160	3,377
Hvolsvöllur new geothermal field	10.1	850	2,377
Hárlaugsstaðir	9.7	1,280	3,732
Krókur/Þjórsártún	9.4	1,200	3,507
Hreppar 50 l/s	9.3	2,750	29,913
Skeið	8.5	2,310	8,783
Hvolsvöllur electric boiler	7.3	2,490	725

7 The Future Master plan and Recommendation

For the RDHU multiple efforts are needed to improve the resource situation. Test drilling is under preparation at Laugaland aimed at increasing the sustainable production capacity from the system and/or improving the reinjection process into the system. It is essential to explore geothermal resources closer to Hvolsvöllur because if successful, costly measures to upgrade the transmission line between Hella and Hvolsvöllur can be avoided. While this exploration is ongoing, it is necessary to set up temporary electric heating of return water in Hvolsvöllur. Additionally, it is crucial to seek more reserves for the utility since the current reserve shortage is a fact and it is not viable to wait for the results of geothermal exploration in Hvolsvöllur or exploratory drilling in Laugaland. Investing in geothermal exploration in the western area of the utility is not a waste, as any usable resources found there will benefit the utility's future plans, even if they are not

immediately developed. An improved long-term resource outlook for the utility benefits both the utility and the municipalities it serves. In Figure 5 a proposed roadmap is presented for the next years to addressee the RDHU hot water shortage and in Figure 6 is more specific roadmap for Hvolsvöllur.

- Meet peak power demands for the winter of 2023 to 2024 by increasing the supply temperature from Laugaland. This means increased production in Laugaland over the winter without the need to increase production in Kaldárholt.
- Procure electric heating equipment that can be installed for the winter of 2024/2025. Once this equipment is operational, production in Laugaland can be slightly reduced, but the supply temperature can remain higher than it is now (73°C). It should be noted that production in Laugaland might be aggressive in the coming years.
- Continue geothermal exploration in the western area of the utility:
    - Continue geothermal exploration in Laugaland. The next step is to drill an 800-meter-deep exploratory well in 2024. If successful, it may serve as a production well or otherwise as a reinjection well.
    - Conduct temperature gradient drilling in west area Ás, Hárlaugsstaðir, Herríðarhóll and in Krókur/Þjórsártún. If landowners are willing to cooperate in geothermal exploration and utilization, proceed with temperature gradient drilling in these areas and subsequently select the most promising sites for exploratory drilling.
    - Make every effort to obtain permission from landowners in Kaldárholt heimavæði for exploratory drilling. If this is not successful, expropriation may be necessary to obtain drilling authorization.
- Utilities should seriously investigate how much water is available in Hreppar and at what temperature. Subsequently, a detailed feasibility study, preliminary design, and cost estimate for such a connection need to be conducted. It is essential to know with greater certainty what is available and what it costs if geothermal exploration in the western area of the utility is unsuccessful, so that a connection to Hreppar can be compared with other, less expensive options.
- In the years 2026 to 2027, after geothermal exploration in the western area is completed, a decision can be made on which geothermal area in the western part of the utility is best suited to add more reserves to the utility. If none of the areas we are targeting prove usable, a connection to Hreppar may be the only option. The development and connection of a new area to the utility must be completed by 2030, allowing production in Laugaland to return to sustainable levels.
- Since none of the above measures will solve the transmission problem to Hvolsvöllur permanently, it is recommended to begin geothermal exploration near Hvolsvöllur in 2024. The timeline for these actions is shown in Figure 6.
    - Temporary electric heating of return water in Hvolsvöllur will begin in 2024
    - Apply for exploration permits in the area around Hvolsvöllur (3-5 km radius) with the aim of conducting temperature gradient drilling in the area. If temperature anomalies are found, follow up with exploratory drilling and development if usable geothermal resources are found. These studies must be completed by the end of 2027.

- If geothermal exploration near Hvolsvöllur is unsuccessful, the transmission problem to Hvolsvöllur needs to be solved, whether by upgrading, adding a parallel line, or installing more pumping stations between Hella and Hvolsvöllur.

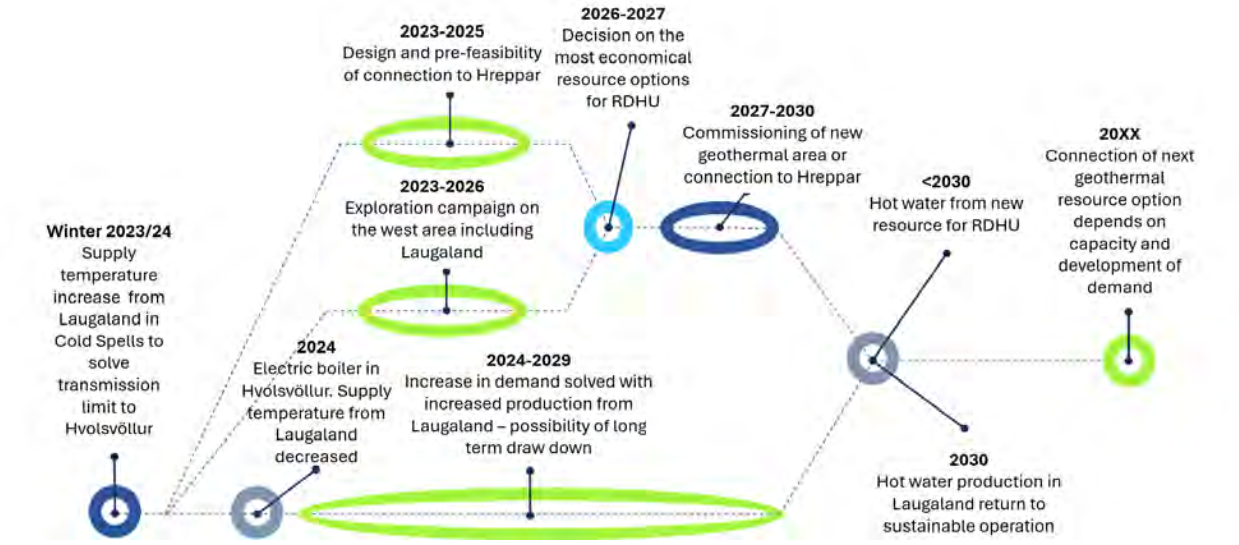

Figure 5: Proposed roadmap for research and actions to support increased demand in the RDHU

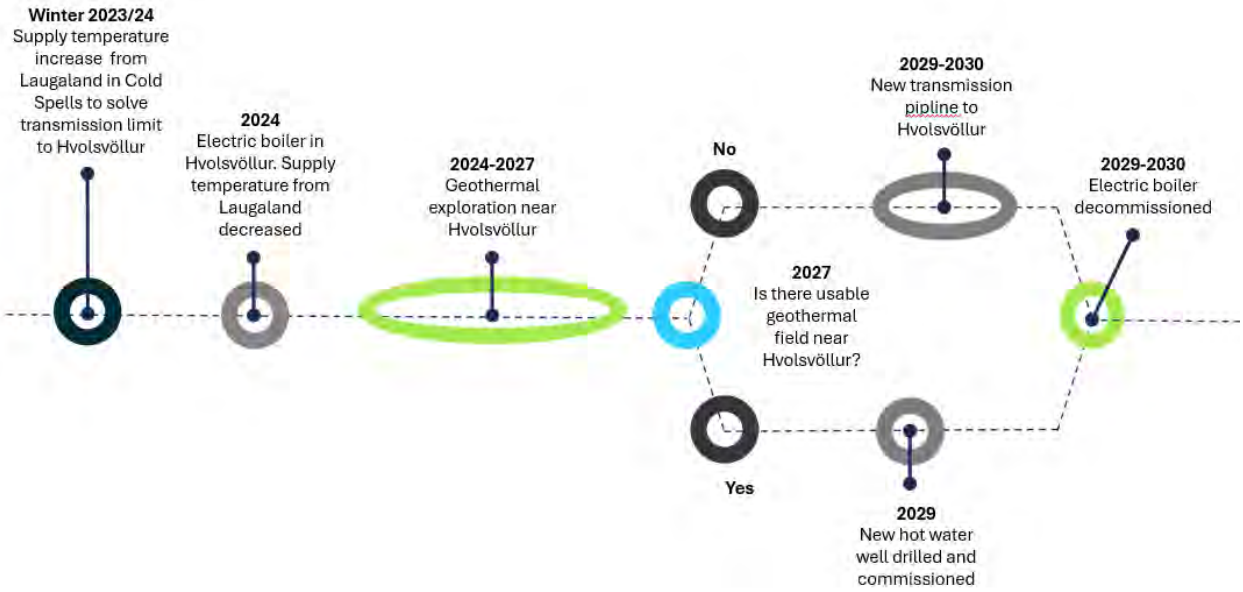

Figure 6: Proposed roadmap for research and actions to support increased demand in Hvolsvöllur

8. Conclusion

The RDHU future master plan provides a strategic framework for addressing the utility's current and future resource challenges. By prioritizing a mix of immediate and long-term actions, the roadmap aims to ensure a reliable and sustainable supply of hot water for the communities served by Rangárveita. Continued research, investment in infrastructure, and strategic planning will be crucial to achieving these goals and securing the utility's future.

The following are short-term actions:

- Increase Production at Laugaland: Implement measures to enhance sustainable production and improve resource stability.
- Geothermal Exploration at Hvolsvöllur: Conduct temperature gradient studies to identify potential geothermal resources.
- Temporary Heating Solutions: Install electric boiler systems to heat return water to address immediate shortages.

The following are the long-term actions:

- Resource Exploration: Continue exploring geothermal resources in the western region and other potential areas.
- Infrastructure Improvements: Upgrade transportation infrastructure to increase capacity and ensure reliable distribution.
- Strategic Partnerships: Engage with stakeholders and landowners to secure agreements for resource development.

Geothermal Heat Pump, Electrification, Power System Model, Externalities, Valuation, Direct Use, Manufacturing, Decarbonization

ABSTRACT

Fuel based end-uses for residential, commercial, and industrial consumers require a technology change to achieve economy-wide decarbonization. Space heating accounts for 42% of residential and 32% of commercial energy demand, much of which is currently met through carbon emitting fuels. Industrial energy use is heavily fuel based with electricity currently representing 13% of energy demand. Geothermal heat pumps (GHPs) and geothermal direct use can eliminate the need for CO_2 emitting and simultaneously allow for more efficient electrification of end uses. Past work has assessed the impact on total energy costs and generation investments but did not identify specific grid services benefited. Energy usage in residential and commercial structures was assessed by leveraging data from ComStock and ResStock models. These models utilize housing attributes, occupancy patterns, weather data, and sophisticated energy simulations to generate hourly load profiles for individual buildings identified by unique IDs associated with their locations. Industrial sector energy use was evaluated using information from the Manufacturing Energy Consumption Survey (MECS) as well as plant utilization data from the US Census to estimate hourly plant operations. The change in end-use demand for electricity, natural gas, and other fuels was calculated for different technologies that could meet this need. Using the ReEDS capacity expansion model, we produce regional price profiles that capture the grid benefit associated with the amount and timing of energy shifts in the power system from the adoption of geothermal systems relative to other technologies that could meet space heating, space cooling, and process heat requirements. We find that geothermal systems for meeting end-use demand add value to the energy system. In buildings where geothermal systems increase grid costs, these values are offset by reduced fuel costs and benefits to externalities, including emissions and health impacts.

1. Introduction

Decarbonizing energy systems is a key goal for mitigating the impacts of climate change by reducing greenhouse gas emissions. A transition to a net zero carbon electric power system representing 34% of U.S. total energy consumption is a vital component of this strategy having both a substantial amount of existing zero emissions generation and rapid growth in wind and solar. Carbon free electric power can be utilized to support the decarbonization of other sectors that today are heavily dependent on fossil fuels. Electrification plays a pivotal role in this transition by adopting end-use technologies that use electricity directly rather than fuels.

For residential and commercial buildings, space conditioning (heating and cooling) represents the majority of energy consumption. Space heating in the U.S. is primarily met through natural gas furnaces, although the distribution of heating energy sources varies regionally. Space heating accounts for 42% of residential and 32% of commercial energy consumption and is a ripe opportunity for electrification. Industrial energy use is heavily fuel based with electricity currently representing 13% of energy demand. These sectors, including space heating, cooling, and manufacturing process heat, are substantial contributors to U.S. greenhouse gas emissions. Electrification of these end-use applications has broad benefits for which there exist a range of technology solutions.

Geothermal systems offer a promising solution for electrifying these end uses. Geothermal heat pumps (GHPs) can efficiently electrify buildings while maintaining a stable coefficient of performance (COP) even at low temperatures since heat exchange occurs in the subsurface as opposed to ambient air. Cooling with GHPs can also realize efficiency gains over air conditioning (AC). In addition to space conditioning, process heat for manufacturing could be provided through deep direct use and high-temperature heat pumps. These solutions utilizing geothermal systems, are not the only electrification options for end uses. Understanding the relative benefits is important for determining the right solution for a given building end use.

Metrics like the reduced energy consumption and change in CO_2 emissions provide useful comparisons but do not provide a complete picture of a technology's benefits. Applying flat energy prices helps to convey the costs a consumer sees and the net economic value but has similar drawbacks to examining change in energy consumption alone. The cost of operating them is not equally distributed, given small periods of high system stress potentially reflecting a disproportionate share of costs. Reflecting the value to grid considering the timing and quantity of energy shifts is important for providing a comprehensive measure of the grid costs and benefits of an electrification measure. Focusing on energy costs alone excludes the negative externalities associated with CO_2 emissions and health impacts from criteria pollutants.

To address this, there is a need for valuation methods that incorporate a broader range of factors mentioned. Through the inclusion of grid costs, fuel costs, and externalities, we can develop a more comprehensive understanding of the relative value of end-use technologies, leading to more informed decisions and policies that support sustainable and efficient energy systems.

2. Methods

In order to evaluate the relative value of applying geothermal systems we needed to quantify the changes in hourly end use energy consumption for consumers as well as develop a comprehensive measure of value. This section first describes the methods and data sources developed for

quantifying residential and commercial space heating load changes with GHPs. Next, we describe the approaches used to measure manufacturing process heat demand that could be met through heat pumps or direct use. Finally, we describe a method that incorporates changes in electric power costs, fuel costs, and the cost of externalities, including in building CO_2 emissions and health impacts.

2.1 Development of End Use Load Profiles for Geothermal Systems

2.1.1 Residential and Commercial Space Conditioning

ResStock and ComStock are modeling tools that provide hourly end-use load profile information considering the intricacies of the U.S. building stock.

- **ResStock** represents residential buildings (Present 2024)
- **ComStock** represents commercial buildings (Parker 2023)

The tools utilize OpenStudio and EnergyPlus to perform physics-based building energy simulations to generate hourly end use load profiles specific to end use and energy source. Building energy consumption is broken down by specific end use (e.g., space heating) and energy source for meeting that end use (e.g., electricity, natural gas).

A key feature of these tools is the inclusion of upgrades compared to a base building stock representation. An upgrade case models how energy consumption changes with different home improvements. Critically for this analysis these modeling tools include cases where buildings upgrade to air source heat pumps as well as geothermal heat pumps.

For our analysis we identified upgrade scenarios that changed only the building heating and cooling type, making no alterations building envelope improvements. This allows us to directly compare the changes in energy consumption patterns attributable to changing the end use technology used to provide building space conditioning.

In this analysis we compared the base building configuration against a ground source heat pump upgrade.

- Residential: Energy Star geothermal heat pump
- Commercial: Comprehensive geothermal heat pump package (Hydronic GHP, Packaged GHP, or Console GHP)

ResStock and ComStock include end-use load profile (EULP) results for the 2018 actual meteorological year (AMY) as well as a typical meteorological year (TMY). To integrate the data into our power system valuation method, the data needed to be concurrent with a 2012 (AMY). Aligning weather years is important as meteorology impacts the balance of electric power supply through variable renewable energy sources (solar and wind) and the demand through requirements for building space conditioning.

The computational intensity and workload required to run ResStock and ComStock prohibited full simulations specific to 2012 AMY. We developed, in collaboration with developers to the building stock simulation tools, a regression tool using random forest, that could train on available hourly space conditioning end use demand profiles and generate predictions for alternate weather years.

A strength of random forest is that it is well suited to modeling non-linear relationships between inputs (meteorological conditions) and outputs (end use energy demand).

We validated the quality of the random forest-based tool by training it on a prior elease of ResStock which included simulations for both 2012 and 2018 meteorological years. Using 2018 data to train the random forest model we then predicted 2012 space heating and cooling end use energy demand. Comparing the predictions from the regression against the actual ResStock hourly building simulation results, we found a close alignment between the two datasets.

2.1.2 Geothermal Systems for Manufacturing

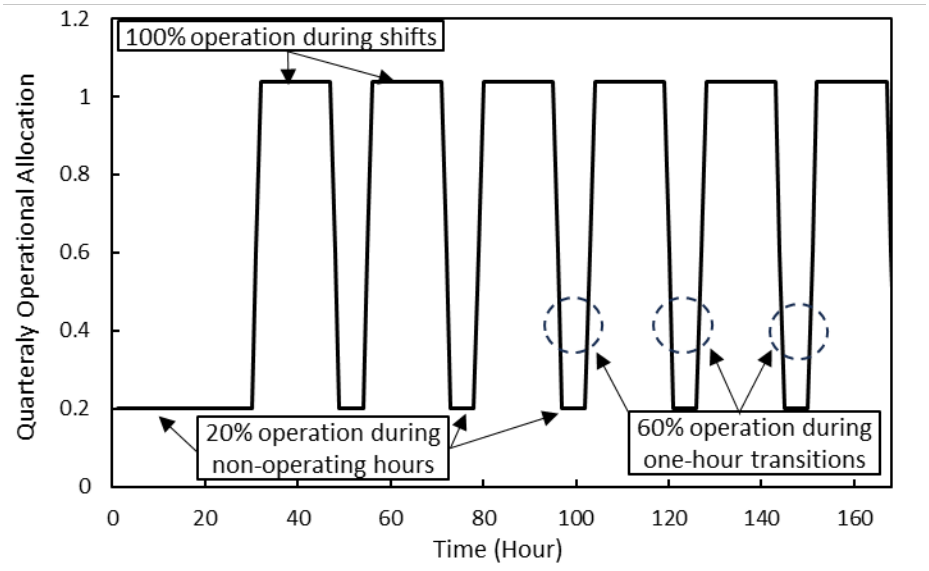
The U.S. Energy Information Administration (EIA) defines the industrial sector as an energy-consuming sector consisting of any facilities and equipment used for producing, processing, or assembling goods. In 2022, the industrial sector consumed primary energy sources amounting to 28.1 exajoules (EJ) accounting for approximately 35% of the U.S. primary energy consumption (EIA 2021). A total of 76% of the energy consumption in the industrial sector was consumed in the manufacturing sector (mining = 12%, construction = 7%, agriculture = 4%) (EIA 2022). In this section, the manufacturing end-use energy consumption data was analyzed to develop time-varying thermal demand profiles, particularly using the 2018 Manufacturing Energy Consumption Survey (MECS) released in 2021.

The EIA periodically surveys and analyzes the end-use energy consumption in the manufacturing sector (e.g., 2018 MECS, 2014 MECS, 2010 MECS). The end-use fuel consumption database in MECS consists of end-use energy consumptions by 1) net demand for electricity, 2) residual fuel oil, 3) distillate fuel oil and diesel fuel, 4) natural gas, 5) hydrocarbon gas liquids (HGL), and 6) coal for various end-use categories (e.g., process heating, process cooling and refrigeration, conventional boiler) in 82 manufacturing subsectors ranging from Food categorized by the North American Industry Classification System (NAICS) as 311 to Miscellaneous (NAICS = 339). In this study, 65 subsectors were selectively analyzed while duplicated sectors were excluded to avoid any uncertainties. For example, although 3112 Grain and Oilseed Milling category includes seven sub-categories from 311211 Flour Milling to 311230 Breakfast Cereal Manufacturing, the MECS data only includes 311221 Wet Corn Milling among the seven sub-categories. This study therefore excluded 3112 Grain and Oilseed Milling and analyzed 311221 Wet Corn Milling. Among the different end-use categories, this study focused on any energy consumptions for process heating and conventional boiler end-use categories where geothermal heat pump (GHP) and deep direct-use (DDU) applications may supply extensively energy needs. Future research on additional end-use categories, including process cooling and refrigeration and facility HVAC, is recommended to extend potential opportunities the decarbonizing the energy demand using geothermal applications.

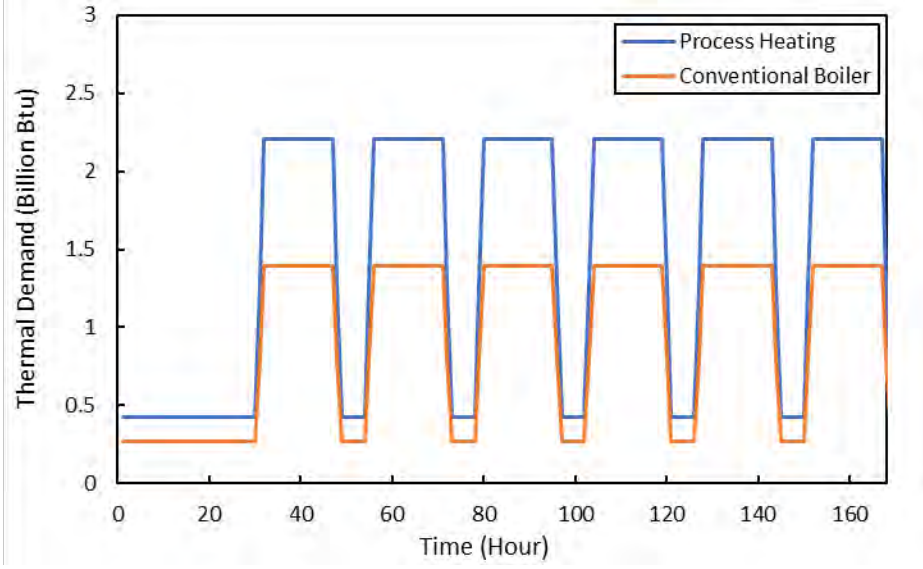
As discussed in Oh and Beckers (2023), the end-use energy consumption data is not always allocated to the thermal demand with 1:1 efficiency (i.e., the actual thermal demand can be higher or lower than the energy consumption depending on the system efficiency). To estimate thermal demand, in this study, the end-use energy consumption data was incorporated with different coefficients of performance (COP) in terms of the type of energy sources: COP = 1 for net demand for electricity, COP = 0.8 for natural gas, and HGL, and COP = 0.7 for residual fuel oil, distillate fuel oil and diesel fuel, and coal. For example, energy consumptions for conventional boilers in the 311221 Wet Corn Milling subsector were 1 TBtu by electricity, 8 TBtu by natural gas, and 1

TBtu by coal. However, the estimated thermal demand total was 8.1 TBtu, instead of total energy consumption of 10 TBtu when the different COP factors are taken to account.

Even though the MECS and the U.S. Environmental Protection Agency (EPA) Greenhouse Gas Reporting Program (GHGRP) database have been analyzed for the annual thermal demand in the manufacturing sector by previous researchers (e.g., McCabe et al. 2015; McMillian et al. 2016; McMillan et al. 2021; Oh and Beckers 2023), there are limited resources and publicly available data for hourly- thermal demand profiles based on standardized facility operation hours. This study estimated the hourly thermal demand profiles using average plant operation hours per week data obtained from 2018 Census Quarterly Survey of Plant Capacity Utilization (QPC) data where quarterly statistics on utilization rates and average plant operation hours per week data are available for manufacturing subsectors based on the NAICS codes. As a first step, the number of shifts and operating days were defined for each manufacturing subsector in terms of the weekly average operation hours in the QPC database. The assumptions included one shift represents an 8-hour operation at full capacity from 8 am to 4 pm, and one day can consist of up to three shifts (i.e., full operation during the whole day). There was a one-hour transitional operation at 60% full capacity before and after the operation at full capacity (i.e., the weekly operation hours are allocated to fit one-and two-shifts, or three-shift with five or six operating days per week), and a 20% of full capacity was assumed for non-operating hours. For example, the 2018 QPC for Quarter 1 demonstrates that the average weekly operation hours for the 3112, 5, 6 Grain and oilseed milling, dairy, and animal slaughtering and processing sector was 99.6. In the analysis, the 96 hours were allocated in six operating days (from Monday to Saturday) with two shifts (from 8 am to 12:00 am) for operations at full capacity, while the rest of 3.6 hours was allocated for operations at the 60% transitional and 20% non-operating hours. This process allows us to estimate the time-varying demand shape from 20% to 100% capacity of the facility (Figure 1(a)). Then, the annual total thermal demand estimated for process heating and conventional boiler end uses was incorporated into the demand shape (Figure 1(b)).



(a)



(b)

Figure 1. Manufacturing thermal demand profile for 311221 Wet Corn Milling example subsector: (a) quarterly operational allocation from 20% to 100% and (b) thermal demand profile for process heating and conventional boiler end uses.

In the second step, the thermal demand profiles for each of the 65 manufacturing subsectors analyzed in this study (e.g., Figure 1(b)) were then divided by the number of establishments obtained from 2018 MECS to normalize the demand profiles per establishment, assuming there is no significant difference in energy consumptions among the facilities in the same NAICS categories. For the final step, the electricity consumption by GHP and DDU to supply the manufacturing thermal demand (i.e., normalized hourly thermal demand profile in each subsector) was estimated to generate electric consumption profiles in kWh (hourly electric loads). The DDU estimation was based on correlation models by Oh et al (2024) for the GHP estimates were based on the PANYNJ project (While electricity consumed in the DDU system was assumed as the pumping power to circulate water throughout the deep boreholes at 2.1 km or 3.3 km depth (Oh et al. 2024), those consumed in the GHP system were estimated as a combination of the GHP operational and water circulating pumping power. Figure 2 represents example electricity consumption profiles to supply the estimated thermal demand total in 311221 Wet Corn Milling subsector by GHP and DDU applications.

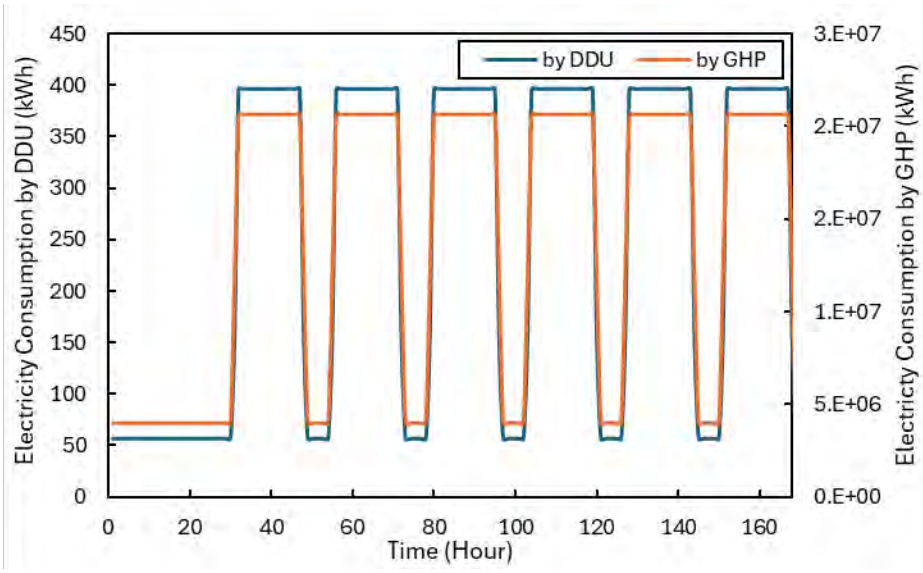


Figure 2. Electricity load profiles by GHP and DDU applications to supply the total thermal demand in 311221 Wet Corn Milling per establishment

2.2 Quantifying Relative Value

2.2.1 ReEDS Background

The Regional Energy Deployment System (ReEDS), developed by NREL, is a capacity expansion model that simulates the evolution of the U.S. power system (Ho 2021). ReEDS considers the electric power demand along with the cost and characteristics of generation and storage technologies that could meet this demand, selecting a mix of technologies that minimizes total system costs. The unique topology of demand, available resources, and transmission infrastructure are included in ReEDS and play a significant role in what decisions are made within the model.

2.2.2 Power System Cost/Value: reValue

Power system simulation tools produce prices that are a direct reflection of resource utilization, and necessary investments support the needs of the system. The prices, composed of energy prices and resource adequacy prices, represent wholesale prices within restructured power markets, and can communicate periods of increased system stress when changes in energy consumption have significant cost or value to the system.

Energy prices in power system models are analogous to Locational Marginal Prices (LMP) a pricing mechanism used in wholesale energy markets to determine the cost of electricity at specific locations within the power grid. It represents the marginal cost of supplying an additional unit of electricity at a particular node or location on the grid at a specific time, taking into account factors such as generation costs, transmission constraints, and demand patterns. LMPs vary across the topology of the power system and time periods based on supply and demand dynamics.

Resource adequacy refers to the ability of an electric power system to reliably meet the electricity demand of its customers at all times, ensuring there are sufficient resources available to avoid shortages or interruptions. Capacity markets are a mechanism where sufficient capacity from

eligible participating generators is procured in excess of a defined margin above peak demand in compliance with NERC guidelines. A competitive capacity price is paid to participating generation and storage technologies for committing to a specified fraction of their generating capacity required to generate during periods of high system stress. These prices provide financial incentives for generators to invest in and maintain sufficient capacity to support resource adequacy, thus ensuring the reliability of the power system. These are analogous to capacity markets that exist in restructured power markets in the U.S. Payments for participating resources occur on an annual basis but the time periods that govern the need for this resource can be mapped to specific periods of high system stress. This enables the price signal for resource adequacy to be allocated to specific periods along with the previously discussed energy prices.

Cambium is an NREL analysis product that utilizes the combined analysis for ReEDS capacity expansion modeling with PLEXOS production cost modeling to generate key metrics relevant to power system planners and decision-makers. Region specific hourly prices of electricity that incorporate the price of energy and capacity for resource adequacy are one included metric. The hourly price generated can be utilized to evaluate the expected revenue of a participating power generator or storage asset. It can also be utilized to understand the costs to the grid of supplying energy for a specific end use load profile.

While Cambium is a powerful analysis tool, there is a high degree of computation and modeling effort required to generate the necessary outputs. This effort is performed for a limited number of cases as part of the annual ReEDS Standard Scenario results, which are released and available for use in other analysis efforts. For analysis of future power systems that differ substantially from the preexisting scenario assumptions included in Standard Scenarios, the Cambium workflow is not feasible.

A new development to ReEDS is an analysis tool called reValue, which generates hourly prices analogous to those produced by Cambium. The capability works by allocating ReEDS prices for energy and capacity requirements in each ReEDS time period to the full hourly dataset. While using ReEDS alone limits the understanding of how operational constraints like ramping and unit commitment impact energy prices, its prices are a direct reflection of the economics that govern ReEDS decision making. Utilizing ReEDS with revalue has a much lower computational intensity and is feasible to run quickly for bespoke scenarios required for an analysis effort.

For this effort features were added to reValue to support analysis of the grid value of hourly electric power changes associated with the adoption of geothermal systems. Combining the hourly electric power prices with end-use load shapes allows for a calculation of the annual cost to the grid of supplying that end-use. The end-use load shapes and magnitudes change based on the application of geothermal systems to meet that need. Calculating the difference between annual cost by specific end use determines the relative cost or value to the grid of adopting a geothermal system as compared to alternatives.

Building sizes can differ substantially by end user and reValue includes metrics that normalize the annual costs to a comparable floorspace equivalent. The valuation tool scales and can be quickly applied to value any number of specific end-use energy profiles and locations. Grid valuation calculated using reValue reflects wholesale prices with an option to include a price escalator to estimate retail prices.

2.2.3 Quantifying Non-Electric Power Values

While an important metric examining only the power system value of a geothermal system applied to a building end-use is important, it does not consider the larger system of impacts. As an example, were a building to electrify a natural gas furnace used for heating, the increase in electric power consumption would appear as an increase in cost relative to maintaining an existing heating system. This would omit the direct financial benefits of reduced fuel consumption as well as the benefits of reduced in building emissions for climate and health impacts.

The fuel consumption associated with an end-use technology is utilized and calculated against wholesale natural gas prices in ReEDS. These natural gas prices are aligned with those used in AEO 2023 and can optionally include price elasticity if required for a ReEDS simulation. The use of wholesale natural gas prices keeps the calculation of fuel price consistent with the quantification of power system value, although applying an escalator to reflect retail gas prices is an available option.

To calculate benefits of changes to in-building emissions we consider these impacts as externalities in order to calculate them in terms of a value equivalent. For the cost of CO_2 emissions associated with an end-use emissions we applied a $51/ton social cost of carbon consistent with a moderate value proposed by the Whitehouse Interagency Working Group (IWG 2021). In addition to CO_2 we estimated costs associated with air pollutants including fine particulates, NOx and SOx using emissions intensity factors specific to the modeled end use. The impacts of air pollution depend on both the type and location of emissions relative to downwind populations. We utilized a linkage to ReEDS regions of a reduced complexity air pollution model (RCM) based upon data available from the Center for Air, Climate, & Energy Solutions, which provides information to apply three possible integrated air assessment models (AP3, EASIUR, and InMAP) with two concentration-response function studies (American Cancer Society and Harvard Six Cities Study). The RCM is used to calculate the cost of health damages associated with emissions which can be included in the externalities of an associated end use (Kim 2020).

3. Results

3.1 Selected Buildings

As an illustrative example of this approach, we applied the valuation described in the prior section to residential and commercial buildings in Washington State. The selected profiles were obtained from ResStock 2024.2 and ComStock 2024.2. The selected residential and commercial buildings all fall into a common region sharing climate and energy prices, and all had available GHPs upgrades to constraint valuation.

The selection of representative residential buildings, shown in Table 1, was made to allow for a comparison in the change of value on the basis of the initial building heating type and whether the building possessed air conditioning. For building heating, the selected buildings either utilized resistive electric heating or a natural gas furnace. For space cooling, buildings either possessed a conventional air conditioner or had no existing cooling system. When the GHP upgrade is applied to the selected buildings, it is utilized both for building heating and cooling regardless of whether the building had cooling in its base configuration.

Table 1 Residential Building Base Characteristics

Building ID	Heating Fuel	Heating System	Cooling System
25	Natural Gas	Natural Gas Furnace	None
249	Natural Gas	Natural GasFurnace	AC, SEER 10
311	Electricity	Electric Furnace	None
500	Electricity	Electric Furnace	AC, SEER 13

Commercial buildings, shown in Table 2, were selected to allow a comparison in the change of value for buildings depending on their base heating system. In contrast to the selected residential buildings all commercial buildings have installed cooling. For heating systems, it includes gas and electric furnaces similar to the residential buildings but also includes an air source heat pump. This allows a contrast between two types of building heat pumps and the associated annual benefits.

Table 2 Commercial Building Base Characteristics

Building ID	Building Type	Heating Fuel	Heating System	Cooling System
333469	Warehouse	Natural Gas	Furnace	DX
333463	Warehouse	Electricity	ASHP	ASHP

3.2 Analysis of Residential Buildings

Using the method discussed in the prior section we calculated the comprehensive cost of meeting the building space conditioning for the selected residential buildings, shown in Figure 3. For all the selected buildings the application of GHPs had a lower annualized cost compared to meeting the same requirements with the base HVAC equipment. This pattern held for buildings 25 and 331 which lacked air conditioning in their base configuration.

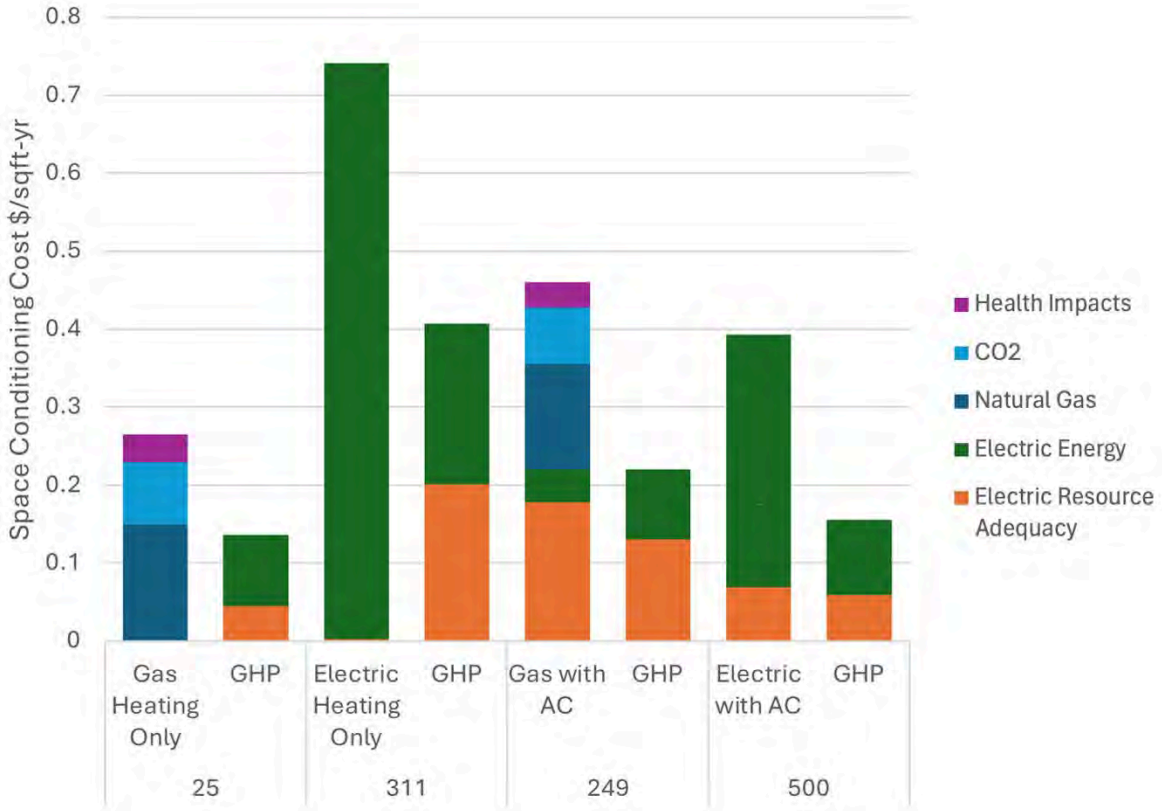

Figure 3. The annualized cost per square foot of meeting space conditioning needs for residential buildings with and without GHPs.

The electric power costs are separated into energy and resource adequacy requirements. The addition of GHPs altered the distribution of these two components. Building 331 with a resistive electric furnace and no AC was dominated by energy component, with the addition of GHPs combined electric power costs fall. The addition of summer electric power demand to meet cooling results in an increase in the cost to meet resource adequacy, which tends to be governed by summer peaking time periods. For buildings 249 and 500, which included AC, the upgrade to GHP reduced the resource adequacy component of electric power costs due to improved summer cooling efficiencies, shown in Table 3.

Table 3 Reduced Cost of GHP Upgrade for Residential Buildings by Component

Building ID	HVAC Type	Net Value of GHP Upgrade ($/sqft-yr)				
		Electricity	Fuel	Externalities	Electricity + Fuels	Combined
25	Gas Only	-0.136	0.149	0.116	0.013	0.129
331	Electric Only	0.334	0.000	0.000	0.334	0.334
249	Gas with AC	0.000	0.135	0.105	0.135	0.240
500	Electric with AC	0.237	0.000	0.000	0.237	0.237

The value of a building upgrading to a GHP is indicated by the difference between the cost of heating using the original system and a GHP upgrade. Buildings 25, which electrified natural gas with a GHP, showed an increase in electricity costs, which were offset by a greater reduction in avoided fuel costs. Building 249 showed no net change in electric power costs, as the electric costs incurred to electrify heating were coincidentally offset by savings through greater cooling efficiency relative to the base AC system. The value of the externalities from CO_2 emissions and health impacts from criteria pollutants were at a similar magnitude to the calculated natural gas costs.

The total combined benefits were greatest for the buildings with electric resistive heating (buildings 331 and 500) due to the energy and cost intensity of this end-use. Buildings using natural gas as a heating fuel had a smaller benefit, still showing net savings for electricity and fuel costs. The savings were further bolstered when the externalities of CO_2 and health impacting emissions were included.

3.3 Analysis of Commercial Buildings

In contrast to the analysis of residential buildings commercial warehouses with substantially larger floor area showed lower costs for space conditioning. For the selected buildings costs are lower with GHP applied compared to the base heating and cooling technologies. In building 333469, with natural gas as a primary heating, the GHP upgrade allows for a reduction but not complete elimination of natural gas for heating based upon the assumed size of the geothermal system. This has a small increase in electric costs of 0.007 $/sqft-year, which, when combined with the substantial fuel cost reduction, shows a 0.037 $/sqft-year savings, shown in Figure 4. Factoring in externalities grows the savings from GHP to 0.068 $/sqft-year.

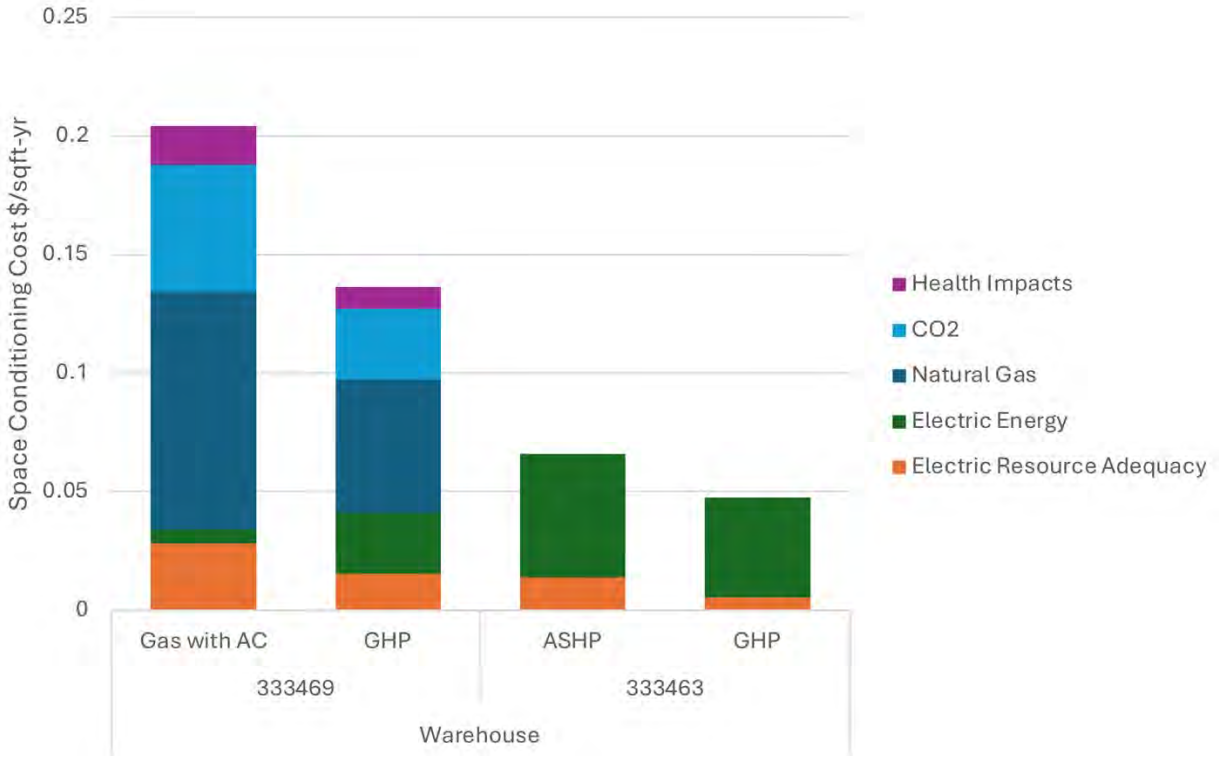

Figure 4. The annualized cost per square foot of meeting space conditioning needs for commercial buildings with and without GHPs.

Building 333463 differs from the base building electric heating comparison in the prior section as it utilizes more efficient air source heat pumps to provide space conditioning. The addition of GHPs have a comparably smaller 0.018 $/sqft-year or 28% of baseline costs. These benefits were obtained from an equal cost reduction between resource adequacy costs and energy costs. Proportionally this has a visibly greater effect on the resource adequacy costs which are halved primarily due to substantially higher summer cooling efficiencies.

4. Conclusions

As part of our analysis, we identified a method to evaluate the comprehensive benefits of applying geothermal systems to meet end use demand. By leveraging ReEDS prices through reValue we can quantify the hour specific impacts to grid prices from associated electric power consumption. The inclusion of externalities, including CO_2 and health impacts from air pollution, provides a more comprehensive valuation of electrification through geothermal systems. The combination of these measures provides an improved measure of comparison between end use technologies.

To enable this analysis, we identified data sources and work flows to allow analysis of space conditioning for residential and commercial buildings as well as applications in the manufacturing sector. We applied this method to a selection of residential and commercial buildings in Washington state to compare how and where savings were realized and how focusing on the combined impacts creates a more comprehensive understanding of the relative benefits of applying GHPs.

The next steps in our work are to apply the calculated residential, commercial, and manufacturing end-use load impacts at a national scale. For space heating and cooling we will be shifting to county aggregates based upon original heating and cooling type to compare both upgrades from base end use technology as well as comparisons across space conditioning upgrades. This will capture substantial differences in the climate, building configuration, and preference for space conditioning technologies that are extraordinarily regionalized. County aggregations address computational challenges and keep the overall data size to an interpretable level. The health impacts of emissions will also vary substantially depending on the location and downstream effects with other regions having much higher marginal impacts than in the region selected.

We plan to report results highlighting regions where geothermal systems are best suited on the basis of their net operating value. This will provide important context for comparing the benefits to the energy system of a whole of end-use technology upgrades including geothermal systems. For manufacturing energy, which in part uses DDU, which is dependent on suitable conditions, an analysis will be done to determine the regional feasibility of applying DDU.

Keywords

Numerical Modeling, ATET, Open Loop Geothermal, New York City, Geoexchange

ABSTRACT

This study aims to assess the feasibility of utilizing open loop aquifer exchange for the Penn South Neighborhood of Manhattan, New York City. This neighborhood energy system will serve over 6.5 million square feet (60,400m2) of heated and cooled space. Aquifer thermal energy storage (ATES) was originally considered as part of a larger thermal energy network (TEN) to provide high peak load capacities to meet extremes and to ameliorate saltwater intrusion. However, initial investigation produced serious concern that the shallow unconfined glacial till was not deep enough to avoid mixing oxygenated and anoxic waters. In particular, iron dissolved in anoxic water precipitates into iron oxide in oxygenated water. The Penn South neighborhood subsurface, however, does have favorable aquifers with high transmissivity for a properly designed open loop system. This study aims to build on the work done previously for the ATES model but focuses on the utilization potential of an open loop geothermal and its associated risks, challenges, and benefits in the heavily populated New York neighborhood.

A 3D geologic model was developed to represent the phreatic glacial aquifer formation, weathered bedrock, and other minor sedimentary formations in the area. The simulations were conducted using TOUGH2 (EOS1) and visualized in PetraSim. Injection and extraction rates and accompanying enthalpies were matched and calculated to a preliminary load profile of the surrounding residential and commercial buildings to ensure that the model was representative and accurate.

Some of the challenges with developing a geoexchange system of this magnitude include the depth to bedrock in the project area, management of the thermal plume, the presence of nearby dewatering wells, and building foundations that extend through the entirety of the target formation and into the bedrock. The depth to bedrock across the service area varies from about 20m to 92m. Since the thermal plume size is also a function of the screen length or thickness of the target formation, careful planning for well separation is necessary when storing the system's heat in the

subsurface of a dense urban area. While many recharge zones for the phreatic aquifer are cut off because of civil engineering practices, there is still some recharge from the higher elevations to the north and a large volume of water arises from fractured bedrock. Nearby dewatering wells are common for building basement areas, subways, and utility corridors.

As New York City continues to push towards the electrification of all building heating and cooling, groundwater as an energy resource must be prioritized. The heat capacity of groundwater or ground-source fluids is about 4 times that of air and should become the primary choice for policymakers, utility companies, and building managers in the energy transition. Administering groundwater as an energy resource at an urban scale requires careful study and engineering. The results of this study will help to quantify the potential for open aquifer exchange in the Penn South Neighborhood aquifers and inform the feasibility of implementing similar systems in other areas that target phreatic glacial aquifers in dense urban areas.

1. Introduction

Geothermal and geoexchange systems for heating and cooling are increasingly recognized as the most efficient decarbonization application for buildings. Building heating and cooling makes up in excess of 50% of community emissions in many locales throughout the world. This is also true of places like New York City where importation of fuel oil for building heating seasons causes a high concentration of emissions for the metro area.

The New York State Utility Thermal Energy Networks and Jobs Act of 2022 (UTENJA) continues to make a significant impact. While conventional gas and electric utilities are now proposing demonstration projects for geothermal and geoexchange district energy, other organizations are taking notice. To comply with Climate Mobilization Act, passed by the New York City Council in 2019, building portfolio managers are turning to engineering firms specializing in subsurface energy exploitation. One such building portfolio manager is Penn South, also known as Mutual Redevelopment Houses Incorporated.

Like all buildings, Penn South must decarbonize their heating and cooling, fed by a $7MW_e$ combined heat and power plant (CHP). To stop the combustion of fuels on-site, Penn South sponsored a community-based geoexchange district energy investigation. Neighboring building owners, including Amtrak's Penn Station, the State University of New York's Fashion Institute of Technology, Tishman Speyer's historic Morgan North Postal Facility, and community faith groups sent in supporting letters. With a groundswell of community engagement, grants became available from the New York State Energy Research and Development Authority. The contributions of the investigation led by Egg Geo LLC will provide lessons learned and guide future industry best practices for wide-scale building stock decarbonization in the challenging urban environment.

Challenges for the neighborhood geoexchange district energy system include space limitations, retrofit costs, equipment, capitalization policies, among others. Usually geothermal and geoexchange is touted as having smaller footprints than the typical power plant, for example. In Manhattan's dense urban setting, even the small drill rig footprint can be difficult to permit and deploy. Equipment in place varies widely across organizations involved. There are more than 30 structures and 6 million square feet of conditioned floorspace that would be affected by HVAC conversions. Some partner building operators face organizational capitalization policies that will

force them to use combustion equipment in place, even as the TEN becomes a connection option across the neighborhood.

1.1. Site Plan

Chelsea is a neighborhood on the West Side of Manhattan, New York City. The neighborhood's boundaries are roughly 30th Street to the north, Sixth Avenue to the east, 14th Street to the south, and the Hudson River/West Street to the west (Figure 1Figure 2Figure 3). Notable buildings in this area include Penn South (15 housing buildings), Amtrak Penn Station (1 building), Patrick Moynihan Train Hall (1 building), SUNY Fashion Institute of Technology (9 buildings), Tishman Speyer's Morgan North (1 building), Saint Eleftherios (1 building), Holy Apostles (3 buildings), among others.

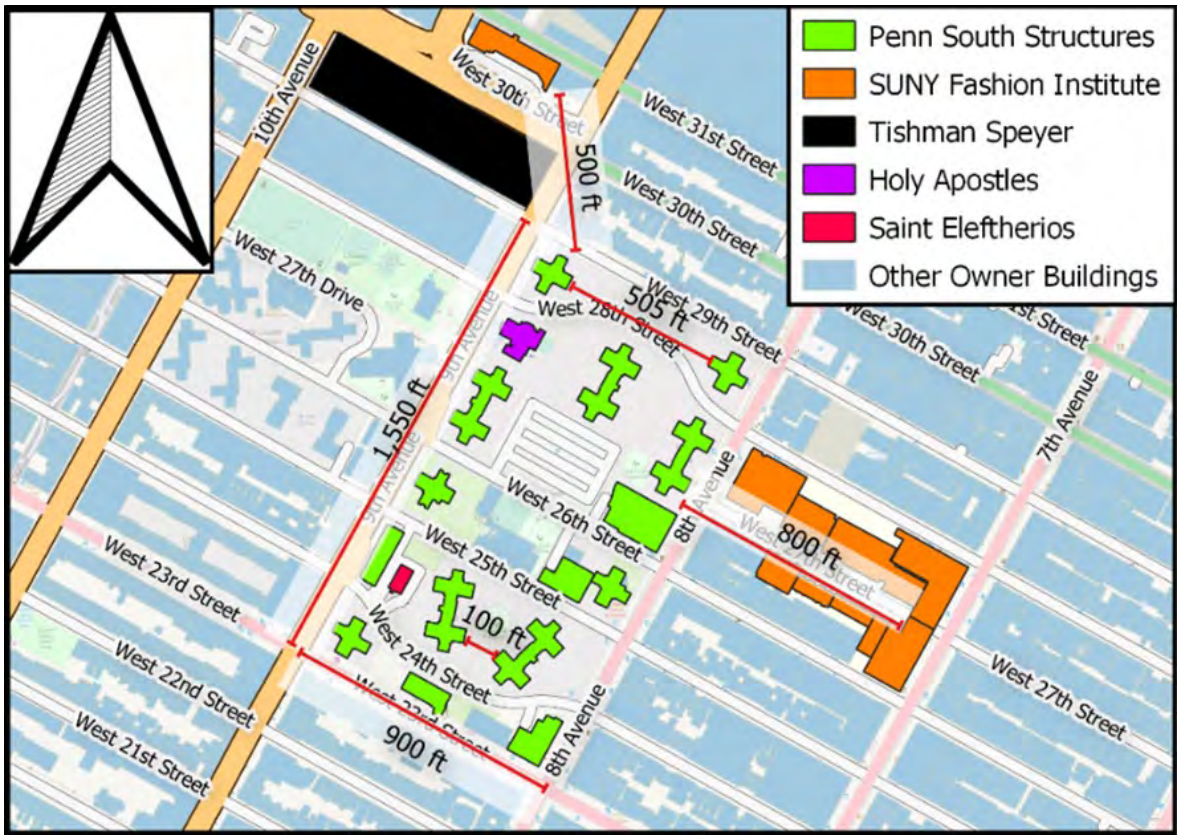

Figure 1: Site plan of the Chelsea neighborhood including the Penn South structures and other nearby buildings that are part of the study

Figure 2: Aerial view of the site obtained from Google Earth

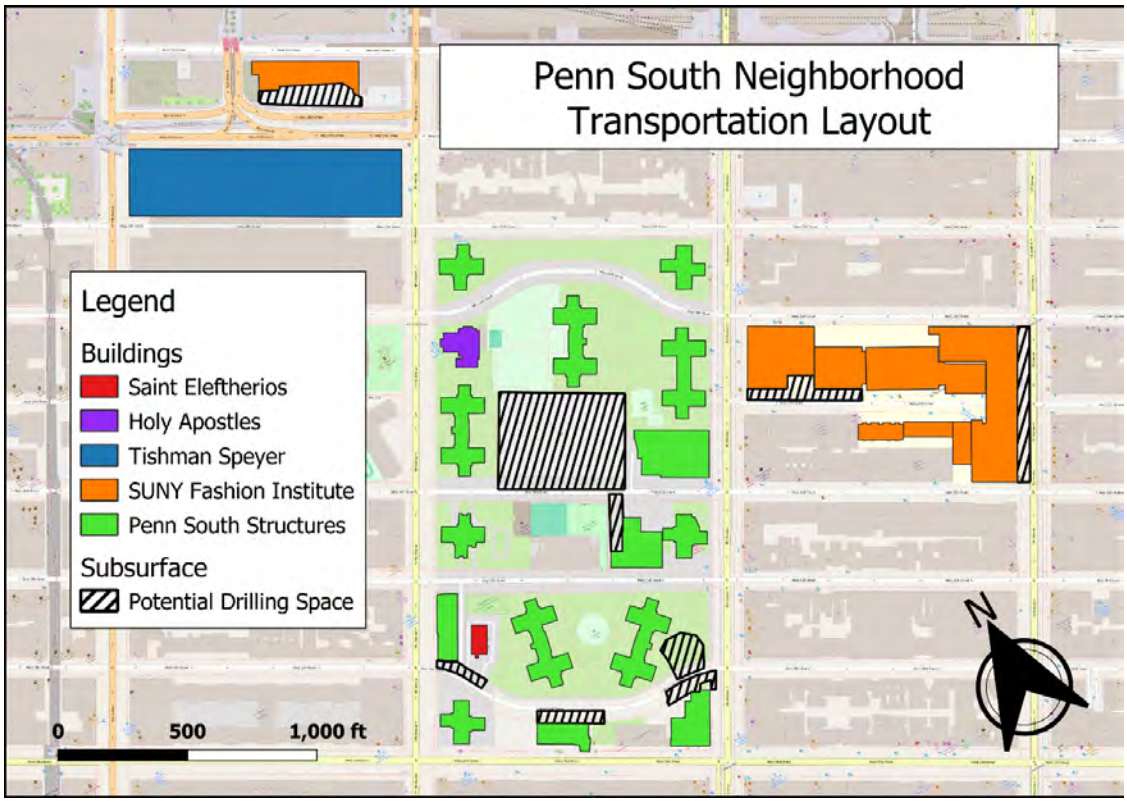

Figure 3: Site plan with the potential drilling space (~250,000 sq ft)

1.2. Open Loop Aquifer Exchange

An open loop doublet system consists of a series of supply and return (or injection) wells that draw ambient temperature groundwater from an aquifer for heat exchange in the building, then return the thermally-altered water back into the aquifer. Commercial doublet systems require high-producing aquifers, such as the glacial sand and gravel aquifer and bedrock aquifers beneath the project site. The water table around a pumping supply well is drawn down into the shape of a cone and mounds up around the return wells. The return groundwater is warmer than the ambient temperature during the summer, as heat is extracted from the building and transferred to the groundwater injected back into the ground. In the winter, the process is reversed; heat is extracted from the groundwater and transferred to the building for heating, so the return water is colder than the ambient temperature.

The supply wells should be located on the upgradient side of a site, relative to natural groundwater flow direction, and the return wells on the downgradient side. In this manner, the thermally-altered return water enters the natural groundwater flow and moves away from the project site. The return wells must also be separated from the supply wells such that their respective areas of influence do not overlap, i.e., the re-injected water is not drawn back into the supply well, a condition known as thermal “short circuiting”.

2. Methods

2.1. Geologic Modeling

The first step in estimating the available capacity of an open loop exchange system in the Penn South Neighborhood is to achieve a high level of detail on the geologic and hydrologic characteristics of the subsurface. The southern portion of Manhattan Island consists of unconsolidated glacial deposits ranging from just a few feet thick to more than 250 feet in some areas. These deposits host an aquifer system that is rich in quartz and has very low percentages of fine materials such as silts and clays. Aquifer tests indicate a wide range of aquifer hydraulic conductivity in the glacial deposits. The highest values were found on the western and northern sides of the island near the study area (Figure 4) with small, localized exceptions in stream channels to the north where bedrock outcrops are present. Values used in this analysis, derived from local well data is presented in Table 1 and Table 2.

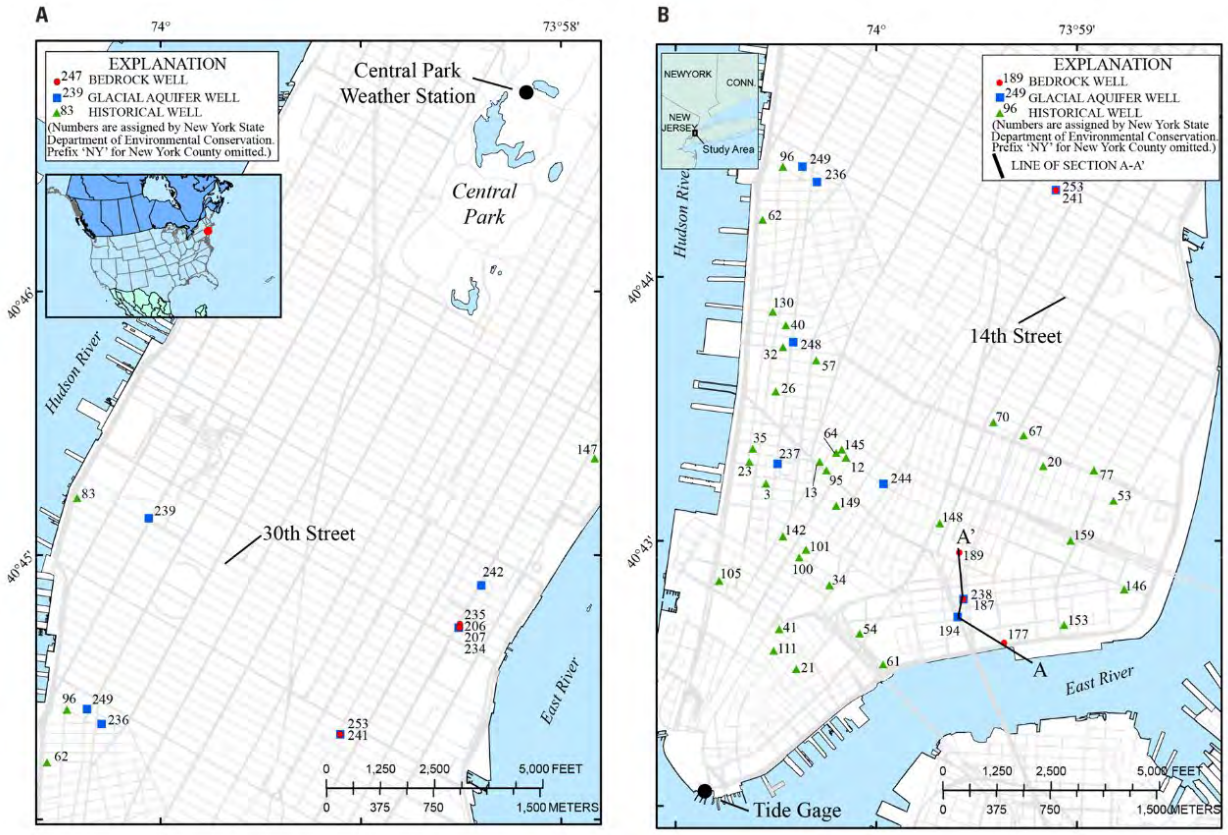

Figure 4: Wells surrounding the thermal energy network study area in Manhattan, New York City (Stumm & Como, 2017)

Table 2: Rock types used in the analysis and their hydrological values

Rock Type	Glacial Till	Bedrock
Density	2200 kg/m^2	2700 kg/m^2
Porosity	0.3	0.01
Permeability	1.5E^{-09}m^2	0 m^2
Wet Heat Conductivity	1.8 W/(m*K)	3.2 W/(m*K)
Specific Heat	1300 J/(kg*K)	740 J/(kg*K)

Across the project service area, the unconsolidated gravels are thickest on the Penn South Campus, where more open green space appears as potential urban drilling locations. The Penn South affordable housing community has a campus at the center of the study area with a length of 465m by 265m. The property constraints define the possible well locations of the open aquifer geothermal system.

Additional geologic data including surface land elevation, and depth to bedrock was gathered from the United States Geological Survey and the New York State Department of Environmental Conservation with the goal of producing an accurate geologic model that could be used to produce reliable numerical simulations to produce data on necessary well separation ("USGS Groundwater Data for the Nation," n.d.) ("Downloadable Well Data - NYSDEC," n.d.). TOUGH 2 (EOS1) was used as the modeling software for this analysis. TOUGH 2 is a numerical simulation program used for multi-dimensional, multiphase, and multicomponent fluid flow and heat transfer through porous and fractured media. Petrasim was the graphical user interface to visualize the simulations and results. The data described above was imported to PetraSim for model creation before the initialization of the numerical model. This data was interpolated and used to create geologic layers that represent the unconsolidated glacial deposits and bedrock across the entire length of Manhattan Island (Figure 5Figure 9). It was important to start with a geologic model for the entire region first to interpolate data on the Penn South site as there exists very limited data immediately surrounding the neighborhood.

Figure 5: The well data (red dots) displayed were imported into PetraSim and used to create a geologic model of the entire Manhattan Island

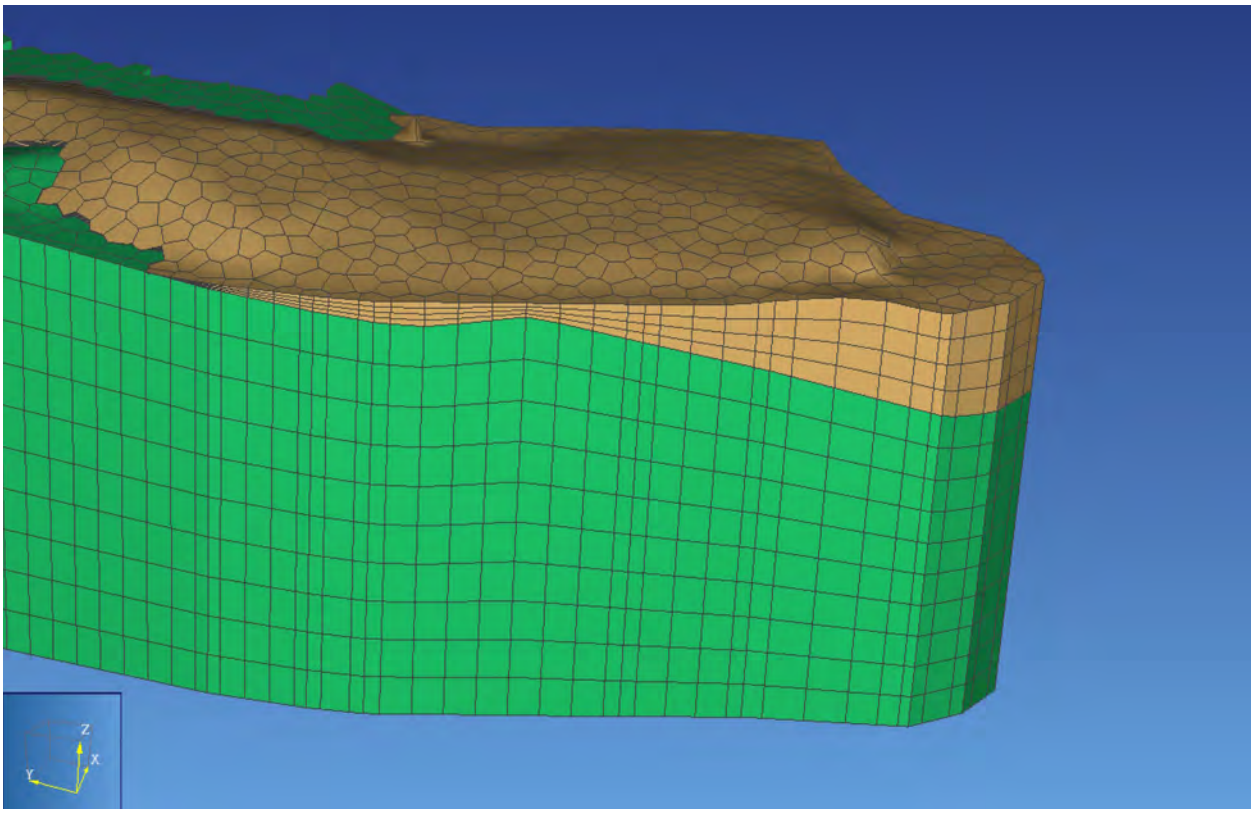

Figure 6: A sideview of the completed geologic model. Glacial till is represented by the tan cells and bedrock is represented by the green. Vertical distance (Z axis) has been exaggerated by 8x

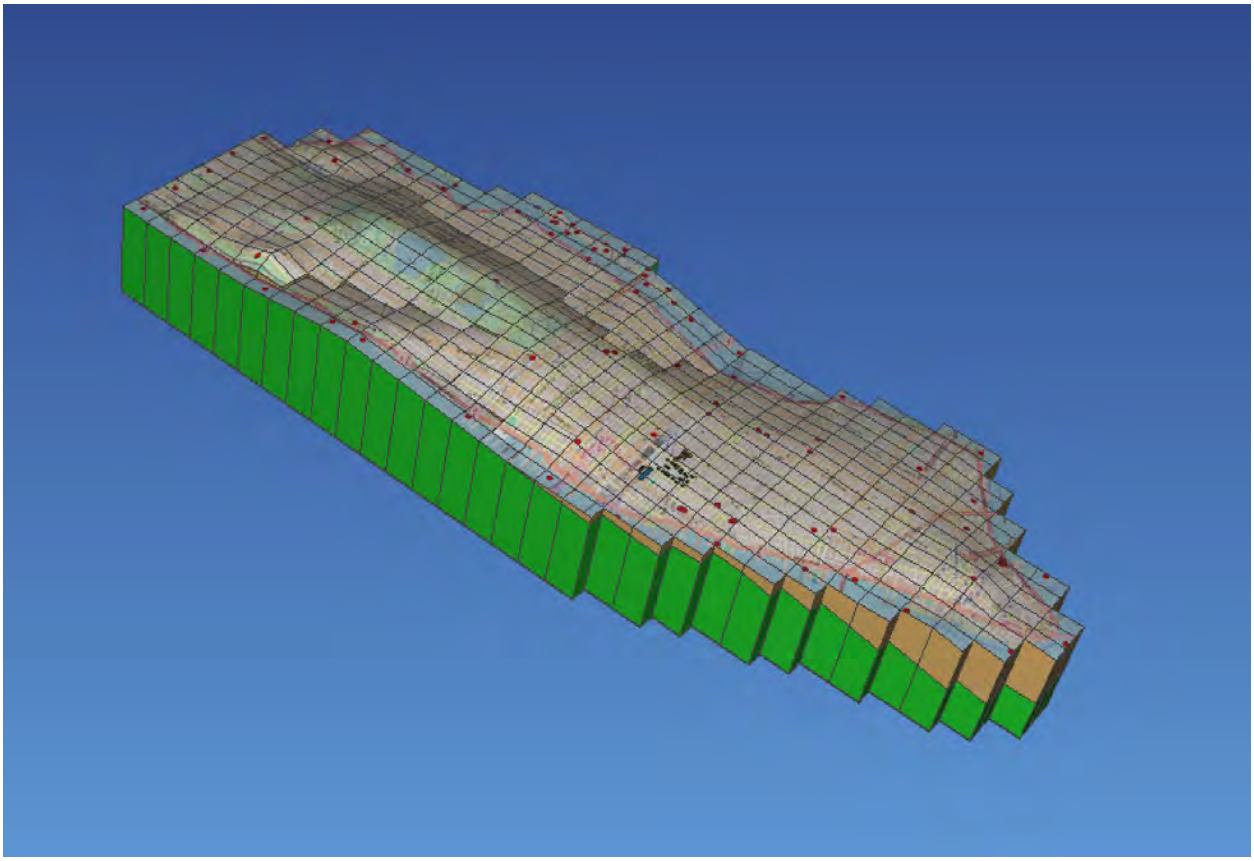

Figure 7: A screenshot of the Manhattan Island geologic model. The site is displayed as a small cluster of buildings on the western side of the peninsula

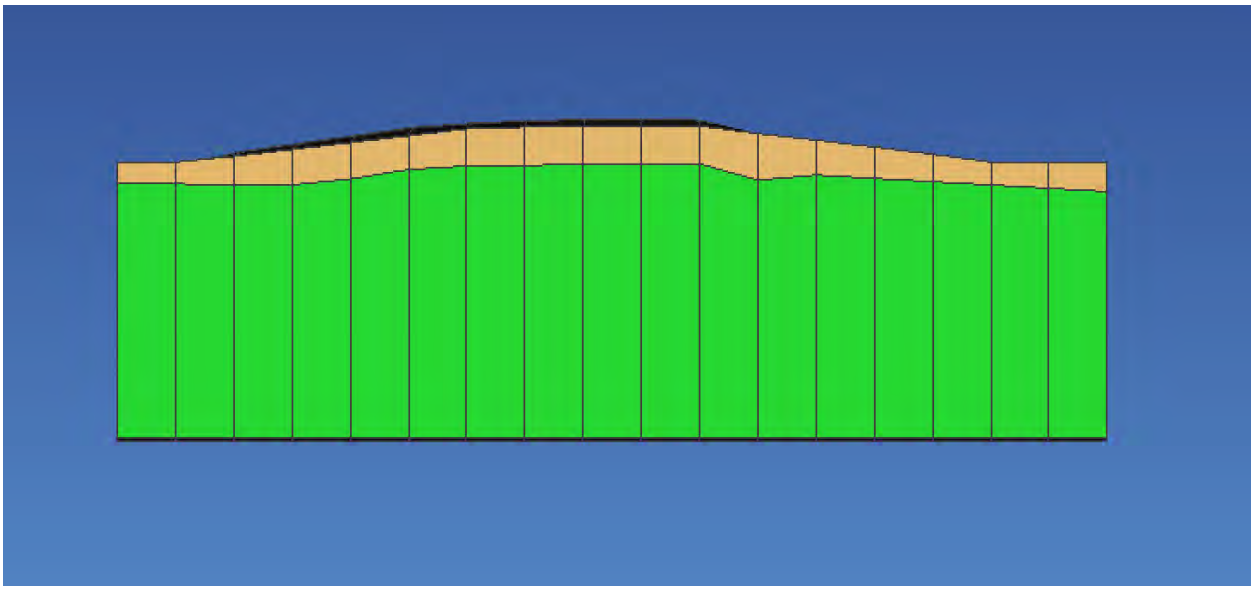

Figure 8: Cross section of the Manhattan Island geologic model from east to west through the Penn South site

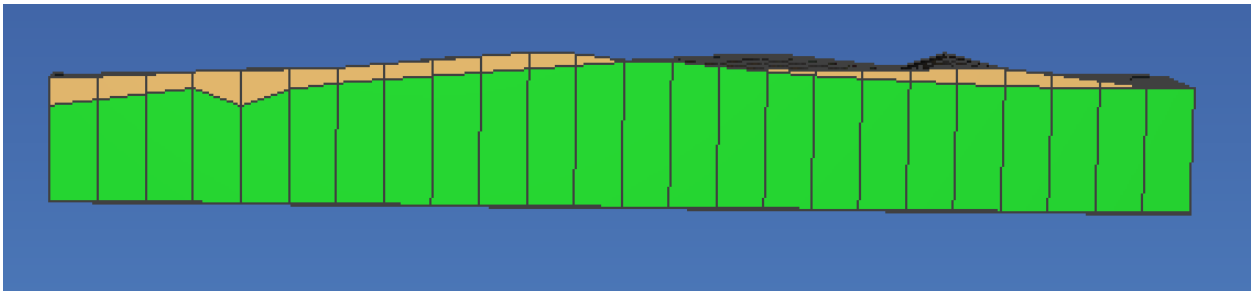

Figure 9: Cross section of the Manhattan Island geologic model from south to north through the Penn South site

The next step was to crop the model down to just the project site (Figure 10). This allows for a more detailed look at the geologic conditions directly beneath the project site. The glacial deposits overlay a bedrock with varying degrees of metamorphism, weathering, and composition. Schist, gneiss, and occasional marble make up the majority of the bedrock encountered under Manhattan Island. For simplicity we will refer to any rock beneath the glacial deposits as bedrock and assume an average permeability. Although some areas of bedrock have higher permeability due to metamorphism and heavy weathering, the majority is intact gneiss with very low permeability and conductivity compared to glacial deposits above.

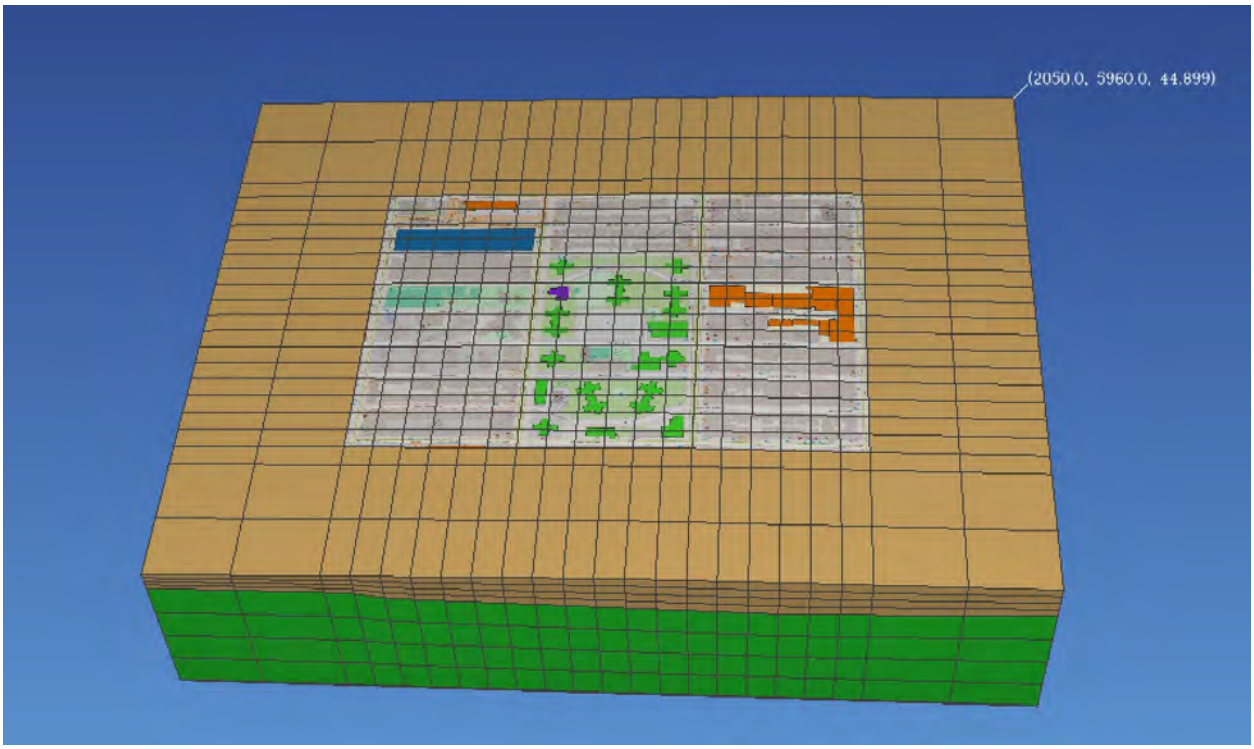

Figure 10: The geologic model of the Penn South site cropped down from the larger Manhattan Island model

Because the target aquifer is so shallow, many of the building foundations in the neighborhood extend at least halfway through the aquifer and some into the bedrock, creating an interesting element when modeling the flow of fluids through the glacial till during simulated production. Foundation depths for each of the neighborhood buildings were gathered and integrated into the

model using detailed region functions included in the Petrasim software (Figure 11). For simplicity, an average depth of 25 ft was assigned for the concrete foundations.

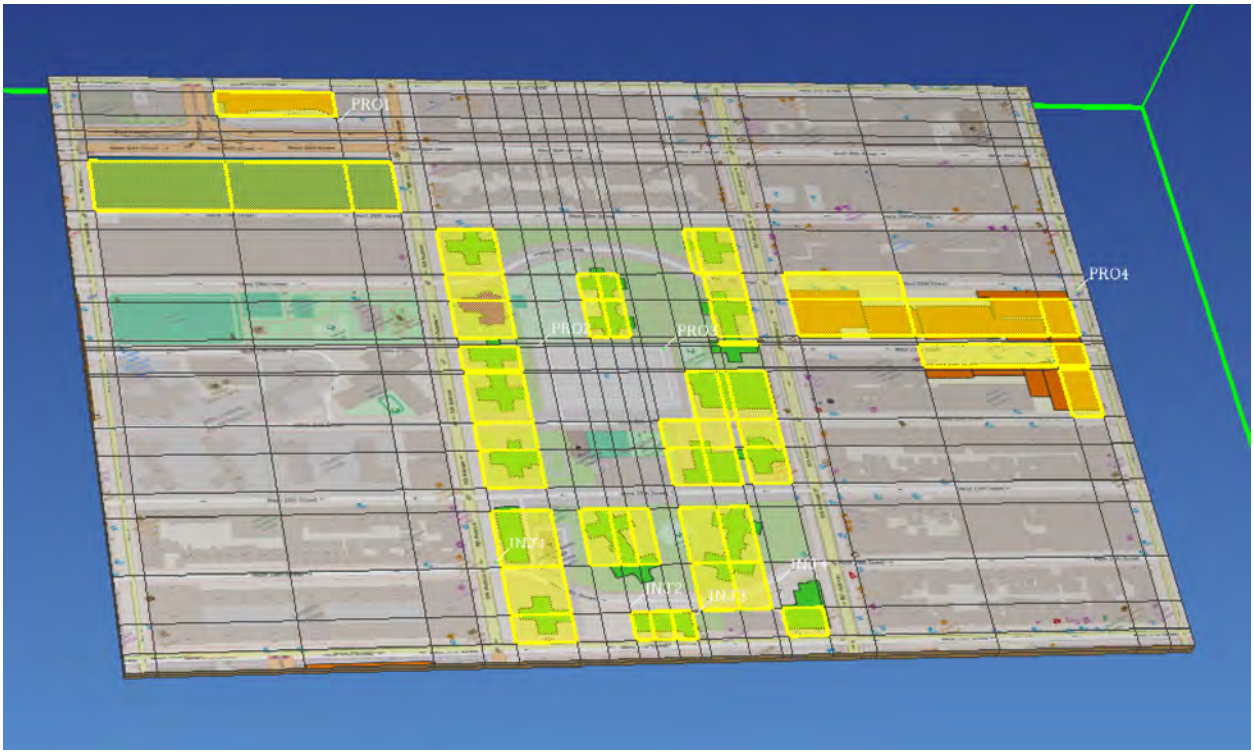

Figure 11: The cells highlighted in yellow were selected to represent the concrete foundations of the buildings. Each cell was selected and assigned to the concrete material down to 25 feet

These cells associated with building foundations are assigned the geologic characteristics below (Figure 12). The hydrological characteristics of concrete can be hard to estimate, especially if it has been buried under the water table for decades. Most concrete used for foundations has a porosity of under 10% but is usually considered impermeable if it has been poured recently (reference). However, the concrete's porosity/permeability values may increase over time due to erosion. These factors led to the decision to assign porosity/permeability values slightly higher than standard concrete, but still less permeable than the surrounding glacial till. Additionally, other values such as the specific heat and wet heat conductivity can vary widely depending on the type of concrete and its age/condition. These values were also chosen from an average (Skutnik et al., 2020).

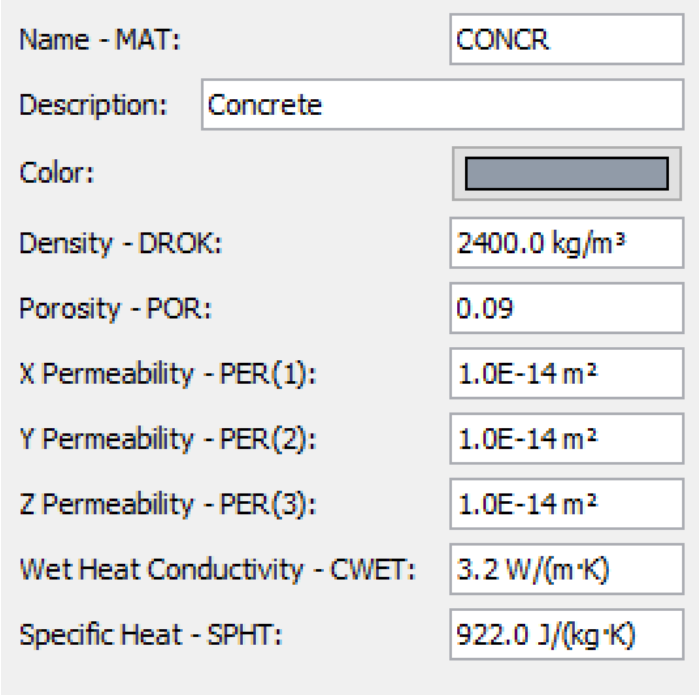

Figure 12: Geologic properties of the building foundations on site

2.2. Hydrologic Investigation

Next, local well data was analyzed to assist in determining the highest possible yield from the formations beneath the project site. This task proved to be difficult, and a test well will be required to obtain reliable numbers. Although there are dozens of wells in the area producing from the glacial aquifer, no production data could be obtained because they are privately owned. Despite this, a preliminary study of the glacial aquifers in the area was conducted. A report prepared by the Geological Survey titled "Properties of Aquifers on Long Island, New York" published estimated aquifer yields for a variety of glacial aquifers nearby the project site. These values varied greatly (between 25 and 300 gpm) due to varying rock characteristics (thickness of glacial till, clay and silt content, formation permeability etc) (McCymonds & Franke, 1972). To gain a better understanding of the possible yields at the project site, a very similar aquifer on Shelter Island of Suffolk County was studied (Soren, 1978). The glacial till in this area has very similar characteristics to that of Manhattan Island and the average thickness of the formation is very similar to the site as well (~50ft) (Figure 13). Measured water extraction from this aquifer average around 130 gal/min, but the report also states that the "highest possible yields and specific capacities were not obtained". The same publication also suggests that the highest yields in the area could be hundreds of gal/min higher than those recorded. Additionally, other aquifers with similar characteristics across Minnesota (Zhang, n.d.) have sustainable aquifer yields between 1,000 and 2,000 GPM. With this research in mind, two scenarios were considered in the sensitivity analysis – one that assumes a maximum yield of 300 gal/min and one of 600 gal/min as the best-case scenario. Sustainable yield rates on site will need to be determined by a test well and pump test.

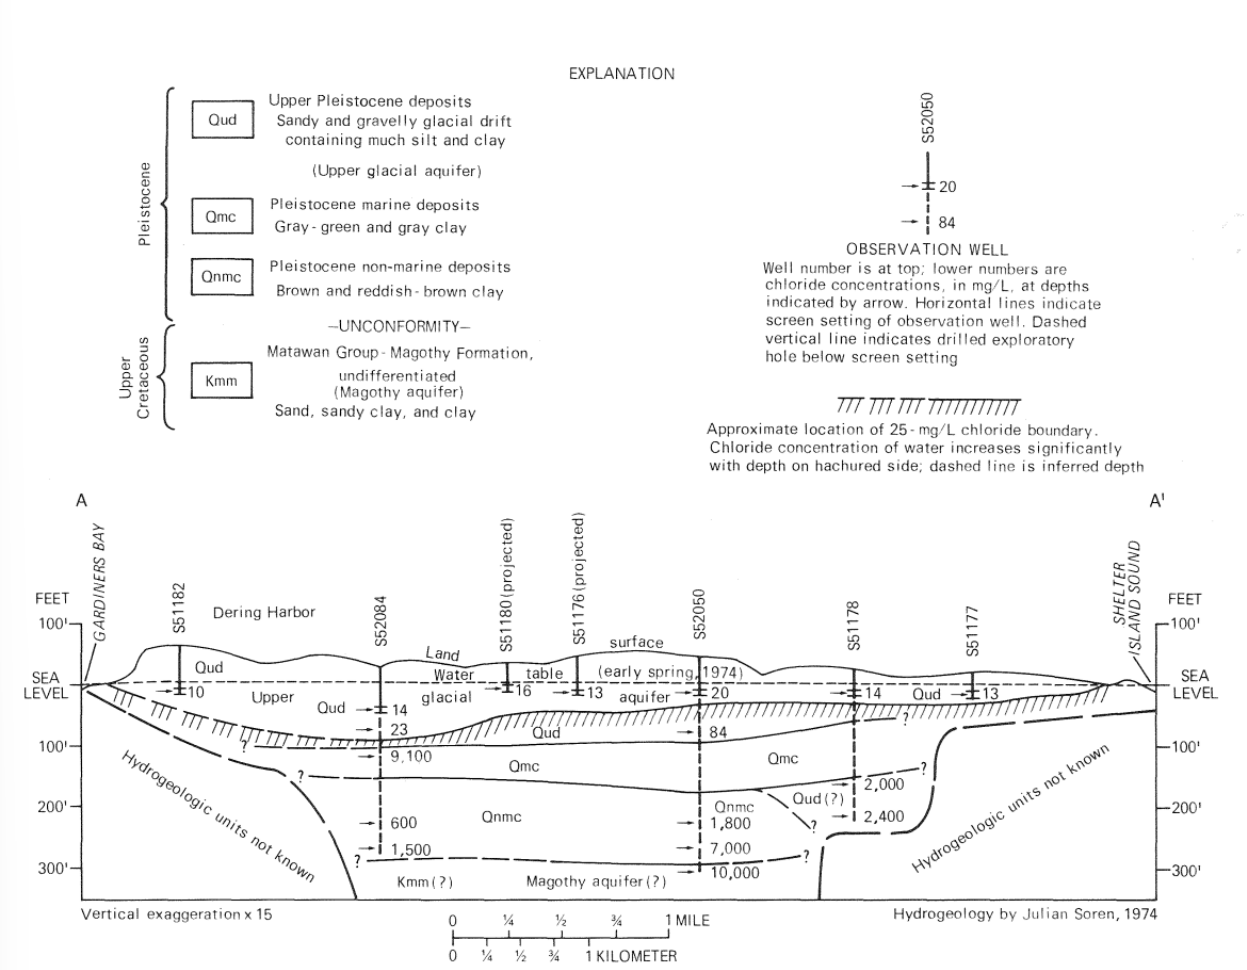

Figure 13: Geologic vertical slice of Shelter Island in Suffolk County (Soren, 1978)

2.3. Advective Flow Modeling

To accurately model the effects of an open loop geothermal configuration, the advective flow under the project site must first be understood and modeled. On Manhattan Island, the majority of the recharge zones are north of the site. From here, the flow of the subsurface water follows the topography of the island (NNE to SSW). There is a small ridge that runs down the center of the island that also contributes to the flow by forcing much of the water to either the east or west coasts to either the Hudson River or the East River (Figure 14). For the Penn south project site, this means that the flow will run slightly diagonally from the north boundary of the site to the south boundary (Figure 15).

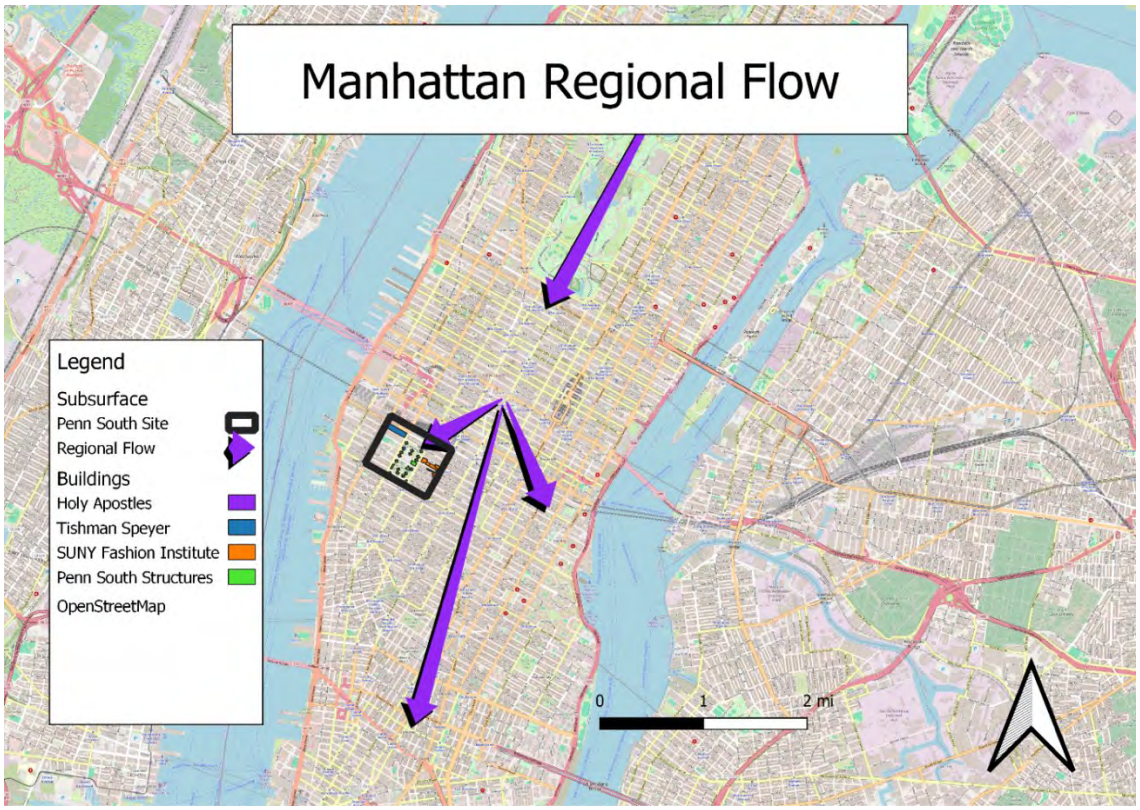

Figure 14: General regional flow of groundwater on Manhattan Island and across the site

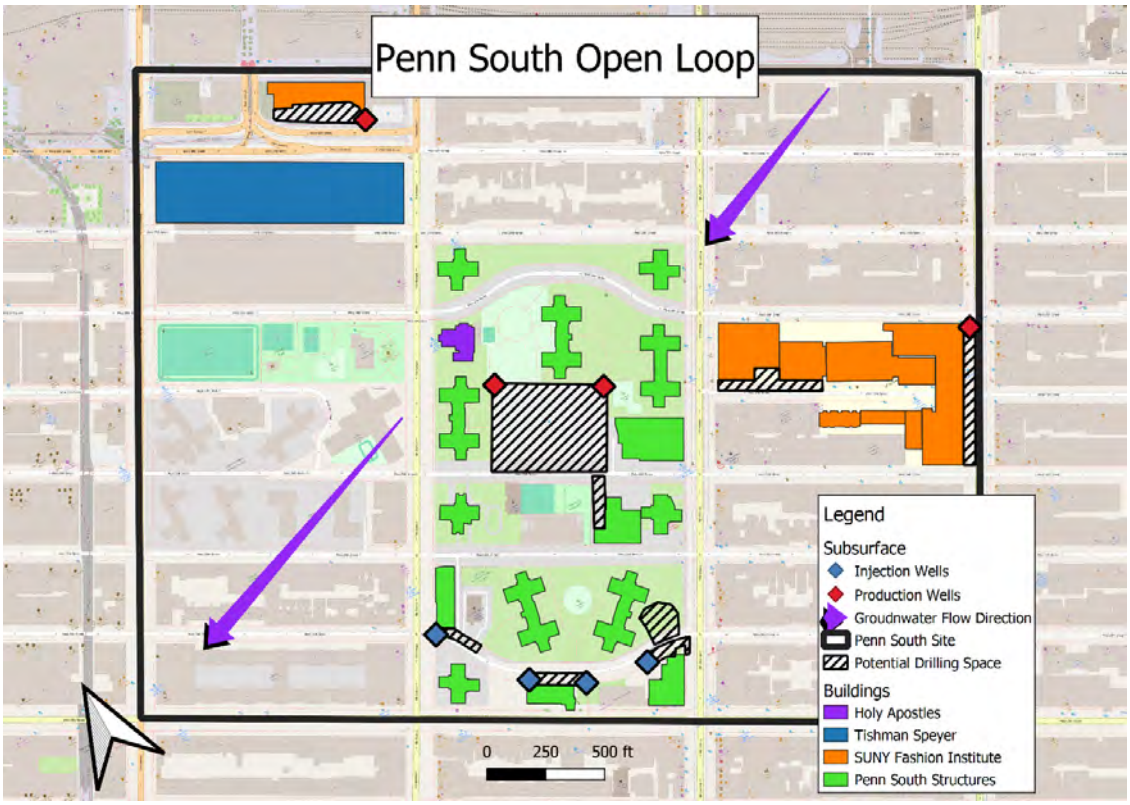

Figure 15: Regional flow across the Penn South site

To model the advective flow in PetraSim, a technique was used that requires multiple save files that build on top of each other. First, the depth to water was obtained for the north and south sides of the site. Using some simple math, the pressures at the bottom of the glacial till were estimated for each side (Table 3). To obtain pressure values for the rest of the depths on the north and south sides, all the cells but those immediately bordering the north and south sides were disabled, the pressure at the bottom of the glacial till was set to a fixed state, and the model was allowed to run for 1000 years. This produced an accurate prediction of the pressure at all depths of the model boundaries (Figure 16).

Table 3: Pressures at each side of the model used to drive the regional groundwater flow (high to low)

Depth to Water (ft)	
North Elev	31
South Elev	24
North Water Elev	24
South Water Elev	3.8
North Depth to Water	7
South Depth to Water	20.2
Average Depth to Water	13.6
Average Depth to Bedrock	50

Pressure at Depth (Pa)	
North Pressure @ 50ft	128573.784
South Pressure @ 50 ft	89104.6224

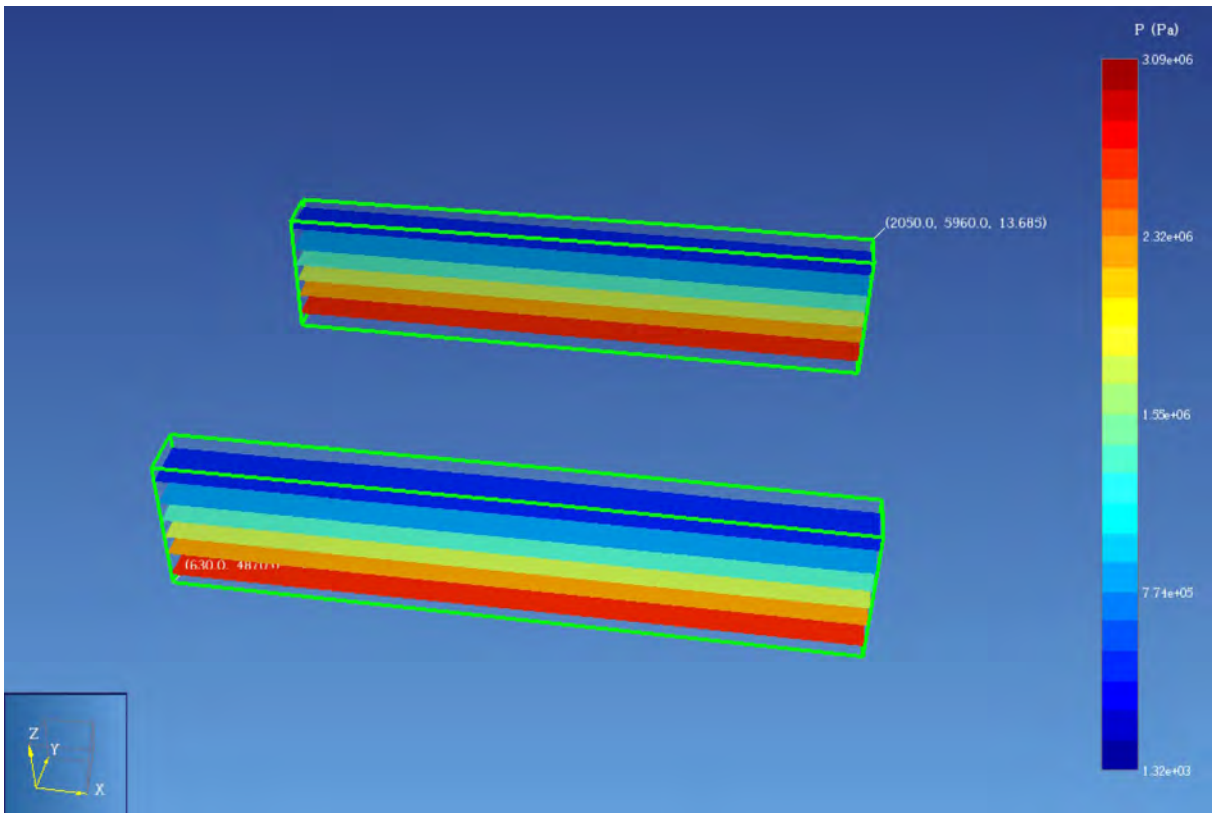

Figure 16: Pressure (Pa) displayed in the cells on the north and south edges of the site model after the 1000-year simulation

Next, the north and south boundary cells at all depths were set to a fixed state with infinite volume to simulate the extent of the subsurface north and south of the site. The disabled cells between the two zones of differing pressure were enabled, and the model was again allowed to run for 1000 years to obtain equilibrium between the two zones (Figure 17). The result is an accurate model of the advective flow beneath the project site (Figure 18). This process is called natural state modeling, and the output will be used as a base to run production scenarios on top of the simulated advective flow.

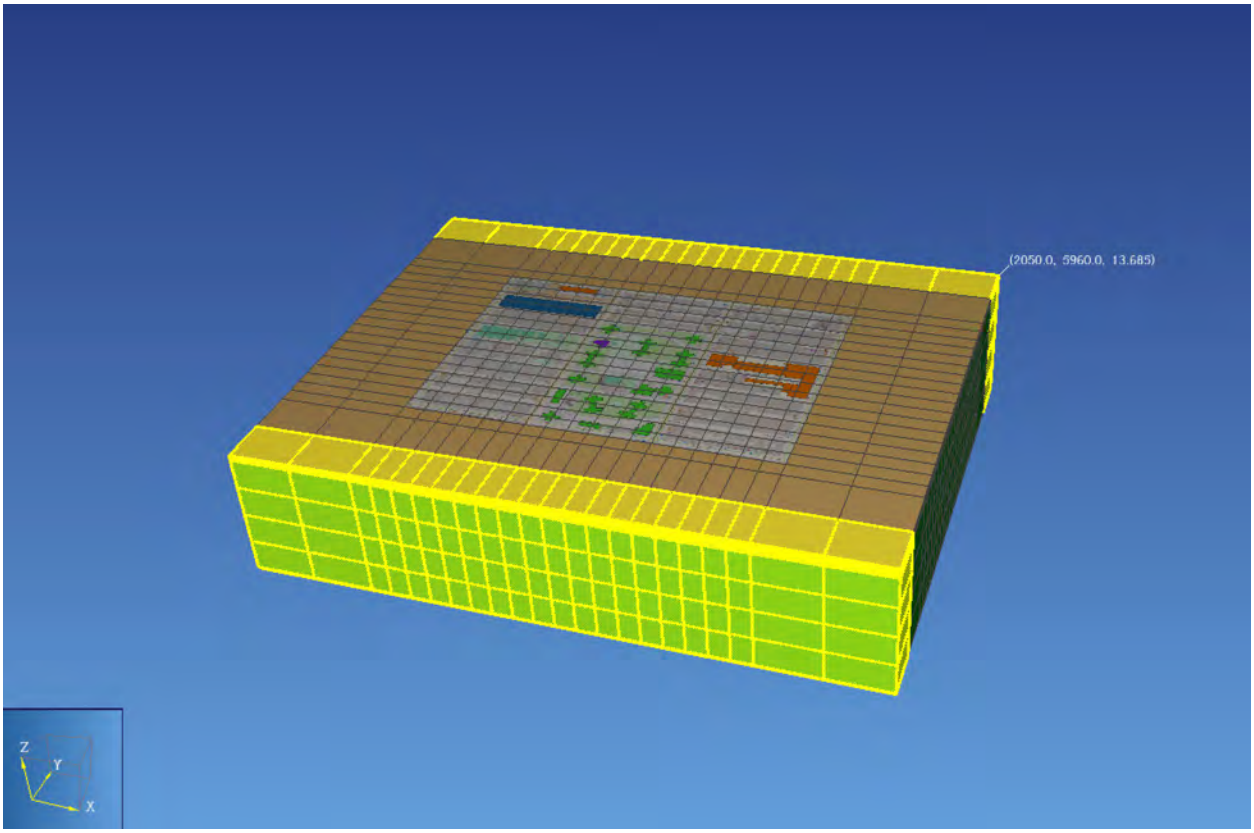

Figure 17: A screenshot of the site model before the natural state (advective flow) modeling. The cells highlighted in yellow with their varying pressures were set to a fixed state

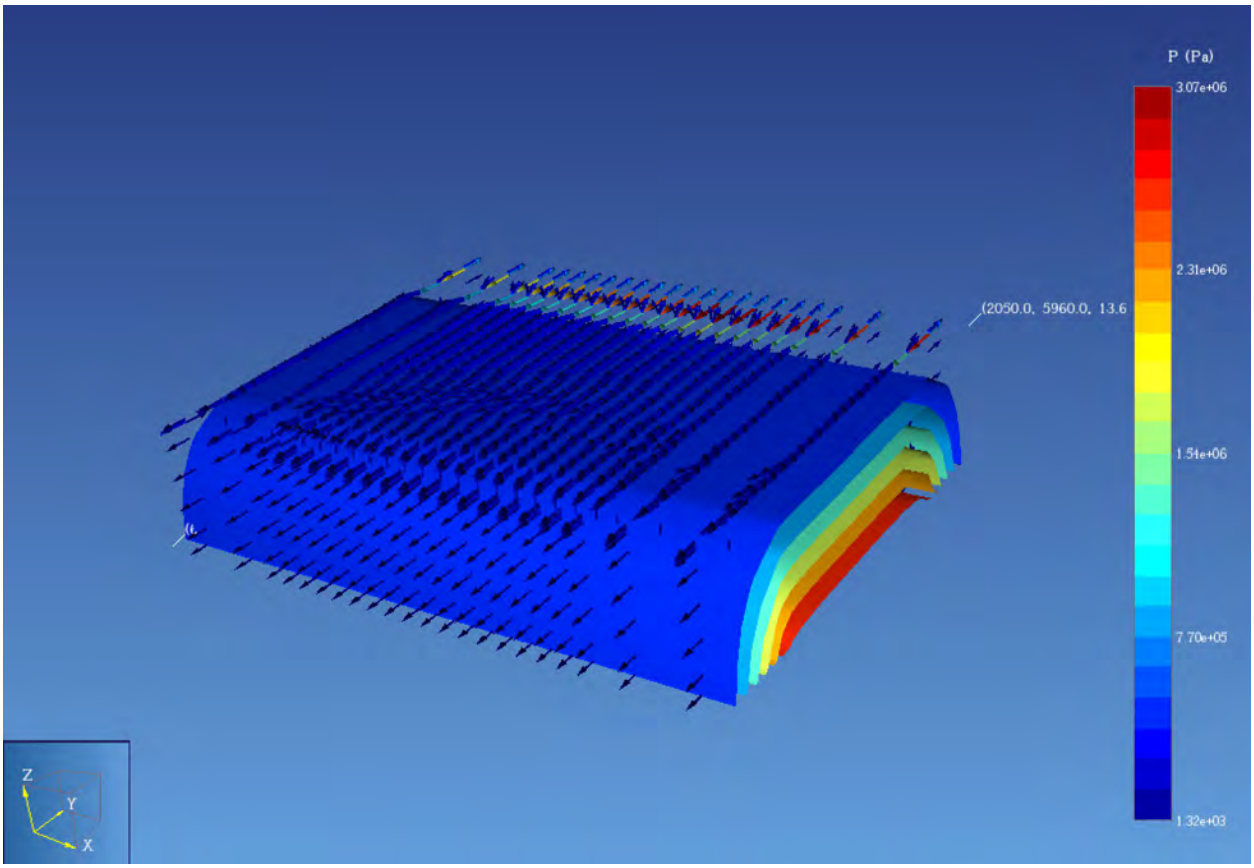

Figure 18: Pressure (Pa) displayed across the site model and vectors indicating the groundwater flow across the site

2.4. Simulations

Two scenarios (A and B) were considered to simulate the thermal performance of a doublet system at this project site and to inform on well spacing. As noted previously, two pumping flow rates were simulated, one low (300 gpm) and one high case (600 gpm). An additional two scenarios (C and D) were also simulated with the building foundations included for each flow rate to compare the reach of the thermal plumes. All four scenarios simulated the baseline condition of ~seven months of cooling (5170 hours) alternating with ~five months of heating (3590 hours), which would be the anticipated case for buildings in this geographic region. Additionally, for all four scenarios, the heating and cooling system is anticipated to run on a 12F delta T for heating months and 18F delta T for cooling months. Because the groundwater is projected to be about 52F, it is estimated that 40F water will be injected during heating months and 70F water will be injected in the cooling months. Each of the four production simulations ran for 25 years (Table 4).

Industry norms generally require at least 1000 ft of separation between injection and production wells, and at least 200 ft between wells of the same likeness. At first glance, and considering these industry norms, four production well locations and four injection well locations were chosen. More specific well locations and varying layouts will be explored in future studies, but it suffices the scope of this study to gain a better understanding of potential well yield, necessary separation estimates, the effect of building foundations, and an estimated load to be met by an open loop

configuration in this neighborhood. The example well layout used for this experiment is displayed in Figure 19.

Table 4: Modeled Scenarios

	Flow Rate / Well (GPM)	Total Flow Rate (GPM)	Foundations Included (Y/N)
Scenario A	300	1200	N
Scenario B	600	2400	N
Scenario C	300	1200	Y
Scenario D	600	2400	Y

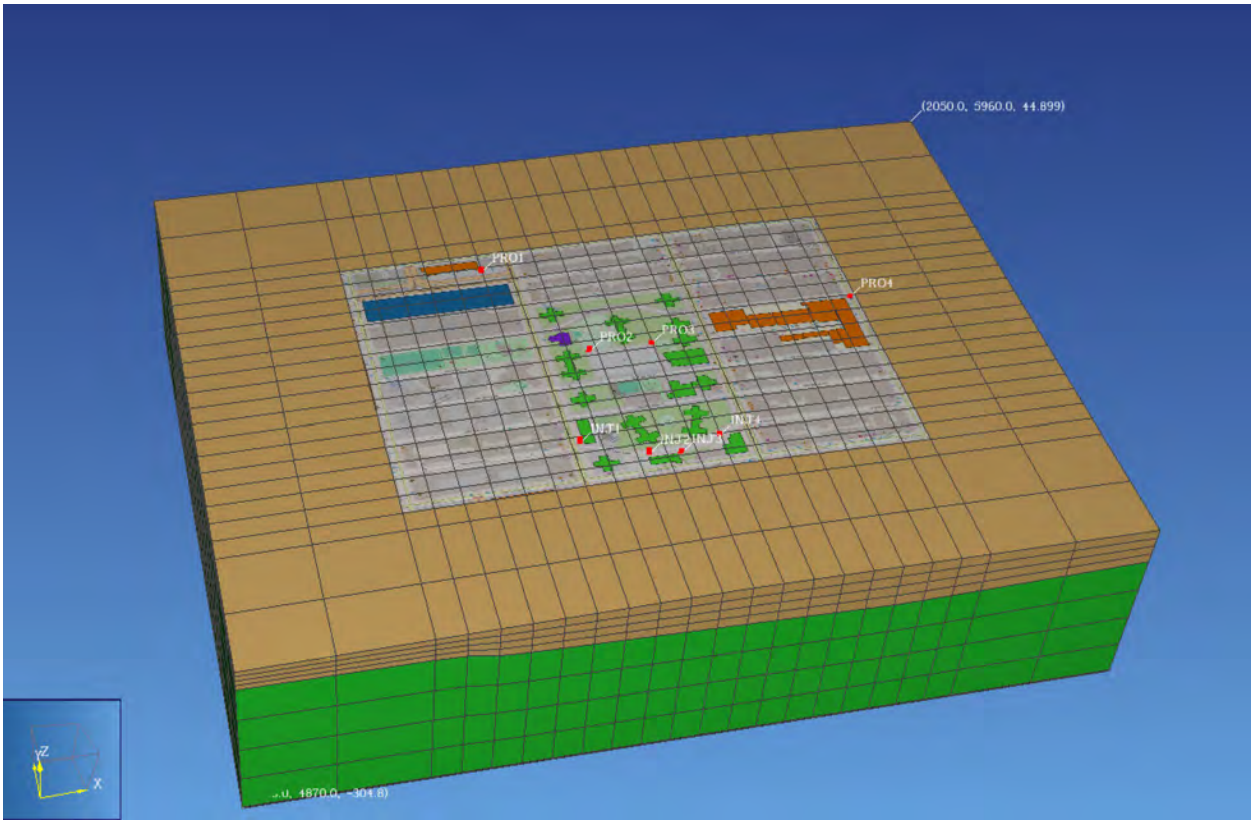

Figure 19: Well locations for the simulations. The 4 wells to the north (PRO1-4) extract water from the formation and the 4 to the south (INJ1-4) inject water after it has been used for heat exchange

3. Results

The results for each scenario are displayed and discussed below. To help visualize the flow of heat and fluid (groundwater) through the aquifer, three screenshots were used to display the results after 25 years of operation for each scenario. The first figure presents temperature as isosurfaces across the site and displays the injection and production wells. A horizontal slice at a depth of 45’ is also included. This depth was chosen because it is the average middle depth of the open hole sections of all 8 wells. It represents the most likely depth for thermal short-circuiting to occur (Figure 20). Additionally, a temperature log across 25 years for production well 2 and 3 has been included. These two wells were chosen because they are the closest geographically to the injection wells and most likely to be influenced by the plume from the injection wells. Because the well temperatures

for the scenarios with and without foundations included did not change, well temperature screenshots were not included for scenarios C and D.

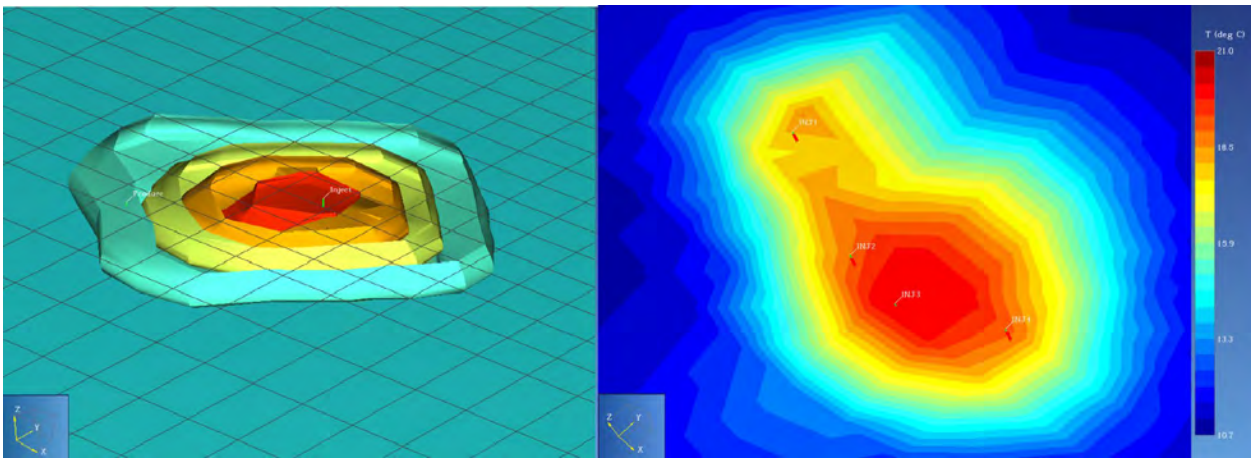

Figure 20: Example results displaying the temperature isosurfaces in the narrative to visualize the most important output from an otherwise large and complex 3-dimensional model (Left).). An example result of a horizontal slice is also included (Right) Temperature in Fahrenheit across 25 years is also computed at the production wells and plotted below (not pictured here).

3.1. Scenario A

This scenario simulated 300 gpm per well or 1200 total gpm for 25 years under the alternating seasons of heating and cooling cycle described above. Advective flow was considered in this scenario using the natural state modeling described above. The output (SAVE) file from the natural state modeling was used as the initial conditions file (INCON) for the following production scenarios. The aquifer displayed no hydraulic stress in yielding this rate. Additionally, after 25 years, the temperature at the production wells increased by less than 0.01F. This shows virtually zero thermal short-circuiting and no thermal saturation despite a heating dominant load profile.

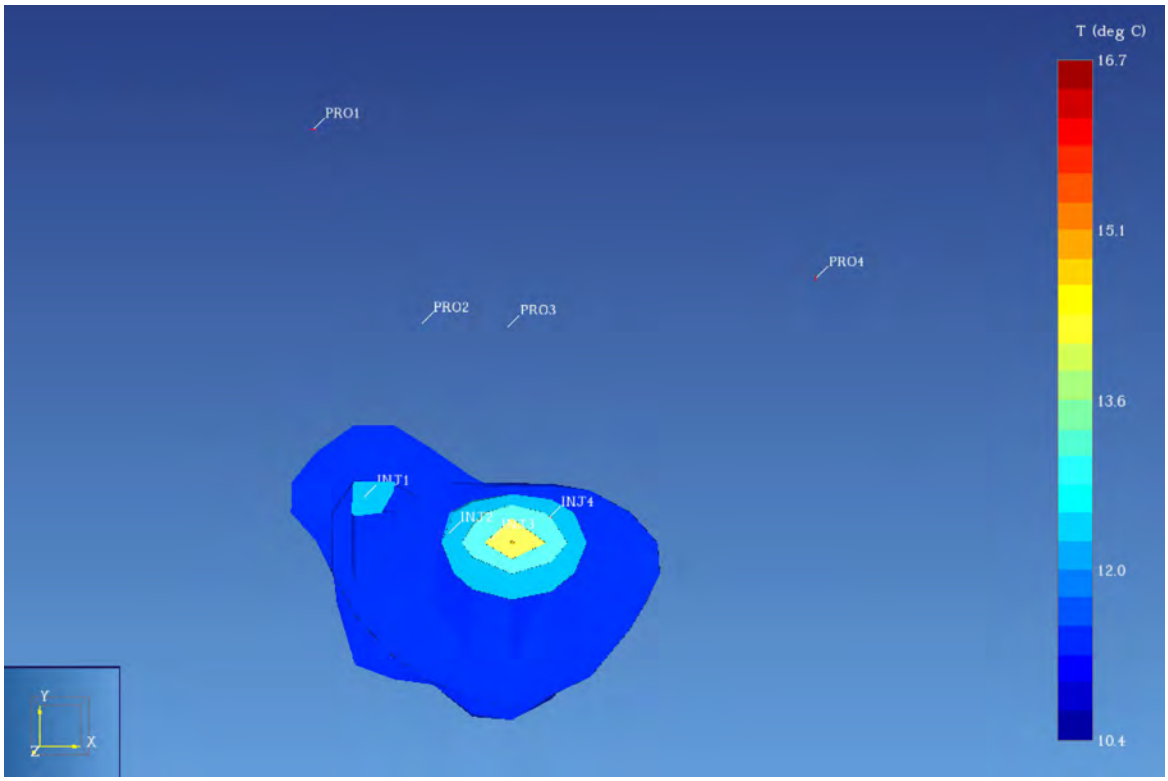

Figure 21: Scenario A - Temperature isosurface results after 25 years of pumping at 300 gpm

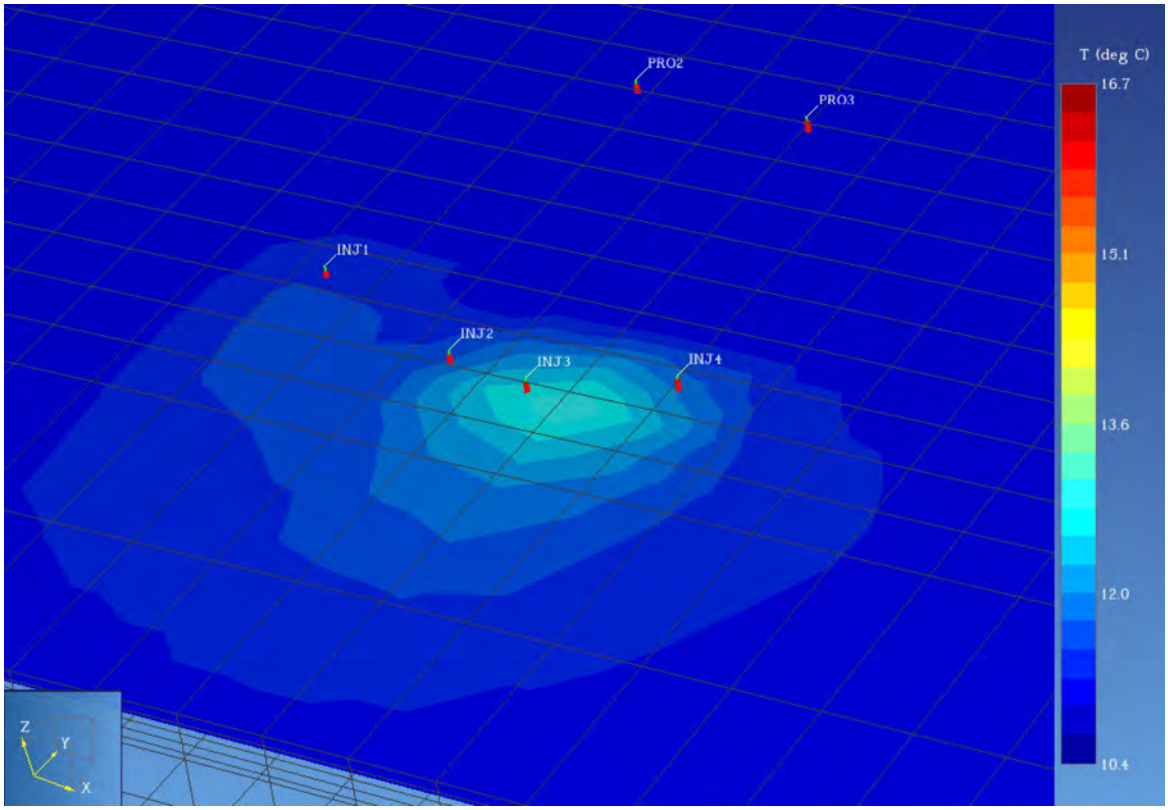

Figure 22: Scenario A - Horizontal temperature slice at 45' below surface after 25 years of pumping at 300 gpm

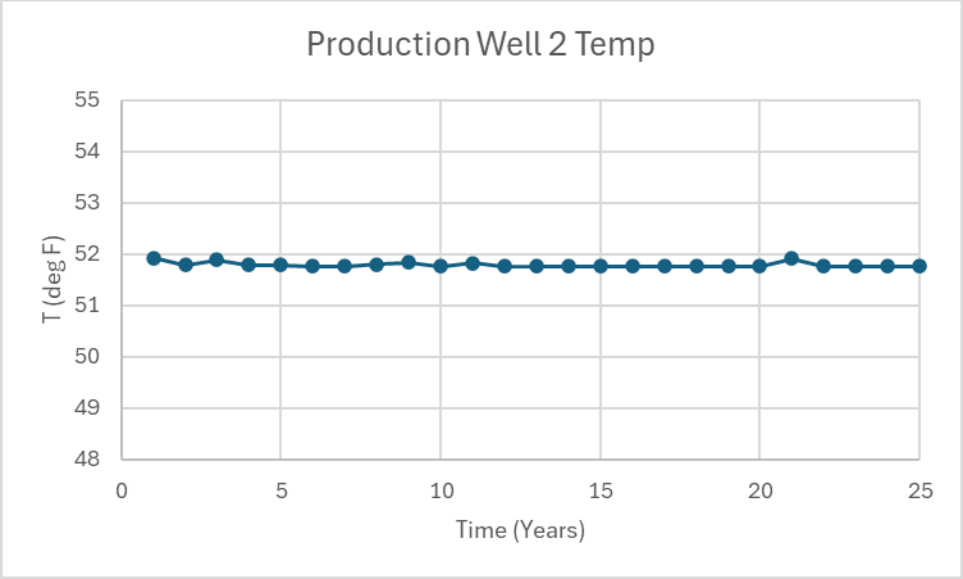

Figure 23: Scenario A - Temperature results at production well 2 plotted across 25 years of pumping at 300 gpm

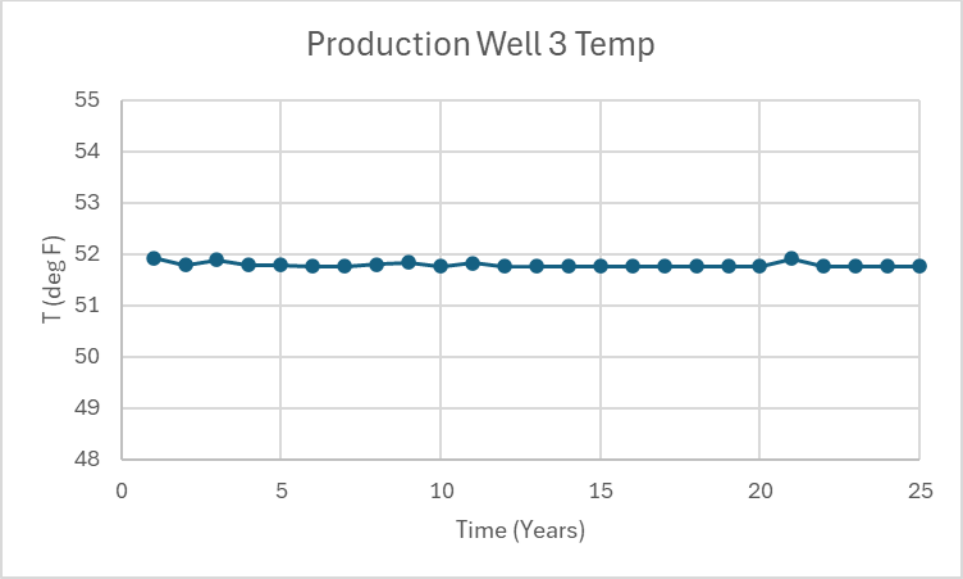

Figure 24: Scenario A - Temperature results at production well 2 plotted across 25 years of pumping at 300 gpm

3.2. Scenario B

This scenario simulated 600 gpm per well or 2400 total gpm for 25 years under the alternating seven months of heating and five months of cooling cycle described above. Advective flow was considered in this scenario using the natural state modeling described above. The aquifer displayed no hydraulic stress in yielding this rate. Additionally, after 25 years, the temperature at the production wells increased by less than 0.01F. This shows minimal thermal short-circuiting and no thermal saturation despite a heating dominant load profile. Despite the increased production, there was little change in temperature at the production wells. This is likely due to the advective flow that flushes thermally altered injection fluid away from the site. This result indicates that the

limiting factor for this system will likely be the aquifers ability to sustainably yield water, not the constrictions of the site boundaries.

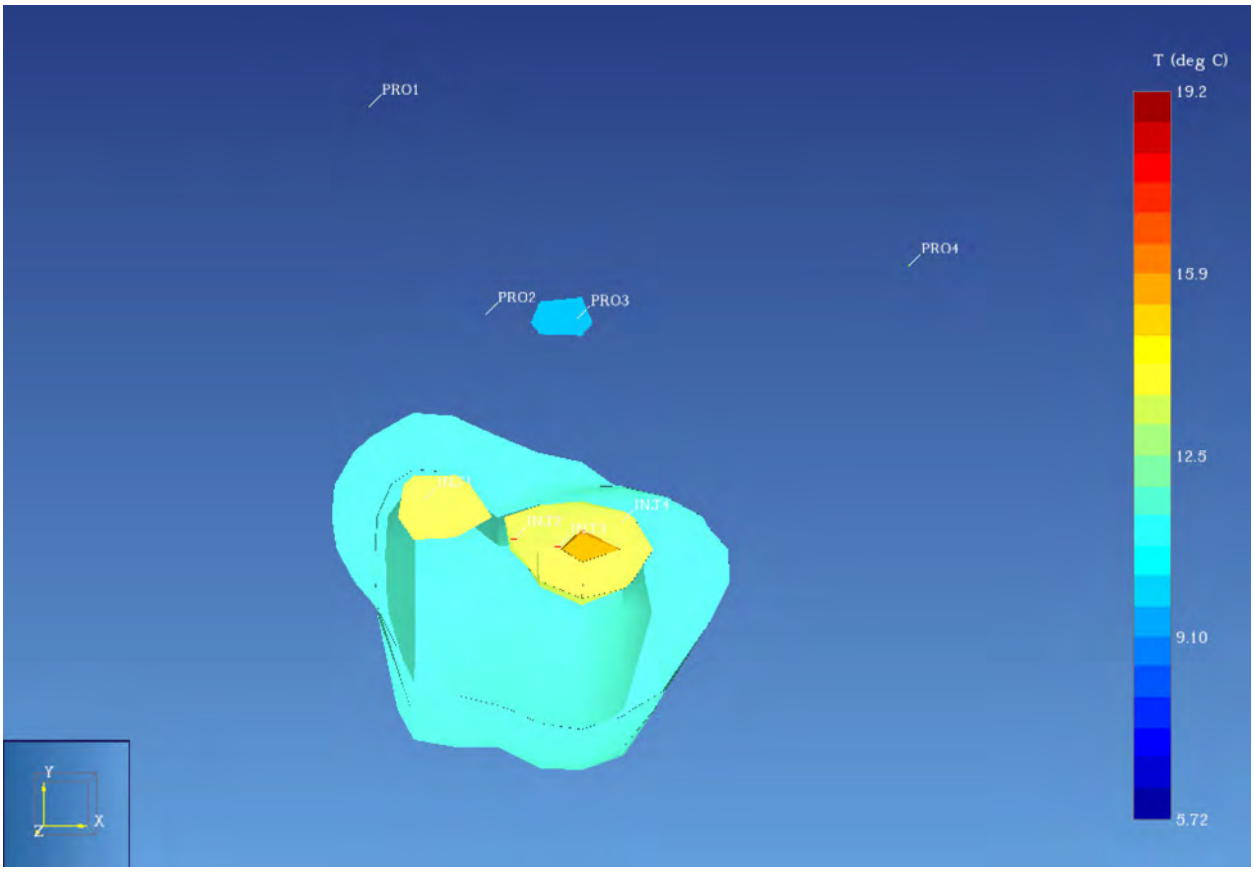

Figure 25: Scenario B - Temperature isosurface results after 25 years of pumping at 600 gpm

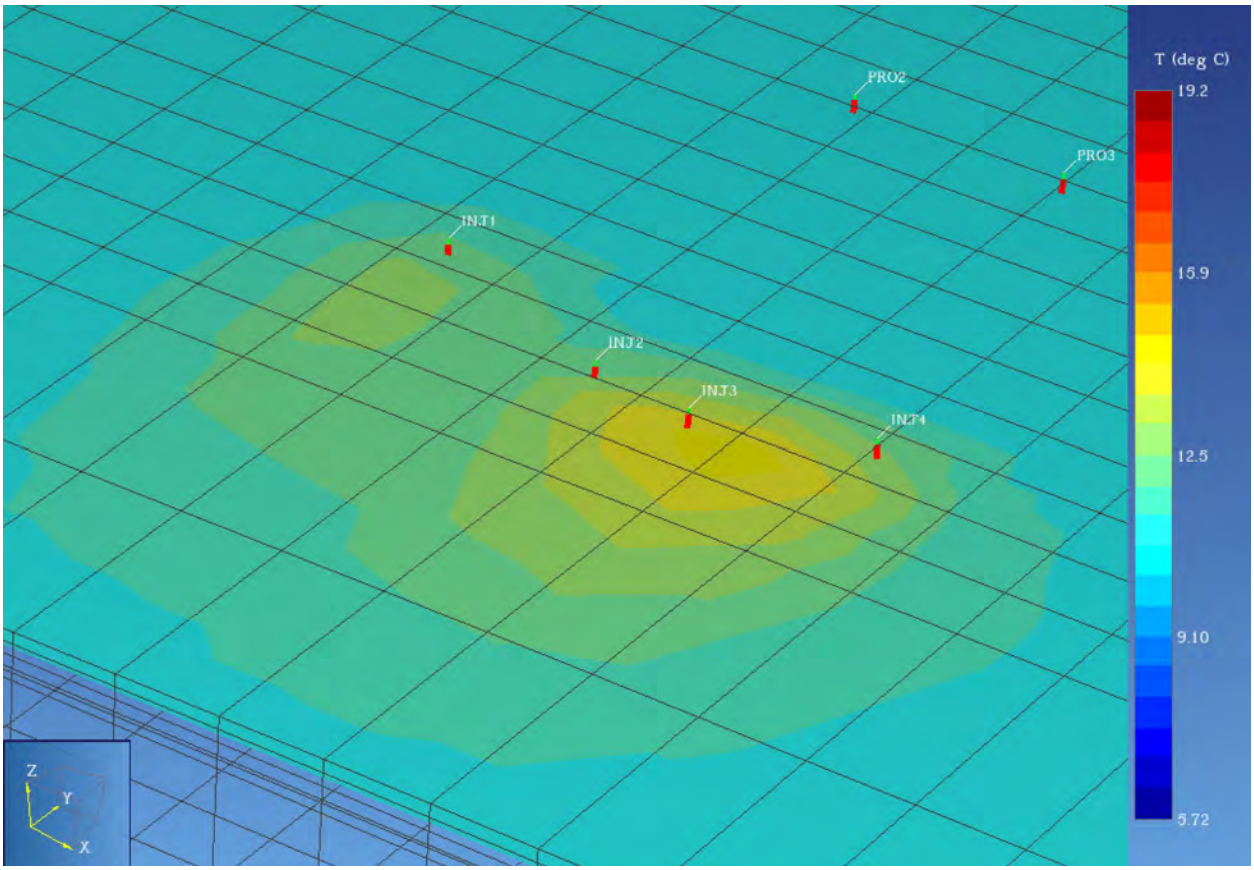

Figure 26: Scenario B - Horizontal temperature slice at 45' below surface after 25 years of pumping at 600 gpm

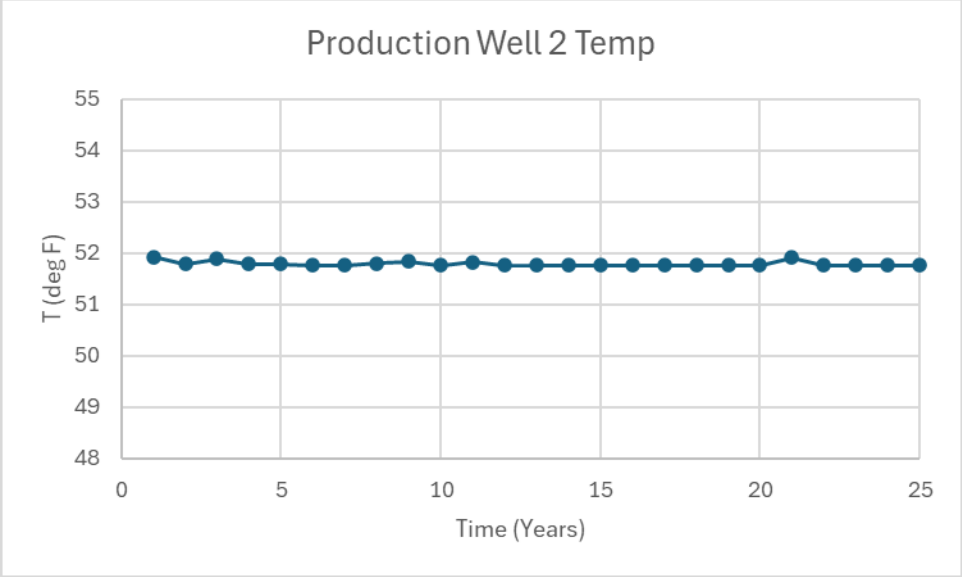

Figure 27: Scenario B - Temperature results at production well 2 plotted across 25 years of pumping at 600 gpm

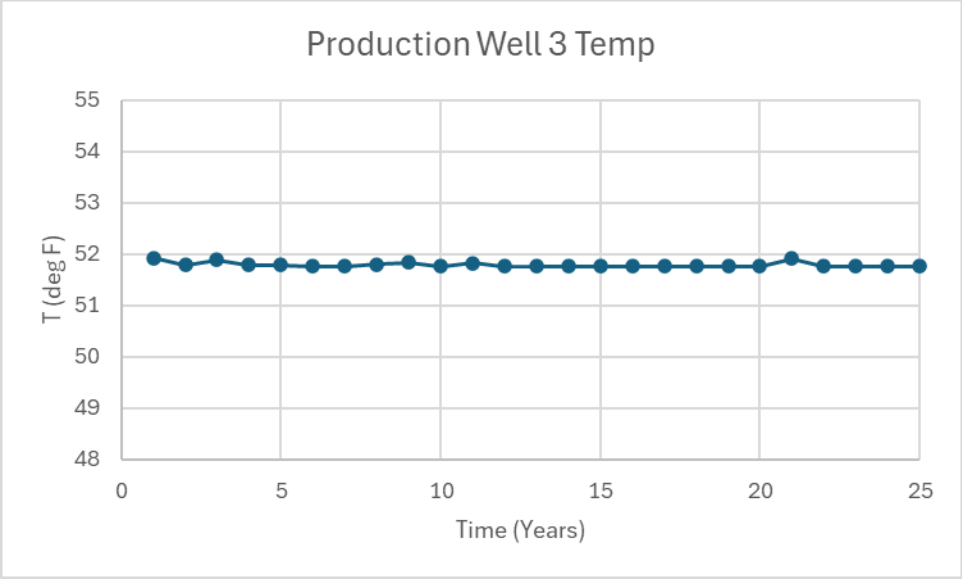

Figure 28: Scenario B - Temperature results at production well 3 plotted across 25 years of pumping at 600 gpm

3.3. Scenario C

This scenario simulated 300 gpm per well or 1200 total gpm for 25 years under the alternating seasons of heating and cooling cycle described above. Advective flow was considered in this scenario using the natural state modeling described above. Building foundations were included in this model to an average depth of 25 ft below the surface. Results were very similar to Scenario A.

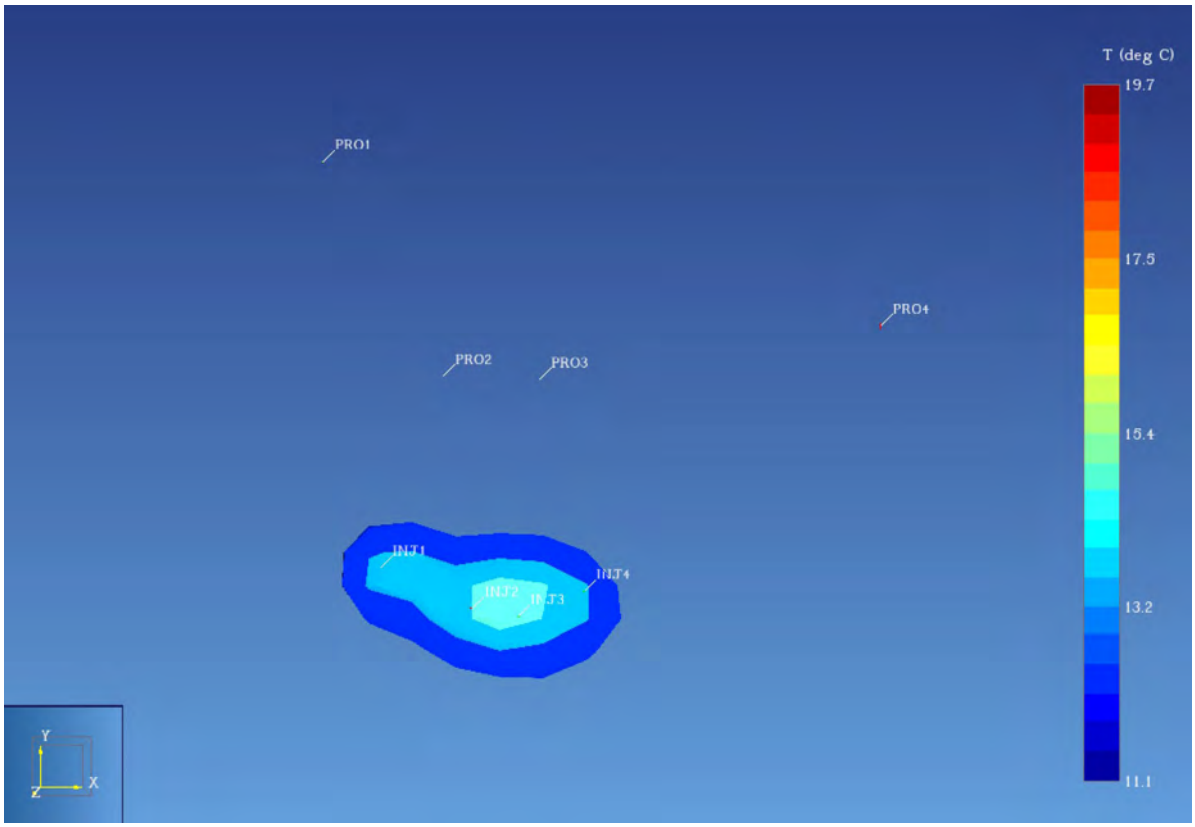

Figure 29: Scenario C - Temperature isosurface results after 25 years of pumping at 300 gpm with building foundations added to the model

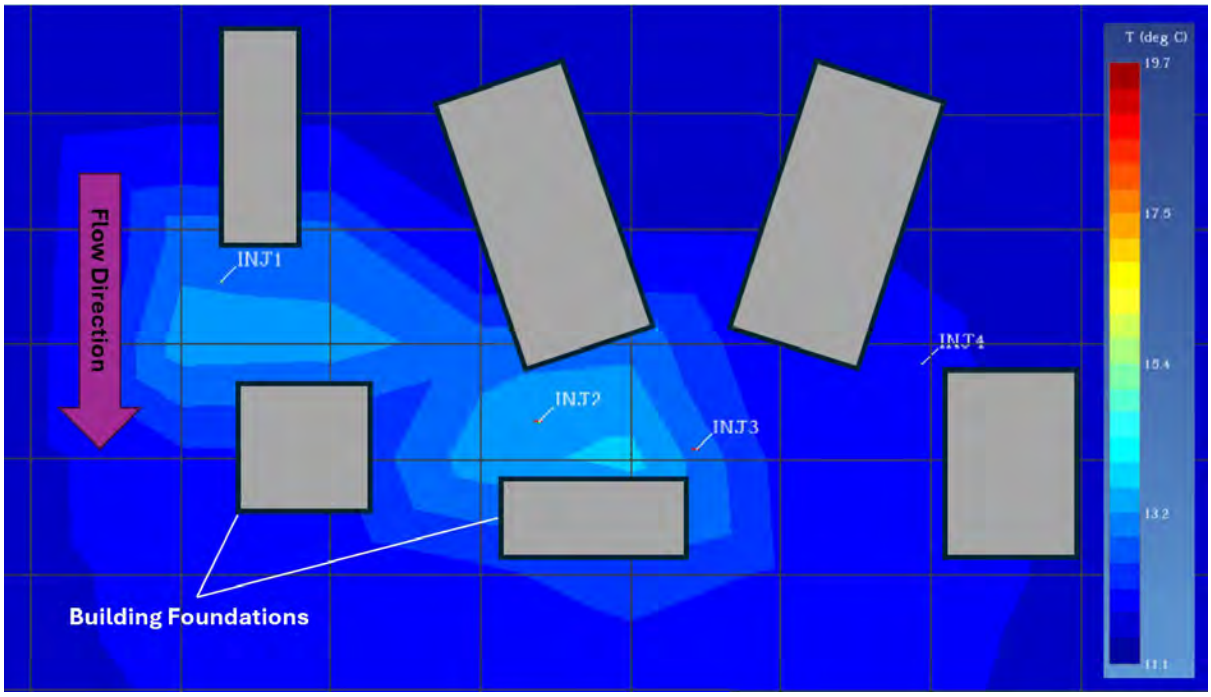

Figure 30: Scenario C Horizontal temperature slice at 45' below surface after 25 years of pumping at 300 gpm with building foundations visualized

3.4. Scenario D

This scenario simulated 600 gpm per well or 2400 total gpm for 25 years under the alternating nine months of heating and three months of cooling cycle described above. Advective flow was considered in this scenario using the natural state modeling described above. Building foundations were included in this model to an average depth of 25 ft below the surface. Results were very similar to Scenario C.

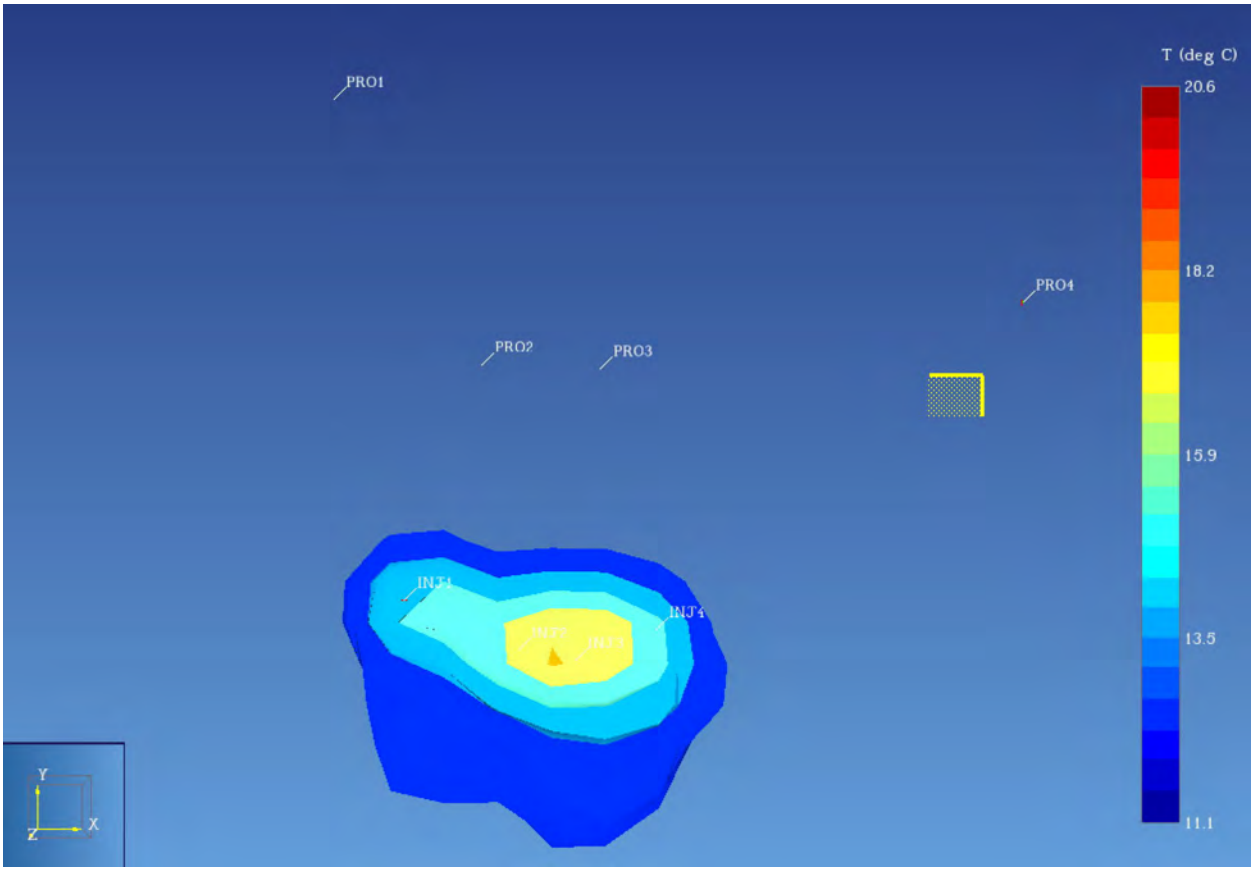

Figure 31: Scenario D - Temperature isosurface results after 25 years of pumping at 600 gpm with building foundations added to the model

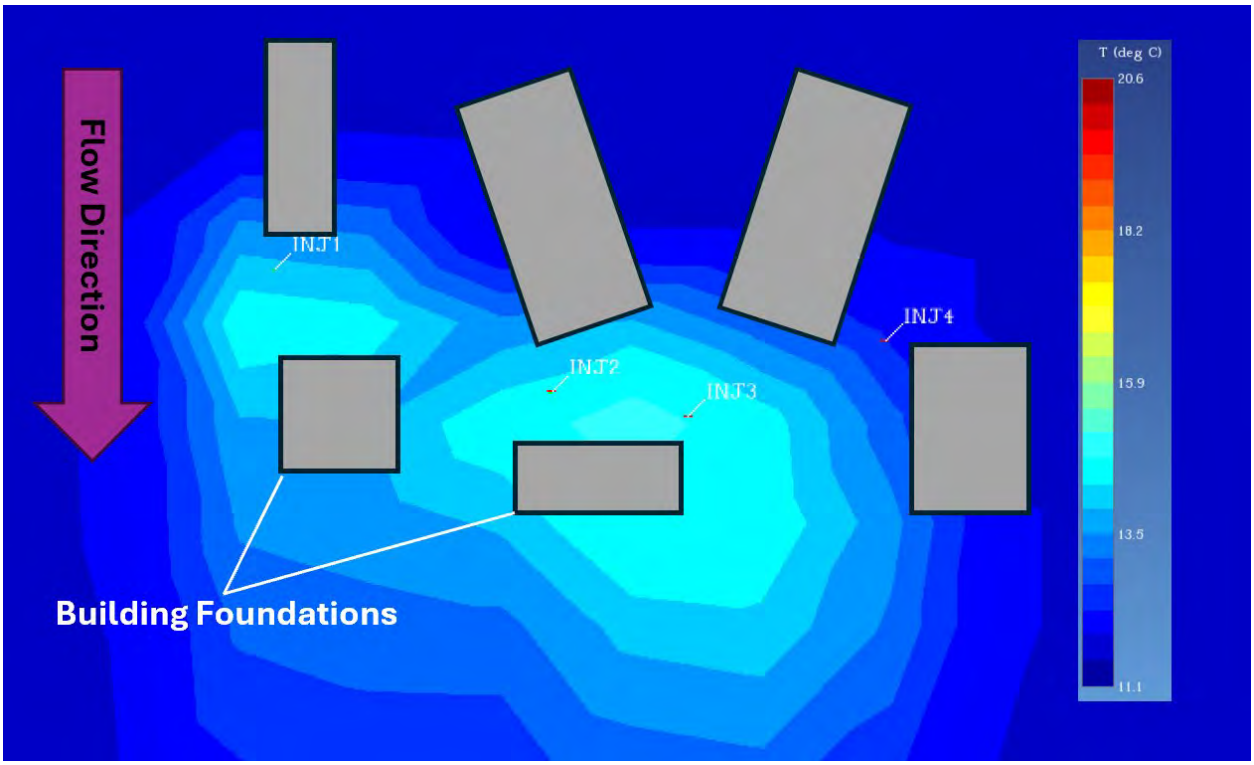

Figure 32: Scenario D Horizontal temperature slice at 45' below surface after 25 years of pumping at 600 gpm with building foundations visualized

4. Conclusion

Originally, a closed loop array had been considered for this site. An early system design was conducted, and it was estimated that there was enough green space to meet 15% of the peak with a closed loop system. The open loop array estimates were combined with the original closed loop estimates. The separate performance of each of these systems is displayed in Figure 33. The combined systems (closed and open loop) have the potential to meet the heating and cooling loads about 51% of the time (Scenario B & D). This number is initial and approximate and will change depending on the results of a test well. It should also be noted that although the system only meets the heating and cooling loads around half the time, the percent of BTUs met is over 70% (Table 5). Additionally, more work should be done in future studies to determine the optimal well layout. This was not explored fully in this study because a full design relies on the results of a test well. Instead, a realistic example layout was chosen to test the well separation needs. The results suggest that, due to the high advective flow in the area, the necessary well separation between production and injection can be far closer than the industry standard if needed. The closest distance between a production and injection well in this example is the 1085 ft between INJ1 and PRO2. Even in Scenario B, after 25 years there was still over 800 ft between the two wells with no thermal influence.

Table 5: Best case scenario combined system results

System Heating and Cooling for 15% of Peak Closed Loop and High Yield Open Loop				
Sum of Total Heating Met (BTUs)	Sum of Total Cooling Met (BTUs)	Sum of Unmet Heating(BTUs)	Sum of Unmet Cooling (BTUs)	% of BTUs Met

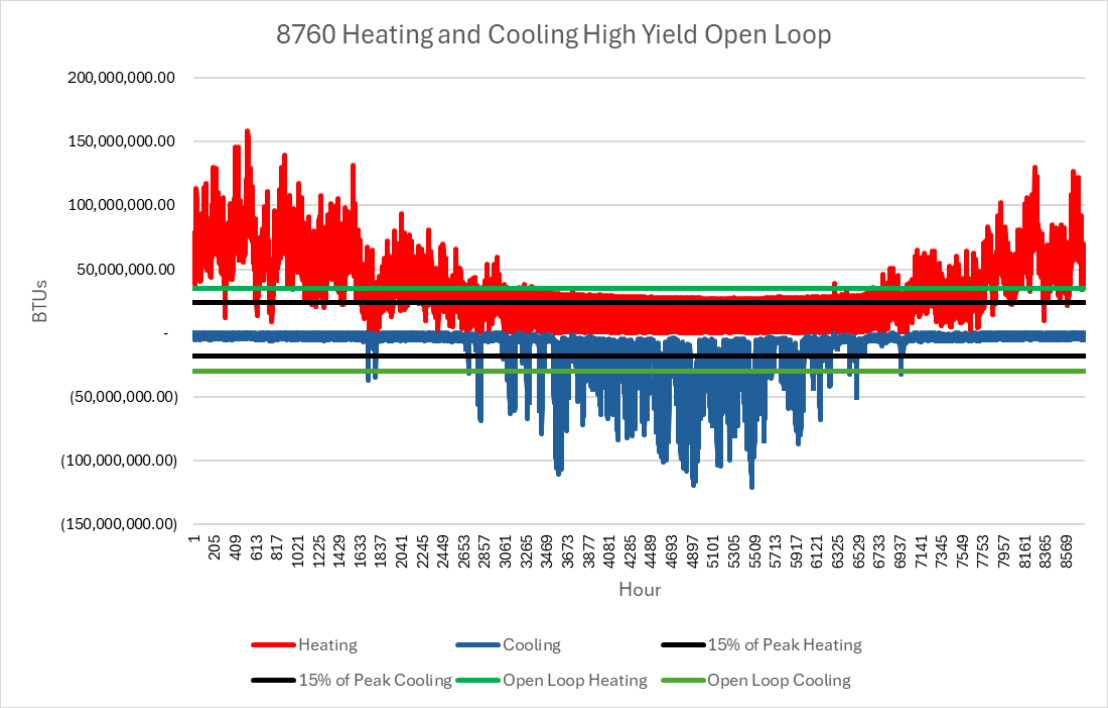

Figure 33: Separation of the closed loop system (15% heating/cooling) and the open loop system (green horizontal lines) compared to the overall 8760 heating and cooling loads.

Figure 34 and Figure 35 were prepared for comparison between the scenarios with and without concrete foundations. Generally, the thermal plumes were obstructed by the foundations. In scenarios that included the foundations, the fluid was forced between or under the building foundations. This contributed to lower temperatures immediately down gradient from the wells. Obstruction of groundwater flow around and under the foundations is easily observed in Figure 34, but the shapes of the high temperature portions of the plumes in Figure 35 are still very indicative of a shift groundwater flow either laterally or beneath the foundations. Although the inclusion of foundations didn't have an effect on the temperature of the production wells for this well layout, we learned that it has the potential to affect the results of other simulations. These results suggest that subsurface elements not usually included in groundwater modeling may have dramatic effects on the results of simulations and should be considered if we are to produce accurate subsurface models in dense urban areas and for systems that exploit shallow aquifers.

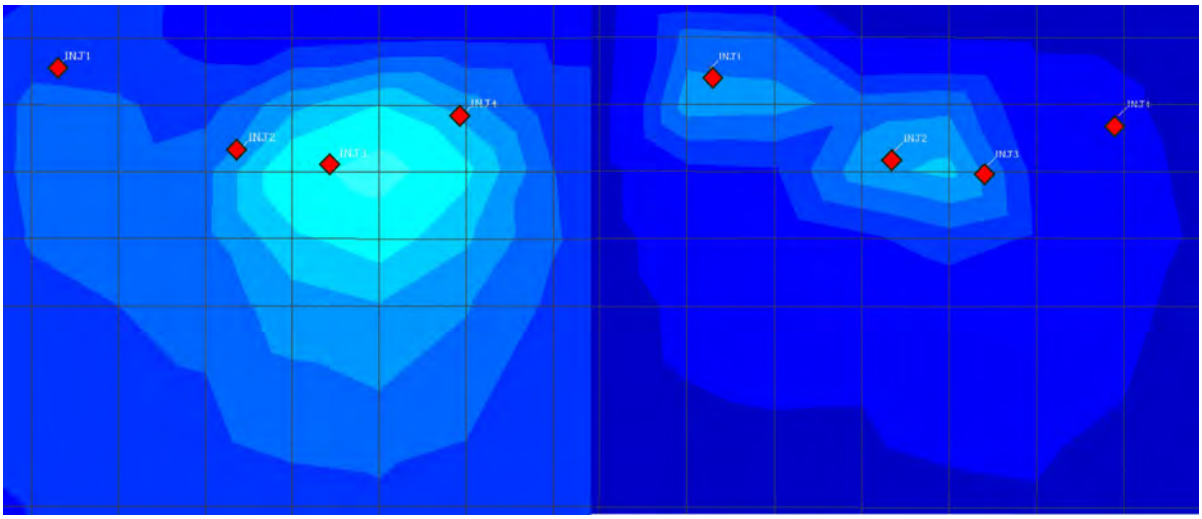

Figure 34: (Left) Temperature isosurface (45 ft deep) from Scenario A (300 GPM) with wells displayed in red. (Right) Temperature isosurface from Scenario C (300 GPM) with building foundations included in the model

Decarbonization in urban areas, such as New York City, presents a tremendous engineering challenge. The regulatory environment created by the UTENJA and the Climate Mobilization Act promote the application of geothermal and geoexchange technologies in New York State and New York City. Geothermal and geoexchange technologies offer building portfolio managers a responsible electrification technique that can reduce their operational costs over the long term wherever the appropriate sources and sinks are available. Aquifer thermal energy transfer is one of several subsurface exploitation methods that can provide engineering firms, building managers, and policymakers with city-scale decarbonization. Future studies will be necessary to fully ensure the success of a potential geothermal system in the Penn South neighborhood. To achieve the transition to clean energy, the Penn South neighborhood will need to optimize the open loop well layout, but also consider implementing additional clean energy sources including wastewater energy transfer and closed loop geothermal techniques. Understanding the geologic conditions and the surface system engineering necessary to utilize those conditions is absolutely essential to maximize heating and cooling performance. Special care should be taken to understanding the

depth of glacial till, the permeabilities of shallow bedrock, regional advective flow, and other elements that may influence the flow of groundwater including building foundations, subway dewatering, and localized stream channels that increase the depth to bedrock.

Keywords

Geothermal energy, taxonomy, heat pumps, thermal energy networks, geothermal networks, district heating and cooling, 5GDHC, community geothermal

ABSTRACT

Geothermal technologies can all provide the stable, dispatchable, non-intermittent energy that our energy system needs, yet the challenge of differentiating among these technologies and clearly defining them for the public and decision-makers is impeding progress. Even within the scope of district-scale geothermal technologies, there are multiple naming systems which are not always clearly linked to the specific designs and outcomes. In order to scale the provision of the different types of technologies that tap geothermal energy, technically accurate, clear, and standardized terminology needs to be adopted. This study proposes a taxonomy for geothermal energy networks (GENs), within the context of definitional clarity for geothermal technologies, district energy systems, and thermal energy networks (TENs). We introduce a taxonomy rubric that connects nomenclature and design choices to expected system outcomes. The proposed taxonomy is the product of extensive interviews and stakeholder engagement, with members of the geothermal and ground source heat pump communities, as well as academic, industry, advocacy, workforce, customer, policy and environmental justice groups. Across these industry stakeholders, the link between technology components, system design, performance, and terminology is desired and seen as necessary to industry success. One state regulatory leader referred to TENs as the first new utility in a hundred years. As multiple states and countries create policy to enable geothermal and thermal energy networks at the utility-scale, this proposed taxonomy rubric is intended to provide a clear nomenclature upon which to build statutory language and regulatory frameworks.

1. Introduction

The greek root of the word geothermal is a reasonable descriptor, ‘earth heat’, and we further define *geothermal energy as all thermal energy that is generated or stored at or below the surface of the earth, including in soil, rock, and water*. Near to the surface the majority of this energy is stored solar thermal energy accumulated across millenia and replenished at an increasing rate due

to global warming. Deeper geothermal energy comes from the core of the earth which is similar to the surface temperature of the sun and is replenished by radioactive decay. Both of these energy sources are considered both renewable and a large enough reservoir to be functionally inexhaustible. According to the U.S. Department of Energy's *GeoVision: Harnessing the Heat Beneath Our Feet* (2019), these thermal resources have been largely untapped in the US.

Despite the scale of this non-intermittent renewable energy source, none of the technologies that tap this energy have yet scaled to match the opportunity. One consistent hurdle to scaling is a limited understanding of geothermal energy among policy experts and decision makers in part driven by inconsistent, and therefore confusing, use of terminology to describe the technologies that tap this energy.

Unlike many renewable energy technologies such as solar and wind, all geothermal technologies can offer non-intermittent baseload renewable energy that is dispatchable, stable, and reliable. Beyond this, geothermal technologies are varied in their depth (from shallow to deep), temperature (from super hot to ambient), distribution (from a few spots to everywhere), application (from power to heating and cooling) and scale (from single buildings to regional utilities). This diversity is one source of the definitional challenge which the authors propose to address through the following geothermal energy nomenclature. There are many more possible combinations and exceptions to this categorization, however the simplicity of these four main categories depicted in **Figure 1** has proven useful to a wide range of stakeholders.

(1) Geothermal Power: Uses high temperature geothermal energy for electricity generation. Temperatures are typically higher than 120℃ / 245℉. However, lower temperatures can be used with binary power plants (Febrianto et al. 2019).
(2) Geothermal Direct-Use: Uses temperatures in the range of 30 ℃ / 85℉ to 120℃ / 245℉ (Østergaard and Svendsen 2017) for direct use of hot water to provide space heating and domestic hot water for one or more (usually multiple) buildings.
(3) Geothermal Heat Pump*: Uses ambient temperatures to provide thermal energy for heating and cooling for individual buildings, and can provide domestic hot water.
(4) Geothermal Networks: Uses ambient temperatures interconnecting to provide heating and cooling for multiple buildings, and can provide domestic hot water.

* Geothermal heat pumps will be referred to in this study interchangeably as ground source heat pumps, and are also sometimes referred to as water-source heat pumps.

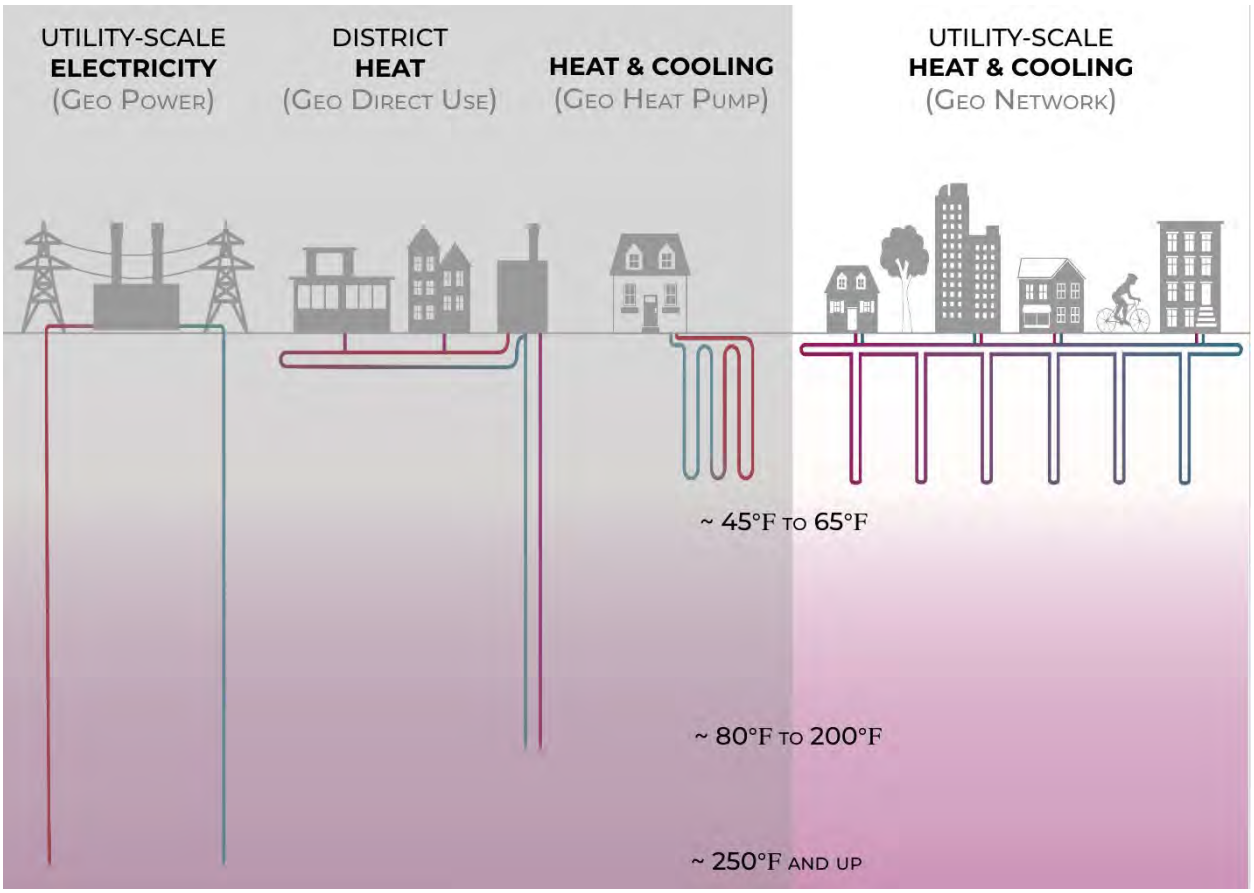

Figure 1. Geothermal Energy: Geothermal technologies by temperature harvested and applications. Includes geothermal power for electricity generation, geothermal direct-use for district heating, geothermal heat pump for heating and cooling of individual buildings, and geothermal networks for heating and cooling multiple buildings.

This study focuses on the terminology used to describe the newest of this geothermal technology family, the geothermal networks, which this publication will also refer to interchangeably as geothermal energy networks (GENs). Geothermal energy networks are generally understood to be thermal energy networks that access shallow geothermal energy - with thermal energy networks understood to be distribution infrastructure interconnecting heat pumps in multiple buildings together with distributed thermal resources.

In order to clarify terminology for GENs, this study first clarifies the word geothermal, as above, and next defines these GENs through first a consideration of district energy system nomenclature, then a consideration of the emerging thermal energy networks nomenclature, and finally followed by the integration of each of these into one consistent proposed taxonomy.

The district heating and cooling (DHC) system nomenclature and the thermal energy networks (TENs) nomenclature have largely evolved in different contexts. DHC systems have developed most in societies with a centralized planning of the energy supply, with many examples in Europe. In the U.S. such DHC systems are most common on campuses. The TENs and GENs subset of these DHC systems have emerged only in the past decade within the context of building decarbonization.

As Buffa et al. (2019) argue, even within the scope of district-scale technologies, there are multiple naming practices that are not clearly linked to the specific designs. To enable optimized scaling of this relatively novel technology there is a clear need for accurate, consistent, and standardized terminology to link designs to outcomes. This work is an effort to meet this need and is organized into six main sections: (1) introduction, (2) methodology, (3) background on existing terminology, (4) risks of ambiguous terminology, (5) proposed taxonomy and (6) conclusions.

2. Methodology

The methods used to inform the taxonomy rubric proposed include an extensive stakeholder engagement process, a literature review and learnings from ongoing pilot projects in Massachusetts.

2.1. Stakeholder Engagement

The stakeholder engagement process which informed the proposed taxonomy consists of three main initiatives including community charrettes, open reporting and informing policymakers.

2.1.1. Community Charrettes.

Community charrettes are a gathering of multiple stakeholders to discuss a common challenge or opportunity (Condon 2012) and have been used by HEET for this purpose since January of 2020. They are designed to ensure all stakeholder groups are represented in the development of a concept with the shared purpose of resolving conflicts and mapping solutions. Many community charrettes abide by Chatham House Rules, to encourage the sharing of information and minimize any perceived risks.

One of the early charrettes for GENs was conducted to develop site selection criteria and included collaborators from the following stakeholder groups: New York and Massachusetts state energy offices, gas utilities, geothermal solution providers, academics, municipalities, building developers, climate advocates and environmental justice advocates. The HEET charrette series for GENs has been ongoing since 2020 and spans a range of topics intended to share knowledge and methodology on how to install and grow these systems across the country. The HEET charrette series represents an inclusive and iterative approach to designing parameters and defining desired outcomes of a thermal energy transition.

2.1.2 Transparent Reporting

Charrette reports are published open source through Creative Commons CC-BY-SA licensing so that the public has access to methods, data and findings for each discussion. Progressive reporting is a key element of stakeholder engagement, allowing for a broader range of stakeholders to track progress and contribute their own ideas. By centering transparency and accountability, HEET developed trust and credibility with many stakeholder groups which led to enhanced collaborations. This active approach to stakeholder engagement has resulted in the formation of several national networks of stakeholders including groups focused on geothermal network policy, regulation, advocacy and system modeling. The access to many experts across multiple disciplines through both the charrettes and the national networks has informed the understanding that led to the proposed taxonomy rubric.

2.1.3 Informing Policymakers

HEET is actively engaged in informing policy makers to drive progress within the thermal sector. The stakeholder engagement process described coupled with HEET's research and innovation efforts enables the systematic investigation and analysis of issues yielding evidence-based insights and recommendations for policymakers and stakeholders.

The ongoing charrette series is also responsive to policymakers, frequently addressing topics informed by the needs, concerns or opportunities in the thermal transition policy landscape. This fosters policy relevant collaboration among government, industry, and academia through the charrettes. Common threads and concerns across stakeholders influenced the development of the taxonomy rubric proposed and the clear need for such an effort emerged in part from policymakers' request for clear links between technology, nomenclature, and outcomes.

2.2 Literature review

A literature review of academic journals, books and policy documentation was performed on current terminologies being used to describe conventional district heating and cooling systems (DHC) and fifth generation or 5GDHC installations. This review focuses on clarifying the technologies more commonly referred in the U.S. to as thermal energy networks and geothermal networks. The literature review results are summarized in section 3 below.

3. Background on Existing Taxonomy

The nomenclature for district heating and cooling systems has matured in Europe. The adoption of district-scale heating and cooling systems has been more prevalent in Europe than in the United States and has been primarily driven by the high demand for space and water heating in cold climates in Europe (Gjoka et al. 2023). The evolution of current district energy terminology began with district heating and expanded to encompass district heating and cooling systems. This terminology system has evolved to categorize district systems into distinct generations, reflecting changes in their characteristics and applications. This generational classification system provides a framework for understanding the development and refinement of district-scale heating and cooling systems in Europe and elsewhere, evolving generation after generation towards simultaneously lower temperatures and higher efficiencies.

Generations based DHC terminology is used in the U.S. within the district energy community and on college campuses but does not have widespread recognition or adoption in policy. This is perhaps how a parallel terminology evolution occurred, rooted in the geothermal and ground source heat pump industry, resulting in geothermal networks and thermal energy networks (TENs). The ground source or geothermal heat pump industry and the district energy industry language practices intersect in this new and rapidly emerging space of 5G, TENs, and GENs.

In this section we review: a) the terminology of district heating and cooling systems, b) the evolution towards fifth generation (5G), and c) the geothermal network and thermal energy network terminology that is mainly used in US policy manuscripts.

3.1 District Heating and/or Cooling

District heating systems are clearly defined by Woods (2023) as the distribution of heat to multiple buildings from one or more heat production facilities. Similarly, district cooling or coolth, is the distribution of chilled water to multiple buildings from a main chiller plant (Woods 2023). As

Woods (2023) clarifies, district heating and cooling systems are methods for transporting energy, but are not tied to a specific energy source. Additionally, Woods (2023) emphasizes that this definition encompasses a broad range of scales, going from small housing complexes to large district developments that could reach city-wide deployments.

Most existing district heating systems use fossil fuels as the supply method. Werner (2023) provides a global review of district heating and cooling systems from 1990 to 2014, for which the dominant heat supply was mainly powered by fossil fuels to heat water that was then utilized for direct use. As Werner (2023) describes, the fuel sources were recycled heat from combined heat and power (CHP) plants that use fossil fuels, as well as from boilers that burn fossil fuels to heat water for direct usage. In Europe 72% of the fuel in DHC systems is from recycled heat from combined heat and power plants, and 27% is from renewable sources. Globally the proportion of fossil fuels is larger, thus the recycled and renewable heat is lower, at 56% and 9% respectively.

District systems do not necessarily provide both heating and cooling, most are for heating only. Werner (2023) estimates that there are about 80,000 district heating systems globally, with about 6,000 of those in Europe. By contrast, Werner (2023) estimates that there are only about 150 district cooling systems in Europe, and mentions that there is a lack of data to estimate the global amount of cooling systems.

Societies with more central planning have more district systems. District systems have been implemented at larger scales in countries where the energy system is centrally planned and not driven solely by the market. Several European countries with high heating demands have adopted district systems to a large extent. Russia, Denmark and Sweden have high proportions of residential homes connected to DH, with 75%, 65% and 59% respectively (Woods 2023). Finland and Germany follow them, with penetrations at 38% and 14% (Woods 2023).

Conventional DHC systems can experience significant energy loss. Even though district systems are a more efficient way to heat and cool buildings than individual solutions, there are several disadvantages related to their use of energy. Traditional district heating and cooling systems (2G - 4G) experience significant thermal losses because they operate at relatively high temperatures of 25 C to 90 C. Additionally, to reach those high temperatures, most use fossil fuel sources that produce greenhouse gas (GHG) emissions. Furthermore, DHC systems require separate infrastructure in the form of combustion plants or chillers to be able to provide both heating and cooling. The markedly different fifth generation or 5GDHC heating and cooling systems address these concerns.

3.2 Nth Generation District Heating and Cooling systems

In recent years, 5GDHC systems have found a common definition in numerous academic studies. 5GDHC systems are described thoroughly by Buffa et al. (2019), Boesten et al. (2019), Sulzer et al. (2021) and Lund et al. (2018). They define 5GDHC systems as having the following characteristics: non-linear, bi-directional energy flow, and decentralized. They provide ambient temperature fluid to decentralized water-source heat pumps in the buildings on the loop, which deliver the required thermal energy for heating and cooling the building space (Gjoka 2023).

Bi-directional energy flow results in more efficient systems. Because of this, 5G systems are more efficient than previous generations of DHC systems. The bi-directional energy flow from the main

loop to the buildings and vice-versa makes 5GHDC systems well suited for urban environments with a high diversity of thermal load profiles. The bidirectional nature and diversity of building loads enables them to effectively "cancel" thermal loads between buildings, increasing the efficiency of the system. Furthermore, this bidirectional feature allows each building on the loop to be not only a consumer, but also a producer of heat. Systems with a single pipe as the main loop enable immediate recycling of low-grade waste heat or coolth. The authors refer to this phenomena as synchronous load canceling.

Integration of 5GHDC with thermal storage and advanced controls could result in further efficiencies. Due to the ultra-low or ambient temperature loop, 5G systems have the ability to integrate thermal storage infrastructure for different time scales (Boesten et al. 2019). This would allow the development of synergies with other energy sectors and optimisation of the use of energy (Gjoka 2023). Although currently underutilized, the use of artificial intelligence (AI) for prediction of thermal loads and optimization of thermal energy could make 5G systems even more efficient (Buffa et al. 2019).

Systems that use a single-pipe at ambient temperature are not explicitly described in the 5G systems. The work of Buffa et al. (2019), Boesten et al. (2019), and Lund et al. (2018) describe 5G systems as having two pipes that are near ambient temperature, with one pipe for circulating colder fluids and the other pipe for hotter fluids. Even though there is a lack of literature references to single-pipe ambient-temperature 5G systems, they share many of the characteristics described in the 5G literature, and the authors conclude should be considered within their broader definition.

DHC systems are common in Europe, but implementation of 5G is progressing slowly. Buffa et al. (2019) evaluate 40 geothermal 5G networks in Europe that provide heating and cooling to buildings using heat pumps installed at customers' substations. Boesten et al. (2019) outlines a case study of a 5GDHC system in Mijnwater, Hareen, Holland as an example of a two-pipe 5G system that has been implemented at a city wide scale. So when Garcia-Cespedes et al. (2023) examine the use of 5G systems with geothermal heat pumps in Europe, they identify two main barriers that explain their current limited deployment: 1) high capital costs for ground-source heat pumps and the ground heat exchangers (boreholes) and, 2) limited awareness in the general public, investors, public and academic institutions.

3.3 Geothermal Energy Network Policy Terminology

Legislation mandating climate action such as the Climate Leadership and Community Protections Act (2019) enacted by New York State, and the Massachusetts Global Warming Solutions Act (2008), have structured a policy environment open to novel approaches to greenhouse gas reduction. One such solution, the geothermal network, has spread rapidly since its first appearance in a Massachusetts regulatory proceeding at the Department of Public Utilities (DPU) Docket No. 19-120 in 2019. The following section reviews the terminology used by policymakers in Massachusetts, New York State, Colorado, Vermont, Minnesota, Washington State, and Maryland.

3.3.1 Terminology in Regulation

The *geothermal network* term and the concept in general were introduced into the U.S. policy space in regulatory filings in the Commonwealth of Massachusetts. In the Department of Public Utilities (DPU) Docket No. 19-120 (2019), Eversource Gas proposed to implement a geothermal

demonstration project to study the effectiveness and scalability of providing low-carbon heating and cooling in Massachusetts (43). The term used in the proposal and subsequent proceedings were *geothermal networks* and *networked geothermal*, used interchangeably, the latter of which went undefined. While the ruling for this proceeding did not include a definition for geothermal networks, a report released by HEET shortly before the docket (Buro Happold 2019) and submitted to the department did describe the technology as decentralized, bi-directional, and consisting of a single-pipe ambient temperature loop with heat pumps in buildings and borefields. This proposal to investigate this renewable and carbon-free alternative to natural gas networks was approved by the Massachusetts Department of Public Utilities in 2020.

Since 2019, the term *geothermal network* has been continuously used in MA in regulatory documents by gas utilities and by the DPU. The term appears in a 2019 settlement with Columbia Gas Massachusetts (Massachusetts DPU 2019) and in a 2020 National Grid Gas regulatory request to pilot geothermal networks (Massachusetts DPU 2020). More recently in July 2024, this term was used by the Massachusetts DPU Pipeline Safety Division as it issued the first safety guidelines for networked geothermal projects (Massachusetts DPU 2024).

In New York State, the emerging fusion between geothermal heat pumps and district energy was identified as a vital technology to meet the state's climate goals. To accelerate its adoption, in 2021, NYSERDA launched Program Opportunity Notice (PON) 4614, a multi-round funding initiative to support the development of *Community Heat Pump Systems*. The definition of these systems allowed for two configurations: 1) a centralized heat pump system, or 2) decentralized heat pumps located at every building. The centralized electric heat pump would produce hot water which would then be used in the buildings via radiators for hydronic heating. The decentralized system would use water at ambient temperature as a thermal source for space comfort and for domestic hot water. Thus, the program allowed for systems that fit within district energy definitions for both 4G and 5G technologies. Through this program, 48 feasibility studies, and over 50 projects, have received funding.

To date no federal regulation is relevant to this discussion, however it is of note that the federal Department of Energy uses the term Geothermal Heat Pump to describe the heat pump technology inclusive of the borehole or geothermal energy exchange. In addition the DOE's Geothermal Technology Office released in 2022 a first-in-nation FOA (0002632) titled Community Geothermal Heating and Cooling Design and Deployment which is inclusive of any district solution that includes geothermal energy.

3.3.2 Terminology in Legislation

In 2021, the Commonwealth of Massachusetts passed An Act Creating a Next Generation Roadmap for Massachusetts Climate Policy (2021), which among many other things is the first law in the US to allow gas utilities to pilot geothermal networks. It did not, however, use the term from earlier regulatory filings but instead used the phrase 'utility-scale renewable thermal energy' and permitted gas companies to bill for thermal energy within these permitted demonstration projects. In 2022, An Act Driving Clean Energy and Offshore Wind (2022), defined "clean energy" and "clean energy research" as inclusive of geothermal energy including *networked geothermal* and deep geothermal energy, and further repeated the term networked geothermal in listing data collection efforts. This 2022 legislation also allowed such projects to be paid for with funds from the gas pipe replacement program.

In 2022, New York State (NYS) pioneered the term *Thermal Energy Networks,* choosing not to use the phrase Community Heat Pump Systems from other state efforts. New York State enacted the Utility Thermal Energy Networks and Jobs Act (UTENJA) (2022), mandating the seven largest gas utilities to propose *thermal energy network* pilot projects for review and approval by the NY Public Service Commission (PSC). UTENJA introduced the term *Thermal Energy Networks, abbreviated as TENs* to the policy landscape. TENs were defined as a utility-scale system that provides thermal energy with pipes carrying water at ambient temperature that is used by heat pumps at every building. The heat pumps allow thermal energy to be used for heating and cooling and for hot water. This definition is consistent with both 5G district energy and with Massachusetts' description of networked geothermal.

The TENs terminology proposed by UTENJA indicates the intent to transition existing gas utilities to deliver thermal energy instead of gas. However, despite the TENs definition used, gas utilities in New York proposed 3G and 4G systems for projects in their initial submissions to the PSC, some of which included fossil-fueled central plants. Thus the TENs terminology, despite its definition, gets misinterpreted in NYS to include fossil fuels spurring an effort to name fossil fuel free TENs as clean thermal energy networks, or CTENs.

Other states followed NYS in the use of the term TENs. In 2023, Vermont and Colorado passed bills using the TENs terminology, and in 2024 Washington State followed. The bills were An Act Relating to Thermal Energy Networks (2023), and An Act Concerning the Implementation of Measures to Advance Thermal Energy Service (2023) and An Act Relating to Promoting the Establishment of Thermal Energy Networks (2024), respectively. However, the bills from Vermont and Washington define TENs only as utility-scale infrastructure that supplies thermal energy, and does not define the technology further. Nevertheless, Washington legislation specifies that the commission should approve projects based on whether it is a distributed system with ambient temperature fluid and high efficiency heat pumps, making them 5G compliant. Notice that geothermal heat pumps are not clearly specified as a requirement in any of these states.

Colorado, clearly aware of the growing nomenclature challenge, actually lists a variety of competing terms to refer to the geothermal district systems. Colorado defines the technology as assisting to reduce greenhouse gas emissions by supplying thermal energy to two or more buildings that are not a campus. They also mention that the technology should consist of pipe loops between buildings that carry noncombustible fluids at a desired, but unspecified, thermal temperature. Unlike Washington and Vermont, Colorado includes the word geothermal in its bill. Specifically, it refers to these systems as a "*geothermal exchange district, networked geothermal system, geoexchange system, geogrid system, community geothermal heating and cooling district,* or a *geothermal heating district"*. Despite the variety in the *geo* terms included, the definitions provided by the Colorado legislature do not explicitly indicate the generation source of this type of district heating and cooling.

Nevertheless the examples from NY, VT, WA and CO exemplify the proliferation of the now more common terminology in the US policy landscape, *thermal energy networks.* The inconsistent definition of this terminology across these states and the lack of technical clarity has resulted in TENs being an ambiguous term that is approached differently in each state.

Maryland and Minnesota added more options, with some specificity to the mix. Maryland's Working for Accessible Renewable Maryland Thermal Heat (WARMTH) Act, introduced the term

geothermal heating and cooling system and defined it as a system that uses one or more geothermal heat pumps that can be either closed loop or open loop.

Some states, such as Minnesota, use more traditional terminology. The Minnesota legislature passed a relevant amendment in Natural Gas Utility Innovation Plans (2023), using the term *District Energy* defined as a heating and cooling system powered by solar thermal, the constant temperature of the Earth or aquifers to heat or cool multiple buildings via a network of pipes.

No federal legislation has been passed directly naming this technology yet, however a bill filed in August 2024 by Senator Markey, title the 'Pipeline Accountability, Safety, and Environmental Standards (PASES) Act' uses the term *networked geothermal systems*.

4. Risks of Ambiguous Terminology

The proliferation of ambiguous terminology in the US policy landscape has created uncertainty and hindered the adoption of this technology. The term 5GDHC was not explicitly mentioned in policy documents reviewed, highlighting the disconnect between terminology evolution in Europe versus in the United States. Outside of the policy space the term is used in the U.S. among district energy providers, researchers, and the district energy community, primarily to describe the increasing use of fifth generation on campuses. Within the district energy community there was a recent debate around definitional differences between 4G and 5G, another sign that this emerging technology remains in the definitional process.

Community and stakeholder groups agree on the need for a clear and concise term that stakeholders can universally understand. There are a number of risks that arise from the use of ambiguous terminology in policy documents, including:

A. Misleading impact expectations – Ambiguous terminology may lead to benefit expectations for one design getting misallocated to a different design. Key examples:
    a. A Thermal Energy Network with no boreholes or other forms of thermal storage may not deliver the benefits to the electric grid of a Geothermal Energy Network.
    b. Without specifying ambient-temperature loops, cooling benefits could be lost together with the efficiency of bidirectional energy exchange.
B. Greenwashing possible – Ambiguous terms can be exploited to exaggerate environmental benefits, misleading stakeholders and hindering genuine progress. For example, in New York some preliminary proposals under UTENJA did not eliminate reliance on fossil fuel combustion. The authors are not weighing in on those projects merits but are instead highlighting the gap between the intent of the UTENJA legislation not matching some of the proposed projects.
C. Optimization and Scalability hampered – Without clearly linking terminology to design, maximizing favorable outcomes such as ultra high efficiency design of 5G systems may not be easily achieved and modularity may be lost leading to unintended limits on regional interconnectability to improve efficiency and resilience.
D. Stakeholder Confusion – Unclear terminology can confuse stakeholders, including policymakers, industry professionals, and the public, hindering effective communication and collaboration, increasing the sense of risk, and reducing trust, and therefore action.

A common language is needed for policy and technical clarity in order to minimize risk and maximize trust in decisions. The International Energy Agency (IEA) emphasizes the importance of clear and consistent terminology in energy policy, stating that "a common language is essential for effective communication among policymakers, industry stakeholders, and the public" (IEA 2020). Future policy frameworks should prioritize precise terminology to facilitate the transition to renewable energy sources and avoid perpetuating ambiguity. Furthermore, in terms of technical outcomes, the authors agree with Buffa et al. (2019), who argue that the nomenclature used for lower temperature networks compared to traditional direct use district heating systems, can lead to misinterpretations.

5. Proposed Taxonomy

In appreciation of the enormous potential of the recently emerged ambient-temperature single-pipe bi-directional thermal energy infrastructure with decentralized geothermal heat pumps and centralized management of thermal resources, this proposed taxonomy focuses on clarifying the nomenclature for such a system within all other possible similar systems. It is the single-pipe ambient-temp distributed geothermal heat pump system that initially sparked the recent rapid spread of policy actions due to the potential to multi-solve the policy challenge of decarbonization and specifically the equitable transition beyond gas networks. Other district energy systems and designs are excellent as well and may be the ideal choice for a given location, so this taxonomy is not intended to select a winner but instead to clarify the names of the competitors - or the team of competitors.

Given the clear step change from centralized to decentralized district energy when moving from 4G to 5G, and incidentally also the challenge of 5G being actively used and understood to be a cell phone network in the U.S., we see value in the rise of novel terminology overlapping with the term 5G. We further appreciate the value of the word network rather than the word district as stakeholders of all backgrounds more readily understand network to be bi-directional and decentralized with the word district indicating the presence of a central plant.

Given the growing public preference for the pithy TENs abbreviation based on the term thermal energy network, we then consider the various boundaries on this term. The original TENs definition in New York's UTENJA legislation established it as single-pipe and ambient-temperature, which connects directly to the public expectations of a scalable utility technology and places it as a subset of 5G and thus not duplicative terminology. Subsequent evolutions have moved the boundary to include less easily scalable designs and 4G systems. This substantially increases the risks outlined in section 4, so we conclude that the definition of a thermal energy network should return to, in clear relationship with the district energy nomenclature, an ambient-temperature bi-directional 5G system of a single-pipe design. This differentiates TENs as an efficient subset of the 5G system with an interconnectability-based growth model - a technology that shifts the scale potential from district to utility. Should there be a need, particularly in the U.S. where 5G is so strongly associated with cellular service, to use a name other than 5G for a two-pipe ambient system we suggest distinct language be developed.

All such ambient-temperature networks feature the ability to connect to multiple and diverse thermal energy sources, sinks, and storage - or resources. The thermal resources can include not only geothermal boreholes which tap bedrock thermal but also other thermal exchange systems including those tapping aquifers and thermal reservoirs such as ponds, lakes, rivers and the ocean - all of which fit within the definition of geothermal energy. In addition, thermal resources can

include heat from other industrial sources and processes such as data centers, brewing, and waste water or sewers. Furthermore, infrastructures such as swimming pools, irrigation and snowmelt systems can be used as thermal resources, the former as storage and the latter as mechanisms to balance a system increasing the needed cooling or heating capacity. There has been much discussion in New York of TENs which use no geothermal at all and there are excellent examples such as a wastewater based TEN in Denver Colorado.

Given the need to differentiate the impact of geothermal heat pumps on outcomes, including grid impacts, we further specify the term geothermal energy networks (GENs) to refer to a subset of TENs systems that includes some baseload geothermal energy. It is critical to understand that with these definitions TENs and GENs are potentially interconnectable and part of a vision of a new thermal utility infrastructure. We further appreciate that the geothermal energy differentiator results in an acronym, GENs, that implies to many stakeholders an energy generation capacity, which matches the technology described.

Thus, in conclusion, we reinforce the well-established and existing district energy generational nomenclature and see value in further specifying, within the ambient-temperature 5G category, the single-pipe TENs, and within TENs, the geothermal energy based GENs. A taxonomy or classification rubric that links key design parameters to the performance and main characteristics of any thermal energy network is presented in this section. The classification rubric used divides any thermal energy networks into three main components, (1)Thermal resources, (2)Distribution, and (3)End-users. This classification is highly relevant to regulatory, ownership, and finance models and is depicted in Figure 3 and also described in Varela and Magavi (2024).

Figure 3. The geothermal energy networks or thermal energy networks can be subdivided into three main components: thermal resources, distribution and end-users with typical examples of each pictured. Figure modified from Varela and Magavi (2024).

5.1 Thermal Resources

The choice of thermal resources define key features of any DHC system. 5GDHC systems, including TENs and GENs can have a wide variety of thermal sources. Traditional DHC systems use sources from fossil fuels and combined heat and power (CHP) plants that generate high temperatures leading to higher thermal energy losses during the distribution. Table 1 shows how key thermal networks features vary depending on the type of fuel used for the supply of energy

into the system. For example, high temperature primary thermal sources means the system is likely a centralized system and only provides heating.

Table 1 also shows that geothermal networks are a subset of thermal networks that include geothermal energy sources. Other renewable energies such as solar thermal can also be used as thermal sources and connected to the thermal network.

The capture of thermal energy resulting from industrial or civil processes can include heat recovered from waste-water treatment facilities, sewer lines, subway tunnels, and more. Capture of excess or waste heat where available can be more cost effective than boreholes as a heat supply. It is of note that boreholes or other forms of geo-exchange, however, also provide cooling and sufficient energy storage to provide electric grid load flattening and shifting capacity.

Inclusion of boreholes can make the system more efficient by increasing short and longer term thermal storage. If a majority of buildings connected to a loop reject heat during the summer, this thermal energy can be stored in the subsurface and a portion can be leveraged months later during the winter when most buildings will be heating dominant. The subsurface dissipation rate together with the borehole spacing, design, and management drives the percentage stored at different time intervals. Geothermal heat pump designers have worked for decades to minimize long duration storage - avoiding system ‘thermal drift’ - however a managed thermal network provides the opportunity to design some borefields or thermal exchange to maximize this long duration storage.

5.2 Distribution

The number of pipes used in the distribution system is a key design parameter affecting the performance of the system. Conventional DH systems often operate with a four pipe design, using high temperatures for direct use of hot water without providing cooling. Because there is no load cancellation, if a heat pump is used, the COP of the system is equal to the COP of the heat pump as shown in Table 2. Buffa et al. (2019) define the 5G systems as having two pipes and highlight the increased efficiencies encountered by using ambient temperatures. TENs and GENs or differentiated as a subset of 5G with a single pipeline for the distribution system.

The TENs and GENs distribution system design consists of a single pipe circular ‘loop’ with both end-users and thermal resources distributed anywhere around the loop. This design allows for reduced infrastructure costs, efficient bidirectionality, and adaptable interconnectability at any point on the loop to both add and subtract end-users and thermal resources. This design also requires thermal management to ensure the loop does not shift outside the design temperature range and may require strategic addition of thermal resources. As these loops can interconnect, becoming thermal resources to each other while increasing efficiency and load predictability, this system design provides a growth model for the managing thermal utility.

Single Pipe Design Notes:

1. While the diameter of the main pipe is often a cost consideration, the costs of using a pipe with a larger diameter should be balanced with the potential gains. Including that having a pipe with a larger diameter enables the addition of future thermal loads to the loop and allows lower power pumping. Pumping energy use follows the affinity laws, so slower is disproportionately less power used. A slower loop speed may further reduces pumping power required by shifting the loop into laminar flow.
2. The thermal storage capacity of the volume of water - or water with glycol - filling the loop is calculable and can cover some demand from building heat pumps without drawing on the borefields or other thermal resources. At the Colorado Mesa University installation the five interconnected loops met all heating and cooling demands of the buildings without calling on the borefields during the shoulder seasons nearly 40% of the hours of the year.
3. That this thermal storage tank is in motion has led the lead author (who has an affection for flywheels) to describe the behavior of these single-pipe distribution loops as 'thermal flywheels'. The author's hypothesis, shared with one of the designers of Colorado Mesa, Cary Smith, is that a large diameter and slow moving main loop could aggregate hourly building loads over the duration of time it takes to complete a loop rotation, thus reducing the peak demand calculations from a hourly load to a multiple hour aggregation of loads. This is supported by findings that a larger pipe diameter provides more thermal inertia, and even short-term thermal storage along the distribution pipe (Guelpa and Verda 2019) resulting in more thermal mixing and simultaneous balancing of thermal loads - making the system more resilient and also smoothing spikes in thermal demand.

5.3 End-User

The end-user or customer has traditionally been solely a consumer of energy in DHC systems. However, in 5G systems and in TENs and GENs, the buildings or end-users are not only consumers but also producers (or prosumers) of heat. The simultaneous connection of consumers and prosumers to the same loop results in the total or partial cancellation of their thermal loads.

Diversity in both type and timing of load profiles is optimal to allow for cancellation and reduction of loads in 5G systems. Load profiles are usually associated to building typology, so ensuring a variety of building typologies to be connected in the thermal networks increases the overall efficiency of the system.

For 5G systems a heat pump or array of heat pumps is needed at every building. These heat pumps are known as ground source heat pumps or a water source heat pumps or geothermal heat pumps. We have chosen to use the term used by the U.S. Department of Energy, the geothermal heat pump or GHP, however we acknowledge that water source is the most accurately descriptive term. Regardless of the name these are more efficient, longer lasting, and have less refrigerant leakage than the more widely known air source heat pump (AHSP).

To minimize energy losses in the building, a weatherized building with an optimal building envelope is a modern necessity. Sizing public infrastructure and private heat pumps and distribution systems for an inefficient building is a waste of resources, though it can be done in the case of an unalterable historic building for example. As for the building typology, all types of residential and commercial buildings are eligible to be connected to geothermal energy networks.

Finally, balancing the aggregated end-user loads drives optimal long term performance of the system. Thermal management can address excess demands or loads and is the purview of the thermal utility. Balanced annual loads ensure that the subsurface temperature does not increase - nor decrease- after multiple years of operation. If the thermal loads are not balanced and subsurface temperatures are drifting up or down over years, additional boreholes or other thermal sources/sinks or strategies for thermal management such as dissipation of excess heat may be needed for the system to operate optimally over a long duration. This thermal management and optimization is the obligation of the managing thermal utility.

A conceptual representation of a GENs with diverse thermal resources and end-users is depicted in **Figure 2**.

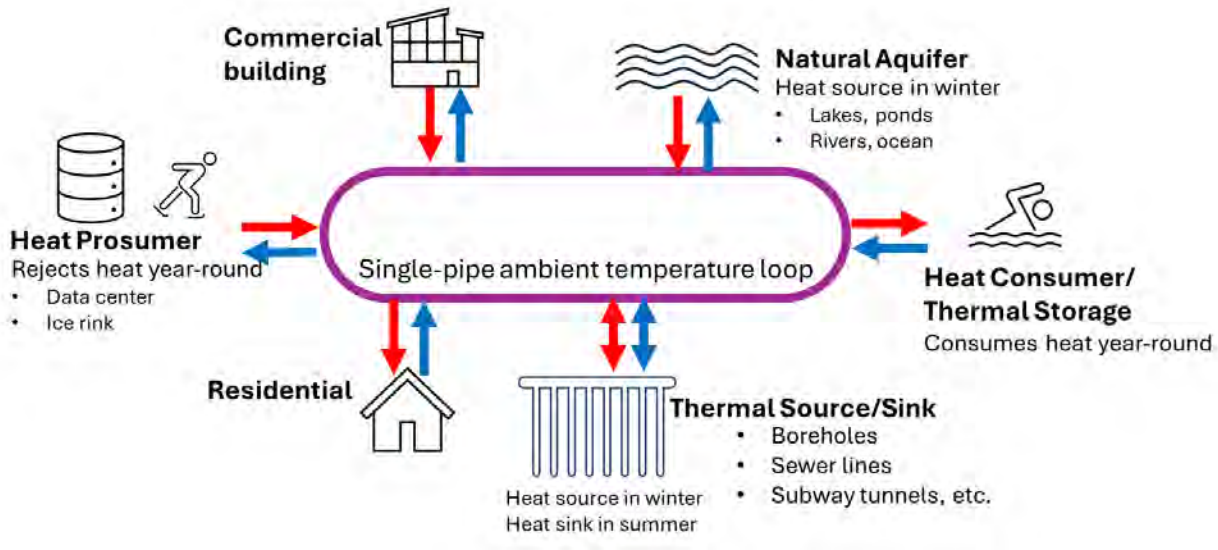

Figure 2. Conceptual representation of a geothermal energy network: a system for heating and cooling using interconnected heat pumps with a single-pipe ambient-temperature loop. Buildings and thermal resources connected to the system have the ability to be both a consumer and a producer of heat.

A schematic representation that summarizes the concept of geothermal networks and thermal energy networks and how they relate to 3GDHC, 4GDHC and 5GDHC is depicted in **Figure 3.** This schematic representation shows that geothermal networks as defined in this work, are a subset of the 5GDHC systems that use a single pipeline with ambient temperature for the main loop.

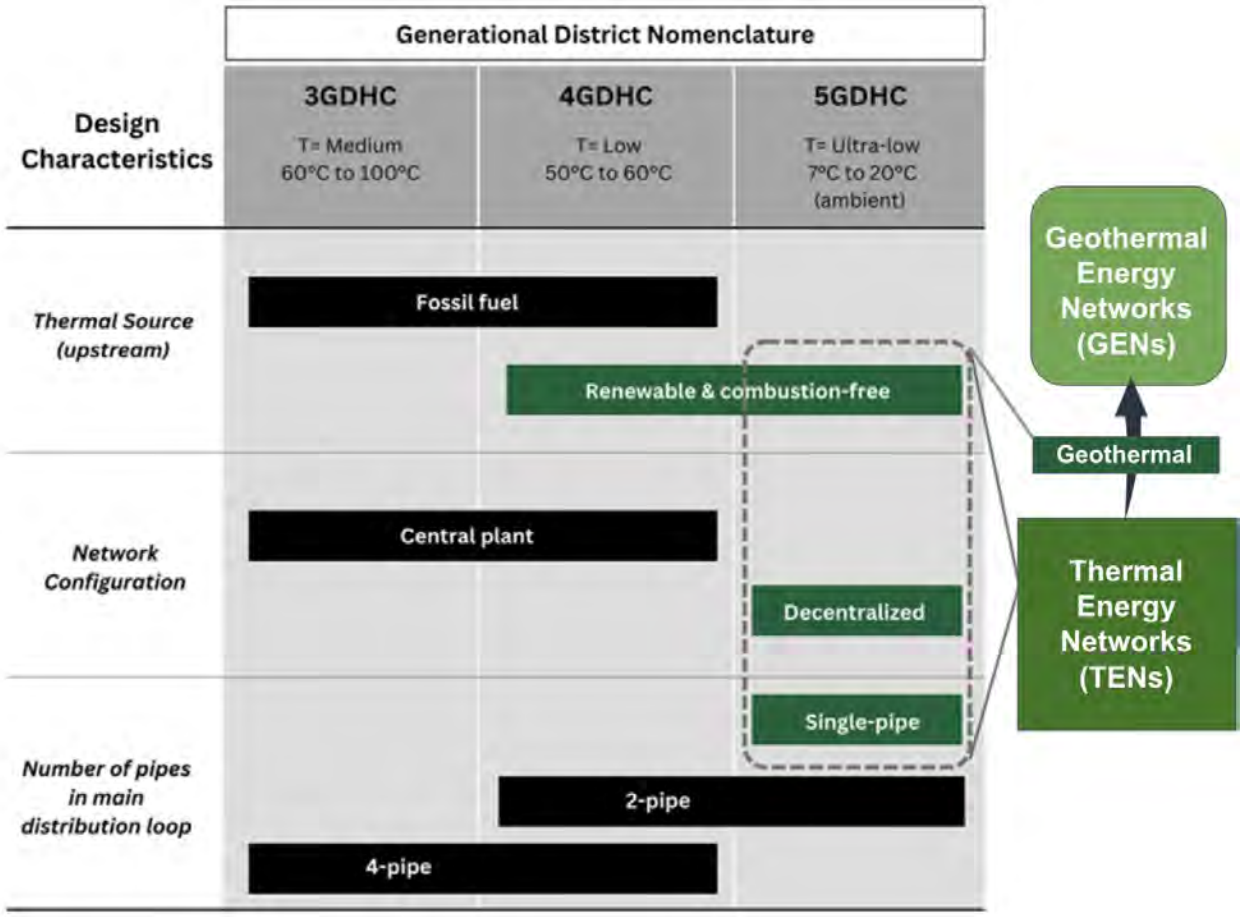

Figure 3. Schematic diagram of district energy characteristics for 3GDHC, 4GDHC and 5GDHC. GENs are shown in green and are a subset of the 5GHDC systems and, by tapping geothermal energy, are a further subset of TENs.

6. Conclusions

This study aimed to improve clarity for all stakeholders on terminology related to geothermal energy networks, with the purpose of supporting the growth of these technologies as a tool to decarbonize the built environment. Stakeholders from widely varying industries and sectors report that the greatest barrier to maximizing impacts of geothermal heat pumps and energy networks is a lack of knowledge and understanding among both decision makers and the public. A clear nomenclature can greatly reduce confusion and increase trust, leading to more widespread understanding of the ground-breaking potential of geothermal energy networks.

Yet geothermal energy networks exist at the intersection of multiple technology communities including the district energy community, the geothermal energy community, and the ground source heat pump community. Each has their own naming and language norms. As do policy experts, academics, and engineers. This work did not attempt to meet the needs of any one group but rather to find the common ground between them. Furthermore, this work did not address language appropriate to engineering docs or technical specifications, which requires an additional rigor in definitional clarity, but rather addressed the more public-facing policy terminology.

Addressing widespread language use necessarily requires acceptance that the public or key stakeholders may not accept or adopt this work. If our clarification of geothermal technologies, our division of a thermal network into three parts, our introduction of the GENs term, or any other part of this work is not yet used and useful then this work will need to evolve again until the terminology and categorizations in use are clearly defined and linked to operational outcomes and impacts. It is that potential impact - an energy system that meets the needs of our shared future - that is, after all, the end game.

Table 1 Thermal energy networks taxonomy rubric for parameters related to thermal resources.

Function	Parameter	Parameter Option	Temperature	Features	Network Configuration	Combustion	Operational GHG Emissions	Taxonomy
Thermal Resources	Renewable	Geothermal (deep)	High temperature 60C - 120C	Deeper boreholes higher risks and costs. Requires high geothermal gradient	Centralized	No	Low (closed loop binary system)	Geothermal District
		Geothermal (shallow)	Low temperature 7C - 20C	Local, feasible in most geologies.	Decentralized	No	Low*	Geothermal Energy Network
		Water bodies (lakes, ponds, rivers, ocean)	Low temperature 7C - 20C	Lowers cost compared to drilling boreholes	Both	No	Low*	Geothermal Energy Network
		Solar thermal	High temperature	Can be integrated at the building or loop level	Both	No	Low	Thermal Energy Network
		Concentrated solar	High temperature 60C - 120C	Requires large land area and only feasible in certain climate zones	Centralized	No	Low	Thermal Energy Network
		Biomass	High temperature 60C - 120C	Requires industrial process	Centralized	Yes	Low	District Energy
	Waste Heat	Waste-water treatment facilities		Generally used for low temperatures	Centralized	No	Low	Thermal Energy Network
		Sewer lines		Distributed geographically	Decentralized	No	Low	Thermal Energy Network
		Rejected heat		Can be rejected heat from industrial processes or commercial buildings	Both	No	Low	Thermal Energy Network
	Non-renewable	Fossil fuel plant (coal, gas)	High temperature 60C - 120C	Requires	Centralized	Yes	High	District Energy
		Combined heat and power	High temperature 60C - 120C	Leverages the by-product of power production	Centralized	Yes	Medium to high	District Energy

Table 2 Thermal energy networks taxonomy rubric for parameters related to the distribution system or main loop.

Function	Parameter	Parameter Option	System Features	Network configuration	Main Pipe Diameter	Main Pipe Temperature Range	Load Canceling	Generation
Distribution	Number of Pipes in Main Loop	Single pipe • Ambient temperature loop	• More efficient in canceling thermal loads between buildings	Decentralized	Larger (6 inch to 12 inch)	Ultra-low, near ambient	Yes	5G
		Two-pipe loop • Supply and return	• More efficient than 4-pipe • Generally is either heating or cooling • Can have a heat pump to do cooling	Centralized	Small systems: 4 to 12 inches Large systems: 12 to 36 inches	low (50-60°C) or ultra-low	Not bidirectional	4G/5G
		Four-pipe loop • Two inlet temperatures • Two outlet temperatures	Direct use of high temperatures • No heat pump • No cooling	Centralized	Small systems: 2 to 12 inches Large systems: 12 to 24 inches	low (50-60°C)	No	4G
	Heat Exchange Medium	Water	• Cost efficient • Environmentally friendly	Both	NA			
		Water & food grade glycol	• Antifreeze • Higher cost • Low environmental risk	Decentralized				
		Water vapor	• Inefficient, high heat loss during distribution • Requires central plant • Likely dependent on fossil fuels	Centralized				
		CO2	High pressure (135 to 435 psi)					

Table 3. Thermal energy networks taxonomy rubric for parameters related to the end-user or customer.

Function	Parameter	Parameter Option	System Features	Network Configuration	Energy Usage
End-user	HVAC Equipment	• Heat pumps at every building • HVAC at every building	Space heating and cooling, and domestic hot water	Decentralized	Buildings are consumers and prosumers
		HVAC in every building	Space heating and cooling, and domestic hot water	Centralized	Buildings are consumers only • Primarily unidirectional (from central source to consumers)
	Building Envelope	Energy efficient	Optimal use of energy	NA	Consumes less energy
		Not energy efficient	Needs weatherization	NA	Consumes more energy
	Building Typology	Commercial	Peak energy use: 9 am - 5 pm	NA	Likely anchor tenant
		Residential	Peak energy use: 7 am - 9:30 am, 4 pm - 8 pm	NA	Likely consumer
		Industrial	Peak energy use: variable	NA	Likely prosumer and anchor tenant
	Thermostat Control	Yes - active load management	Optimization of consumption: • Responds to system peak electric consumption	NA	Reduced energy consumption based on high demand periods
		No - preset	No thermostat-based optimization of consumption	NA	No thermostat-based optimization of energy consumption
	Heat Exchanger at Every Building	Yes	• Clear delination of distribution vs. behind the meter infrastructure • Increases cost of system per customer	Isolation of building supply from those in the main loop	Impacts efficiency of the system
		No	• No separation of fluids between main loop and buildings	Fluids from main loop circulate to the building

Development and Preliminary Analysis of a U.S. Geothermal Heat Pump Installation Database

Hannah Pauling, Slater Podgorny, and Dayo Akindipe

National Renewable Energy Laboratory (NREL)

Keywords

Geothermal heat pumps (GHP), data collection, market analysis, geospatial analysis

ABSTRACT

This paper seeks to addresses the significant gap in the literature regarding the installation and adoption of geothermal heat pump (GHP) systems in the United States. While the "2021 U.S. Geothermal Power Production and District Heating Market Report" published by the National Renewable Energy Laboratory (NREL) focused on direct-use geothermal district heating systems, it did not include an analysis of GHP installations (Robins et al. 2021). To bridge this gap, NREL has compiled a novel database currently containing 70,470 records of GHP installations, primarily sourced from state well permits and small-scale studies.

Our methodology emphasizes the collection, cleaning, and standardization of data, addressing challenges such as inconsistent reporting formats and privacy concerns. Despite limitations in data on capacity, costs, and performance, our preliminary geospatial analysis reveals insights into the distribution of GHP systems across urban and rural areas and climate zones.

The paper highlights the importance of publicly accessible data for advancing GHP technology adoption with a discussion of existing data sources and their limitations, advocating for improved collaboration between NREL and industry stakeholders.

1. Introduction

Geothermal heat pump (GHP) technology offers significant potential for sustainable heating and cooling in the United States, yet comprehensive data on GHP installations remains scarce. The National Renewable Energy Laboratory (NREL) aims to address this gap through the development of a detailed database of GHP installations across the country. This effort builds on the foundation laid by the "2021 U.S. Geothermal Power Production and District Heating Market Report" (Robins et al. 2021), which focused on direct-use geothermal systems but did not include GHPs.

So far, the newly compiled database contains 70,470 records, primarily sourced from state well permits and supplemented by small-scale studies. This collection of data provides a foundational resource for analyzing the spatial distribution and adoption trends of GHP technology. However, key metrics such as capacity, costs, and performance are sparsely populated, presenting challenges for comprehensive analysis.

This paper details the methodology used in the creation of the database, including data collection, cleaning, and standardization processes. It also discusses the initial findings from geospatial analysis, offering insights into the distribution patterns of GHP installations across various regions and climate zones. The importance of publicly accessible data for policy development, market analysis, and strategic planning in the renewable energy sector is emphasized, highlighting the need for ongoing collaboration between NREL and industry stakeholders.

2. Database: Description, Metrics, and Main Sources

The GHP database compiled by NREL predominantly consists of records derived from state well permits. These permits often provide detailed location information but lack other key metrics such as installed capacity, costs, and performance data. Within the 70,470 records, geographic coordinates are available for 98.4% of the entries, while metrics such as capacity and costs are sparsely populated and present in less than 1.5% of entries. These additional metrics are primarily sourced from specialized studies focusing on specific GHP systems and cannot be universally applied.

Because of its reliance on well permits, the database does not capture installations using horizontal configurations, which are common in residential applications because of lower installation costs. This omission underscores the need for more comprehensive data collection practices that include all types of GHP installations.

GHP reporting practices vary widely among states, with disparities in the accessibility of drilling permits that specify well usage. At the federal level, GHP manufacturers report annual heat pump unit sales to Energy Star, providing a broad overview of industry trends but offering limited insights into capacity, costs, and performance metrics. Analysis often necessitates assumptions based on established benchmarks, such as the 12 kW per heat pump unit guideline used by Lund et al. (2020).

Installation costs are heavily influenced by drilling expenses and site-specific subsurface conditions, while performance metrics exhibit variability because of a wide range of utilization factors, even among identical GHP units. Despite these challenges, existing studies, such as Cox et al. (2022), enable scenario-based analysis incorporating factors such as drilling costs, thermal conductivity, and utilization rates to present a range of costs and performance metrics. In addition, various modeling tools facilitate the modeling of geothermal market demand, including GHPs, despite limited data availability on GHP demand itself.

These insights emphasize the necessity for improved and standardized data collection and reporting practices to better understand and optimize GHP system performance, costs, and deployment across various regions.

3. Methodology

3.1 Data Collection

Our approach to compiling data on GHP installations primarily relied on state well permits as the primary data source because of challenges encountered with other data collection methods. Initial attempts to gather information from heat pump manufacturers and distributors proved unsuccessful, leading us to prioritize state well permits for their availability and detailed location information.

Permitting practices vary widely from state to state. Drilling permits may be managed by various departments within a state, including Environmental Protection, Water Rights, Natural Resources, the Engineer's Office, and in some cases, the Department of Health. This diversity in management can complicate data collection, because each department may have different reporting standards and data accessibility.

Even when well permits are publicly available and easy to find, they may lack specific end-use identifiers that include heat pumps. For this reason, any well permits without clear end-use identification were excluded from our analysis to ensure accuracy and relevance.

Despite these challenges, the reliance on state well permits provided a substantial dataset, offering valuable insights into GHP installations across various regions. However, the absence of end-use identifiers in many permits suggests a need for more standardized reporting practices to facilitate comprehensive data collection.

3.2 Data Cleaning and Consolidation

Each permit provided valuable location data, though variations in reporting formats necessitated significant standardization efforts to streamline the analysis. Some states require a separate permit for each well, while others only require one permit per property. This inconsistency required extensive consolidation to ensure that each system in the database is represented by a single entry. For instance, a system with 40 boreholes should be associated with one entry, not 40, to avoid redundancy and ensure accurate analysis.

The database will be made publicly available upon completion, so efforts are being made to address privacy concerns. Many well permits include sensitive information such as the owner's name, address, and phone number. To protect privacy, these details will be excluded from the public release of the database. Additionally, discussions are underway to identify and mitigate other potential privacy issues.

To enhance the utility of the database, we are implementing a robust data cleaning and standardization process. This involves normalizing location data to a consistent format, ensuring that all entries adhere to a uniform structure, and cross-referencing permits to eliminate duplicates. These steps are crucial to maintaining the integrity and usability of the database for researchers, policymakers, and industry stakeholders.

4. Geospatial Analysis

While the database represents only a fraction of total U.S. GHP installations, its rich location data supports preliminary geographic analysis. Despite the gaps in data on capacity, costs, and performance, geospatial analysis can provide valuable insights into the current state and potential growth areas for GHP technology.

4.1 Climate Zones

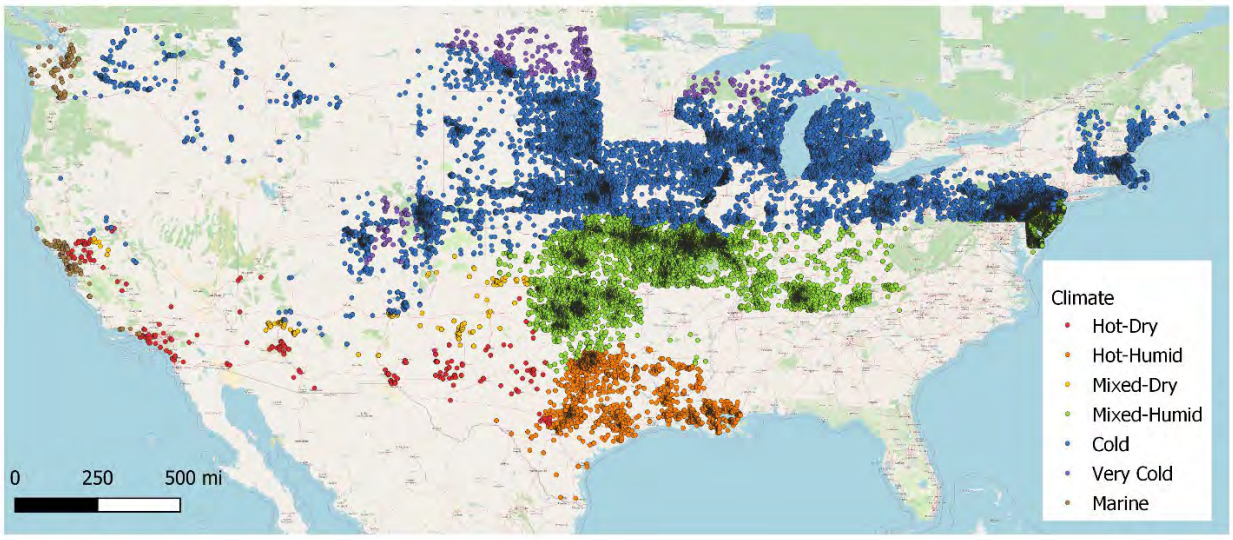

Figure 1: Geographic distribution of GHP installations across the United States, color-coded by climate zone. The Building America climate zones are described in Baechler et al. (2015).

The map in Figure 1 illustrates the concentration of GHP installations across different regions, highlighting variations in adoption patterns influenced by climate. The vast majority of systems in the database are found within Mixed-Humid and Cold climate zones. Notably, several states, particularly in the southeastern United States (Hot-Humid region), are still missing from the database. Despite this gap, valuable insights can still be drawn from the existing distribution.

GHP systems are highly efficient in both heating and cooling, making them particularly attractive in regions with significant seasonal temperature variations. Mixed-Humid and Cold climates experience such variations, allowing GHP systems to provide substantial energy savings and comfort. Cold climates, in particular, have a higher demand for heating during the winter months, further enhancing the appeal of GHP systems in these areas.

Even with the exclusion of the southeastern United States, the data shows that significantly more systems are located in humid climates compared to dry ones. One potential explanation is that the eastern half of the United States, which primarily encompasses humid climates, has a significantly higher population density compared to the western, drier regions. Higher population density leads to more residential and commercial buildings, thereby increasing the demand for heating and cooling solutions.

Additionally, the soil and ground conditions in humid climates are often more favorable for GHP installations. Moist soil conditions improve the thermal conductivity of the ground, enhancing the efficiency and effectiveness of GHP systems.

4.2 Urban Areas

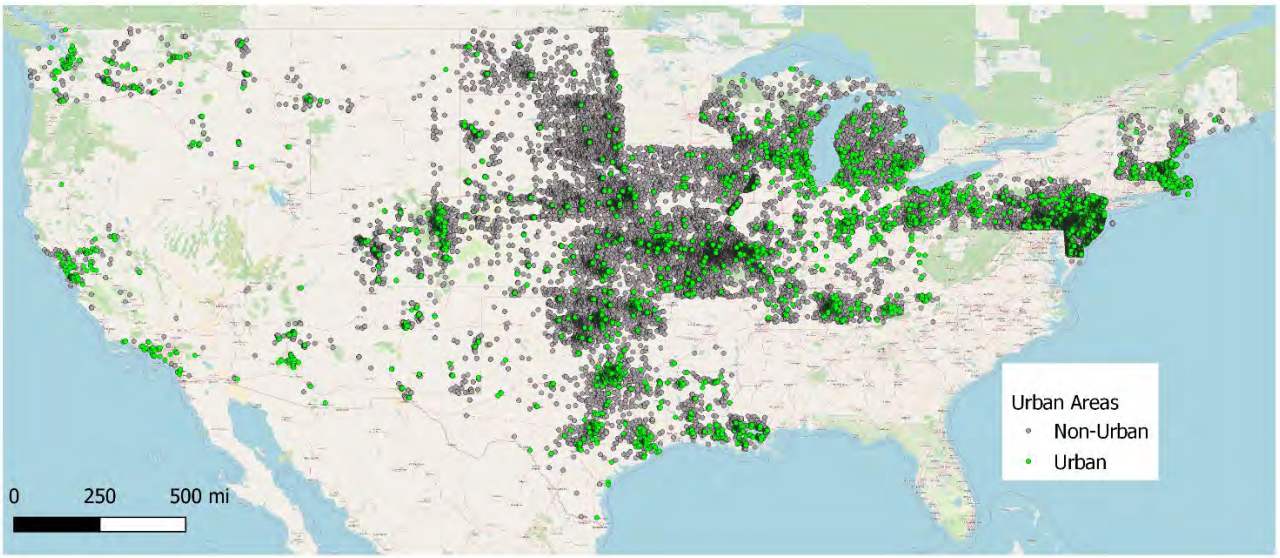

Figure 2: Geographic distribution of GHP installations across the United States, color-coded by urban areas. Urban area outlines from U.S. Census (2020).

The map in Figure 2 shows the nationwide distribution of urban areas and nonurban areas (suburban and rural). Currently, only 34.64% of GHP systems in the database are located in urban areas, despite the typically higher population density in these regions. In contrast, a significant 65.36% of installations are situated in rural and suburban areas.

Urban areas tend to have a higher concentration of multifamily housing, which could partially explain the lower number of systems. Instead of having many small systems for single-family housing, there could be a tendency toward fewer, larger installations.

As previously noted, the database primarily relies on well permits as its data source. Consequently, horizontal GHP configurations, which do not require well permits, are largely absent from the database. If included, these horizontal systems would likely be found predominantly in nonurban areas because of their larger space requirements compared to vertical systems. This absence of horizontal system data suggests that the actual disparity in distribution between urban and nonurban installations may be even more pronounced than the data currently reveals.

5. GHPs in the United States

Publicly accessible data on GHPs is crucial for accurate assessment, strategic planning, and informed decision-making in the energy sector. However, the current availability of such data is sparse and fragmented, posing significant challenges to stakeholders. Comprehensive and detailed

data collection, including information on various installation types and their performance, is necessary to support the broader adoption and optimization of GHP technology. This would enable more accurate market analysis, better policy development, and enhanced efficiency in energy use and management.

The U.S. Energy Information Administration Residential Energy Consumption Survey (RECS) offers some insights, but only lists ~250 GHP sites. GHP manufacturers report annual shipment numbers to Energy Star, but these figures are aggregated at the national level, making state-by-state data unavailable. This lack of granularity complicates efforts to understand regional market dynamics and deployment patterns.

The 2022 International Energy Agency geothermal report (GTO 2024) estimates a nationwide capacity of 20.2 GWth, derived from the U.S. Energy Information Administration data and incremental shipment data. However, this report also lacks state-specific information, limiting its utility for localized analysis.

The U.S. Energy Information Administration's nationwide capacity estimates from 1989 to 2011 were based on data from the Oregon Institute of Technology's Geo-Heat Center. Since the center ceased operations, the U.S. Energy Information Administration has assumed annual estimates from 2012 onward to be static, equal to those of 2011. This methodology results in outdated and potentially inaccurate data. These data limitations highlight the need for more detailed and disaggregated reporting to better support the growth and optimization of GHP technologies across various states and regions.

7. Conclusion

Creating a database for GHP installations in the United States is a critical step toward understanding and optimizing the use of geothermal energy. While significant progress has been made in compiling location data, there remains a pressing need for more detailed and consistent reporting on key metrics such as capacity, costs, and performance. Improved data collection practices and ongoing collaboration between NREL and industry stakeholders are essential to support the broader adoption of GHP technology. By leveraging detailed geospatial analysis and making data publicly accessible, we can enhance public awareness, drive market growth, and inform strategic decisions in the renewable energy sector.

ABSTRACT

Geothermal district energy systems (DES) with ambient-temperature loops, also known as thermal energy networks, are one option for decarbonizing space heating and cooling loads. Geothermal fifth-generation DES include an “ambient” temperature thermal loop that connects heat pumps at each building with thermal balancing sources such as geothermal borehole fields. Heating and cooling are provided via a water-source heat pump at each end-user.

This project seeks to analyze the nationwide potential for ambient-temperature loop districts by creating a new module within the Distributed Geothermal Market Demand Model (dGeo). dGeo is an agent-based modeling tool for distributed geothermal resources; it can investigate potential on a nationwide or statewide scale using geospatial data for all 50 states and thermal demands for existing buildings. This process allows for high-level estimates of technical and economic potential for ambient-temperature loop districts across the United States.

A lookup table was created using GHEDesigner to size borehole fields for different thermal loads and ground conditions experienced across the country. A cost and financing structure, along with incentives, were applied. Cost estimates include costs for the distribution network, borehole field installation and operation, and circulation pump operation, while savings are calculated based on energy bills for building owners (agents). This newly developed module can be used for assessing which areas of the country have the highest potential for agent benefits from ambient-temperature loop installation and assess the impact of future cost and price scenarios.

Initial results for statewide analysis (for Vermont) and nationwide (for United States) are provided. Future work includes expanding the module to consider mixed residential and commercial districts as well as evaluating multiple cost scenarios.

1. Introduction

Decarbonizing heating and cooling is a critical step to achieve carbon reduction goals, as traditional heating has significant on-site carbon emissions (often from burning natural gas or fuel oil). Even traditional district heating and cooling systems which utilize steam or chilled water often use fossil-fuel-based systems in the central plant. In 2020, commercial and residential building energy consumption accounted for 40% of the United States' primary energy consumption (U.S. Energy Information Administration 2020). In the European Union, heating and cooling of buildings accounted for more than half of the energy consumption in 2020 (International Energy Agency (IEA) 2023). It is critical to decarbonize heating and cooling loads in ways that are economical, equitable, and compatible with a renewable electric grid.

District energy systems connect buildings in a community with a thermal network (generally one or several pipes running under the street) to provide heating and cooling. Ambient-temperature loops (ATL) are a specific subset of district systems which provide water at near-ambient temperatures (generally in the range 10°C to 25°C) to localized water-source heat pumps located in each building to meet heating and cooling loads. The water in the loop may exchange heat with multiple buildings and other energy sources (such as boreholes, waste heat from refrigeration, or heat from a sewer heat exchange system). One common way of moderating the loop's temperature is to run the fluid in the loop through geothermal boreholes in a borehole field. This allows the ground to act as a heat exchanger and transfer heat to or from the loop. These shallow closed loop geothermal systems, also known as geo-exchange, can be used to provide consistent low-temperature energy streams.

District systems enable a thermal resource with a relatively high capital cost (such as a geothermal borehole system) to be shared among a large number of users and amortized over a long period of time (30 or more years). Distributing costs in this manner may increase equitable access to decarbonization and reduce energy bills.

A recent study by Liu et al. (2023) found that converting existing HVAC systems to individual geothermal heat pumps reduced loads, energy prices, transmission requirements, and emissions. Ambient-temperature districts are thought to have equal or greater potential to reduce load on the electrical grid compared to individual geothermal heat pumps, resulting in significant grid cost savings.

A diagram for an ambient-temperature loop system is shown in Figure 1. The main thermal loop carries water (or a glycol-water mixture) between loads in the community and exchanges heat with the ground via the geothermal borehole field. These systems have various names in the literature including thermal energy networks and fifth generation district energy systems.

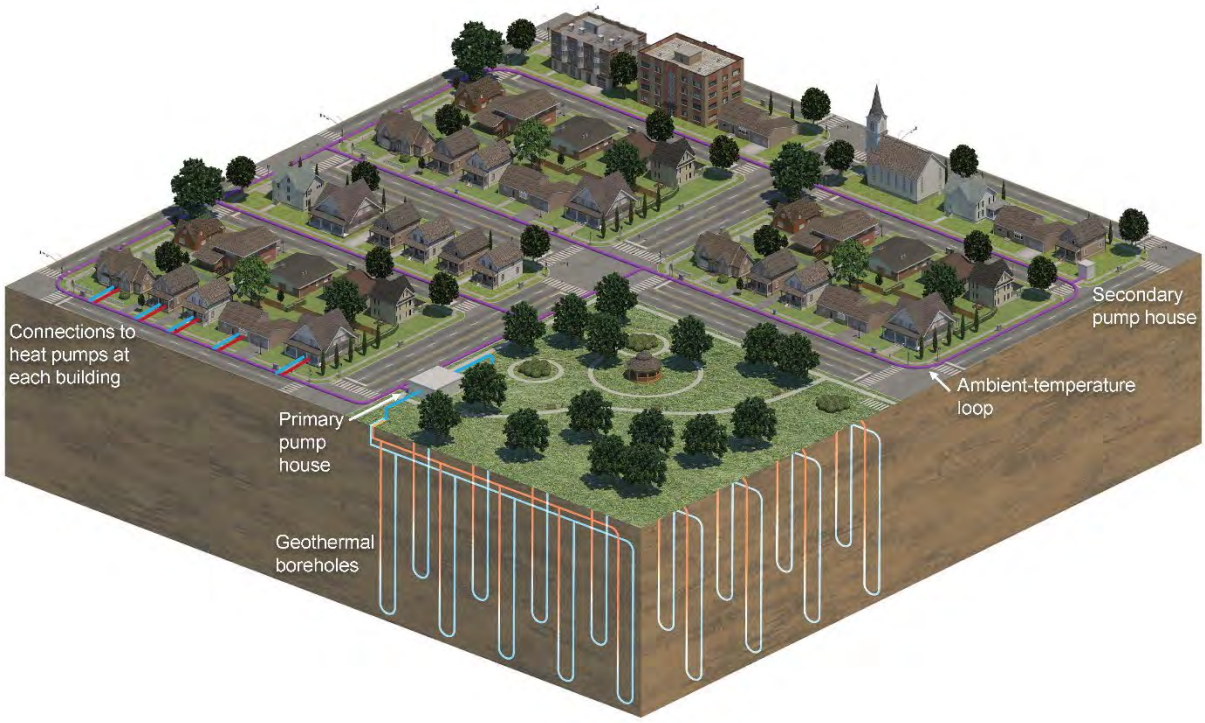

Figure 1. Example ambient-temperature loop district system with a single pipe thermal loop (purple line). This loop connects with heat pumps at each building to meet heating and cooling loads and exchanges heat with the ground via geothermal boreholes, under a park. *Graphic by Besiki Kazaishvili, NREL.*

The major components covered in this project, shown in Figure 1, include buildings with heat pumps, a single-pipe thermal loop, a geothermal borehole field, and a pump house. The pump house contains the pumps for the borehole field, the circulation pumps for the main thermal loop, any auxiliary heating or cooling, and the control system.

These systems have been deployed on campuses and in communities with promising results. Examples include Colorado Mesa University (Woodruff 2022; Schulman 2020; Oh and Beckers 2023; Electric Power Research Institute, n.d.), Minewater (Brummer and Bongers 2019; Verhoeven et al. 2014; Boesten et al. 2019), and Whisper Valley (Marin 2022; Wolfson and Mapel 2020; "Whisper Valley," n.d.). Unlike most previous examples, the Eversource DES in Framingham, Massachusetts is retrofitting an existing community in the United States through a utility-led installation (Eversource, n.d.; HEET 2022), which provides a clear example for how district systems can be installed in existing communities.

The National Renewable Energy Laboratory developed the Distributed Geothermal model (dGeo) as part of its Distributed Generation Market Demand Model (dGen) to explore the technical, economical, market, and adoption potential for geothermal heating and cooling technologies in the United States (Liu et al. 2019; McCabe et al. 2019; Beckers and Young 2017; Gleason et al. 2017). dGeo is an agent-based modeling framework that uses geospatial-based data on geothermal resources, thermal demand, building characteristics, and energy prices to evaluate technical performance, cost-competitiveness, and potential adoption of geothermal heating and cooling systems. While dGeo does not model each building in the United States, it simulates "a *synthetic*

population of commercial and residential buildings that is statistically representative of the true population" (McCabe et al. 2019).

Given the potential benefits to the electrical grid, decarbonization, and energy justice, this study investigated the potential of ambient-temperature districts for national deployment. The initial focus of dGeo was geothermal heat pumps and geothermal direct use for district heating. In this project, a new capability was added to dGeo for modeling ambient-temperature loop district energy systems using geothermal boreholes. This module investigates high-level techno-economic performance of ambient-temperature loops across the United States.

2. dGeo Ambient-Temperature Loop Methodology

The new ambient-temperature loop module uses the same dGeo agent-based modeling framework as previously documented (Liu et al. 2019; McCabe et al. 2019; Beckers and Young 2017; Gleason et al. 2017). Geospatial data layers for dGeo modeling include:

- Building type count for the residential (such as single-family detached and single-family attached) and commercial (such as restaurant, hotel, and office) sectors at the census block level based on the Federal Emergency Management Agency's HAZUS 6.1 dataset (FEMA 2023).
- County heating and cooling load in the residential and commercial sectors based on statewide and regional data and county level building counts from the U.S. Energy Information Administration's Residential Energy Consumption Survey and Commercial Buildings Energy Consumption Survey.
- Residential Energy Consumption Survey /Commercial Buildings Energy Consumption Survey microdata by climate zone to allow sampling of current building HVAC system types, HVAC lifetimes, and housing square footages.
- National and state incentives (such as rebates or tax credits) for geothermal technologies.
- Shallow ground thermal conductivity ranges by climate zone.
- Current and projected future regional energy prices for electricity, propane, natural gas, and distillate fuel oil, collected from the U.S. Energy Information Administration's Annual Energy Outlook datasets.
- Neighborhood road lengths by census tract.

Non-geospatial inputs include:

- Current and future costs for well drilling, heat pump and baseline HVAC systems.
- Project financing inputs.
- Current and future HVAC system performance.

2.1 Creating Borehole Field Look-up Tables

While ambient-temperature loops can be designed to use a variety of thermal sources and sinks, this study only considered the use of geothermal borehole fields. Sizing a borehole field for every potential district across the United States would have prohibitively high computational costs.

Instead, a look-up table was created to represent the different thermal loads and ground conditions across the country. This table was then used to size borehole fields.

For each set of inputs in the look-up table, GHEDesigner (a ground heat exchanger design tool) was used to size the number of boreholes and length needed to meet the thermal load (Jeffery Spitler et al., n.d.; Jeffrey Spitler, West, and Liu 2022; Mitchell et al. 2023). The recorded metric was the total borehole length required per gross building load (sum of absolute value of annual heating and cooling loads in the district). Thus, the output can be used to scale the size of the borehole field based on the total load in each district.

A multi-dimensional look-up table of 540 scenarios (= 15 × 3 × 3 × 4) was developed by independently varying climate zone, ground thermal conductivity, number of buildings and ratio of annual heating to cooling load (see Table 1).

Table 1. Lookup table inputs

Variable	Inputs
Climate zone*	1A, 2A, 2B, 3A, 3B, 3C, 4A, 4B, 4C, 5A, 5B, 6A, 6B, 7A, 7AK
Ground thermal conductivity quartile	25^{th}, 50^{th}, 75^{th}
Number of buildings	3 options (between 25-300, range varied by climate zone)
Ratio of annual heating to cooling loads	4 options (from 0.002 – 12, range varied by climate zone)

**ResStock building loads were not available for climate zones 7B or 8A. Those loads were thus excluded from this analysis.*

Within the United States, there are eight climate zones and three moisture regimes (A, B, C), using the categories designated by the Internation Energy Conservation Code (IECC). For each climate zone, a representative city was selected and ResStock (National Renewable Energy Laboratory, n.d.) timeseries building data was retrieved. Building data from actual meteorological year 2012 was used to be compatible with ReEDS for future grid impact analysis. For each climate zone, the average ground temperature (Xing 2014) and each of the three quartiles for ground thermal conductivity (Liu, Warner, and Adams 2016) were used as inputs for the geothermal borehole modeling.

The number of buildings and ratio of heating to cooling loads specified as inputs for the look-up table (as described in Table 1) were determined based on analyzing loads across each climate zone. The goal was to create three different district sizes by specifying a number of buildings, while maintaining district borehole field size between 200 and 1000 total boreholes. Climate zones with more balanced loads can hold more buildings in each district within these bounds, while climate zones with highly unbalanced heating and cooling loads use fewer buildings. Additionally, the ratio of heating to cooling was varied to capture differences between different building types and load profiles. While the heating and cooling loads may be scaled up or down to capture a specific

ratio, the hourly variations are still present. This allowed the lookup table to capture a wide variety of potential district building compositions.

Once the buildings were selected for a given climate zone and the loads scaled to match a given ratio, the building loads were summed for each hour of the year across all the buildings in the district and then converted into ground loads via the heating and cooling coefficient of performance (COP). The resulting timeseries ground load values were then input into GHEDesigner to size the appropriate borehole field.

The general model settings for GHEDesigner were:

- 30-year design period
- Minimum entering temperature of 0°C and maximum entering temperature of 35°C for the heat pump
- Initial COP values of 4 for heating and 6.5 for cooling (Liu et al. 2023), then iterated to find new COP values based on fluid temperature leaving borehole field during simulation and a residential heat pump COP curve
- Maximum borehole depth of 175 m
- Borehole spacing of 6.1 m
- 20% glycol mixture
- 1.25-inch single U-tube pipe

2.2 Other Pre-processing and Inputs

Before running dGeo, the distribution network (the length of thermal loop piping to be installed) was sized for each census tract based on road lengths and land area. First, the distribution system was sized to be 75% of the road lengths in each census tract, excluding major roads (based on (Reber 2013)). Then, upper and lower limits were applied to cap distribution network sizing based on a study of European district energy systems (Sánchez-García et al. 2023).

Additionally, the census tract was flagged for potential space constraints if the land area required for the borehole field is greater than 5% of the tract's total land area. These census tracts may require a more in-depth assessment of land availability and heat exchange options. Borehole locations underneath roads or deeper concentric boreholes may increase the chances of installing borehole fields in dense urban areas.

The HEATNETS model (Simpson and Zhu 2024) was used to estimate operational energy and cost. Given load cancelling, loop thermal inertia, and heat exchange between the thermal loop and the surrounding soil, borehole field heat exchange may not be required at all times, with the working fluid instead circulating only in the thermal loop. The borehole fields may operate less in the shoulder seasons, which reduces pumping power needed to operate the system. HEATNETS was used to choose reasonable parameters for the dGeo system estimates, including a borehole capacity factor of 50%. Thus, for operational energy, the borehole field pumps are only considered to run 50% of the year.

2.3 District Costs

Estimating the capital and operational cost for these district energy systems is critical to determining their economic feasibility. In addition to costs, the potential incentives and financing structures must be considered.

Because district geothermal system adoption is limited in the United States, the financing structures are still to be determined. The study team assumed that the district-level components—including the borehole field installation, control system, distribution piping, and operation costs—are all covered by a commercial entity. Those costs are then passed on to agents through monthly bill payments based on each building's annual heating and cooling load. Agents are then responsible for heat pumps and building retrofits, as well as a portion of the district cost.

The potential economic benefits are quantified by the net present value for the agent. This value is based on the annual energy savings from the new system compared to baseline HVAC energy consumption, the agent's annual costs for the upgrades, and the agent's portion of the district cost.

Cost assumptions are highly uncertain due to the technology's early development stage. Cost estimates were gathered from the literature and publicly available financial data on utility installations. However, a range of values will be assessed to look at the impact of different values on economic potential.

The structure for building the cost estimate is as follows:

- District cost (assumed by commercial entity):
    - Borehole field:
        - Drilling cost per foot of depth (per borehole).
    - Distribution system:
        - Horizontal thermal loop pipe installation under community streets, cost per meter.
        - Central pump house or plant with controls, piping, and auxiliary systems, cost per kW of pumping power (to scale with system size).
        - Pump cost (for circulation of thermal loop and operation of borehole fields), cost per kW or HP.
    - Engineering, procurement, and construction, as a percent of installed cost before incentives.
    - Operations and maintenance, as a percentage of total installed cost before incentives.
- Agent cost (assumed by building owner):
    - Heat pump cost per ton.
    - Hook-up cost per building to connect to distribution network.
    - Retrofit cost per ton (only applied if the current HVAC system is not ducted).
- Incentives:
    - Federal investment tax credit (ITC) applied to district costs.
    - Federal tax incentive and state and local incentives (if available) applied to agent costs.

- Additional assumptions:
    - Pump operation costs assume borehole fields are run 50% of the time, with commercial electric rates applied.

2.4 Simulation Steps

An ambient-temperature loop simulation in dGeo begins with the same initial process documented previously (Gleason et al. 2017; McCabe et al. 2019; Liu et al. 2019), including referencing spatial databases and creating agents. Agents are assigned heating and cooling loads and HVAC system types, ages, and costs. After this general set-up, the ambient-temperature loop module in dGeo performs the following tasks:

1. Performs district sizing calculations for district energy systems within each census tract:
    - Ground thermal conductivity is randomly assigned as either 25^{th}, 50^{th}, or 75^{th} percentile of thermal conductivity for that climate zone.
    - Imports ground heat exchanger (borehole field) sizing lookup table, discussed in Section 2.1.
    - Sums the agent thermal heating and cooling loads in the census tract and scales to a reasonable size for a single district.
    - From the look-up table, assigns to the census tract a ratio of total length of borehole heat exchanger needed to gross heating and cooling load (m/kWh) based on the total thermal load, ratio of heating to cooling load, climate zone, and ground thermal conductivity of the district.
    - Assigns the distribution length needed to connect all agents in the census tract into districts based on pre-processed data (discussed in Section 2.2).
2. Sizes the heat pumps and calculates energy savings based on the geothermal heat pump module (Liu et al. 2019).
    - Compares current baseline capital and energy costs to proposed heat pump costs.
3. Calculates district sizing and costs for each census tract:
    - Sizes the borehole field based on the total gross load within the census tract (representing a total borehole field size that would likely be distributed amongst multiple borehole fields supporting multiple districts).
    - Estimates district system cost by applying the cost structure defined in Section 2.3, and then applies commercial financing and incentives.
    - Applies district costs to agents in each census tract based on $/kWh of total demanded thermal load.
4. Calculates agent financials:
    - Applies residential incentives and financing.

- Converts agent costs and energy savings into cashflows and then calculates net present value.
- Marks agents with positive net present value as economic potential.

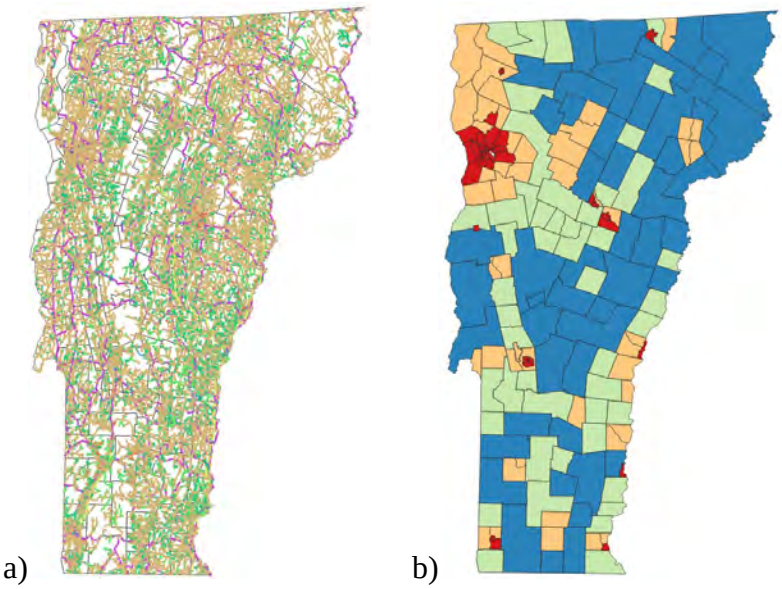
5. Repeats every 2 years.

Note that district sizing and cost calculations are done at a census tract scale. Most census tracts will need to include multiple districts. The study team assumed that each district in a given census tract has the same mix of buildings and the required costs are scaled up to the census tract level.

In the dGeo geothermal heat pump module, the market potential and adoption over time are calculated using adoption data and Bass diffusion curves. However, there is limited data available on district systems in general and no clear adoption data available at this time. Therefore, the ambient-temperature loop analysis will only go as far as economic potential and will not calculate market potential or adoption rates as was done previously for geothermal heat pump (Liu et al. 2019).

3. Initial Results and Discussion

Many geospatial data layers are used as inputs for dGeo. Figure 2 provides examples for the road lengths and thermal demand density spatial data for Vermont (chosen arbitrarily).



a) b)

Figure 2: a) Roads (different colors represent different road types), and b) thermal demand density (warmer colors represent higher thermal demand density) in Vermont.

To demonstrate dGeo's potential, a state-wide run was completed for Vermont, followed by a nationwide run for the entire United States, with results for 2032 shown in Figures 3 and 4. An advanced costing scenario was used, with cost values for well drilling, distribution system, etc. at

the lower end of current estimates. The median relative favorability of ATL for each census tract is shown, with darker colors representing a more economically favorable median agent net present value and lighter colors representing a less economically favorable median.

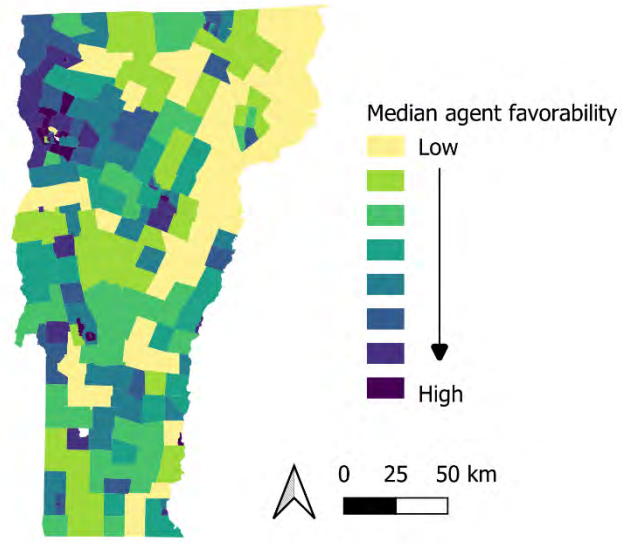


Figure 3: Vermont census tract median agent economic favorability in 2032.

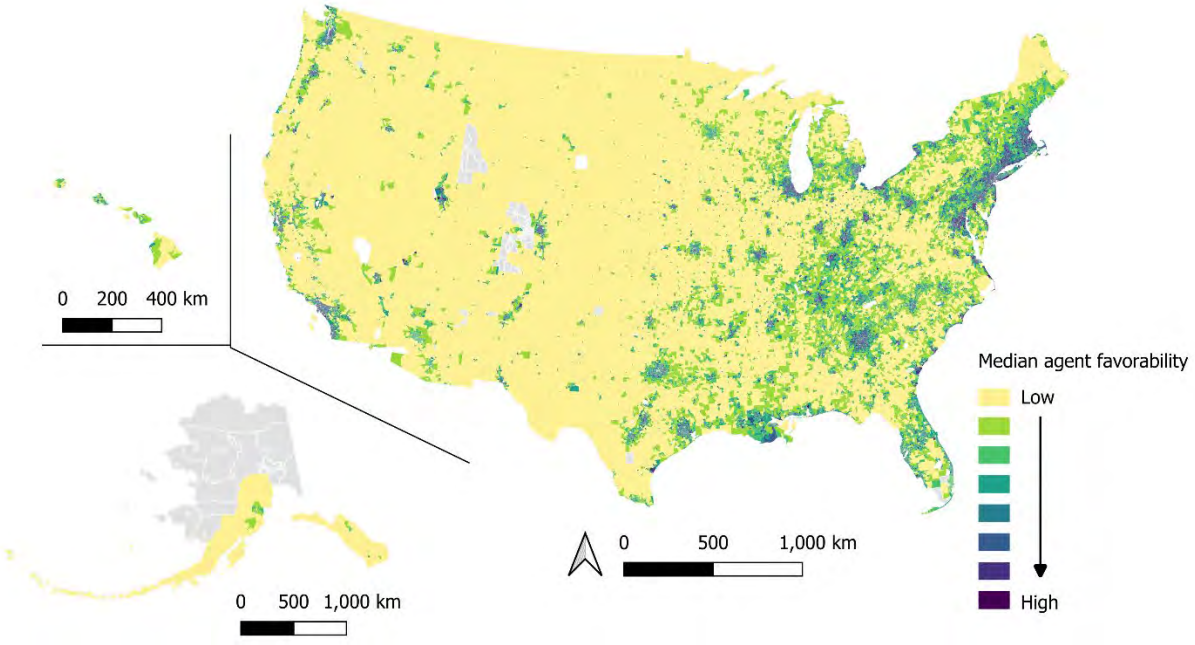

Figure 4: United States census tract median agent economic favorability in 2032. (Representative building models were not available for regions shaded in grey.)

To create the maps in Figures 3 and 4, the net present value for each agent was calculated for 2032. These net present values account for the additional capital costs of the heat pump installation,

shared ambient-temperature loop capital costs, and each agent's potential energy savings from switching from an original HVAC system to a geothermal heat pump. The year 2032 was used because the federal investment tax credit is still in place at this time, significantly decreasing capital costs. As expected, cities in each state tend to have higher favorability. More urban settings are likely to have reduced transmission costs per load, which can be a significant factor in the total capital costs. There are also differences in favorability seen among tracts in individual cities.

Figure 5 shows the ATL economic potential (given an advanced costing scenario) for Vermont, defined as the sum of the HVAC system size for all agents with a positive net present value when switching from their baseline HVAC to an ATL system. Every two years, dGeo adds new agents, updates HVAC costs and ages, adjusts energy costs, and generates new results. The number of agents with positive net present value generally increases over time until the federal investment tax credit expires at the end of 2034, after which the economic potential decreases significantly.

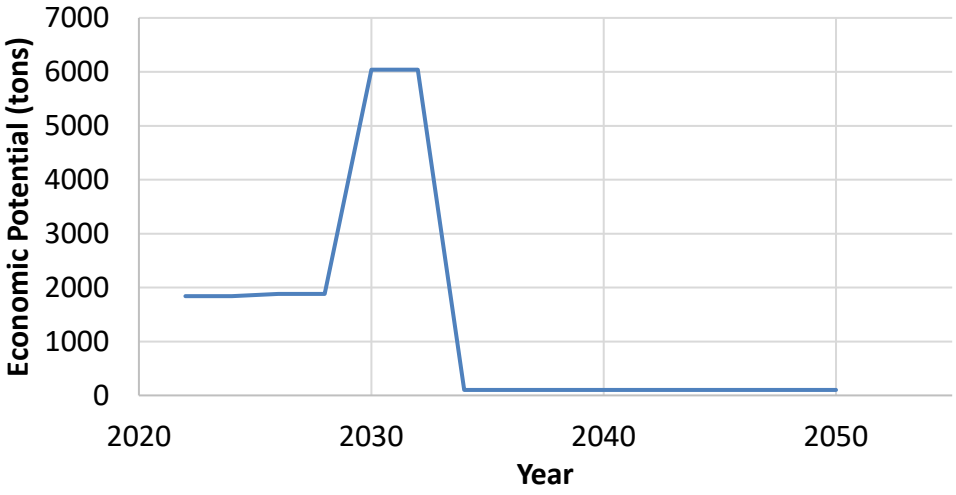

Figure 5: Vermont economical potential for agents with positive net present value over time.

The preliminary economic potential shown in Figure 5 accounts for most current incentives and rebates, but it does not account for any additional value to the electric grid or benefits for retiring natural gas infrastructure. These benefits to utilities are expected to be significant and may influence future adoption of ambient-temperature loop systems. Additionally, these initial results only consider residential buildings, and it is expected that performance would be improved when residential and commercial buildings are considered on the same loop.

These results are based on the economic potential for each individual agent. For district systems to work effectively, a critical mass of agents would need to agree to join a network. The study did not consider this aspect of district adoption, instead focusing on determining which agents would find district systems economically viable if district systems were an option in their community.

4. Conclusions and Future Work

In this project, dGeo was expanded with a new module to consider economic potential for ambient-temperature loop systems in the residential sector. A methodology was created for building a look-up table to size borehole fields for ambient-temperature loop districts across the United States. Cost correlations and financial structure assumptions were added to the module. The developed methodology compares the costs and benefits of ambient-temperature loop systems against baseline HVAC systems for agents in each census tract in the United States.

This new module can be used for assessing which areas of the country have the highest economic potential for ambient loop installations and what the impact is of different futures cost and price scenarios.

This research is ongoing, with additional improvements planned for the dGeo code. National simulations are still being processed, and the cost models continue to be updated as additional information becomes available. Future work includes expanding the module to consider mixed residential and commercial districts and considering multiple cost scenarios.

Heat pumps, geothermal heat pump, ground source heat pump, geothermal network, thermal energy network, database, heating and cooling, 5GHCD

ABSTRACT

Geothermal networks, defined as networked ground-source heat pump systems, are a clean energy alternative to fossil fuels for heating and cooling buildings, and a scalable solution with the potential to decarbonize entire neighborhoods. The individual components used in these networks are well developed technologies, such as pipes, pumps, and geothermal heat pumps. Nevertheless, there is a knowledge gap regarding how to optimize design parameters for performance and costs for the entire system, to account for region-specific conditions and localized heating and cooling needs for the buildings within the network. Additionally, there is a current lack of standardized methods for comparing these systems.

This study introduces a systematic and quantitative approach to comparing geothermal networks and provides the first open-source database where the datasets can be accessed and analyzed. In the US, geothermal networks have been most commonly adopted in university campuses. Recently, geothermal networks gained widespread attention from gas utility companies, cities, and states, as a strategy to reach net-zero emissions goals. Massachusetts is one of the leaders in this space, with five approved demonstration projects, each at different stages. In order to facilitate the optimized adoption of these systems, it is necessary to compare them and apply lessons from existing installations to those in earlier feasibility or planning stages.

This paper selects and examines key parameters to be systematically measured and recorded before and after the installation of geothermal networks, allowing for a quantitative comparison of these systems, as well as optimization of future ones. These recorded parameters fall into three categories: thermal resources (borefields, boreholes, etc.), distribution (main pipe system), and end-users (buildings, weatherization, etc.). This categorization of parameters, paired with cost data, will allow for fair comparison of geothermal networks with other heating systems. The creation of this open-access database for geothermal networks will therefore inform and facilitate the development of these projects, enabling decarbonization of buildings on a wider scale.

1. Introduction

By shifting from distributing gas to delivering emissions-free heat, gas utilities are becoming unexpected actors in effecting a decarbonization of heating systems in the Northeastern US. A network of geothermal (or ground-source) heat pumps, connected at a neighborhood scale, is at the heart of this transformation. These systems, that will be referred to in this study as geothermal networks, are also known as thermal energy networks (TENs), geothermal energy networks (GENs) or 5GDHC systems (Magavi et al., 2024). Geothermal networks have three main parts:

1. The **thermal resources** (sources, sinks, and storage) which are most frequently boreholes

2. The "**end-users**," or the buildings and customers which receive heating and cooling

3. The **distribution** system, which consists of the horizontal piping connecting the thermal resources and the end-users

Together, these form a closed-loop system, with water circulating through the boreholes, the main loop in the street and the service loop that connects to the buildings. In the winter, that water primarily carries heat from the boreholes to the buildings, and with the use of a heat pump at the building, that water can then be used for space (and water) heating. In the summer, this process is reversed, and the water primarily carries heat from the building to the boreholes. Systems such as these can facilitate a clean thermal market on a societal scale, where buildings that reject heat year-round, like data centers or ice rinks, could be connected to those that constantly require heat, like swimming pool facilities. Sharing heating and cooling loads into a common network makes the overall system more energy efficient. Because we are at the very initial stage of this transformation, capturing and disseminating lessons and data from these geothermal networks will be an important factor in supporting their growth. In order to facilitate this growth, this study is focused on creating a database of geothermal networks that can be used to inform the feasibility and design of future networks, as well as support data-driven policy for these systems.

Heating buildings accounts for 4 gigatons of CO2 nationwide, or 10% of global annual emissions (International Energy Agency [IEA], 2022). Within Massachusetts, for example, emissions from buildings account for 45% of the state's greenhouse gas emissions, and most of these emissions come from space and water heating systems (Mass.gov, n.d). Gas is currently the most commonly used fuel for heating in the state; 52% of households use natural gas, followed by 22% relying on fuel oil and kerosene. Electricity is used to heat 18% of the homes in the state. The electrification of heating and cooling systems is an important step in the US' journey towards net-zero in 2050. Installing heat pumps for heating and cooling, instead of relying on fossil fuel-based systems, will significantly reduce greenhouse gas (GHG) emissions related to the building sector. Networked geothermal heat pumps (GHP) are not only a highly efficient way of decarbonizing the building sector, but can also be implemented at scale while addressing equity in the energy transition. Furthermore, geothermal networks provide a path for decarbonizing high-emission industries, including gas utility companies.

Even though geothermal networks employ technologies that have been used for decades and mechanical equipment that is widely commercially available, there is a lack of standardized methods for quantitatively comparing the cost, efficiency, and design parameters between different

geothermal networks. Furthermore, there is debate on best practices for how to design these systems to maximize efficiency and cost. Generally, there is also a lack of research and data regarding the performance projections of these networks, their energy storage capacity, and optimal network parameters (Schulman and Magavi, 2022). This is largely because, until recently, geothermal networks were mainly implemented on university campuses in the US. It is only in the past three to five years that they have been considered as a societal scale decarbonization pathway, following the "Gas To Geo" proposal by HEET (2024) in Massachusetts seven years ago. This lack of information represents an obstacle to the wider expansion and implementation of these systems. It impedes not only the technical comparison of these systems, but it makes it difficult to leverage lessons from existing installations for others that are in earlier feasibility or planning stages. To fill this critical gap, this research project is focused on producing the first open-source database for geothermal network systems, in order to allow for a systematic comparison between these systems. This database will also support the development of data-driven legislation and regulation for geothermal networks that will enable a rational path to wider implementation of these systems.

1.1 Research Questions

The three central research questions that drive this project are:

1. How can lessons learned from the few existing networked ground-source heat pumps be leveraged to optimize the coefficient of performance and cost of future installations of these systems, and enable wider adoption to support decarbonization?

2. What are the optimal parameters that should be systematically measured and recorded before and after the installation of a geothermal network, to allow for a quantitative comparison amongst existing systems, as well as optimization of future ones?

3. How can the parameters be categorized and grouped in such a way that they allow for a fair and systematic comparison between different heating and cooling systems?

1.2 Goals of the Database

Creating an open access database for geothermal networks can inform and facilitate the development of these projects, enabling a societal-scale decarbonization of buildings. Systematically recording and assessing properties from existing geothermal networks into a database will be beneficial for a variety of reasons, including:

1. Enabling the quantitative comparison of these systems by identifying parameters that may be significantly influencing the overall coefficient of performance and costs;

2. Contributing to prediction models that estimate the future performance of existing installations;

3. Informing the planning and optimization of parameters for future installations through analyses made possible by this database;

4. Recording costs related to heating and cooling of buildings with the legacy systems versus the geothermal network system, which will allow quantification of cost differentials;

5. Identifying costs and energy use by stages, such as thermal resources, distribution, and buildings, which will allow for fair comparison with other heating systems.

6. Catalyzing the adoption of geothermal network technology through increased knowledge of their efficiency or coefficient of performance and costs;

7. Demonstrating impacts on emissions, environment, and human health, by recording emissions and air quality effects before and after the installation of geothermal network;

8. Supporting the development of data-driven legislation and regulation related to the proliferation of geothermal network systems;

1.3 Sustainability Framing

By creating a database for networked ground-source heat pumps, this project will contribute to the advancement of several of the UN's Sustainable Development Goals (SDGs). The UN SDGs are 17 global objectives that aim to achieve sustainable societies by addressing current global problems such as hunger, poverty, human health, pollution, and climate change, as well as many others. At its core, this project supports the transition of heating and cooling of buildings to renewable and clean energy for the communities involved. Thus, this work furthers SDG7, which focuses on affordable and clean energy. The potential scalability of these systems means that this project also has the potential to contribute to the transformation of the communities involved in these pilots into sustainable cities and communities, contributing to SDG11. Because the installation of these systems will require a skilled workforce that includes drillers, pipefitters, HVAC installers, and engineers, it will also spur job creation and economic growth, contributing to SDG8. Furthermore, when deployed at scale, these networked geothermal systems will contribute to the reduction of GHG emissions by replacing heating systems based on gas and oil with ground-source heat pump technology, thus contributing to SDG13, which promotes climate action. Lastly, there are clear benefits to human health. Natural gas has been shown to contain small amounts of non-methane gasses that can be detrimental to human health and air quality (Michanowicz et al., 2022). The use of gas stoves for cooking or heating without ventilation has been shown to result in an increased risk of asthma, wheezing, and bronchitis in children (Kile et al.,2014). Thus, reducing or eliminating the need for gas in buildings also has the potential to contribute to SDG3, which focuses on good health and well-being.

1.4 Organization

This study is organized into five main sections: introduction; background; methods; results and discussion; and conclusion and further work. The background section provides a brief overview of ground-source heat pumps and compares them to air-source heat pumps. This section also introduces the concept of geothermal network systems, as well as their benefits and challenges. Additionally, it describes the current momentum of these systems, reflected by the interest from utility companies, the number of states that have passed legislation supporting their growth, and the feasibility and pilot projects which are already underway. It is this momentum that has sparked the need for the database proposed by this study.

The methods section explains the process used for creating this database. A key aspect of this project was to collect a set of parameters that captures the main characteristics of the system while remaining simple to record and report. The methods section describes the process of gathering

input from various stakeholders regarding what parameters should be recorded and how they were categorized.

The selected parameters are presented in the results and discussion section. This results section presents the classification of the parameters into thermal resources, distribution, and end user or buildings. It also describes the categorization of the parameters into two further groupings: an essential or basic collection, and an enhanced, in-depth or case study collection.

This study ends with the conclusion and future work section. This segment describes how this database can be used and how it may further evolve. This part also discusses the expected growth of the database, the challenges it faces, and the impact it can have.

2. Background

This section aims to provide the background context for the creation of the database. In order to do this, three main questions are addressed: 1) Why use geothermal heat pumps? 2) Why use geothermal networks? and 3) Why do this now?

2.1 Why Use Geothermal Heat Pumps?

The wider implementation of heat pumps can contribute to GHG reduction, as well as improving air quality which affects human health. The use of heat pumps instead of fossil fuel-based systems will significantly reduce GHG emissions, even taking into account the current electricity generation mix (IEA, 2022). As the electric grid transitions to cleaner generation, this advantage will further increase. Additionally, moving away from the use of natural gas for heating and cooking in residential homes will improve the air quality and is expected to have a positive effect on health. This is important because negative impacts to air quality have been documented resulting from natural gas leaks in residential homes in the larger Boston area (Michanowicz et al., 2022). Additionally, outdoor air quality is impacted by pipeline gas leaks, which can pose disproportionate burdens on marginalized populations (Luna and Nicholas, 2022).

Heat pumps also have the benefit of being very energy efficient. A metric used to evaluate the efficiency of heat pumps is the coefficient of performance (COP), which is a ratio of the useful heat output by the system, divided by the energy consumed. Because heat pumps move heat from a source (ground, air, water) to a sink (indoor location), the temperature difference between the source and the sink strongly influences the COP. However, even in climates where the average winter temperatures are above -10 °C, air-source heat pumps have an average annual COP above 2.4, which is equivalent to an efficiency of 240%, as demonstrated by Gibb et al. (2023). Gibb's team composed of members of the Regulatory Assistance Project in Belgium and Oxford, Exeter, and Ulster Universities, set out to study the COP of air-source heat pumps throughout 17 European countries. They also found that in colder climates with winter temperatures above -30 °C the average COP of air source heat pumps was 1.5, equivalent to an efficiency of 150%. Interestingly, they report that heat pumps are more common in countries with colder winters such as Finland, Norway, and Sweden, compared not only to warmer countries like Portugal, Spain, and Italy, but also to countries such as France, Germany, Switzerland, and the UK.

Importantly, geothermal heat pumps (GHPs) have a higher COP than air-source heat pumps. This is because the subsurface temperature remains relatively constant throughout the year compared to air temperature, as well as the fact that GHPs do not have to spend energy on defrosting (Gibb

et al., 2023). Which means that GHPs are not only more efficient, but also better suited for colder weather.

Additionally, there is a large innovation potential for improving the COP of a GHP system. This can be via thermal exchange innovations or interactions with environmental factors. For example, a modeling study by Wołoszyn and Golas (2017), faculty members from the department of Mechanical Engineering and Robotics from the AGH University of Science and Technology in Krakow, found that the coefficient of performance of a horizontal ground heat exchanger is strongly influenced by the soil moisture. This is due to water increasing the thermal conductivity, which influences the COP. Wołoszyn and Golas (2017) proposed using a water irrigation system to increase the COP in their system.

In addition, GHPs are not only more efficient than air-source heat pumps, but a life cycle assessment by Violante et al. (2022) showed that they also have a lower overall long-term environmental impact. The study by Violante et al. (2022), from the Italian National Agency for New Technologies, Energy and Sustainable Economic Development, showed that GHPs are more beneficial, with lower impacts on three of the four categories studied, including human health, climate change, and resources. For the fourth category, ecosystem quality, ASHPs showed lower impact. Nevertheless, the study concluded that because the lifespan of the geothermal source or borefield can be estimated at 100 years, the resulting impact of the vertical U-bends in the borefield is reduced. Furthermore, the study suggested that GHP systems be connected to photovoltaic systems so that the electricity required by the heat pumps is generated using renewable energy.

GHPs have the further benefit of functioning as base load dispatchable energy. Currently, the strong seasonal fluctuation in the energy demand of buildings is largely being met by fossil fuels (Buonocore et al., 2022). As buildings are decarbonized and electrified, this will shift the energy demand to be highest in January (heating season), followed by a second peak in July (cooling season), which results in the so called “falcon curve” (Buonocore et al., 2022). Due to the baseload and dispatchable nature of GHPs, they are one of the technologies that can address the seasonal increases in energy demands, thus contributing to the reduction of seasonal peaks in electricity demand.

2.2 Why Use Geothermal Networks?

Geothermal network systems have further advantages over individual building GHP systems, including higher system COP, lower costs of installation, and scalable solutions to decarbonizing entire neighborhoods. Critically, they also provide a path for high emitting industries, including gas utility companies, to have a pathway to decarbonization and thus buy-in to the state’s net-zero targets.

The system COP of existing geothermal network systems is larger than that of individual buildings with GHP. The COP of the geothermal network system increases as buildings with diverse energy needs are connected to the same thermal network. For example, if the network consists of a data center (which even in the winter rejects heat), this heat can then be used by the other residential or commercial buildings that are connected to the geothermal network. Because of this, the heating and cooling needs of buildings in the geothermal network can be partially met even without tapping into boreholes. Colorado Mesa University has a geothermal network system that has been operating since 2008, and the average annual COP of the entire system has been calculated at 5.6,

with a winter season COP of 8.9 (Xcel Energy, 2023). This means that during the winter season the system has an efficiency of 890%. For every unit of energy (or electricity) input into the system, 8.9 units of energy (or heat) are put out. These efficiencies are very high, and they are higher than the efficiency that can be achieved by individual geothermal heat pumps.

Unlike air-source heat pumps, geothermal networks represent a utility-scale approach to decarbonization, providing an evolutionary new business model for gas utility companies. In order to reach 2050 net-zero emissions targets, gas utility companies must adopt new business models to decarbonize their operations.

The initial cost barrier to ground-source heat pumps can be overcome by geothermal network systems. These costs can be integrated as part of the utility infrastructure in new developments (Liu et al., 2017), or the up front infrastructure costs can be covered by the gas utilities installing and operating these systems using existing utility financing models.

2.3 Why Now?

A confluence of recent studies on GHPs, combined with the net-zero decarbonization targets of numerous states, the installation of pilot projects by gas utility companies in MA, and a nascent but favorable regulatory environment, make the present a particularly promising moment for the expansion of geothermal networks.

2.3.1 Research on GHP Impacts

Research findings show that if deployed at a national scale, GHP coupled with weatherization can offer significant savings on the electrical grid in terms of transmission lines and electrical capacity needed. Recent work led by the Oak Ridge National Laboratory and commissioned by the Department of Energy shows that if GHP are installed in 68% of residential and commercial buildings in the US, they could reduce the nationwide electricity generation capacity by 410 GW and eliminate the need for the construction of 43,500 miles of transmission lines by 2050 (Liu et al, 2023). The US' current electricity capacity is 1,300 GW, so eliminating 410 GW of future capacity generation is significant, representing about 32% of the current electricity capacity. For further reference, 43,000 miles of transmission lines would be equivalent to crossing the US 16 times from east to west. Even though Liu et al. (2023) do not consider the additional energy savings that would be accrued if networked GHP were installed, the benefits of GHP are significant. While the energy savings of installing geothermal networks at scale are expected to be even more compelling than those of GHP, there is a current lack of research in this area.

2.3.2 Gas Utilities Pilot Projects in Massachusetts

In 2017, the Home Energy Efficiency Team (HEET), a non-profit climate solutions organization, proposed the idea of geothermal network systems as an alternative business model to gas utility companies in Massachusetts. There are multiple benefits to this approach, including:

1. Gas utility companies have the technology and know-how to install new energy distribution systems, particularly subsurface pipes in public rights of way,

2. Utilities would benefit from the decarbonization journey, allowing their business to grow while still meeting Massachusetts' net-zero decarbonization target,

3. Utilities would be able to retain their customers and billing systems, minimizing disruption to their customers,

4. Utilities are uniquely positioned to install these systems at a societal scale, as they have already engaged in, and financed, this process in the past, through the creation of the current gas distribution system,

5. This approach incentivizes the elimination of emissions from an industry that is difficult to decarbonize in a way that can provide equitable access to clean energy,

6. Compared to other electrification methods geothermal network installed at scale by utilities ensures equitable access to heating and cooling, while avoiding rising costs of the gas system burdening those that cannot afford to electrify their homes,

7. Utilities are required by regulators to collect data from their systems with an emphasis on safety, affordability and reliability. Regulators could also require utilities to share their data with this proposed database, with the intention of improving outcomes for the public.

Massachusetts has an aging gas infrastructure, with a quarter of the piping in need of being replaced in the next 20 years, which would incur an estimated cost to gas customers of $34 billion (Seavey, 2023). But such a large investment in gas infrastructure is not in keeping with the Massachusetts 2050 Decarbonization Roadmap. In light of this issue, HEET and Buro Happold (2019) undertook a feasibility study for networked geothermal systems in MA. They found that for low-density residential areas and medium-density mixed use areas individual geothermal networks would meet 100% of the heating and cooling needs of these street segments. Thus, the large capital investment needed to replace Massachusetts' aging gas infrastructure could instead be used towards geothermal networks. Additionally, interconnected geothermal networks could expand beyond the locations with gas infrastructure in need of repair or replacement.

Massachusetts is advanced in piloting utility-led, neighborhood-scale retrofits of geothermal network systems (Smith, 2024). Over the past seven years regulators have approved six installations in the state, five of which will be installed by gas utility companies (Schulman and Magavi, 2022). The positive results from the HEET and Buro Happold (2019) study led to the commissioning of the first utility-owned neighborhood-scale retrofit geothermal network system in Framingham, with the project led by Eversource Gas. While this first pilot is currently in commissioning and is expected to begin operations in the fall of 2024 (Eversource, 2023a). The Framingham project will serve 36 buildings and 125 individual customers, including commercial buildings, public housing from the Framingham Housing Authority, a school, a fire station, a gas station, and single-family homes (Eversource, 2023). This geothermal network system is being financed entirely through Eversource Gas, using the same ratepayer-based financial structure established by gas utility companies to deliver gas.

Gas utility companies have spent a significant amount of capital to build the gas distribution network in place today. They can recover that cost by amortizing it in a longer timeframe (30 or 50 years) and distributing it amongst their customers on their monthly bills. This model could also be used to finance the networked geothermal system. Similarly, all of the Eversource Gas customers in Massachusetts are contributing to the installation of the geothermal network system in Framingham, just as all of them are contributing to every new gas pipe that goes in the ground.

There are also three other geothermal network projects at different stages within the state. National Grid completed the design phase of a geothermal network system in Lowell and is expected to start construction in 2025. HEET won an award from the DOE to design a second loop, as an expansion to the Framingham first loop. The design of the second loop in Framingham will be finished in the fall of 2024. Additionally, Mayor Michelle Wu together with National Grid announced that the first geothermal network for the City of Boston will be installed in the Franklin Field community (Wu, 2024) and will start the design in the fall of 2024.

In the state of Massachusetts, regulatory mandates support the expansion of geothermal network pilots. The recent regulatory order by the Massachusetts Department of Public Utilities is expected to propel the expansion of geothermal network systems by gas utility companies. The order requires utility companies to evaluate the use of non-gas options, such as geothermal networks, as alternatives to expanding the gas system or making additional investments in gas infrastructure (DPU, 2023).

Throughout the state, communities are interested in these pilot projects; 13 communities in Massachusetts are currently undertaking feasibility or site selection studies for the development of a geothermal network in their localities, as depicted in Figure 1. These studies are being sponsored by HEET through the Learning from the Ground Up (LeGUp) research project, funded by the Massachusetts Clean Energy Center. Communities conducting feasibility studies are Arlington, Deerfield, Gloucester, Lexington, Lowell, Salem, Somerville, and Worcester. The communities engaged in site selection and community engagement are Acton, Ashland, Melrose, New Bedford, and Newton (Heet.org, n.d.).

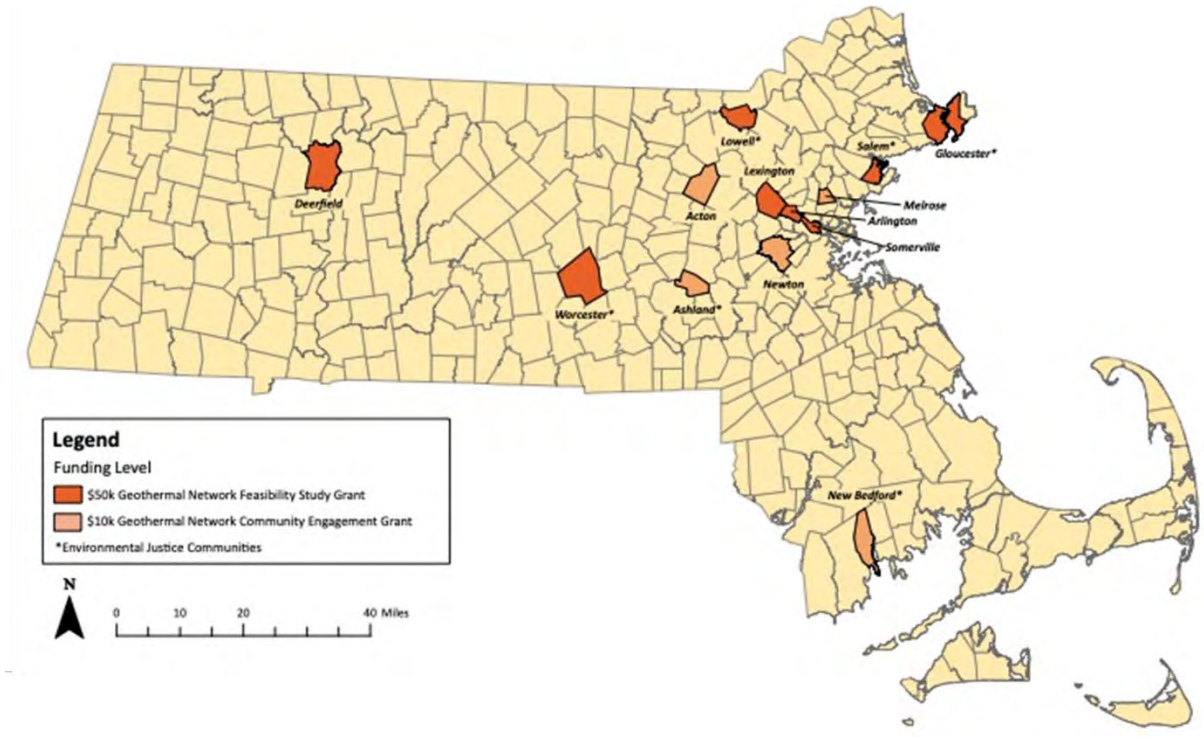

Figure 1: Massachusetts communities undertaking geothermal network feasibility or site selection studies. Figure modified from Heet.org, (2024).

2.3.3 National Landscape for Geothermal Networks

Even though Massachusetts is a leading state in the type of utility-led neighborhood-scale geothermal network systems that would ideally populate the database for this project, only the first Framingham project will have sufficient data to be input into the database in the first year of its launch. However, networked geothermal systems have existed for many years on university campuses (Oh and Beckers, 2023). Colorado Mesa University has a network geothermal system that has been operating since 2008, and Xcel Energy recently published a study on its performance (Xcel, 2023). Another system that has been operating for several years is Whisper Valley, TX which started operations in 2016. Whisper Valley is a newly built residential community, with the geothermal system planned since the design phase of the community. Given data availability, this project aims to populate the database with data from Colorado Mesa University, Whisper Valley, TX and other existing networks in addition to the Framingham, MA project in the first year after its launch.

On a national level, there is increasing support for geothermal networks that points to a future expansion of these systems. The Department of Energy granted $13 million to support community geothermal heating and cooling solutions (Department of Energy , 2023). As part of this funding, 11 projects were awarded grants for the design phase of geothermal projects. The states where these projects are being designed include AK, CO, OK, VT, CT, IL MA, MI, MN, and NY, as shown in Figure 2. A subset of these projects will receive further funding from the DOE for construction in 2025.

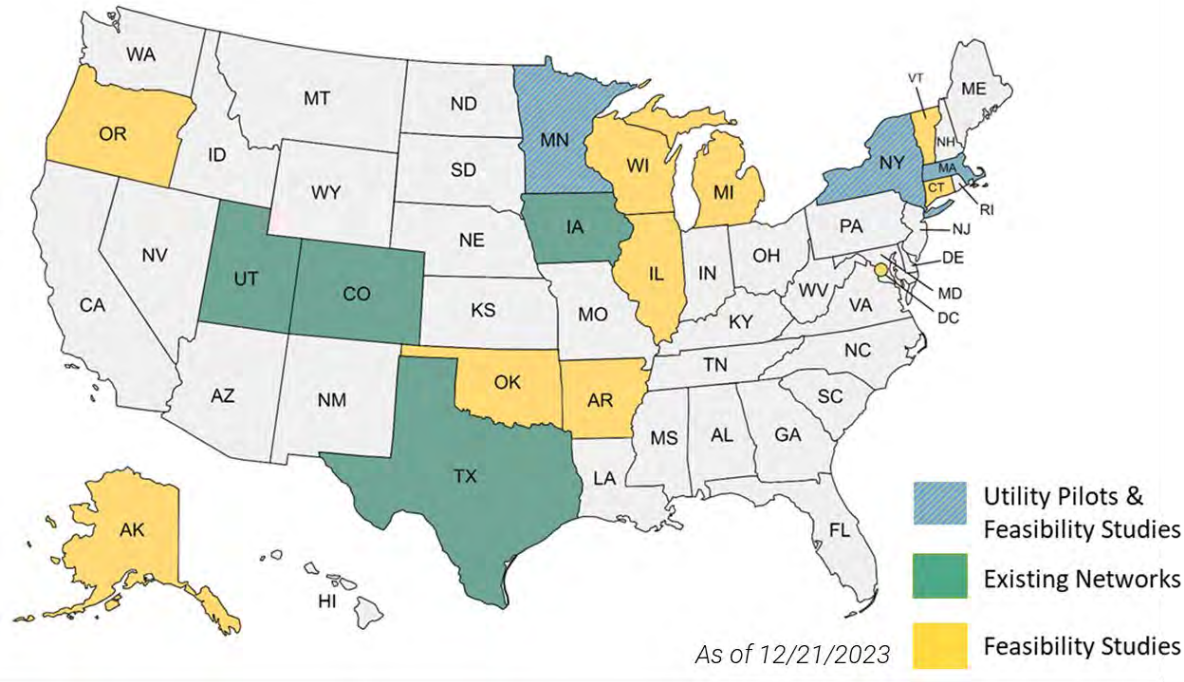

Figure 2 Map showing states with geothermal network installations and feasibility studies. Figure modified from Building Decarbonization Coalition and HEET (2024).

Changes in legislation are happening state by state, to support the growth of geothermal networks by gas utilities. Traditionally, gas utilities have been restricted by law to only provide gas to their

customers. In order for gas utilities to undertake geothermal networks as pilot projects or as a new business line, legislation must be changed to support this. As mentioned previously, in Massachusetts, the DPU approved the development of geothermal networks as pilot projects and encouraged the expansion of these. However, it still needs to approve the installation of geothermal networks as regular business for the gas utilities and not just as pilot projects. Other states have also filed legislation for the support of geothermal networks, as shown in Figure 3. To date six states have passed legislation enabling the gas to geo transition pathway, including NY, CO, MD, WA, MN, and VT.

Gas utility companies are becoming increasingly interested in geothermal networks. Gas utilities interested in geothermal networks have formed the Utility Networked Geothermal Coalition (UNGC), a group of gas utilities that have come together to share their collective knowledge in this area. This coalition includes 28 gas utilities, and together they serve nearly 50% of the gas customers in the US (Building Decarbonization Coalition and HEET, n.d.). The states that this coalition serves are depicted in Figure 4. In December of 2023, 15 of these utilities visited the pilot project in Framingham, MA.

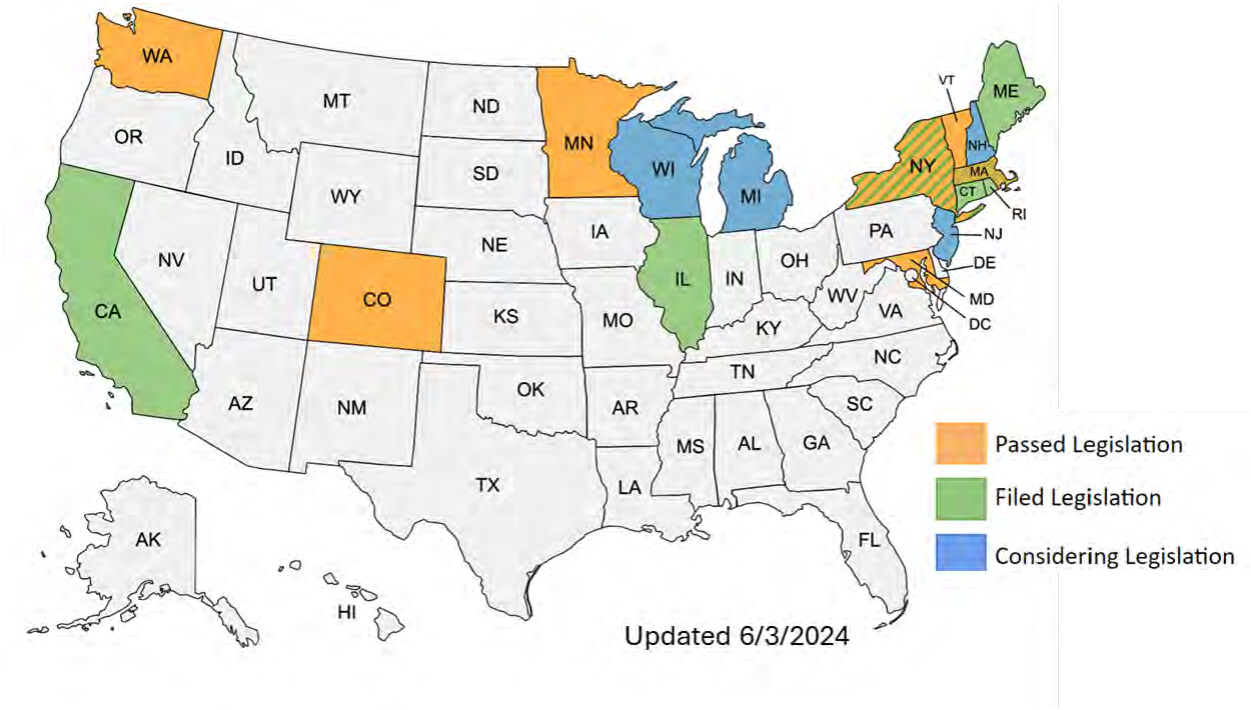

Figure 3 Map of geothermal networks legislation landscape. Figure modified from Building Decarbonization Coalition and HEET (2024).

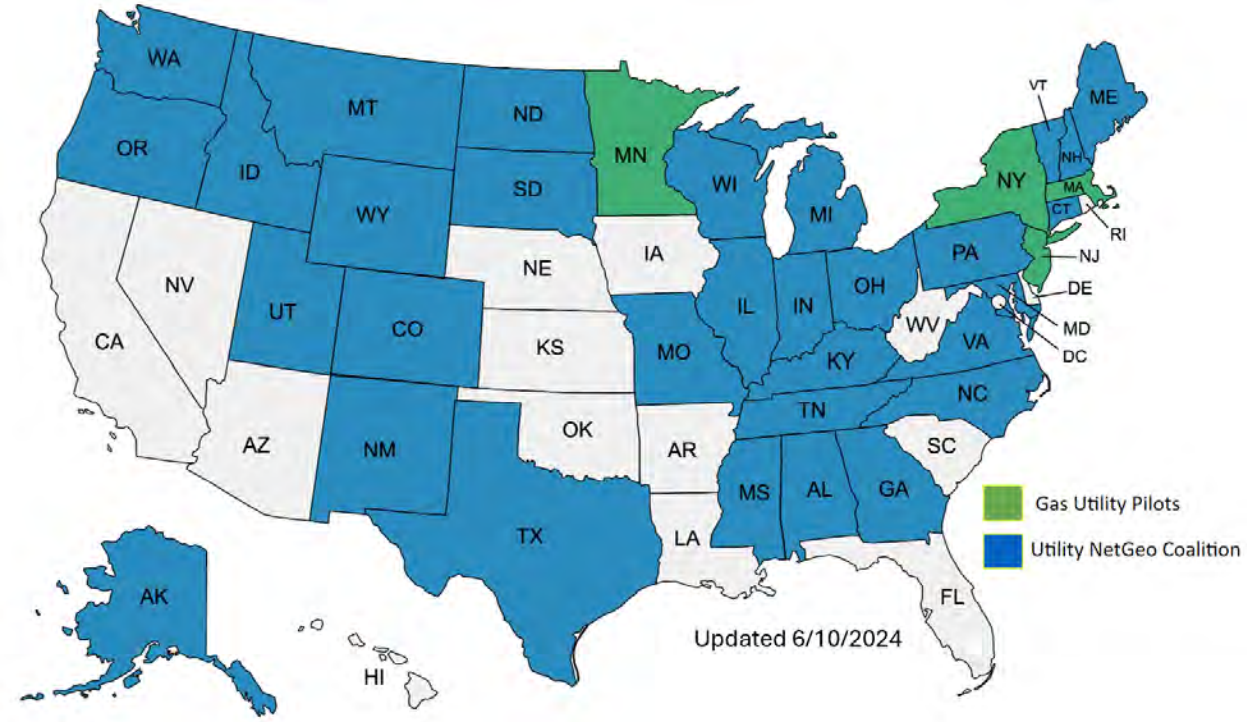

Figure 4 Map of the Utility Networked Geothermal Coalition (UNGC). Figure modified from Building Decarbonization Coalition and HEET (2024).

2.4 Why Do We Need a Database of Geothermal Networks?

While the database for geothermal networks would be the first open-source database of its type, there are other databases and tools related to GHPs that are relevant to this project. These include a geothermal data repository by the DOE and a feasibility tool and database from New York City.

The Geothermal Data Repository (GDR), hosted by the US Department of Energy, is a vast database that collects data from research projects funded by the US Department of Energy Geothermal Technologies Office (GTO), including projects on geothermal networks. This database has a broad focus; the data collected includes not only studies on ground-source heat pumps, but also any studies related to geothermal energy funded by the GTO (DOE, 2024). Most importantly, this database is limited in that it excludes all projects that have not been funded by the GTO, even if they are related to geothermal networks. This means that existing projects, such as the CMU and Whisper Valley systems, cannot be included. Furthermore, even for the geothermal network systems that are funded by the GTO and that can be included in their database, there is no standardization as to what parameters should be collected. Thus, there is also no systematic way to compare one case study of these networked geothermal systems to another.

Although New York City has developed a localized database and tool for geothermal heat pump information, it focuses only on projects within the city, and only on GHPs installed in individual businesses. New York City has a Pre-Feasibility tool for GHPs that includes a database of existing geothermal wells. The tool is very comprehensive, combining the geological, technical, and economic aspects required by the different types of geothermal heat pumps into a pre-feasibility assessment (New York City Major Office of Sustainability [NYCMOS] and USGS, 2018).

However, the database aspect of the tool is not set up to record networked geothermal systems (NYCMOS, 2024).

The creation and open accessibility of a database for geothermal networks can inform and facilitate future developments of these projects, enabling the pursuit of decarbonization. Communities doing feasibility studies can use the database to inform their choice of parameters and calculate prediction models (Simpson and Zhu, 2024) for their own systems. The potential beneficiaries of this database include consumers, utility companies, and regulators, among others. Building occupants, and, in a more indirect manner, the state residents are also beneficiaries of this database, as it would help enable state 2050 decarbonization goals (Executive Office of Energy and Environmental Affairs [EOEEA], 2020). Other states, beyond New York, Colorado, Washington, Minnesota and Maryland are also following Massachusetts' lead in the implementation of geothermal networks, some by receiving grants from the DOE (DOE, 2023) or through clean energy funding such as in Washington, D.C. Ultimately, the database will enable decarbonization efforts, as it will inform communities, developers, and regulators that are considering installing geothermal networks for heating and cooling as an alternative to gas and other fossil fuels.

3. Method

The methodological approach followed in this study consisted of collecting a large set of parameters related to geothermal networks, classifying them according to different criteria, and prioritizing them into an essential group and an enhanced group. The methodological approach is explained in more detail in the following steps,

3.1 Collected Input from Stakeholders

An initial list of parameters was collected from stakeholders, including gas utilities with geothermal pilots, modelers, academics, and engineers.

3.2 Identified Categories of Parameters

The initial set of parameters was classified into groups related to their commonality or functionality. Nine functional groups were identified. These functional groups were further classified into three groups, depending on where they fit in the stages of the system.

3.3 Grouping of Variables by Described Feature

Grouped variables by the feature they described, stage, and attribute. The parameters were classified by the feature described, as well as by their location in the overall geothermal network system and a single qualifying attribute. The data was arranged as a relational database, with seven tables that are related to each other via a key.

3.4 Defined Essential Mode and Enhanced Mode

In order to increase participation in the database, two modes of input were selected: an essential and an enhanced version. The essential mode contains fewer parameters that can at a high level describe the system. The enhanced version contains a larger set of parameters, which can be used for a more in-depth study of the geothermal network. These enhanced parameters will allow for a quantitative comparison of the energy usage by building for at least one year before and one year

after the start of operations of the geothermal system. The initial parameter list, which contained around 200 parameters, was revised and classified into the categories listed above. Additionally, parameters that were deemed unnecessary in both the essential and enhanced versions were flagged.

3.5 Consulted Experts

This step involved reaching out to experts and requesting their input on the proposed parameters for inclusion in the database. The expert group was composed of professionals in the field, such as energy consultants, designers of geothermal network systems, and utility companies that have geothermal network pilot projects, as well as researchers and modelers of these systems.

3.6 Selected Datasets

This step involved identifying the first datasets that can be used to populate the beta version of the database. These datasets were drawn from the Colorado Mesa University System, which has been in operation since 2008, and the Framingham, MA pilot project, which is currently in the commissioning stage and is set to start operations in fall of 2024. These datasets were selected based on the longevity of the system (CMU) and the likelihood of obtaining comprehensive datasets to populate the database (Framingham and CMU).

3.7 Defined Final Parameter List

With input from stakeholders and experts in the field, the parameter list to be included in the first beta-version of the database was selected. The selection was performed by considering the list of ideal parameters in comparison with those that are easier and more cost-effective to measure.

Getting geothermal network owners to share their data and populate the database is critical for the database to be useful. The state of Maryland has stipulated in their regulations that any geothermal network system in their state must share their data with this database (WARMTH Act 397, 2024). The implementation of similar regulations in other states would ensure that the database is comprehensive and remains up to date.

4. Results and Discussion

Many stakeholders contributed to the initial stage of parameter collection. The engagement process for this resulted in a comprehensive list composed of more than 200 parameters. One of the challenges of this study was to find a balance between identifying a comprehensive list of parameters, while still incorporating those that can be measured in a cost-effective way. Additionally, the data included in the database must be reported in such a way that individual buildings —and therefore customers— cannot be identified. This restriction must be followed so that utility companies do not violate customer privacy when reporting geothermal network data to this database.

4.2 Classification of Parameters

A high-level understanding of the data collected was acquired through a first categorization. More than 200 parameters were collected through the engagement of different stakeholders. The data

was interpreted, organized, and classified into nine categories related to their functionality. These categories include borefield, system, system performance, environment, subsurface, buildings, energy usage and demographics, as shown in Figure 5. Each of these categories will include a set of parameters that affect how the geothermal network system will perform.

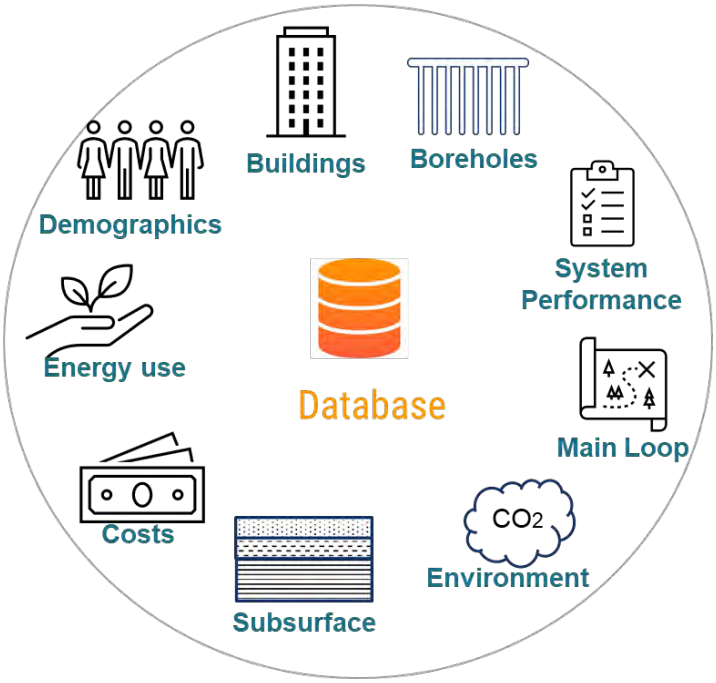

Figure 5 Categories of Parameters by Functionality. The parameters are grouped into nine categories including boreholes, system, system performance, environment, subsurface properties, costs, energy usage, demographics, and buildings.

The borefield category includes data related to the ground-heat exchanger (i.e. boreholes). For example, the borefield category will include information such as number of boreholes, geometry of boreholes, and length or depth of boreholes. This category also includes design parameters related to the borefield, such as borehole and U-tube diameters, material of the U-tube, type of grout, grout conductivity, and configuration of the ground-heat exchanger. Future versions of the databank will add other thermal resources such as dedicated thermal energy storage, solar thermal, etc.

In order to compare the geothermal network system to the gas distribution system, the parameters were also grouped in terms of where they are in the cycle of the system: upstream, distribution, and end-user. For the geothermal network system, upstream refers to thermal resources. The distribution refers to the single pipe or main loop that connects the thermal resource to the buildings and the end-user refers to the individual buildings, as shown in Figure 6.

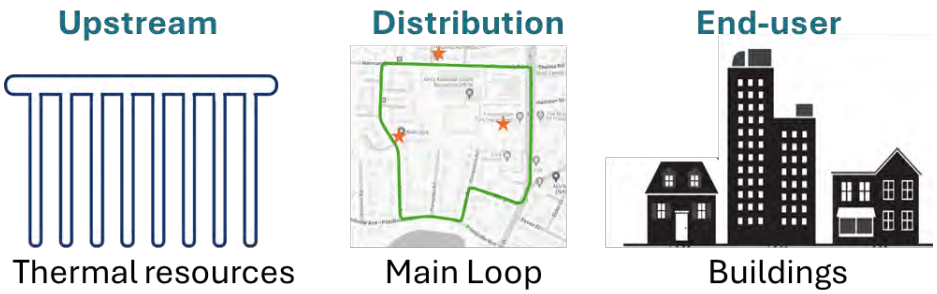

Figure 6 Category of Parameters by Position in System Stage. Parameters are grouped according to where they are in the energy value chain.

4.2 Essential Parameters

This section presents the list of parameters that were selected for inclusion in the essential mode. These are a high level set of parameters that describe the system while making it easier for owners and operators of geothermal networks to include their systems in the database.

4.2.1. Main Loop

The complete list of parameters that refer to the general system are listed in Table 1. These include a subset of non-technical parameters grouped as general information, and a set of technical parameters about the distribution system or main loop. The non-technical parameters capture basic information about the location of the loop, the ownership model, the designer company, and provide a narrative of key learnings on efficiency, design, and operation of the system. With the purpose of shedding light on the beneficiaries of these projects, this section also records whether the community where the loop is located is an environmental justice community as defined in the Justice 40.

The so-called ‘just energy transition’ refers not only to the residents or businesses on the loop, but also to the workforce employed in the construction and maintenance of the loop. Because of this, this section also captures whether the workforce employed in the construction of the loop meets federal prevailing wage standards.

In acknowledgment that the lessons learned in the design, construction, and operation of each system are valuable knowledge for other geothermal network systems, Table 1 has an option where these learnings can be uploaded in a narrative form.

The technical parameters for the main loop include the number of buildings that are in the loop and whether they are an existing or a new construction. This includes the number and type of thermal sources and sinks, which most commonly will be borefields. Information about the main pipe is key, such as the inner diameter and material of the pipe and length and location of the main loop. Note that the larger the diameter of the main pipe, the larger the thermal inertia, thermal storage, and capacity that the system has for expansion. Larger pipe diameters have only an incremental increase in cost and may allow for future buildings to be connected to the same geothermal network system. This section also captures the design flow rate of the system and the temperature range in which it is designed to operate. Table 1 also records the number of pumps

that are needed for the fluid to reach the desired flow rate and the type of fluid that circulates through the system. Water or water mixed with glycol are common fluids used as working fluids. Although there are examples of systems in northern climates such as Canada where the working fluid is 100% water, a percentage of glycol of up to 25% is often added to avoid pipes freezing and increase the system's thermal capacity. Additionally, costs are an important aspect of this database, and for the main system the compound cost of installing the main pipe per linear foot is recorded.

4.2.2. Thermal Resources

The complete list of parameters captured for boreholes are listed in Table 2. While future versions of this database will capture thermal sources that are different from boreholes, such as ponds and lakes, this first beta version of the database is set up to only capture thermal sources and sinks that are vertical or deviated closed-loop boreholes. For each borefield, the average characteristics of the boreholes are captured without providing detail on each one of them. For example, the database records the number of boreholes, the geometry of the boreholes (vertical or deviated), the geometry of the heat exchanger inside the borehole: concentric or U-bend, distance between boreholes and average borehole length.

Because test boreholes are important for gauging the subsurface properties and performance of the system, the database captures the thermal conductivity, thermal diffusivity, and borehole thermal resistance measured in the test boreholes. The database also includes the type of grout and the thermal conductivity of the grout. A basic geological description of the geological column encountered is captured.

Average costs are captured per borefield in the form of average cost per unit of drilled length and average cost per unit of lateral lengths trenched. Trenching is needed to connect the piping from the boreholes to the main loop and is often costly especially if it is in a paved area.

4.2.3. Buildings

Parameters are recorded per building and per unit in the building, as listed in Table 3. For each building it is recorded whether it is a new or existing construction, the year of construction, and the total square footage. It also records the number of individual units in the building and whether cooling will also be installed. This is because some buildings may choose to use the GHP system only for space heating. The database also records the number of heat pumps per building and number of additional heat sinks or sources that it may have, such as cooling towers. The database also asks whether a heat exchanger was placed outside the building. A heat exchanger is sometimes placed between the main loop and the building HVAC, to isolate the fluid in the main loop from the fluid circulating in the pipes inside the building. While this can have advantages in terms of resilience or thermal isolation of unique buildings, having a heat exchanger as a default for every building can lower the overall system performance.

In this building section, parameters related to building occupancy are also recorded, including the average occupancy of the building and the building peak occupancy.

4.2.4. Building Units

At the building unit level, the database captures the previous heating system type, including the previous heating system distribution type and fuel type. Weatherization and retrofit upgrades are captured at the building unit type as well. Costs for weatherization and building retrofit changes can vary significantly, depending on the specific upgrades performed. In this section, a multiple-choice option is provided with numerous weatherization and retrofit options that are often performed for energy efficiency and electrification of heating systems. In Massachusetts, weatherization plans usually strive to meet the MassSave standards.

Different geothermal network systems aim for different levels of electrification in the buildings. Because of this, the database captures whether the system aimed for full electrification of the building or if only certain appliances were substituted for electrical options. The cost of the new electric appliances is also recorded. It is also important to capture whether there is another source of heating that will remain in the building apart from the GHP, and determine the source of fuel that it uses.

4.2.5. Pumps, Heat Pumps and Other Sinks

Specificity about the number, type and size of every pump used is important to determine the total amount of energy going into the system. Table 4 captures the pump parameters for the pumps located in the main loop, at the borefields, and in the buildings. Note that these are pumps which are used to circulate the fluid in the pipes.

Table 4 also captures the type, size, and number of heat pumps in every building unit, as well as their seasonal energy efficiency rating (SEER) and their heating seasonal performance factor (HSPF). The cost of every heat pump is also recorded.

4.3 Enhanced Parameters

The enhanced parameter set builds upon the essential set. The number of additional parameters included in the enhanced parameter is smaller as shown in Table 5. However, each parameter itself has a high density of information about the system. At the system level the enhanced set includes a design schematic for the geothermal network. In the general information section, it includes a description of the community engagement strategies as well as more detailed information about workforce demographics involved in designing, building, and maintaining the system.

At the borefield level, the enhanced set includes a map with a layout of the boreholes, drilling logs when available. In terms of temperature, Table 5 records the temperature of the circulating fluid entering and exiting each borefield, as well as downhole temperature measurements (when available) in producing and non-producing boreholes one to three years after the start of operations. These downhole temperature measurements are key in assessing whether there is a temperature drift in the subsurface year-on-year, and how large that drift is. For the geothermal heat pumps to function optimally, they need to stay within a temperature range that depends on their manufacturing. If the subsurface temperature is outside that range, then the geothermal heat pumps will not function optimally, and the system COP will decrease. If a drift in subsurface temperature is recorded, initiatives can be taken to modify the controls of the system such that the subsurface temperatures stay within the optimal operation range. Ground water flow can affect the thermal conductivity of the boreholes. Because of this, the ground water flow rate, if known, is recorded.

At the building unit level, the enhanced set captures monthly or daily energy consumption and their associated costs one to three years before and after system startup. This involves electricity and gas or other fuel bills. In terms of design, the enhanced set asks for a schematic of how the building is connected to the main loop. Temperature measurements of the fluid entering and exiting each building throughout the year are also recorded.

Table 1 Parameters describing the overall geothermal network System. Selected list of parameters to be included in the database from the geothermal network describing the overall geothermal network system. The subcategories include general information about the system and the distribution stage

	Category	Attribute	Variable Name	Input Type	List Name
System	General Info	Site	System Name (Input string)	Unique string	
		Site	Year that system began operatiing (YYYY)	Select from pull-down menu	YEAR
		Site	Country (Select from pull-down menu)	Select from pull-down menu	COUNTRY
		Site	City (Input string)	Unique string	STATE (US only)
		Site	US State (Select from pull-down menu)	Select from pull-down menu	STATE (US only)
		Site	Ownership (Select from pull-down menu)	Select from pull-down menu	OWNERSHIP MODEL
		Site	List other main stakeholders engaged in planing or implemetnation and their respective roles	Unique string

4.4 Output Parameters

Apart from collecting needed data, the database will also perform basic calculations, as listed in Table 6, that are based on the input data. The main calculation related to the overall system performance is the system Coefficient of Performance (COP). This measurement will account for the overall system, including the boreholes, main loop, and buildings.

The database will also calculate the impacts on the environment and human health. Specifically, the database will compute the amount of CO2 and methane emissions eliminated due to electrification of heating as shown in Table 6. For existing constructions, the baseline scenario refers to the emissions before installing the geothermal network that replace the existing HVAC system. For new constructions, the baseline is defined and simulated with a standardized approach. Furthermore, the database will estimate the impact on human health using the disability adjusted life years (DALY) approach.

Table 6 Database outputs

Variable Name
Average annual efficiency of the system
Climate zone
Eliminated CO2 emissions
Eliminated methane emissions
Impact on human health
Impact on electricity consumption

5. Conclusions and Further Work

Geothermal networks are a highly efficient way of electrifying heating and cooling in buildings, and have the potential to do this at scale if this model is adopted by the gas utility companies beyond the pilot projects currently being pursued in Massachusetts and other states.

This project provides the basis for the creation of the first open-source database for geothermal network systems. It argues for the proposed set of parameters that should be collected to allow for a quantitative comparison between these systems as well as optimization of future ones. Furthermore, this study presents a categorization of parameters into three groups: thermal resources, main loop, and end-users. This grouping allows for the comparison of geothermal networks with other heating and cooling systems.

The creation of this database will support the growth of geothermal networks by allowing for a quantitative comparison between different systems and informing the planning and optimization of future ones. Recording costs and calculating the overall system efficiency will highlight the energy efficiency of these systems and help catalyze further adoption. Moreover, this database can serve as a reference point for policy makers as they develop regulations for these systems.

5.1. Further Work

While the main purpose of this study was to set the standard for the parameters that need to be reported to the database, there are other steps that need to be completed to launch the database,

including setting up a graphical user interface (GUI) for inputting data into the system and creating a data architecture for the database.

The GUI for collection of the parameters is currently being built. The interface aims to be simple and easy to use. Additionally, the database architecture is being carefully planned so that the database can be managed as the number of systems that report to it grow. The database is being stored at the Harvard Dataverse (Harvard Dataverse Support, 2020), as this is an open-source platform that commits to maintain the data in perpetuity.

HEET is now in the process of collecting and collating data from two systems to launch the beta version of the database with the geothermal network information available for CMU and Framingham.

Ultimately, for the database to be successful, it needs participation from the data owners of these systems, such as utilities, municipalities, co-ops, and university or industrial campuses. Dissemination of the existence of this database at professional conferences and in technical journals will help emphasize the legitimacy of the database. The preliminary plan for the database was presented as part of an invited panel at the annual conference of the International Ground-Source Heat Pump Association (IGSHPA) on Dec 5, 2023 (Magavi et al., 2023).

As the database becomes populated it will provide benefits for communities interested in geothermal networks. Whether the interested communities are in the pre-feasibility, feasibility, design, construction or operational phases, the populated database is expected to be beneficial. It will enable quantitative comparisons between systems, and contribute to prediction models and optimization. Additionally, it can provide cost comparisons by stages and demonstrate the impacts on emissions, environment and human health.

For geothermal networks to become mainstream and affect societal scale building decarbonization, they will need support from multiple key stakeholders, including regulatory entities, cities, states, utilities, private developers and a skilled workforce. This database is a tool that can inform and connect these different entities with their varying perspectives. In aligning stakeholders around delivering decarbonization through geothermal networks, this database supports global sustainable development goals, national decarbonization goals, and the transition of heating and cooling of buildings to renewable energy for the communities involved.

Acknowledgement

This study is part of the Learning from the Ground Up (LeGUp) project run by HEET and funded by a grant from the Massachusetts Clean Energy Center (MassCEC).

The authors would like to acknowledge the contributions of Angie Alberto-Escobar, Eric Juma, Elizabeth Nigh, Mark Kleinginna from HEET and Juliet Simpson from NREL. Thanks to Michaela Thompson from MIT and Xiaobing Liu from ORNL for editorial revisions and to the numerous stakeholders involved.

Bottom hole temperature correction, Presidio County, heat flow mapping, geothermal resource assessment

ABSTRACT

The reliability of heat flow maps and techno-economic models for geothermal energy projects are significantly influenced by the accuracy of bottom hole temperatures (BHTs) derived from oil and gas drilling operations. However, BHT measurements are often influenced by the cooling effect of drilling fluids, necessitating the application of correction methods to develop an approximation of the rock's equilibrium temperature. Previous methodologies, including those developed by Harrison, Förster, and Kehle, rely on correlating unadjusted BHTs with high-quality, equilibrated temperature logs within specific basins in the United States to determine a generalized offset suitable for each study area.

This research evaluates the efficacy of established correction methods and highlights their significant impact on project economics. We applied these methods to raw BHT data from Presidio County, Texas—a region lacking high-quality equilibrated temperature logs. Using the GEOPHIRES tool, we conducted an in-depth analysis of the thermal regime and the economic feasibility of developing a geothermal plant based on corrected BHT values. Our findings reveal a significant discrepancy of up to 16% between the Harrison method and the other two correction methods, translating to over a kilometer difference in the estimated depth to reach temperatures of 250°C. This variability becomes even more pronounced at higher temperatures, impacting the depth estimation and, consequently, the project's feasibility. Moreover, the techno-economic analysis demonstrates that the choice of correction method can substantially affect the project's economic outlook, with a variance exceeding $10 million in project net present value among the methods for an enhanced geothermal systems (EGS) project scenario in Presidio County. These results underscore the critical need for high-quality temperature logs from abandoned wells to

validate temperature corrections or develop a new correction method tailored to regional conditions.

1. Introduction

Accurate geothermal resource assessment and subsequent development require high-quality depth-to-temperature data. Several sources are commonly used to determine temperature, heat flow, and geothermal potential. The most reliable types of temperature measurements come from tests conducted after enough time has passed for the well temperature to return to equilibrium. However, most available temperature data come from measurements of bottom-hole temperatures (BHT). During drilling, fluid is circulated to cool the drill bit, consequently cooling the surrounding rock in the well. Temperatures recorded immediately following circulation will be cooler than the equilibrium rock temperature. Subsequently, the measured values of bottom hole temperature must be corrected to account for this cooling effect, requiring a reliable correction method. Several correction methods have been developed with a specific data set and/or study area in mind. These correction methods may not be appropriate for broader applications. Here, we compare three common correction methods: Kehle, Harrison, and Förster, as applied to data for Presidio County, Texas.

In an AAPG geothermal survey for data in North America from 1970, Kehle et al. (1970) postulated that surface temperature and time since circulation are the two critical factors for explaining the difference between BHT and the true equilibrium temperature. They presented a mathematical method for correcting BHTs from well headers based on those factors, but this approach relies on knowing the time since circulation, a factor that is commonly not recorded or reliable if recorded in an older well. The correction was later modified by Gregory et al. (1980) to remove the time variable. We have adjusted the equation from Gregory et al. (1980) from feet to meters, resulting in the following correction factor (Tcf_K):

$$Tcf_K(℃) = -3.112 \times 10^{-10}x^3 - 2.307 \times 10^{-7}x^2 + 1.435 \times 10^{-2}x - 1.018 \quad (2)$$

Where x is depth in meters.

While the Kehle correction is widely cited as providing the original method and rationale for correcting BHTs, it is not a commonly used correction method (Crowell et al., 2014; Shalev et al., 2013; Bédard et al., 2017).

Following Kehle, Harrison et al. (1983) devised a correction method for the Oklahoma Geological Survey to compare bottom-hole temperatures and more reliable temperatures obtained from pressure tests from shut-in wells and high-quality temperature logs. They calculated the average temperature for each township in Oklahoma with sufficient data. Due to a lack of high-quality data for comparison in over half of the townships, the state was subdivided according to the underlying geological structures of basin and shelf. Using a correction curve to compare BHTs and high-quality logs, they calculated the following temperature correction factor (Tcf_H):

$$Tcf_H(℃) = -16.512 + 0.0183x - 0.00000234x^2 \quad (1)$$

Where x is depth in meters.

The Harrison correction has since been used in multiple studies for Texas, around North America, and elsewhere around the world (Batir & Richards, 2020; Blackwell, 2011; Blackwell & Richards, 2004; Shalev et al., 2013; Bédard et al., 2017).

The Förster correction method was developed to adjust temperatures from southeastern Kansas (Forster et al., 1996). The study compares hundreds of BHTs to temperatures taken during drill stem tests. Drill stem tests (DST) are taken during a temporary completion of a well, when a portion of the well is sealed off from the rest, and sensors are used to test pressure and temperature, among other things. Since the measurements are taken after a period of quiescence, DST are considered to be closer to actual equilibrium formation temperatures. The correction coefficients are defined using regression analysis to compare BHT and DST, resulting in the following correction factor:

$$Tcf_F\ (℃) = \ 0.012x - 3.68 \tag{3}$$

Where x is depth in meters.

Though the method used to define this equation is similar to what was done to define the Harrison correction, the Förster correction method is not widely used. Compared to the Harrison correction, the equation's simplicity questions whether any correction methods are genuinely appropriate to be broadly applied outside their original study areas.

Fundamentally, these are all empirical corrections. The underlying reason behind the differences in correction curves is primarily due to differences in geological structure, rock type, and/or thermal regime. Further comparison between high-quality temperature logs and BHTs over a broader range of geological settings would enhance our understanding of the relationship between the two measurement types.

Note that these corrections were developed in the last century and only depend on depth. This is a significant handicap and limits BHT correction accuracy. This limit is mainly because the next level of essential information that would allow for a better correction, such as mud temperature, drilling time, time since last circulation, etc., is generally unavailable, particularly for older wells. Given the wealth of data recorded during drilling today, a new standard of well information recording is now feasible and needed. This would allow for much more accurate BHT corrections, reducing development risk.

In this study, we apply each correction method to data for Presidio County, TX, and compare how the differences in corrected temperature can impact the viability of a geothermal project. With more reliable temperature data, even for a small number of wells in the county, we could test the correction methods above and possibly devise a better correction curve. A correction curve designed for a region outside a production basin may be useful across southwest Texas and other areas with similar geology.

2. Methodology

2.1 Geological Setting

Presidio County is in west Texas, along the Rio Grande River, west of Big Bend National Park, and bordering the Mexican state of Chihuahua. The generalized geology of the county consists of three stratigraphic units: Precambrian granite, Paleozoic-Mesozoic sedimentary deposits, and Tertiary volcanics (Figure 1). Overlying Tertiary volcanic tuff and mixed breccia layers thin from ~1,457 meters in the northeastern part of Presidio to ~793 meters in the southwest. The average porosity of the tertiary layers varies widely, which can impact thermal conductivity. The Paleozoic-Mesozoic section, primarily comprised of carbonates with some mixtures of shale and sandstone, reaches a depth of ~6,000 meters in the northeast, which tapers to a depth of ~2,438 meters to the southeast. The shallower occurrence of the basement along the border, supported by geophysical data and drilled wells, may contribute to a greater radiogenic heat flow. The county also has several warm springs in the Rio Grande Valley. The structure is dominated by basin and range-style extensional faulting along the border, including the Bolson graben (Wisian et al., 2024).

Presidio County leadership, the Presidio Municipal Development District (PMDD), the West Texas Economic Development District (WTEDD), and the Rio Grande Council of Governments (RGCOG) are invested in the county's economic development. A recent report authored by WTEDDD and the RGCOG identified energy (particularly renewable energy) as a critical strategy for investment and development (West Texas Economic Development District, 2021).

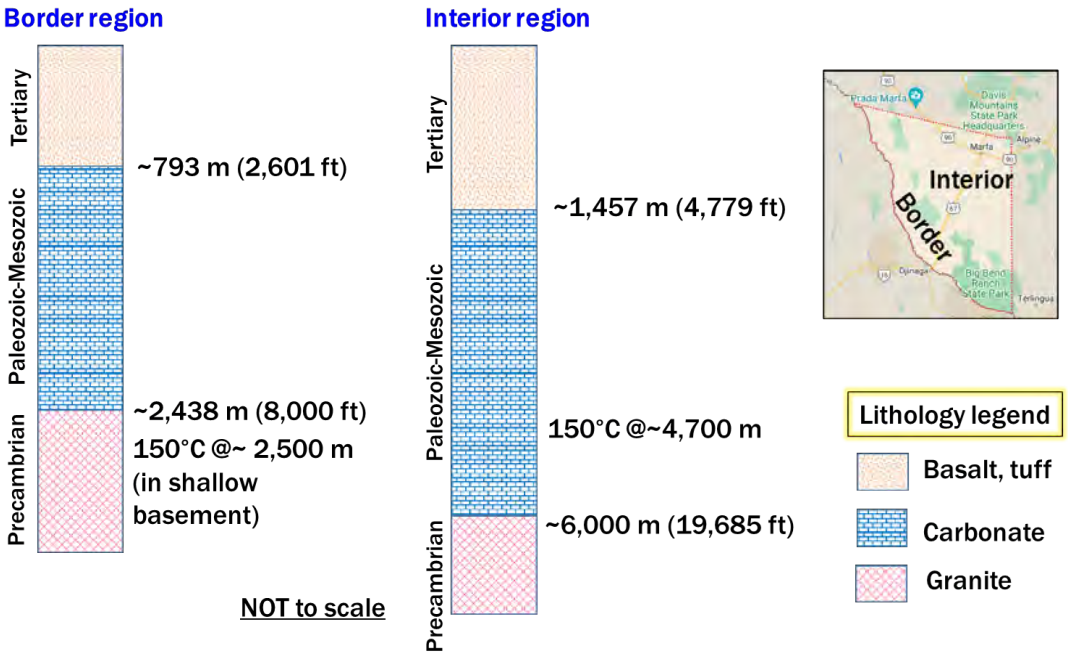

Figure 1: Simplified litho-stratigraphy of the Border and Interior regions, with the inset map of Presidio County (after Wisian et al., 2024).

2.2 Temperature Data

The temperature data for this study consist of BHTs collected from the Southern Methodist University (SMU) node of the National Geothermal Data System (NGDS), using the Borehole Temperature in Content Model Formula and Heat Flow data files, the Bureau of Economic Geology (BEG) comprehensive well database and log library, as well as data points from the Standard and Poor's Enerdeq Browser managed by Information Handling Services (IHS), for data ranging from January 2016 to May 2023.

From the databases listed above, we extracted 120 unique BHTs from 101 wells (Figure 2). The data are somewhat heterogeneously distributed across the county; more data needs to be collected in the county's southeast corner. More than half of the temperature measurements in this data set are from wells less than 1 km deep.

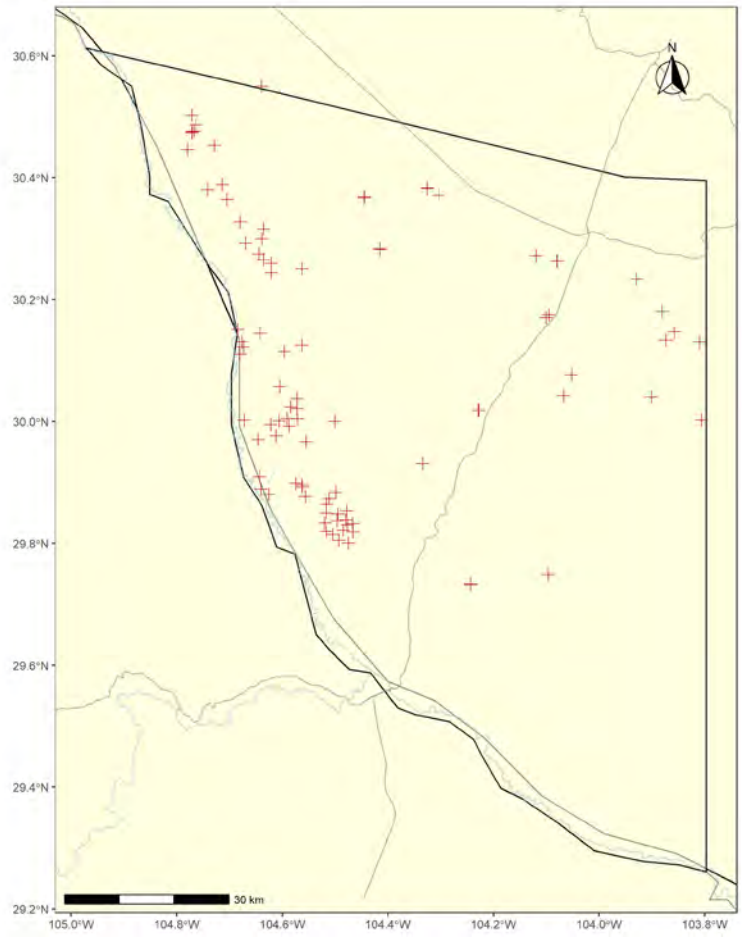

Figure 2: Map of well locations with bottom hole temperatures in Presidio County, TX. The data set includes 120 BHTs from 101 wells. More than half of the BHTs were taken at depths < 1km. The shallow data are mainly concentrated along the border. Data is lacking for the southeastern portion of the county.

We applied each correction method to the data, as shown in Figure 3. We fit each set of points using linear regression, with a top anchor point at 15°C for the average surface temperature. Many

of the shallow wells appear to show a steeper gradient curve than illustrated by the regression. Due to the shallow depth of these points, the high temperatures seen may result from groundwater movement carrying warmer temperatures up through fractures rather than being reflective of an actual high gradient.

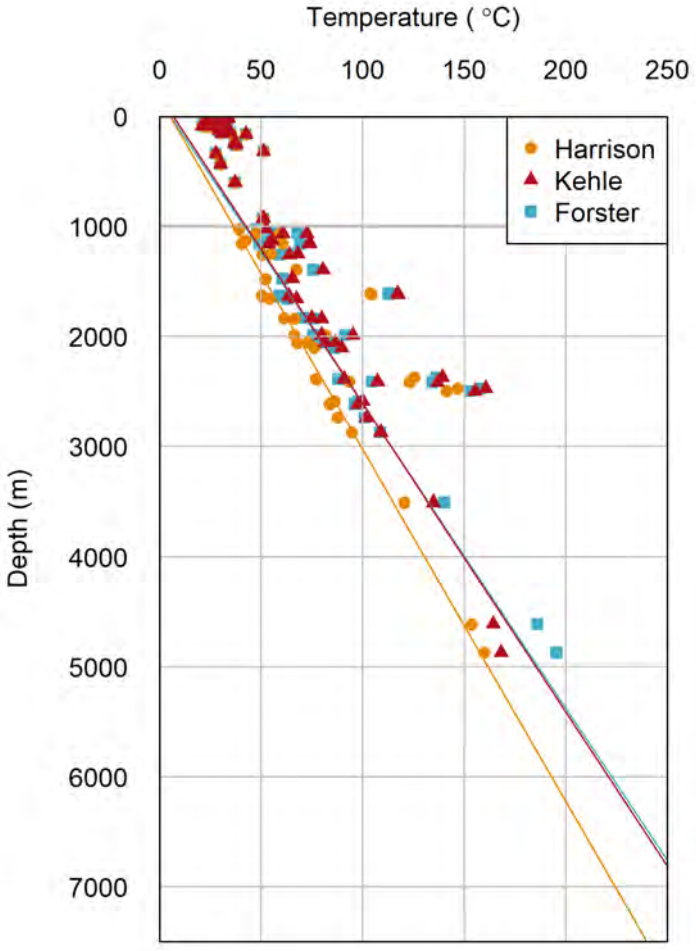

Figure 3: Harrison, Kehle, and Förster corrected temperatures versus depth of data points for Presidio County. The top of the linear regression curve is fixed to an average surface temperature of 15°C. Many of the shallow temperature records show higher-than-expected temperatures. We attribute those temperatures to shallow groundwater movement.

We use the linear regression method above to calculate an average gradient for each correction method and use that gradient to calculate the depth to 150°, 200°, and 250°C for each correction method (Table 1). The difference of close to 1 km between Harrison and Kehle/Förster corrections to reach the same reservoir temperatures has a marked impact on the techno-economic modeling.

Table 1: Resulting depth to temperatures 150, 200, and 250° calculated for Presidio County with Harrison, Kehle, and Forster temperature correction methods.

Correction Method	*Depth to 150°C (km)*	*Depth to 200°C (km)*	*Depth to 250°C (km)*
Harrison	4.31	5.91	7.51
Kehle	3.78	5.18	6.58
Förster	3.73	5.11	6.49

2.3 GEOPHIRES

The potential to advance geothermal energy projects heavily relies on accurate site characterization, which includes understanding the local geology, infrastructure availability, and the region's specific energy demands. This study examines the impact of temperature correction methodologies on the financial viability of geothermal energy initiatives in Presidio County, as highlighted in the recent geothermal study (Wisian et al., 2024).

Our analysis encompasses two primary methods of geothermal energy extraction: Enhanced Geothermal Systems (EGS), which rely on enhanced permeability of rock formations, often facilitated by hydraulically stimulated fractures (Beard et al., 2023), and Advanced Closed-Loop Geothermal System (AGS), which operates by circulating a working fluid through a closed-loop system in the wellbore, harnessing heat through conduction. AGS mainly creates a long path in the ground to transfer heat from the rock into the wellbore and, as with EGS, does not produce formation fluids but instead continuously recirculates its own fluids. Note that the heated fluid can then be used directly for heating or, more commonly, for generating electricity (GeoVision, 2019).

The economic evaluations of these geothermal systems are conducted using the updated GEOPHIRES model (Beckers et al., 2019; Ross and Beckers, 2023)., which integrates a wide array of up to 150 input variables. This comprehensive model facilitates a nuanced economic analysis, calculating essential economic indicators such as Net Present Value (NPV), Value Investment Ratio (VIR), and Internal Rate of Return (IRR). These metrics are pivotal in guiding investment decisions. Furthermore, GEOPHIRES calculates the Levelized Cost of Electricity (LCOE) as well as for heating, cooling, and carbon sequestration—known respectively as LCOH, LCOC, and LCOCS—which provide a standardized metric for comparing the cost efficiency of various energy projects.

To illuminate the implications of different temperature correction methods—specifically, those developed by Harrison, Kehle, and Förster, various simulations were performed across EGS and AGS scenarios for power generation and direct heat use. These simulations are meticulously documented in Table 2, providing a clear comparative analysis of the economic outcomes for each method. Note that for all electricity-producing scenarios, the financial model assumes a sale of the electricity at a price starting at $0.15/kWh and rising with 2% inflation after plant completion

Crucially, our financial models consider incentives from the Inflation Reduction Act (IRA), such as the Investment Tax Credits (ITC) and Production Tax Credits (PTC), which significantly influence project economics. An ITC of 50%, applicable upon project completion, can substantially reduce the LCOE. For example, if an initial LCOE is 15 cents/kWh, applying a 50% ITC could lower it to about 7.5 cents/kWh, thus transforming a marginally viable project into a robustly feasible one.

For all case scenarios in Presidio County, the CAPEX (Capital Expenditure) and OPEX (Operational Expenditure), estimated using the Harrison correction method, were higher than those calculated using the Kehle and Förster methods. This discrepancy is primarily attributed to the geothermal gradient adjustments. The Harrison method predicts a geothermal gradient approximately 14% and 16% lower than those calculated by the Kehle and Förster methods, respectively. Consequently, reaching the desired reservoir temperatures necessitates drilling significantly deeper wells, thereby increasing the initial and ongoing costs associated with the project. For instance, to achieve a reservoir temperature of 150 °C, the required well depths are estimated to be 4.3 km, 3.8 km, and 3.7 km for the Harrison, Kehle, and Förster methods, respectively.

Table 2. Techno-economics scenarios utilized by the GEOPHIRES model

Scenario	CAPEX, M$	OPEX, M$	NPV, M$
EGS for Power Generation			
Harrison	27.1	1.3	17.3
Kehle	24.7	1.3	22.5
Förster	24.5	1.3	22.9
AGS for Power Generation			
Harrison	27.6	1.9	3.5
Kehle	25.6	0.9	6.1
Förster	25.4	0.9	6.3
AGS for Direct Heat			
Harrison	29.1	1.7	36.9
Kehle	27.1	1.7	39.6
Förster	27.0	1.7	39.9

3. Results

The Enhanced Geothermal Systems (EGS) scenarios are conventionally considered the most cost-effective option for electricity production in Presidio County (Wisian et al., 2024). These scenarios involve drilling four wells—two producers and two injectors—to access a reservoir with an in-situ formation temperature of 150 °C. Additionally, the construction of an energy production plant with a projected operational lifespan of 30 years is planned.

Figure 3 illustrates the cumulative revenue over the 30-year project lifespan for the EGS case study, using different temperature correction methods. The estimated net power from this project is around 3.3 megawatts (MW), with a net cash flow estimated. The Kehle and Förster methods are notably similar, contrasting sharply with the more conservative estimates derived from the Harrison method. The latter consistently yields the lowest net cash flow projections for the EGS project. It is worth noting that the Harrison method remains widely used in recent literature for temperature correction, heat flow mapping, and subsequent techno-economic analysis.

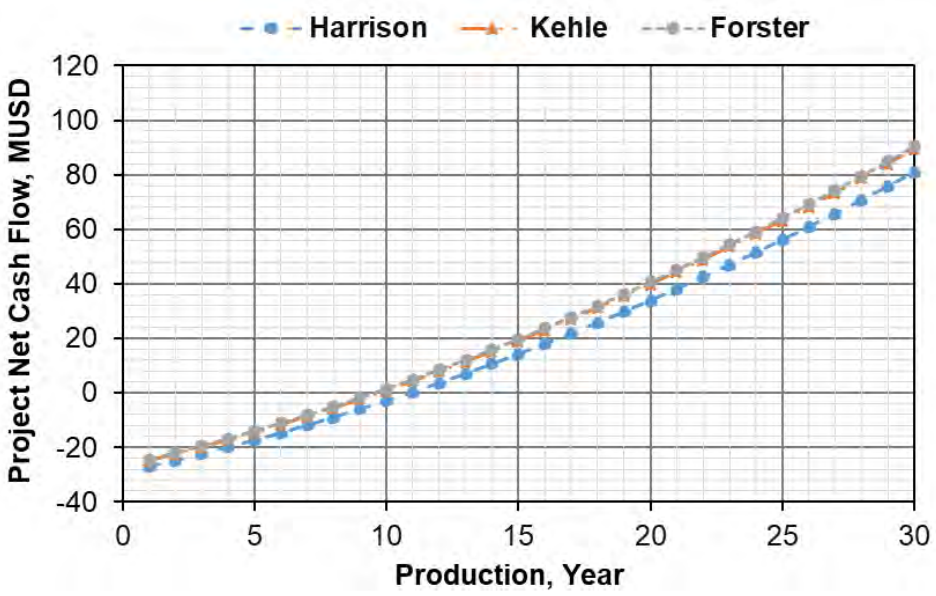

Figure 4: Project Net cash flow over the EGS project lifetime of 30 years based on different temperature correction methods.

Figure 4 illustrates the payback period for the Advanced Closed-Loop Geothermal System (AGS), comparing project economics with and without considering incentives provided by the Inflation Reduction Act (IRA). The AGS design adopted for this scenario is inspired by the innovative approach detailed by Yuan et al. (2021), featuring an 8.5-inch horizontal open-hole with five 3 km laterals each and a 90 kg/sec production flow rate. The vertical depth of the wellbore in each scenario is determined based on the temperature gradient corrections provided by the Harrison, Kehle, and Förster methods.

In scenarios where the downhole reservoir temperature targets 150°C, the estimated average net electricity equals 2.2 MW with a payback period for the AGS system that is initially lengthy, spanning 24.4 years for Harrison, 22.7 years for Kehle, and 22.6 years for Förster correction methods. However, the payback times are significantly reduced when incorporating the financial benefits of the IRA, specifically through the Investment Tax Credit (ITC) or the Production Tax Credit (PTC). With a 50% ITC applied across all AGS scenarios, the revised payback periods are 14.1, 13.0, and 12.9 years for Harrison, Kehle, and Förster methods, respectively. This dramatic reduction highlights the profound impact of IRA incentives on enhancing the financial attractiveness of renewable energy projects.

Furthermore, it is important to note that the NPV for AGS projects, while robust, tends to be lower than that observed for Enhanced Geothermal Systems (EGS) within the same region. The EGS systems, benefiting similarly from IRA incentives, exhibit even shorter payback periods of 10.9, 9.7, and 9.5 years for Harrison, Kehle, and Förster methods, respectively. This discrepancy underscores the greater efficiency and economic viability of EGS systems in Presidio County, likely due to their ability to harness natural subsurface heat more effectively than AGS's engineered solutions. This observation about NPV needs to be tempered by the incorporation of risk–projects move forward when the risk-reward relationship is well understood. It is generally understood that AGS projects have a substantially lower risk (since their subsurface approach is so simple). The lower NPVs of AGS projects will be more acceptable for some investors, given the lower risk.

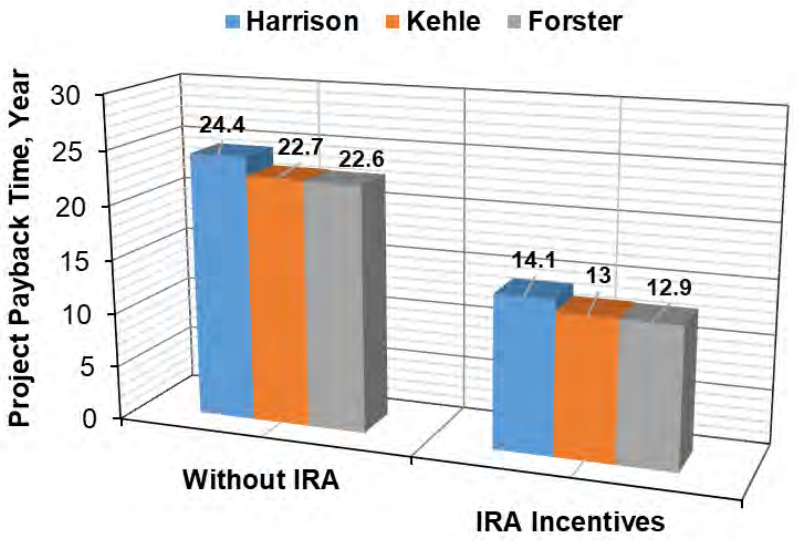

Figure 4: AGS project payback period with and without IRA incentives for Harrison, Kehle, and Förster temperature correction methods.

Geothermal direct heat use presents substantial advantages over geothermal power generation, particularly in terms of efficiency and economic benefits. Direct heat applications, such as space heating, industrial processes, and agricultural uses, typically achieve thermal efficiencies that often exceed 70%, while electricity generation projects at 150 C have efficiencies of <15%, a five-fold improvement. The higher efficiency in direct heat use is due to the lower temperatures required and minimal energy conversion losses, which means more of the extracted thermal energy is

directly utilized rather than lost in conversion processes (Lund and Boyd, 2016). From an economic perspective, direct heat systems demand lower capital investments and operational costs, making them more accessible and cost-effective. This is especially true in regions with lower geothermal gradients where the cost of accessing suitable temperatures for power generation may be prohibitively high (DiPippo, 2018). In such scenarios, the direct use of geothermal energy can provide a practical alternative with a more rapid return on investment.

In the specific case of AGS, direct heat applications can significantly outperform power generation projects. For example, an AGS project focusing on direct heat could yield an average production of 33.4 MWth, whereas a similar project for power generation might only produce about 2.2 MWe. Figure 5 compares AGS projects' cumulative net cash flow geared towards power generation and direct heat use. When incentives are considered in the Inflation Reduction Act (IRA), the economic benefits of direct heat use become even more pronounced. The net cash flow for direct heat use projects is nearly three times higher than that for power generation. Furthermore, the payback period for direct heat use projects decreases to 6 years, compared to 13 years for power generation projects (utilizing Kehle and Förster correction methods).

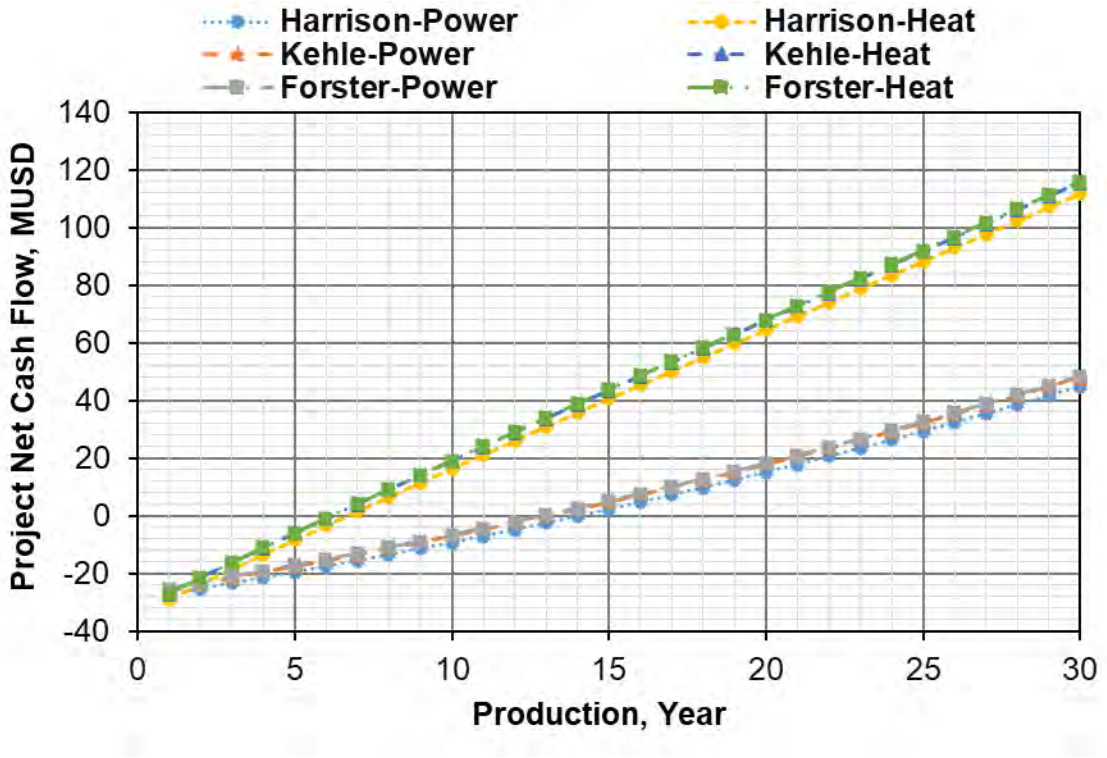

Figure 5: AGS project cumulative cash flow for power and heat generation based on Harrison, Kehle, and Förster BHT correction methods.

Additionally, selecting the BHT correction method can significantly influence the economic outcomes of these projects. For instance, the AGS project's predicted NPV for direct heat use, utilizing the Förster correction method, is approximately $3 million higher than that using the Harrison method. This variance is even more substantial in Enhanced Geothermal Systems (EGS), where the difference can reach up to $5.6 million, highlighting how critical the choice of BHT

correction method can be in determining the economic viability and investment attractiveness of geothermal projects.

4. Conclusion

This study has demonstrated the profound impact that different BHT correction methodologies can have on the techno-economic assessments of geothermal projects in Presidio County, Texas. Specifically, the Harrison method predicts a geothermal gradient approximately 14% and 16% lower than those calculated by the Kehle and Förster methods, respectively. This variance in gradient predictions means that using the Harrison method requires drilling to significantly greater depths to reach the desired reservoir temperatures, thereby increasing both the initial investment and ongoing operational costs.

Our analysis with the GEOPHIRES model shows that these discrepancies can alter the estimated project net present value by as much as $10 million, underscoring the crucial role of selecting an appropriate temperature correction method in geothermal resource evaluation. The study suggests a pressing need for adopting more localized correction methods and highlights the limitations of using generalized empirical models outside their original study regions.

By refining these methodologies through integrating comprehensive datasets, including high-quality temperature logs and advanced data recording techniques, the accuracy and reliability of geothermal assessments can be significantly enhanced, thereby improving the economic viability and reducing the risks associated with geothermal energy projects.

5. Recommendation

The use of current BHT corrections, while cost-effective for preliminary assessments, introduces significant uncertainties when applied outside their calibration areas, impacting the economic feasibility of geothermal projects. To mitigate these risks:

1. Risk Awareness: Stakeholders need to understand the uncertainties and economic risks of BHT-based corrections.

2. Data Quality: Prioritize acquiring high-quality, equilibrated temperature logs to improve correction accuracy and reduce dependency on empirical methods.

3. Data Recording Standards: Enhance recording practices during drilling to capture all relevant variables, supporting the development of physics-based corrections.

4. Targeted Thermal Logging: Conduct thermal logging in a deep well within the study area to refine regional BHT corrections and contribute to broader correction methodologies.

These steps will enhance the reliability of geothermal assessments and reduce the development risks associated with these projects.

ABSTRACT

Underground thermal energy storage (UTES) systems behave like a thermal battery, which preheats or pre-cools the ground to later heat/cool buildings. Borehole thermal energy storage (BTES) is a UTES system in which fluid is circulated in closed-loop pipes installed in a closely spaced borehole array. BTES is gaining popularity over the world because of its wide adaptability in various climates, limited surface area, lower total borehole length compared to traditional geothermal heat pump (GHP) installations, and ability to efficiently provide seasonal energy storage. To maximize the economic value of the cost of drilling and operating a BTES, modeling and optimizing the BTES for the site, climate, building energy loads, available energy sources, and the time-of-day pricing from the electric utility is critical. The round-trip efficiency of a BTES is influenced by factors such as borehole spacing, the way boreholes are connected, and the operating schedules. In the work presented in this paper, we optimize the design of BTES using the numerical simulator FEFLOW coupled with various charge/discharge algorithms.

In the BTES optimization, the following factors are considered: (1) BTES borehole quantity, spacing, and length; (2) method for connecting the boreholes (e.g., radial flow versus independent rings); (3) options for hot and cold storage included seasonal switching of the entire BTES, separate zones within the same BTES, and physically separate hot and cold BTES; and (4) charging and discharging schedules.

This paper presents two types of GHP-based multi-building thermal network BTES case studies. The first type is the storage of diesel engine waste heat to serve an Arctic community's heating needs. The second type is the use of a particular energy storage concept called GABESS (Grid Amplified Building Energy Seasonal Storage). GABESS is a combination of air source heat pump

(ASHP), BTES, and water source heat pump (WSHP), in which ASHP provides warm/cold water during off-peak time to heat or cool the BTES. The heat/cold is later extracted by WSHP to heat or cool the buildings on the thermal network.

1. Introduction

Renewable energy development has increased significantly in recent years because of greenhouse gas emission concerns. Among various renewable energy sources, such as solar and wind, geothermal resources play a critical role in heating and cooling buildings that account for a large part of the greenhouse gas emissions (Dascalaki et al., 2010). A UTES system is one method that takes advantage of shallow geothermal energy. UTES behaves like a thermal battery, which preheats or pre-cools the ground. In the case studies presented in this paper, that stored energy in the UTES is later used to heat or cool buildings. For example, in summer, heat is stored in the underground, and in winter, the heat is extracted to warm buildings with low carbon emissions. Similarly, the cold stored in winter (pre-cooling the ground) can be used to more efficiently cool buildings in summer. Different types of UTES are available—aquifer thermal energy storage (ATES), BTES, pit thermal energy storage (PTES), and tank thermal energy storage (TTES). Akhmetov et al. (2016) reviewed and compared different types of thermal energy storage systems. The U.S. Department of Energy and others have published papers on reservoir thermal energy storage (RTES) for power generation (e.g., Amiri et al. [2024] and McLing et al. [2022]).

BTES is one of the UTES systems in which fluid is circulated in closed-loop pipes installed in a closely spaced borehole array. BTES is gaining popularity all over the world because of its wide adaptability in various climates and subsurface conditions, limited surface footprint, and ability to efficiently provide seasonal energy storage. Moreover, BTES can be combined with other energy generation and storage systems. For example, Euros Energy recently published a system that combines PTES, BTES, and hybrid solar panels for a district heating system. Drake Landing Solar Community, Okotoks, Alberta, Canada consists of BTES, solar collectors, and short-term thermal storage tanks.

One of the design challenges for BTES systems is how to maximize BTES performance considering factors like specific site and climate conditions, energy loads, and the time-of-day pricing from the electric utility. Parameters that can affect the performance of BTES systems include borehole layout (borehole spacing and length), inlet temperature, borehole connection method, and the operating schedules. A variety of research has been devoted to optimizing such parameters (e.g., Ekmekci et al. [2023]; Nilsson and Rohdin [2019]; Olabi et al. [2023]). In this paper, we present two BTES applications illustrating the optimization schemes we performed. One case study is in Baker Lake, Nunavut, Canada, and the other in Vernal, Utah. The numerical simulator FEFLOW (Diersch et al., 2011a, 2011b) was used to model the BTES simulating heat transport to predict outlet temperatures and evaluate system performance. FEFLOW was chosen based on the built-in borehole heat exchanger (BHE) model, which serves as a boundary condition to the finite element grid and the Python scripting API, allowing the team to quickly model complex flow paths and operational constraints.

2. BTES in Subarctic Climate in Baker Lake, Canada

Baker Lake is located in Nunavut, one of the three territories that are not connected to Canada's energy grid. In Nunavut, electricity is produced by diesel generators, and most communities rely

only on fossil fuels for heating, which causes problems such as high cost in fuel transportation, health issues, and air pollution, including emission of greenhouse gases. Previously, a high-temperature thermal energy network was proposed to heat a few community buildings. The system had limitations based on the amount of heat the generators could deliver at any time. Adding a heat storage system to capture waste heat year-round and using a lower temperature thermal energy network increased deliverability and efficiency, expanding the thermal energy network to heat more of the community and meet peak demand loads. The feasibility of introducing BTES at Baker Lake was investigated. The Baker Lake BTES would store waste heat from the diesel generators in summer and other periods when less heating is required and recover the heat in winter to warm buildings, reducing the need to burn heating oil.

2.1 Model Setup

The BTES modeled for Baker Lake was a cylindrical shape with a diameter of 100 meters (m) and a total of 280 boreholes. The length of the boreholes varies from 90 m near the center to 110 m at the outside ring, as shown in Figure 1. Longer boreholes at the outside ring are intended to help capture the heat that conducts out from the bottom of the inner hotter boreholes. To reduce computational time, only an eighth of the BTES is simulated using symmetry with 35 boreholes. The piping is divided into seven radial flow paths with five boreholes in each connection, as shown in the left plot of Figure 2. Spacing between boreholes ranges from 3.5 m to 7 m. Double-U shape BHE is applied in this case (right plot in Figure 2). In summer, hot water (45 degrees Celsius [^{o}C]) that represents waste heat from diesel generators flows through the BHE in the center boreholes of the BTES radially outward along each connection. This creates a thermal gradient, from the hotter center toward the cooler outer edge. In winter, the flow path is reversed, and the water (1^{o}C) flows through the BHE in the outermost boreholes first and then radially inward toward the center to efficiently heat the cold water to as high a temperature as possible. A flow rate of 10 cubic meters per day (m^3/d) is assigned to each connection except for those on the edge, which are assigned to 5m^3/d to account for symmetry representing a total flow rate of 480 m^3/day in the whole BTES system.

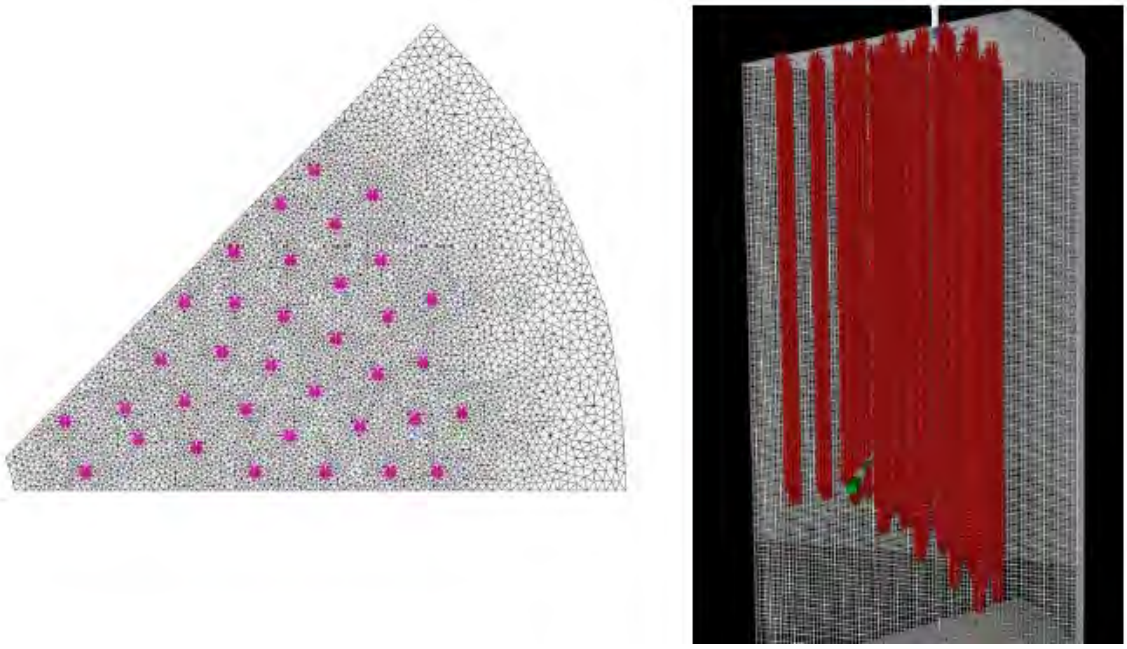

Figure 1: Borehole locations (left plot: top view; right plot: side view).

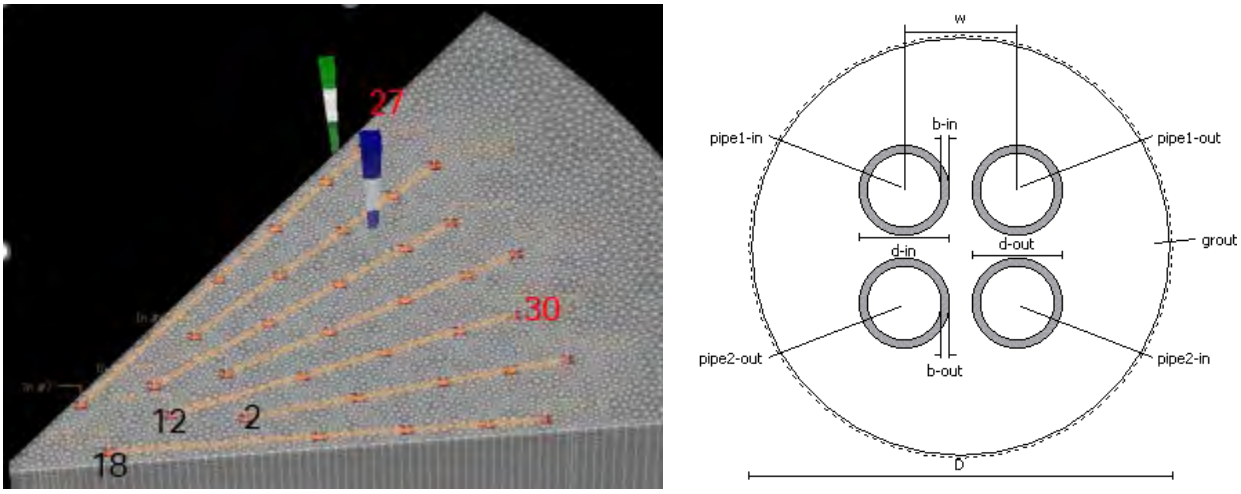

Figure 2: BTES connections (left plot) and Double-U shape BHE (right plot) (Diersch et al., 2011a). The numbering in the left plot indicates some of the boreholes referred to in the outlet fluid temperature discussion in Section 2.2.

2.2 Simulation Results

A script using the Python FEFLOW API was created to run a 7-year cycle simulation. The BTES is designed to operate for several decades; however, the model simulation is run for 7 years at which the BTES cycles reach a steady state. The simulation starts in summer, when hot water created from the diesel generator waste heat charges the BTES, forming a hot central core. In winter, the flow direction is reversed, and cool water flows from the edge of the BTES to the center. By the end of winter, much of the heat has been extracted from the BTES core, which has cooled.

Figure 3 shows the temperatures at the end of the seventh summer and the seventh winter. The fact that the temperatures are still high at the end of winter may imply that much higher heat extraction rates are possible with the initial BTES design. The outlet fluid temperature at the start and end of each connection show similar trends, as shown in Figure 4. After a rapid rise in the initial years, the outlet temperatures at winter's end nearly stabilize between 15°C and 20°C after 7 years. Some of the wells are indicated in the left plot of Figure 2. For example, well 30 (highlighted with a thick purple curve in Figure 4) is the outside end borehole of the third connection from the bottom, and well 2 (highlighted with a thick blue curve in Figure 4) is the inside end borehole of the second connection from the bottom. Well 2 shows a higher temperature because it is in the center of the BTES, which receives hot water in summer.

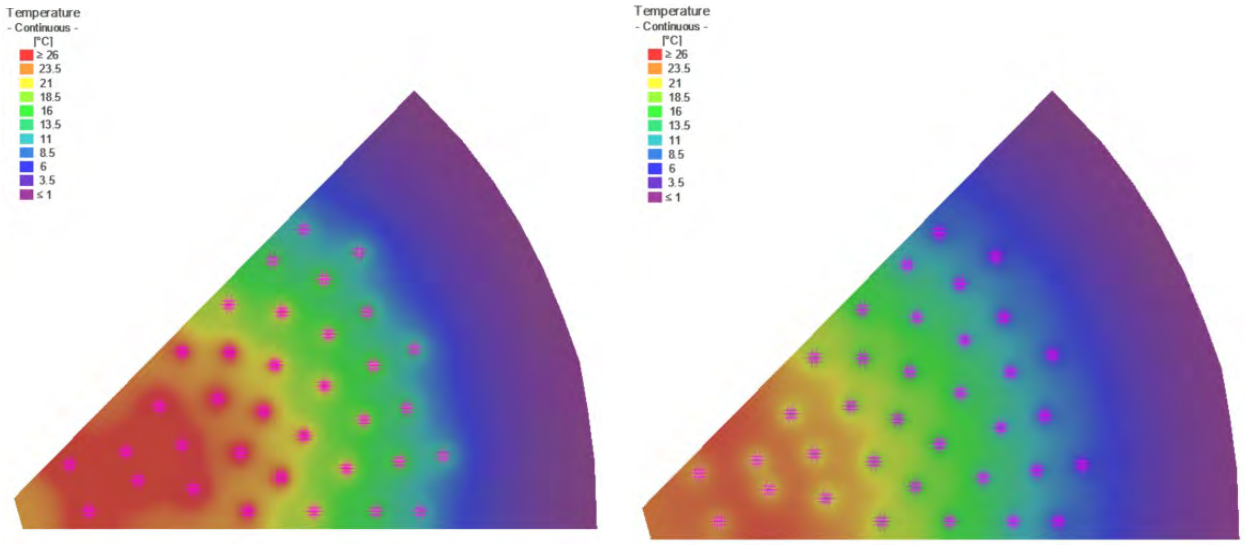

Figure 3: Temperature field at the end of the seventh summer (left plot) and winter (right plot).

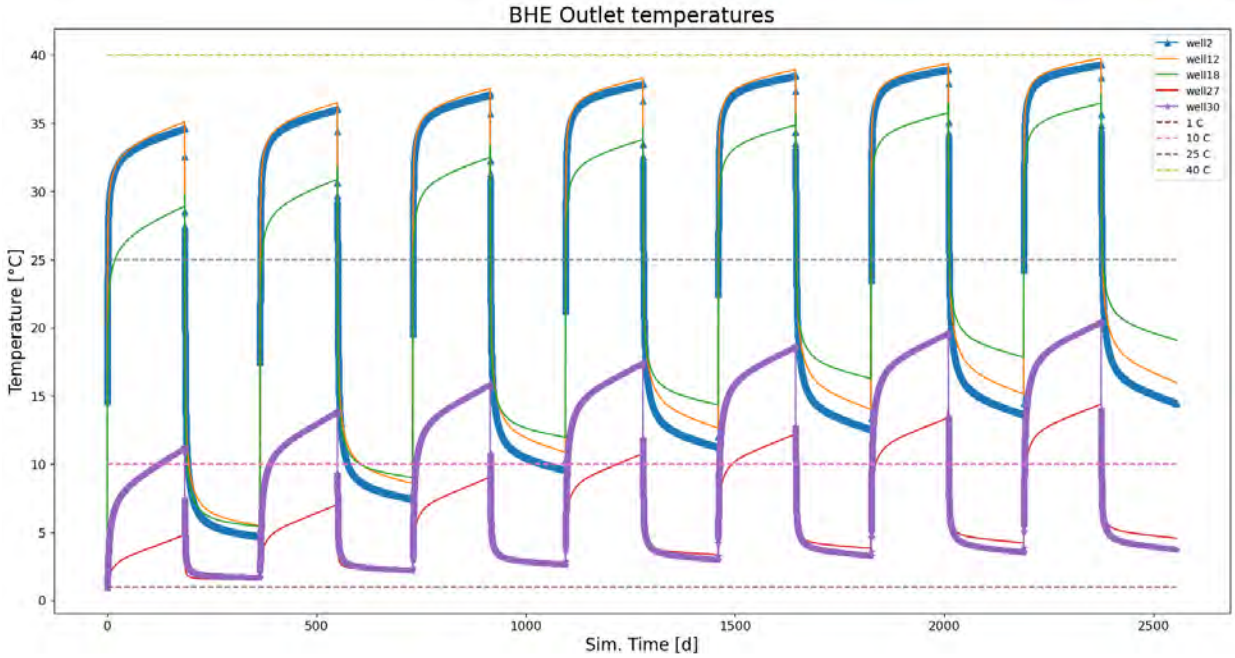

Figure 4: Outlet fluid temperature at both ends of each connection.

2.3 Implementation

The Baker Lake project has been modeled at the conceptual level. Additional detailed modeling has been proposed, along with distribution piping and building retrofit planning.

3. BTES Combined With GABESS in Vernal, Utah

Kitz (2021) proposed the concept of GABESS, which is a combination of three existing technologies in a new arrangement that delivers large grid value. The three technologies are WSHP, ASHP, and BTES, in which ASHP provides warm/cold water during off-peak time to heat or cool the BTES. The heat/cold is later extracted by WSHP to heat or cool the buildings on the thermal network. With the new arrangement in GABESS, we are able to take advantage of the extra heat/cool in off-peak periods and extract the energy during peak load periods. A feasibility study was performed in Vernal, Utah, to evaluate the performance of GABESS system for district heating and cooling.

3.1 Borehole Layout

Figure 5 shows one-fourth of the full-size BTES system with a diameter of 60 m and a depth of 80 m. The one-fourth-size model of the system consists of 103 boreholes with an inside “peaking” zone (34 boreholes) and outside “off-peak” zone (69 boreholes), for a total of 412 boreholes in the full-size system. All boreholes in both zones are connected in parallel, so that flow direction does not have to change between storing heat and cold. According to the sensitivity analysis at the site by Kumawat et al. (2024), the borehole spacing in this case is determined to be 3 m.

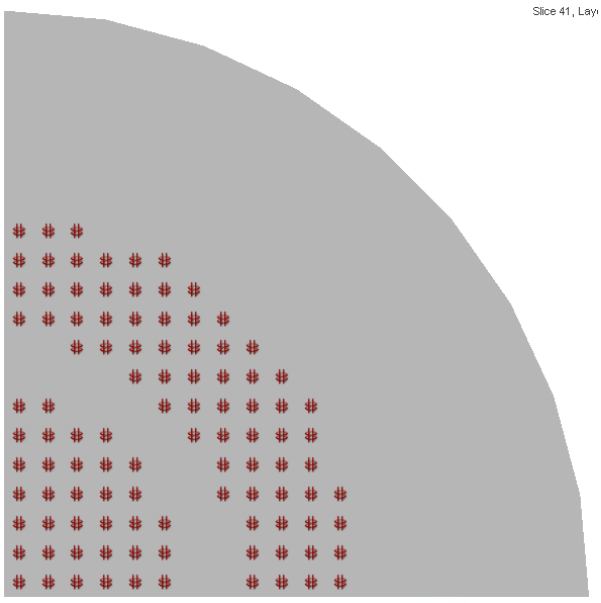

Figure 5: One-fourth of the BTES system. The 103 boreholes are divided into two groups: the central hot zone (peaking zone) and the outside cold zone (off-peak zone).

3.2 Single-Year Simulation

In summer, heat is stored in the BTES system, and in winter, the heat is extracted, which results in different charging and extraction schedules. Diurnal heat demand varies; for example, more heat is required from 5 a.m. to 11 a.m. based on energy demand data. A flexible schedule is proposed to meet energy demand that varies seasonally and diurnally. Table 1 shows an example of the operating schedule of BTES over a year. The "last 2 days" schedule is used to evaluate the capacity of the BTES to meet the peak demand. Input and output of the BTES is constrained by temperature difference (dT in ^{o}C) and flow rate (m^3/d). Working zones for specific time range and ASHP/WSHP are also defined in the schedule. For example, from April 20 to May 19 (except for the last 2 days), ASHP is used to provide heat from 9 p.m. to 6 a.m. and 6 a.m. to 1 p.m. From 1 p.m. to 9 p.m., the outside zone (69 boreholes) of BTES will work with the dT of 4^{o}C and flow rate of 10 m^3/d. A single zone or multiple zones can work independently because of the ring connection of the boreholes. For example, from October 26 to November 24, from 5 p.m. to 5 a.m., only the outside zone is supplying heat, whereas from 11 a.m. to 5 p.m., the center zone is providing heat to the district energy system while the outside zone is being charged by an ASHP.

The temperature fields at the end of the winter and summer seasons are shown in Figure 6. At the end of the winter season, the BTES has cooled by extraction of the heat. The BTES is further cooled by running an ASHP to pre-cool the ground when power is inexpensive and lower carbon. At end of the summer season, the BTES has been warmed by heat from the buildings, and in early fall, the BTES is further charged with heat from the ASHP. Figure 7 shows a time series of inlet/outlet fluid temperature at the cold and hot zones in a single-year simulation. When inlet fluid temperature (shown in blue) is greater than outlet fluid temperature (shown in orange), the BTES is recharged (heat storage), and when the inlet temperature is less than the outlet fluid temperature, the BTES is discharged (heat extraction). The effect of different schedules can be observed in the temperature history, that is, the vibration of inlet/ outlet indicates changing schedule both seasonal and diurnal.

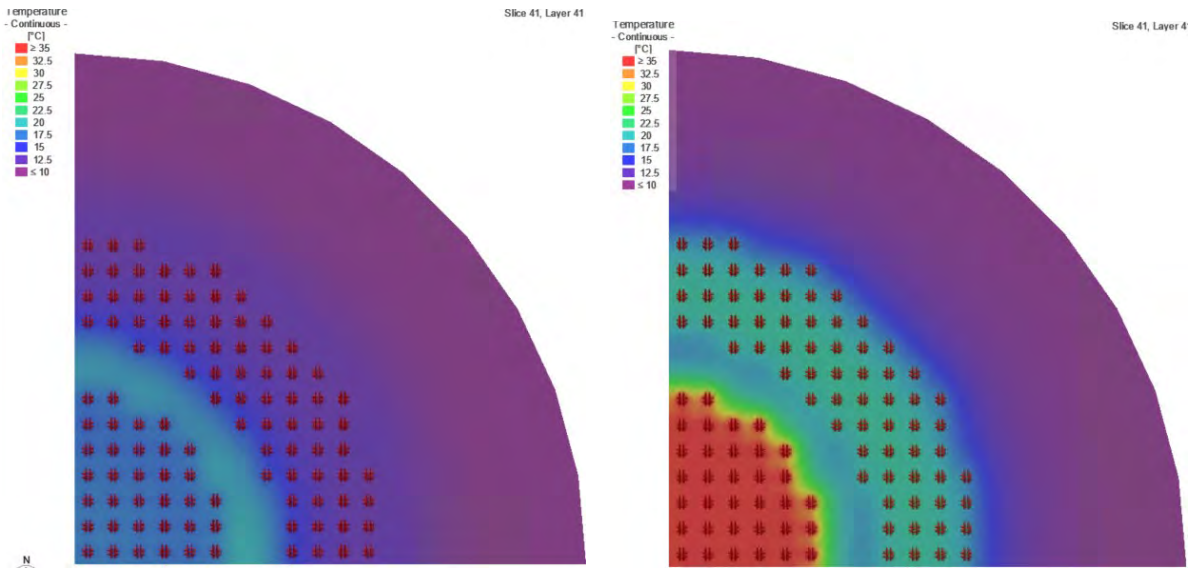

Figure 6: Temperature field at the end of the winter season (left) and at the end of the summer season (right).

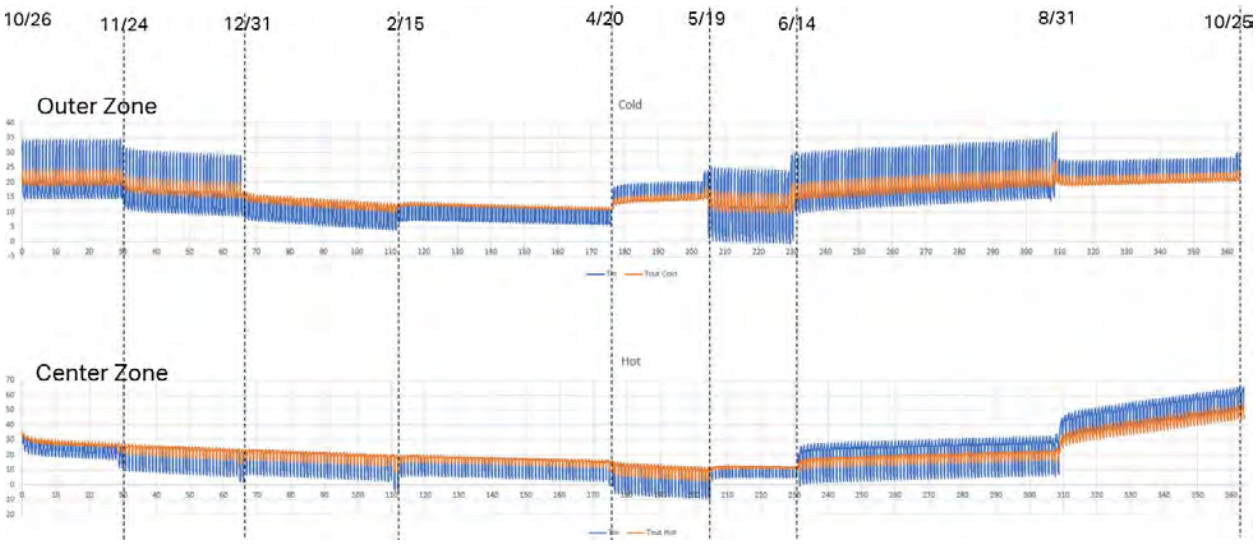

Figure 7: Inlet/outlet fluid temperature of the outer zone (upper) and center zone (lower). Blue represents the inlet fluid temperature and orange represents the outlet fluid temperature.

Figure 8 compares the simulated energy capacity and the actual energy demand (summer and winter separately). The solid dots are the energy demand colored to correspond to periods of a day. For example, blue dots show energy demand from 11 a.m. to 5 p.m. in winter and 9 p.m. to 6 a.m. in summer. The triangles represent heat storage/extraction to/from BTES, and the cross stands for the heat from ASHP. As an example, during the first period of the winter season (October 26 to November 24), heat extraction from BTES between 11 a.m. and 5 p.m. (blue triangles) corresponds to the heat demand (blue solid dots) very well; orange triangles match the orange dots (5 p.m. to 5 a.m. heat needs); and green triangles coincide with the green dots (5 a.m. to 11 a.m.), which is the time that needs most heat in this season. The two green triangles at the end of the period are simulated heat energy in the “last 2 days” described in the running schedule (Table 1), which is used to evaluate the system’s capability to meet peak demand.

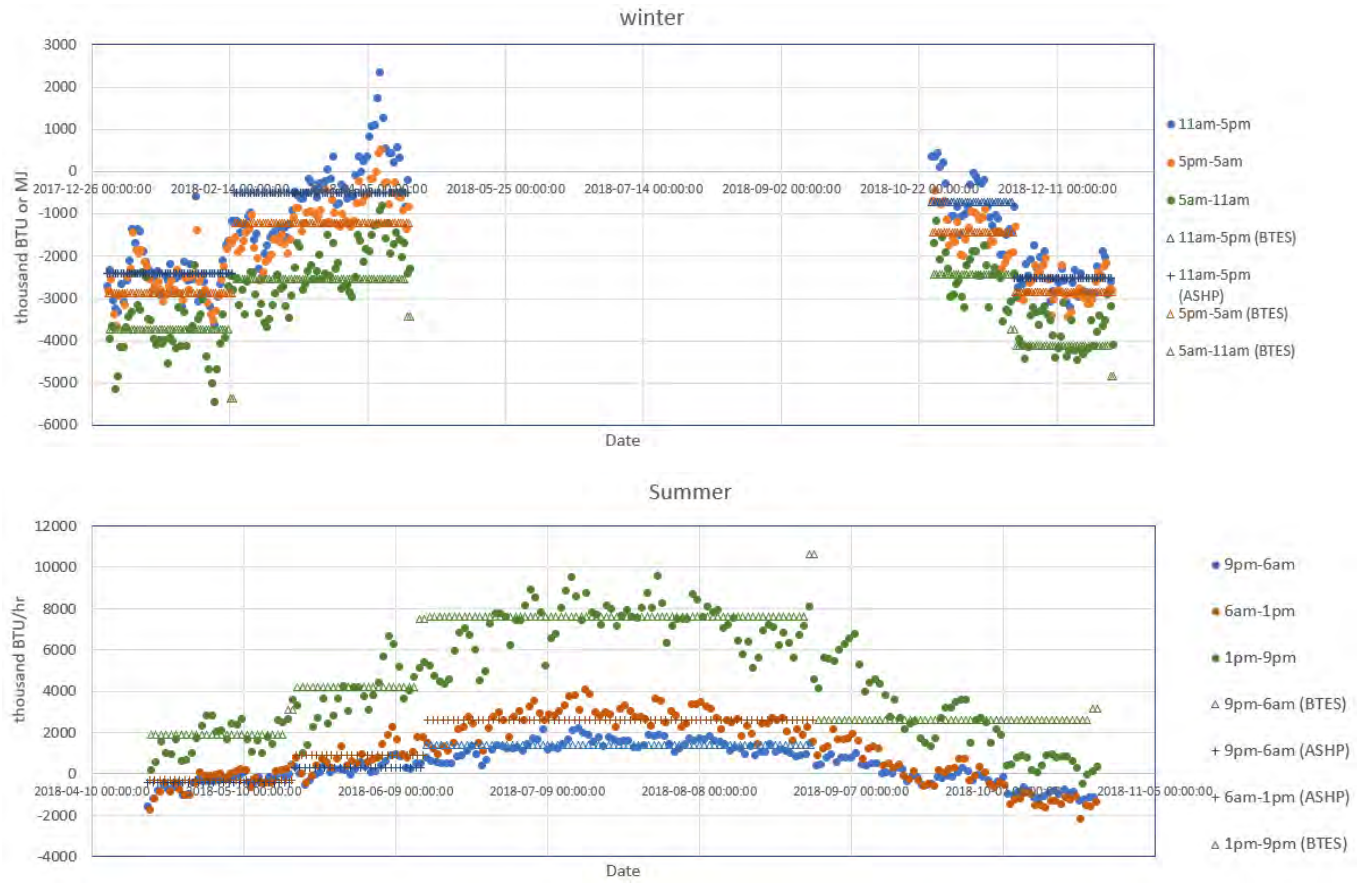

Figure 8: Comparison between simulated heat capacity and energy demand (top: winter season, bottom: summer season). Solid dots are from actual energy demand, triangles from BTES simulation, and cross from ASHP. Different colors correspond to different time ranges within each day.

3.3 Multiple-Year Simulation

Section 3.2 shows simulation results of 1 year, after which we ran 3 years to better evaluate the robustness of the BTES system. Figure 9 shows an underground temperature series at five observation points (obs1 to obs5 from the hot core to the outside cold zone). The temperature at obs5 slightly rises with time, confirming heat loss at the boundary of the BTES system. Obs1 and obs2 show significant seasonal variation (i.e., the underground temperature decreases in winter because of heat extraction and increases in summer from heat injection). Seasonal variation at obs3 and obs4 can also be observed but is not as significant as points close to the hotter core (obs1 and obs2).

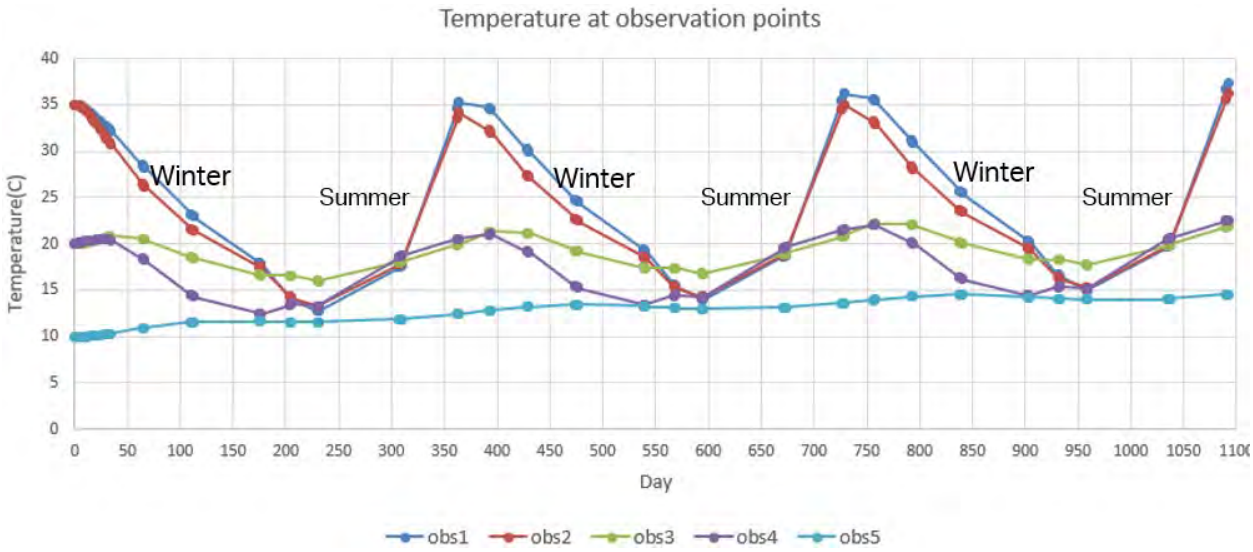

Figure 9: Temperature history at five observation points (obs1 to obs5 from the center to the border).

4. Discussions and Conclusions

Subsurface thermal energy storage systems combined with heat pumps are gaining recognition around the world. Our paper presents two BTES case studies that differ in number of boreholes, borehole spacing, length, borehole connection, and operating schedules. Table 2 summarizes the design and operating parameters of the two case studies: Baker Lake, Nunavut, Canada, and Vernal, Utah.

Table 2: Summary of the parameters in the two BTES case studies.

Parameter	Baker Lake, Nunavut, Canada	Vernal, Utah
Number of boreholes	280	412
Borehole length (m)	90 – 110	80
Borehole spacing (m)	3.5 – 7	3
Borehole connection	Serial	Parallel
Independent zone	No	Yes
Heat source	Diesel engine waste heat	Stored energy from previous season, plus ASHP
Temperature constraint	Inlet temperature	Temperature difference

In Baker Lake, a radial connection with multiple boreholes in each connection is applied in which the boreholes are not as dense as in the Vernal case. The length of the boreholes in Baker Lake, however, is longer and the extended length near the outside of the BTES system is tested and confirmed. In Vernal, we combined a flexible operating schedule with GABESS to shift heat/cold from off-peak time to meet the peak load demand. Results indicate the GABESS is able to meet the high thermal energy deliverability and seasonal storage demands with a small surface footprint.

clustering, unsupervised learning, feature engineering, time-series analysis, geothermal, heat exchangers

ABSTRACT

Artificial intelligence and machine learning applications for above-ground geothermal energy operations are limited despite volumes of data being generated in real-time by facilities all over the world. There is a need to extensively annotate operational data before it is ready for tasks such as condition monitoring, fault detection, and performance forecasting.

In this study, we propose the application of unsupervised machine learning to automatically label fifteen (15) years of operational data for a geothermal heat exchanger. The framework implemented in this study relies on well-established techniques in systematic time-series feature engineering, feature selection, and cluster analyses. Nine clustering algorithms were trained using the extracted time-series features as inputs and were able to identify data groups that represented periods before and after a cleaning activity was done on the heat exchangers. The resulting data labels can be used to assess the effectiveness of different heat exchanger cleaning methods and the development of an optimal maintenance plan. The labels generated automatically are now primed for use in more machine learning applications that rely on a supervised learning approach. The developed framework can also be applied in other parts of the geothermal value chain, such as using unsupervised machine learning to create an effective maintenance plan for scaled-up production wells.

1. Introduction

The quality and amount of operational geothermal data have been consistently advancing. Research indicates that standardising and integrating datasets throughout the geothermal value chain is crucial for maximising value from existing facilities (Krieger et al., 2022; Okoroafor et al., 2022). Digitising monitoring systems and adopting data governance practices have significantly enhanced the interoperability and accessibility of operational data for engineers and scientists focusing on performance improvements. Progress in sensor technology has further broadened the scope of monitoring systems, driving innovative changes in the operation, monitoring, and maintenance of geothermal power plants.

Interest in data science, artificial intelligence (AI), and machine learning (ML) applications within the geothermal energy sector has surged significantly over the past decade (Abrasaldo et al., 2024; Okoroafor et al., 2022). The vast availability of time-series operational data and affordable computing power has enabled real-time, data-intensive analysis. While most AI and ML applications in geothermal energy have concentrated on subsurface reservoir characterisation, recent studies have also explored their use for surface facilities. These studies have utilised simulated, experimental, and actual operational data to create models that help scientists and engineers optimise power plant design, enhance performance, monitor conditions, and make data-driven decisions in the geothermal field (Abrasaldo et al., 2024). Notably, supervised learning has been the predominant approach researchers employ in AI and ML studies within the geothermal energy discipline.

A major challenge in many AI and ML studies in geothermal and other industries is the necessity for extensive annotation of operational data (Buster et al., 2021; Taverna et al., 2022). Sensor data is less useful for supervised machine learning without labelling by domain experts. In applications like condition monitoring and fault detection, these annotations are vital for accurately defining various power plant operation regimes. However, efforts to fully annotate operational data in geothermal energy operations lag behind the vast amount of data generated across facilities, as most operators are already busy with the plant's daily operations.

1.1 Study motivation and objective

This work presents a proposed workflow to automatically generate data labels designed to help operators assess and monitor the performance of heat exchangers in geothermal binary power plants. Potential fouling in heat exchangers significantly hinders the broader adoption of geothermal energy as a reliable electricity source despite the abundance of accessible low to medium-enthalpy reservoirs (Ann Candido & Zarrouk, 2017; Ledésert et al., 2021; Mroczek et al., 2017; Zarrouk et al., 2014). In geothermal settings, fouling primarily arises from the deposition or precipitation of materials as mineral-rich geothermal brine passes through the heat exchangers to vaporise the motive fluid in a binary cycle power plant (Brown, 2011; Ledésert et al., 2021; Mroczek et al., 2017; Yanagisawa, 2015; Zarrouk et al., 2014). The performance reduction of heat exchangers and overall power plants due to fouling has prompted researchers to develop proactive and reactive measures to mitigate the effects of mineral scaling (Ann Candido & Zarrouk, 2017; Penot et al., 2023).

Chemical treatment of geothermal brine before it enters binary plants is a standard method to prevent scale deposition within surface facilities. However, when chemical treatment is not cost-

effective or existing scale buildup in heat exchangers impedes effective chemical cleaning, operators resort to mechanical methods to remove the scale. Mechanical removal of mineral deposits in heat exchangers can be accomplished using boring technology or high-pressure water blasting. Both methods require significant downtime, incurring high costs for operators beyond the labour and material costs of mechanical cleaning. Accurately assessing heat exchanger conditions is critical to determining the optimal timing for mechanical cleaning (Zarrouk et al., 2014).

Given the various factors affecting heat exchanger performance, reliable evaluation is challenging. This study employs a workflow based on unsupervised machine learning algorithms, trained on time-series features extracted from sensor data, to annotate the operational history of heat exchangers in a geothermal binary power plant. These annotations can be used to assess the effectiveness of different cleaning methodologies and identify system and environmental conditions that may impact the success of these interventions. Successfully implementing this workflow could also lead to developing an optimal cleaning and maintenance plan for heat exchangers based on their current condition and performance. The following sections discuss the proposed approach and its applicability in studying heat exchanger performance at the Wairakei geothermal binary power plant in New Zealand.

1.2 Wairakei Geothermal Binary Power Plant

The Wairakei geothermal project, situated north of Taupo in New Zealand, hosts an active geothermal reservoir projected to support the current 353 MW of electricity generation for another four decades (Ciriaco et al., 2022). The Warakei geothermal power plant was inaugurated in 1958 with a 132 MWe conventional geothermal power plant, later expanding to a capacity of 187 MWe following the addition of the 55 MWe Poihipi power station (Thain & Carey, 2009). Subsequently, in 2005, a 14-MW Organic Rankine Cycle (ORC) power plant, comprising two generating units, was commissioned in Wairakei. It was designed to intake 2800 tons per hour of geothermal fluid at a nominal temperature of 127°C (Zarrouk et al., 2014).

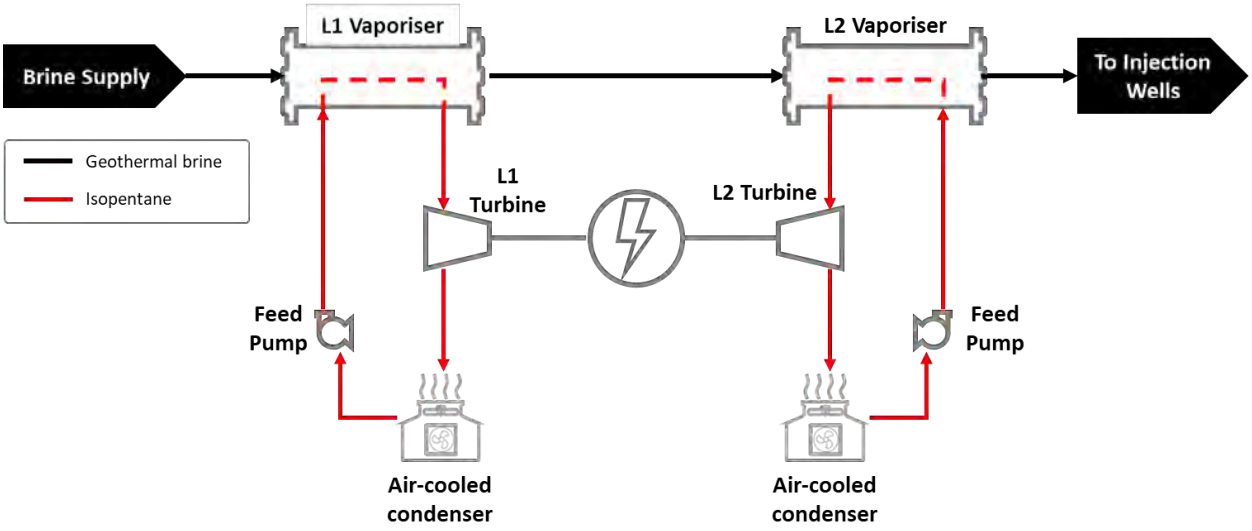

Figure 1. Schematic diagram illustrating one of the two multi-level Ormat generating units forming the Wairakei binary power plant. Note that pre-heaters and recuperators are omitted for brevity.

The Wairakei binary power plant operates on an Organic Rankine Cycle (ORC) using isopentane as the working fluid (Thain & Carey, 2009). Separated geothermal fluid from the Wairakei production wells supplies the binary power plant, where approximately 130 MW of thermal power is transferred from the geothermal brine to vaporise and superheat the working fluid. The superheated isopentane drives the turbines to generate electricity, which is then cooled back to its liquid state using forced-draft air condensers. A feed pump in each generating unit circulates the working fluid to maintain the cycle during regular operation (Zarrouk et al., 2014). In each generating unit, heat exchangers are connected to extract heat from the source fluid in two stages (Figure 1). The lower temperature fluid exiting the second vaporiser level flows through another set of heat exchangers to preheat the working fluid in the individual isopentane circuits. The heat exchangers at the Wairakei binary power plant are shell and tube types, with the geothermal fluid passing through the tube side and the isopentane travelling through the shell side. This configuration facilitates easier cleaning when scaling occurs on the tube side, where the mineral-rich geothermal fluid flows.

1.3 Heat-exchanger scaling and cleaning

Geothermal fluids contain high concentrations of minerals that can precipitate on the surface facilities of a geothermal project when left untreated. Fouling of heat exchangers in the geothermal industry is a well-documented issue (Ann Candido & Zarrouk, 2017; Brown, 2011; Ledésert et al., 2021; Mroczek et al., 2017; Muller et al., 2015; Penot et al., 2023; Yanagisawa, 2015; Zarrouk et al., 2014), with minerals like silica and metal sulfides commonly depositing along the tube side of binary plant heat exchangers. To prevent significant scaling within the heat exchangers, it is standard practice to chemically dose the source geothermal fluid with anti-scalants or pH modifiers before it enters the vaporisers (Ann Candido & Zarrouk, 2017; Johnston et al., 2020; Muller et al., 2015; Zarrouk et al., 2014). When chemical dosing cannot wholly prevent scaling, mechanical cleaning of mineral deposits becomes necessary. Standard methods for mechanical cleaning include drilling out the scale from the heat exchanger tubes or using high-pressure water-blasting. These methods require substantial financial and human resources and result in significant power plant downtime. Chemical cleaning is also an option but has been found to cause undue corrosion in surface pipelines and injection wells (Penot et al., 2023; Zarrouk et al., 2014). Therefore, an accurate assessment of the condition of geothermal heat exchangers and understanding the effectiveness of various cleaning methods are essential to develop an optimal, condition-based maintenance program for geothermal heat exchangers.

2. Methodology

The workflow proposed in this study involves systematically extracting time-series features from operational sensor data and using these engineered features to train several unsupervised clustering algorithms, which generate labels for the input time series. A crucial component of this workflow is an automated feature selection process conducted in two stages to ensure only statistically relevant features are included in model training and to minimise collinearity among the features. The filtered time-series feature matrix is then normalised and used as input to train several clustering algorithms. These trained models are evaluated using clustering metrics that do not depend on ground truth labels. Additionally, a comparison and initial interpretation of the labels generated by the various clustering algorithms are performed as part of the model validation

process. An overview of the approach taken in this study is illustrated in Figure 2. The following subsections briefly summarise the techniques used in the proposed workflow.

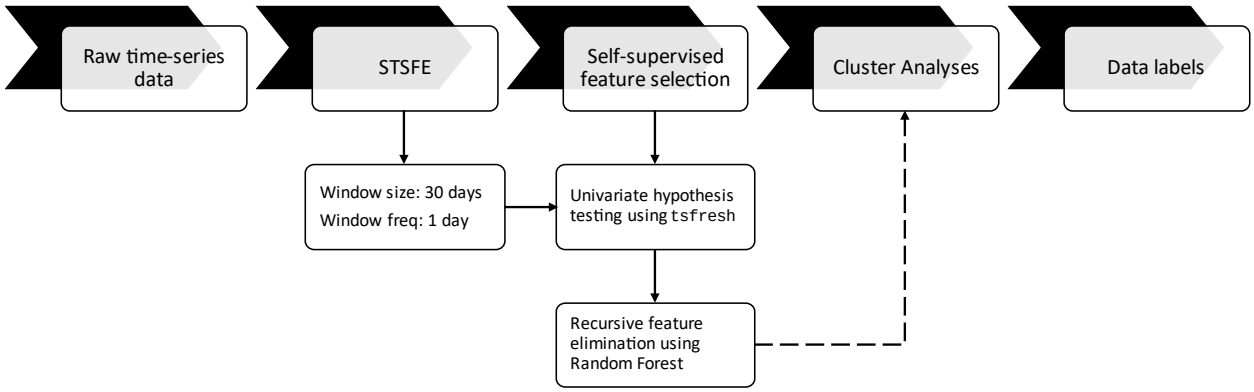

Figure 2. A high-level flowchart of the approach applied in this study combines systematic time-series feature engineering (STSFE), self-supervised feature selection and unsupervised machine learning to annotate the historical performance of geothermal heat exchangers. The generated data labels can be used for further domain-specific analysis and standard supervised machine learning applications.

2.1 Heat exchanger sensor data

Geothermal operators worldwide use various forms of centralised platforms where data collected from sensors are stored, processed, visualised, and archived. The data gathered from these sensors are processed by several control systems to ensure the safe and normal operation of the various equipment in the power plant. This study focuses on data captured by sensors used to monitor and assess the condition and performance of the heat exchangers in the Wairakei binary power plant.

In this study, the two generating units in the Wairakei binary power plant are considered a single system due to the absence of individual pressure sensors and flow meters at each generating unit's inlet. Line pressures measured by sensors at the inlet and outlet of the binary system, along with metered flow rates at the inlet, are used to calculate the flow resistance parameter. This metric, as reported by Zarrouk et al. (2014), is a better measure of the impact of mineral scaling on heat exchanger performance. The temperature difference of the geothermal brine upstream and downstream of the binary plant is also included in the analysis to represent the heat transfer efficiency of the heat exchangers. The monitored parameters are measured in real-time but vary in magnitudes and sampling rates over the periods covered (Figure 3). The various time series used in this study cover fifteen years, amounting to about 7.9 GB of data files.

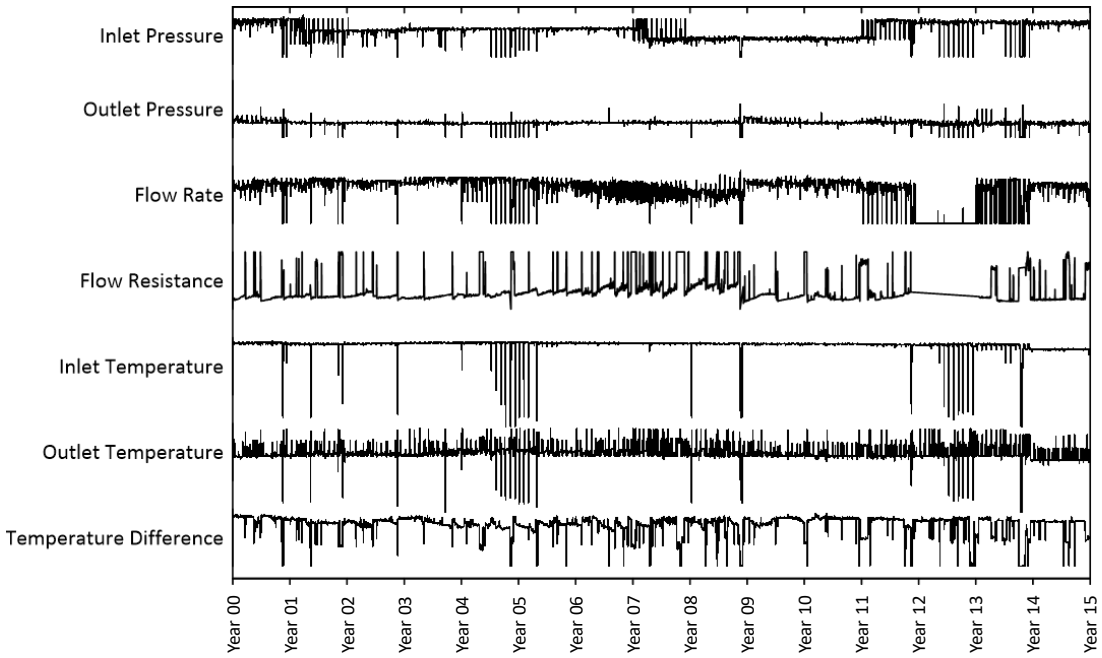

Figure 3. Sparklines of the time series raw values showing changes in relative magnitude across the covered period.

2.2 Systematic time-series feature engineering and self-supervised feature selection

This study proposes a feature-based approach to time-series modelling wherein quantified characteristics of the input time series are used to train the algorithms instead of the raw data values. Directly using raw values can be sufficient in some cases (Box et al., 2016) but is significantly impacted by noise and redundancies due to the large volume of data. Emerging research indicates that utilising appropriate time series features as model inputs improves model performance and interpretability (Fulcher, 2017; Kennedy et al., 2021; Simmons et al., 2021; Teh et al., 2021). The dimensionality reduction achieved by identifying relevant time series features for machine learning also enhances computational efficiency and reduces the risk of overfitting in the resulting models.

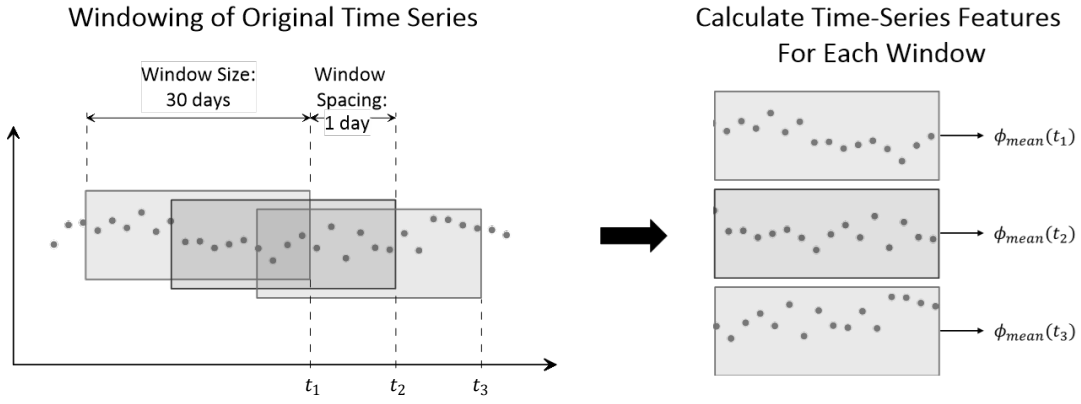

Figure 4. Diagram illustrating the rolling window method: A window of a set size is moved across the original time series at regular intervals. The resulting subsets of time series are then analysed using feature calculators to extract important statistics and characteristics, such as the mean.

In this study, a sensor-specific feature selection process is implemented, similar to the approach described by Teh et al. (2021). Each sensor's time series $\vec{s} = [x_1, \dots, x_t, \dots, x_T]$ undergoes systematic time-series feature extraction and two stages of feature selection. The main difference lies in the target variable used for the self-supervised feature selection process, where the last value of the subsequent window is forecasted rather than a specific statistic of the next window. Initially, a rolling window is applied to all sensor time series, resulting in a matrix of windows $\boldsymbol{W} = [\vec{w}_1, \dots, \vec{w}_n, \dots \vec{w}_N]$, where n indexes each window and N is the total number of windows (Figure 4). Each rolling window is bounded by two timestamps, referenced by the right-most timestamp. A window size of thirty (30) days and a window frequency of one (1) day are utilised, ensuring each window $\vec{w}_n$ contains sensor readings for the last thirty days, overlapping by 29 days with the adjacent windows.

The rolled time series window matrix $\boldsymbol{W}$ undergoes systematic feature extraction using the `tsfresh (v0.19.0)` Python package (Christ et al., 2018). This Python library employs highly parallelisable and efficient algorithms to systematically apply a set of feature calculators $\phi(\vec{w})$ on the window matrix $\boldsymbol{W}$ to extract $Q = 794$ characteristic time series features for each time-series window. The resulting feature matrix $\boldsymbol{W}_\phi$ has N number of rows corresponding to the number of time series windows and Q number of columns:

$$\boldsymbol{W}_\phi = \begin{bmatrix} \phi_1(\vec{w}_1) & \cdots & \phi_q(\vec{w}_1) & \cdots & \phi_Q(\vec{w}_1) \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ \phi_1(\vec{w}_n) & \cdots & \phi_q(\vec{w}_n) & \cdots & \phi_Q(\vec{w}_n) \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ \phi_1(\vec{w}_N) & \cdots & \phi_q(\vec{w}_N) & \cdots & \phi_Q(\vec{w}_N) \end{bmatrix}. \quad (1)$$

In many applications, not all extracted features are relevant or crucial for a specific machine learning task, and some may even be redundant, which can adversely affect model performance. Therefore, the next step in the proposed workflow is a two-stage selection process to retain only the statistically important features during model training. The target vector $\vec{y}$, which includes future values of the time series relative to a specific window, serves as the basis for feature selection. The initial selection phase utilises univariate hypothesis tests integrated into the `tsfresh` library. This step filters out irrelevant features for predicting future time series values, ensuring that only properties capturing the dynamics of future values are retained in the feature matrix. Following this, a second round of feature selection employs recursive feature elimination (RFE) to reduce the feature set further and eliminate collinear variables. RFE is executed using a Random Forest regressor from the `scikit-learn` (Pedregosa F. et al., 2011) machine learning library, which ranks the most influential parameters for predicting future time series values.

2.3 Unsupervised machine learning

Machine learning has garnered significant attention across various research disciplines, encompassing applications in the four primary paradigms: supervised, semi-supervised, unsupervised, and reinforcement learning (Cook, 2016; Murty & Devi, 2015). While the other approaches require full or partial labelling of the input data, unsupervised learning represents the opposite end of the spectrum, relying solely on unlabelled data to reveal hidden patterns and structures within the input data. In this study, various clustering algorithms are trained on the filtered and normalised time-series feature matrix to identify potentially distinct operating

conditions of the studied geothermal heat exchangers. Detailed descriptions of each clustering algorithm (Figure 5) used in this study can be found in the `scikit-learn` library documentation.

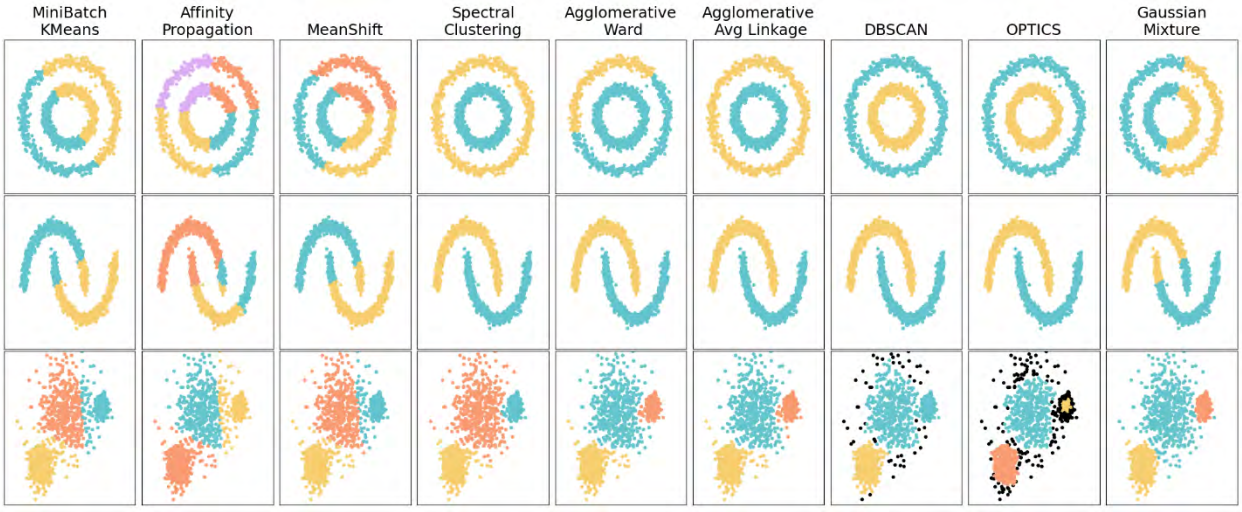

Figure 5. Exemplary behaviour of the different clustering algorithms used in this study on sample datasets with various structures. Adapted from the scikit-learn [33] documentation.

Three evaluation metrics for cluster analyses that do not depend on ground-truth class assignments are chosen: the Silhouette Coefficient (SIL), the Calinski-Harabasz index (CHI), and the Davies-Bouldin index (DBI). These metrics are straightforward to calculate for each clustering algorithm using their implementation in the `scikit-learn` library. The SIL of a partitioning task compares the tightness of each resulting cluster and the separation of each cluster from the other clusters (Rousseeuw, 1987). The CHI, also known as the variance ratio criterion, is calculated as the ratio of the sum of inter-cluster and intra-cluster dispersion, where the sum of distances squared is used as the dispersion metric (Calinski & Harabasz, 1974). Lastly, the DBI measures the clusters' similarity by comparing the separation between clusters and the size of the individual clusters (Davies & Bouldin, 1979).

3. Results

The workflow described in the previous section was applied to 15 years of operational data gathered at the Wairakei binary power plant (Figure 6). Temperature data of the geothermal fluid was also utilised as an indicator of the heat transfer efficiency of the binary unit, as previously mentioned. The flow resistance data displayed a sawtooth pattern, indicating the periods when cleaning and maintenance were performed on the heat exchangers.

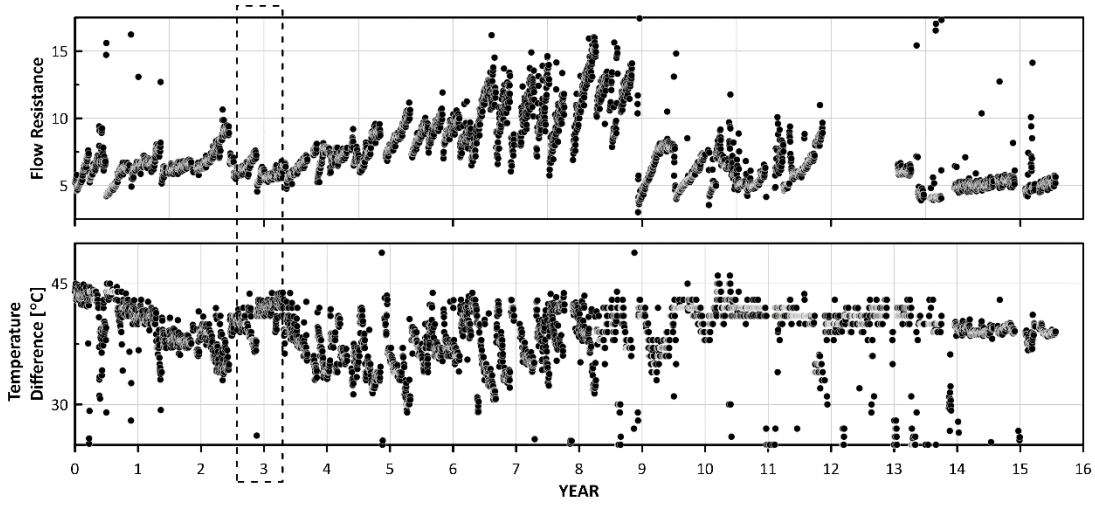

Figure 6. A sawtooth pattern is observed in the historical performance metrics of the heat exchangers where mineral scaling causes the flow resistance to increase over time while successful cleaning activities instantaneously reduce the flow resistance parameter.

3.1 Self-supervised feature selection

The flow resistance and temperature difference time series were subjected to the rolling window process described in section 2.2 and underwent systematic time-series feature extraction and selection using `tsfresh`. A reference target vector, composed of the last value of the succeeding window, was used to conduct univariate hypothesis testing to identify the time series features relevant to the desired task. This first feature selection phase resulted in a high-dimensional time series feature matrix with 539 statistically relevant features at the default false discovery rate of 0.05. Therefore, these relevant features underwent a second selection stage using a recursive feature elimination algorithm with a Random Forest regressor, utilising the same reference target vector as in the previous step. The second feature selection step identified an optimal feature count of fewer than ten for both input time series (Figure 7). After normalisation, the time series feature matrix is ready for training unsupervised learning models.

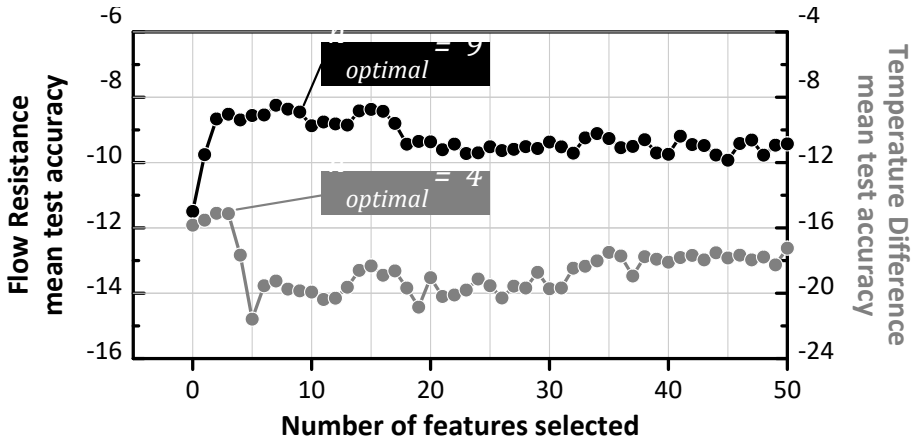

Figure 7. Recursive feature elimination results showed that the optimal feature count for both input time series is less than ten (10).

3.2 Cluster analysis and hyperparameter optimisation

One of the main tasks in cluster analysis is determining the optimal number of clusters for algorithms that require this information at the start of model fitting. This optimal cluster count can be identified by examining how the performance metrics of the clustering algorithms change with different cluster counts. The sensitivity analysis results (Figure 8) indicate a general decrease in the SIL for most algorithms when the cluster count exceeds two. However, the CHI and DBI offer counterindications, with some clusters showing increasing CHI and decreasing DBI values as the cluster count rises. Additionally, it is observed that for cluster counts greater than or equal to four, there is no significant change in performance for most clustering methods, regardless of the metric used.

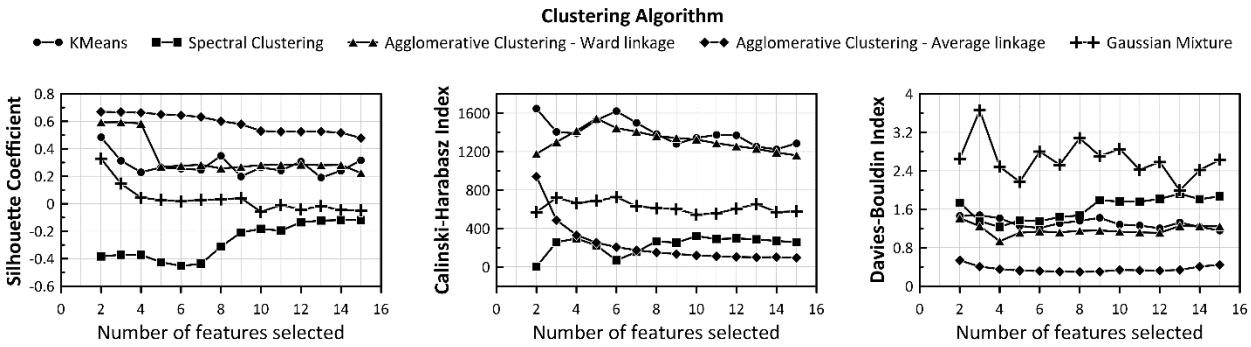

Figure 8. The elbow curve shows SIL, CHI, and DBI trends for clustering algorithms that require the cluster number to be defined prior to model fitting.

After selecting an initial value for the number of clusters, hyperparameter optimisation was conducted on various clustering algorithms using the `Optuna` Python library (Akiba et al., 2019). A multi-objective function was employed to tune the algorithm parameters, aiming to maximise the SIL and CHI and the inverse of the DBI. An overall model performance metric was calculated using the magnitude of the vector created by the SIL, CHI, and inverse DBI values for each trained model, with the best model ideally having the largest value of this metric. However, when overlaying clustering results on the raw time series, models with higher indicative overall performance did not always yield good clustering results, such as trial #41 in Figure 9B. Visual inspection indicated that clusters generated by models with a relatively lower SIL but higher CHI were more reasonable (e.g., trial #52 in Figure 9C). The tuned clustering algorithms were trained on the final input matrix of time-series features to annotate the performance history of the heat exchangers in the binary unit.

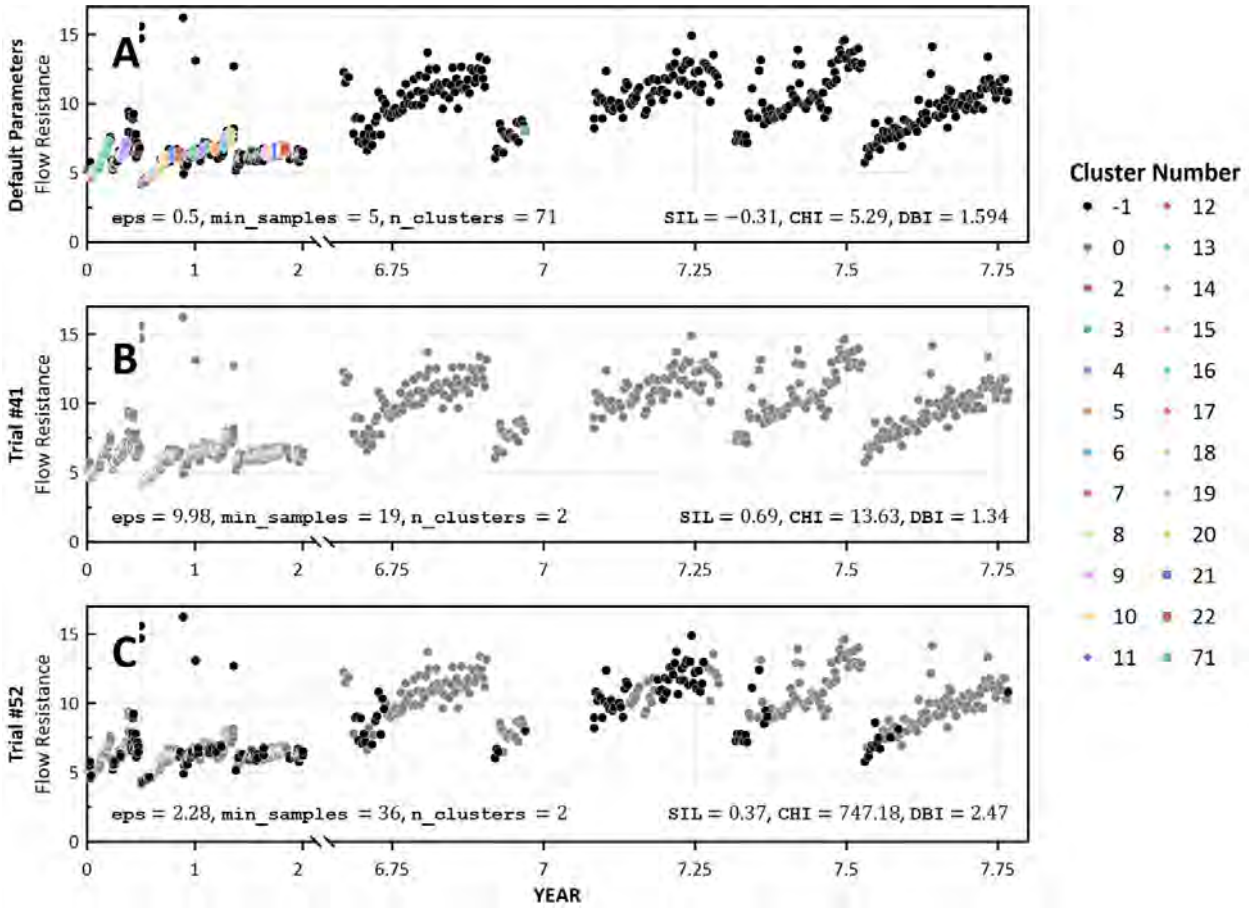

Figure 9. Exemplary clustering results comparing DBSCAN models trained using (A) default hyperparameters, (B) hyperparameters of models with the highest overall performance metric, and (C) hyperparameters of the optimal model.

The cluster labels produced by the optimised algorithms match up well with the maintenance history of the heat exchangers. One cluster group is observed to group the data points after a recent cleaning job, and another cluster is associated with data points before a cleaning activity (Figure 10). Furthermore, because of the distinction produced by the cluster groups, the data points clustered after a cleaning activity can be considered the “effective duration” of the said maintenance job. This information is vital for operators to evaluate the effectiveness of various cleaning methods and assess the environmental and operating conditions under which a particular method may be less effective than at other times. Ideally, a successful heat exchanger cleaning activity should reduce frictional losses in the piping system, leading to a sharp decrease in the flow resistance parameter and an improvement in heat transfer efficiency, indicated by an abrupt increase in the values of the temperature difference time series. Cleaning jobs A, C, and D from Figure 10 exemplify effective interventions that led to a decrease in flow resistance, an increase in temperature difference, and an observed change in cluster labels. Cleaning job B, on the other hand, is an example of an unsuccessful cleaning activity with no significant improvement in the heat exchanger performance and no changes in the cluster label after the activity.

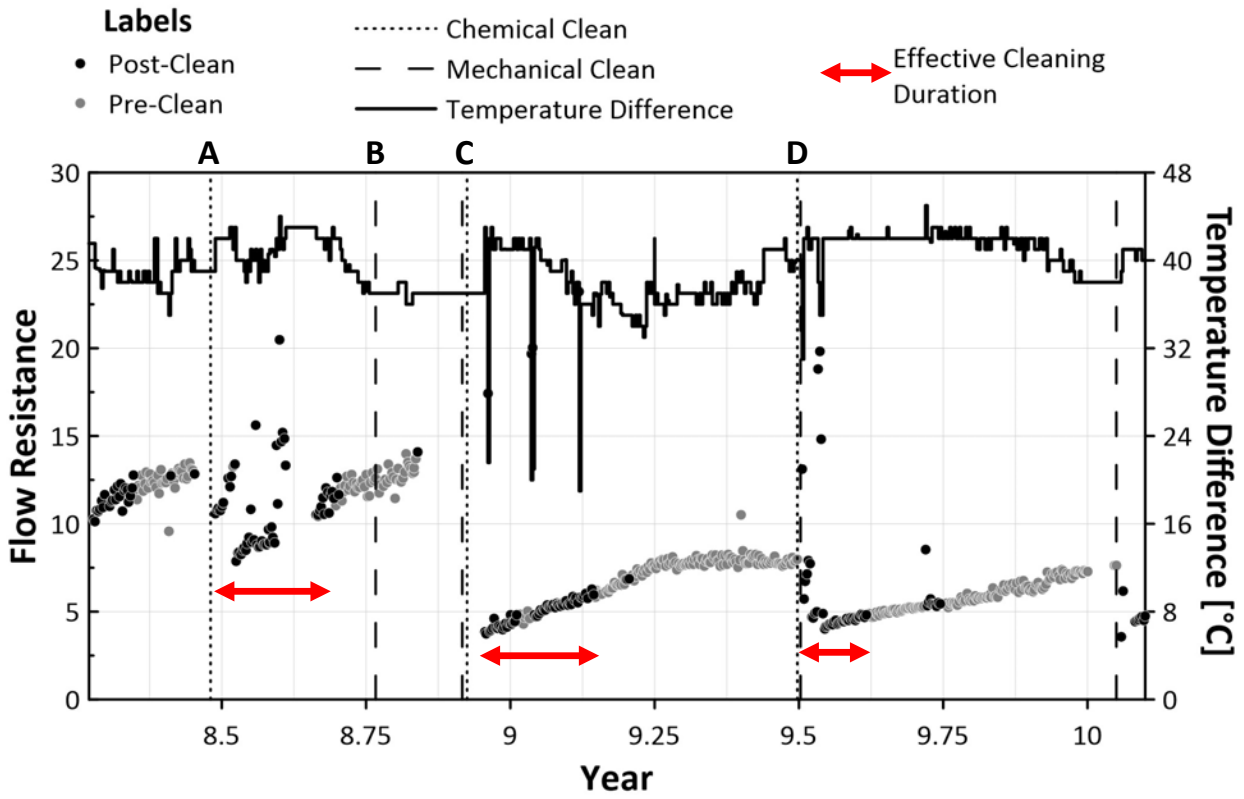

Figure 10. Subset of the labelled performance history of the heat exchangers based on the clustering results of the optimised Gaussian Mixture model.

4. Conclusion

This study introduced a novel method for annotating the performance history of geothermal heat exchangers based on a workflow consisting of efficient, systematic time-series feature engineering, self-supervised feature selection, and cluster analysis. After extracting time-series features from flow resistance and temperature difference data of the Wairakei binary power plant, thirteen (13) features were selected through univariate hypothesis testing and self-supervised feature selection. These final features were then used to train and optimise nine (9) clustering algorithms.

The promising clustering algorithms successfully differentiated between the “clean” and “scaled-up” state of the geothermal heat exchangers. Data points recorded right after a cleaning activity were typically grouped, while another cluster represented data points preceding a cleaning job. The cluster labels reveal that not all cleaning activities are equally effective. Further analysis could quantitatively compare the effectiveness of mechanical versus chemical cleaning of the heat exchangers. Nonetheless, developing a maintenance plan that combines both cleaning methods appears beneficial.

The proposed framework is effective in automatically labelling time-series data from geothermal facilities and can allow scientists and engineers to develop a data story that can enrich the vast amount of data recorded in power plants worldwide. These data annotations can open up more applications of machine learning and other data-driven methods in the geothermal industry, promoting a more efficient and safe production of renewable energy.

ABSTRACT

Modeling field-scale Enhanced Geothermal Systems (EGS) is challenging due to complex fluid flow, heat transfer, and rock mechanics interactions. Existing numerical methods like finite difference (FD), Discrete Fracture Network (DFN), and coupled Finite Element Method (FEM) with finite volume (FV) simulators fall short in accurately capturing EGS complexities. This paper introduces a phase-field model for fracture initiation and propagation in EGS, coupled with the enriched Galerkin method for flow and energy equations. Implemented in the MOOSE (Multiphysics Object Oriented Simulation Environment) framework, this approach is validated through analytical, laboratory, and field-scale simulations, notably for the FORGE geothermal project, showcasing improved accuracy and computational efficiency in EGS modeling.

1. Introduction

Numerical simulation plays a critical role in understanding and optimizing Enhanced Geothermal Systems (EGS) (Figure 1). Complex 3D models are routinely used to simulate these systems, with ongoing research continuously improving modeling techniques (Pardalos et al., 2001). However, EGS presents unique challenges. Simulators need to explicitly represent fractures, account for stress-induced changes in fracture aperture, and model the interplay between fluid flow and thermal effects within fractures (Sanyal et al., 2000). Researchers are actively developing advanced tools to address these complexities. For instance, Xing et al. (2015) present a supercomputer simulation tool that can visualize microseismic events and integrate geological data for detailed fluid flow simulations (H. Xing et al., 2015). The importance of accurate fracture representation is further emphasized by Ilyasov et al. (2009), who highlight recent advancements in seismic processing and fluid/thermal flow simulations for fractured systems (Ilyasov et al., 2009). These advancements underscore the need for integrating various modeling approaches to capture the multifaceted dynamics of EGS.

The Department of Energy's FORGE initiative aims to revolutionize Enhanced Geothermal Systems (EGS) technology by utilizing a dedicated field laboratory near Milford, Utah (Allis et al., 2019; Moore, 2019). This site, characterized by crystalline granitoid rocks overlaid with sedimentary and volcanic deposits, presents an ideal environment for developing and testing EGS

in hot, dry rock formations (Nielson et al., 1986). The Utah FORGE project represents a critical effort in EGS development (R. K. Podgorney et al., 2020). Here, hydraulic fracturing is used to create reservoirs within granite formations for geothermal energy extraction (Nadimi et al., 2020). Accurately simulating these complex fracture networks is essential for optimizing well stimulation strategies and predicting reservoir performance. The referenced studies (Janiga et al., 2022; Xing et al., 2021; Mindygaliyeva et al., 2023; Kumar et al., 2023; Cao and Sharma, 2023; McClure et al., 2024; Riahi et al., 2019; Wu et al., 2020) showcase a range of numerical methods, each with its strengths and limitations (Cao et al., 2023; Janiga et al., 2022; Kumar et al., 2023; M McClure et al., n.d.; Mindygaliyeva et al., n.d.; Riahi et al., 2019; Wu et al., 2020; P. Xing et al., 2021). A key challenge lies in finding the right balance between computational efficiency and the ability to capture the intricate details of the fracture network. Discrete Fracture Network (DFN) approaches (Cao and Sharma, 2023; Riahi et al., 2019) offer detailed representations, potentially exceeding 7,000 fractures, but struggle with scalability, especially for large-scale Utah FORGE simulations lacking extensive pre-existing fracture network data (Cao et al., 2023; Riahi et al., 2019). Additionally, DFN methods may require substantial supporting geological data for robust predictions. While Distinct Element Methods (DEM) like Xing et al.'s (2021) XSite™ offer exceptional accuracy in simulating fracture interactions, their computational demands can be prohibitive for large-scale reservoir simulations (P. Xing et al., 2021).

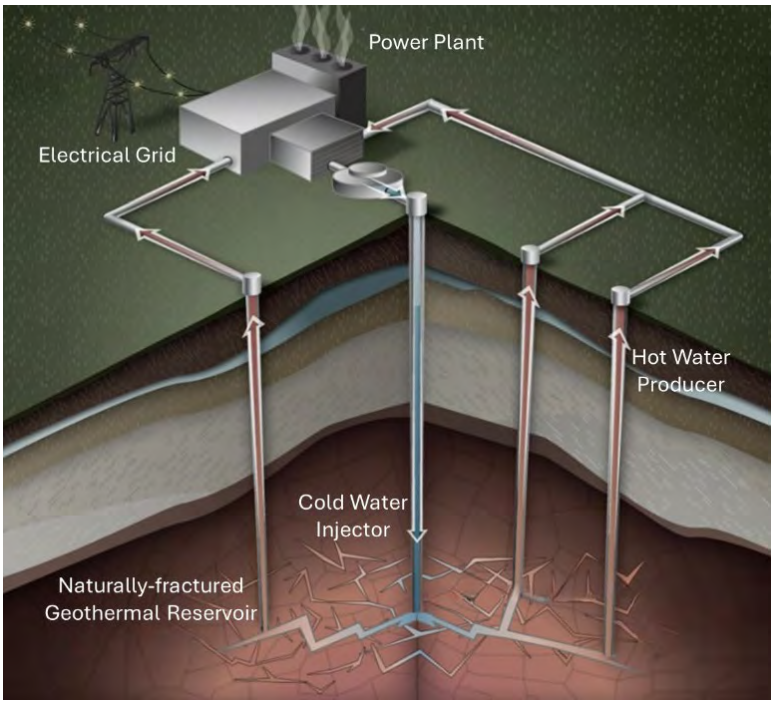

Figure 1: Schematic representation of EGS (U.S. Department of Energy, 2016)

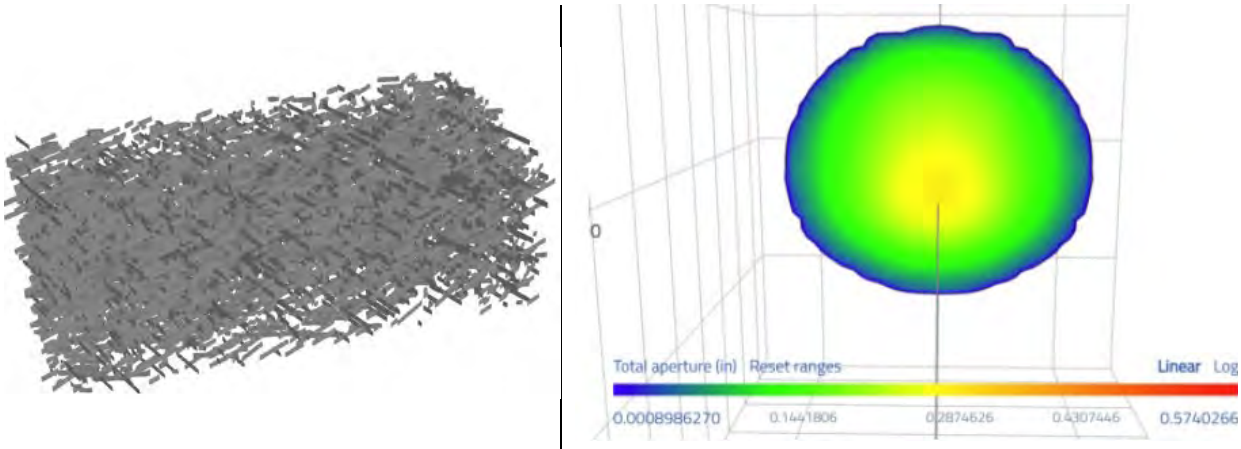
Conversely, computationally efficient finite difference methods (Mindygaliyeva et al., 2023) may struggle to accurately represent the complex geometries of these fractured systems (Mindygaliyeva et al., n.d.). McClure et al.'s (2024) work, aiming for a fully integrated approach, highlights the challenges of model calibration, particularly when dealing with complex systems like the Utah FORGE reservoir (M McClure et al., n.d.). Here, extensive field data integration, beyond planar fractures, might be necessary to achieve reliable results that match recorded microseismicity data. Figure 2 illustrates two limitations encountered when applying numerical methods to simulate the

complex fracture network of the FORGE geothermal project. (a) Highly Detailed DFN Model: This image depicts a Discrete Fracture Network (DFN) model (Cao and Sharma, 2023) with a potentially excessive number of fractures (Cao et al., 2023). (b) Planar Fracture Model with Limited Applicability: This image represents a coupled planar mechanics model with a reservoir model used for stage 3 of the fracturing job (McClure et al., 2024) (Mark McClure, 2023). This method may not be applicable to earlier stages (stages 1 & 2) due to its limitations in capturing complex fracture geometries. Additionally, calibrating such models can be challenging, particularly when attempting to match observed microseismic data beyond planar fractures.

This paper introduces a phase-field finite-element framework for modeling field-scale EGS that addresses the aforementioned challenges. The framework employs a diffusive formulation for thermoporoelasticity to model changes in petrophysical properties based on fracture propagation, ensuring smoother mass and energy transfer (A G Almetwally et al., 2023b). We utilize enriched Galerkin discretization for flow and energy to accurately capture sharp discontinuities at fracture-matrix interfaces with improved computational efficiency with fewer degrees of freedom (Ahmed G Almetwally et al., 2023). By enriching the continuous Galerkin (CG) basis functions with discontinuous piecewise-constants, the enriched Galerkin (EG) discretization effectively captures these discontinuities while ensuring local mass and energy conservation. The framework also incorporates field-scale phase-field finite element modeling, eliminating the need for complex mesh manipulation and enabling seamless representation of fracture evolution (A G Almetwally et al., 2023a). Additionally, a fixed-stress split decoupling technique, combined with specialized solvers, significantly accelerates simulation times (Wheeler et al., 2020). Finally, the framework employs localized mesh refinement around evolving fracture zones, reducing computational costs for large-scale simulations (Ahmed G Almetwally et al., 2024).



a. Highly Detailed DFN Model (Cao et al., 2023): offers high detail but may not scale for large domains with limited fracture data.

b. Planar Fracture Model with Limited Applicability (Mark McClure, 2023): struggles with complex geometries and early-stage calibration.

Figure 2: Challenges in numerical modeling of the Utah FORGE reservoir: a trade-off between complexity and scalability

2. Model Formulation

The mathematical formulation represents a dynamic fracture model for porous media, integrating thermo-poroelasticity theory and phase-field finite-element model (Li et al., 2021; Noii et al., 2019). This approach captures the coupled effects of fluid flow, heat transfer, deformation, and fracture initiation/propagation, enabling simulation under multiple physical processes (Kolesov et al., 2017; Mikelic et al., 2014). Building upon incremental thermodynamically consistent phase-field models (Amor et al., 2009; Francfort et al., 1998; Griffith et al., 1921; C Miehe et al., 2010; Christian Miehe et al., 2010), displacement (u) and phase-field (φ) variables are incorporated into the Mechanics framework for fracture modeling. We validated the model, in reference (A G Almetwally et al., 2023b)(Ahmed G Almetwally et al., 2023), through comparison with analytical thermoporoelasticity problems and experimental EGS observations. The model was validated against the KGD model for fracture length evolution and the Sneddon solution for fracture aperture under varying fluid pressure. Additionally, the model's capability to simulate EGS reservoir creation in granite was confirmed through comparison with a laboratory experiment by Frash et al. (2014), demonstrating an accurate prediction of breakdown pressure and fracture growth patterns.

2.1. Fracture Propagation Model

A coupled mechanics and phase-field energy functional (Equation 1) is employed to calculate the energy, ($E_\varepsilon(\mathbf{u}, p, \varphi)$), associated with displacement ($\mathbf{u}$), pressure (p), and phase-field (φ) variables (Wheeler et al., 2020). This function incorporates terms for elastic strain, surface energy, and fracture energy, accounting for internal forces (stress tensor), pressure-displacement coupling (Biot's coefficient), volumetric plastic dissipation, and work done by fluid pressure and thermal loading. The regularization parameter (ε) controls the fracture zone width, while the fracture energy (G_c) represents the energy required for crack surface creation. The phase-field variable influences the model through factors such as elastic property degradation and volume change. A degradation function ($g_D(\varphi)$) governs the impact of the crack on material elasticity. The stress tensor ($\sigma(\mathbf{u})$) and strain tensor ($e(\mathbf{u})$) model internal forces and deformation, respectively. Biot's coefficient (α) quantifies pressure-displacement coupling, while constants relating temperature to displacement are estimated based on reference (Noii et al., 2019). Fracture width is determined in relation to the phase field using a method proposed in (Wheeler et al., 2020). This involves computing the jump in normal displacements at the fracture boundary using an estimated normal vector derived from level set values of a specific fracture isoline. The fracture width is then calculated using the equation:

$$-\Delta w = \beta \left\| -2\mathbf{u} \cdot \frac{\nabla \varphi_{LS}}{\|\nabla \varphi_{LS}\|} \right\|_{L^\infty(\Lambda)}$$

where Δw is the Laplacian of w, β is a constant chosen to ensure a smooth profile, and $\nabla \varphi_{LS}$ refers to the gradient of the level set function defining the fracture boundary.

$$\underbrace{E_\varepsilon(\mathbf{u},p,\varphi)}_{Energy\ Functional} = \underbrace{\int_\Lambda \frac{1}{2} g_D(\varphi)\sigma(\mathbf{u}):e(\mathbf{u})dx}_{Strain\ Energy} - \underbrace{\int_{\partial A} \tau\cdot\mathbf{u}dS}_{External\ Load} + \underbrace{-\int_\Lambda (\alpha-1)\varphi^2 p\nabla\cdot\mathbf{u}dx + \int_\Lambda (\varphi^2\nabla p)\mathbf{u}dx}_{Hydraulic\ Work} + \underbrace{-\int_\Lambda (\alpha_T+\mathrm{C})\varphi^2 T\nabla\cdot\mathbf{u}dx + \int_\Lambda (\varphi^2\,\mathrm{C}\,\nabla T)\mathbf{u}dx}_{Thermal\ Work} + \underbrace{G_c\int_\Lambda \left(\frac{1}{2\varepsilon}(1-\varphi^2)+\frac{\varepsilon}{2}|\nabla\varphi^2|\right)dx}_{Fracturing\ Energy} \quad (1)$$

2.1. Fluid Flow and Energy Balance Model

The cracked reservoir body, denoted as Λ, is divided into three distinct domains for computational fluid flow analysis: the reservoir, fracture, and transition domains (Wheeler et al., 2020). These domains, identified by $\Omega_R(t)$, $\Omega_F(t)$, and $\Omega_t(t)$ respectively, are distinguished based on the phase-field value φ, corresponding to $\varphi \le 0$, $\varphi \ge 1$, and $0< \varphi <1$. To standardize the material parameters, auxiliary quantities χ_r and χ_f are introduced as follows:

$$\begin{cases} \chi_r = 1, \chi_f = 0 & \text{in } \Omega_R(t) \\ \chi_r = 0, \chi_f = 1 & \text{in } \Omega_F(t) \\ \chi_r = \frac{1-\varphi}{1-0}, \chi_f = \frac{\varphi-0}{1-0} & \text{in } \Omega_t(t) \end{cases} \quad (2)$$

Material constants (density ρ, permeability κ, viscosity η, Biot coefficient α_p, thermal expansion coefficient α_T, Biot modulus reciprocal c_p, heat capacity c_T, hydrothermal-coupling coefficient β, hydraulic conductivity k_p, thermal conductivity k_T) are then expressed uniformly as: $(\cdot) = (\cdot)_r\chi_r + (\cdot)_f\chi_f$.

Conservation of mass and momentum for fluid flow within the system is given by:

$$c_p\frac{\partial p}{\partial t} - \beta\frac{\partial T}{\partial t} + \alpha_p\,\chi_r\frac{\partial \mathrm{div}\,\boldsymbol{u}}{\partial t} - \mathrm{div}\left(k_p \mathrm{grad}\ p\right) = q_p \quad (3)$$

Conservation of energy is represented by:

$$c_T\frac{\partial T}{\partial t} - \beta T_0\frac{\partial p}{\partial t} + \alpha_T T_0\,\chi_r\frac{\partial \mathrm{div}\,\boldsymbol{u}}{\partial t} - \mathrm{div}\left(k_T\,\mathrm{grad}\,T + \alpha_c\,T\,k_p\,\mathrm{grad}\ p\right) = q_T \quad (4)$$

where α_c is the fluid heat convective capacity, T_0 is the initial temperature, f represents body forces, and q_p and q_T are fluid and heat sources, respectively. Coupling between energy, fluid flow, and solid mechanics is achieved through equations of state, source terms, the effective stress tensor, and changes in porosity, permeability, and thermal strains. The thermoporoelasticity system coupled with the phase field for fracture propagation is solved using the Enriched Galerkin scheme for energy/mass conservation and the Continuous Galerkin scheme for the mechanics' momentum balance, coupled with the flow problem through an iterative fixed-stress split scheme (Ahmed G Almetwally et al., 2023; Lee et al., 2016, 2017, 2018).

3. FORGE Project Field-Scale Simulation

Extensive subsurface data collection through deep exploratory wells has facilitated the development of a static finite-element model using the FALCON code; a MOOSE-based code for

modeling EGS (Gwynn et al., 2019) (R. Podgorney et al., 2021). This model integrates detailed 3D petrophysical properties (Table 1) and insitu equilibrium boundary conditions to simulate thermal, hydraulic, and mechanical behavior of the geothermal reservoir.

Table 1: Reservoir Rock Properties at the FORGE Site

Permeability	1.00E-18 m^2	Young's Modulus	6.50E+10 Pa
Porosity	1.00E-03	Drained Poisson's Ratio	0.3
Rock Grain Density	275 kg/m^3	Biot Coefficient	0.3
Specific Heat Capacity	790 J/kg K	Thermal Expansion Coefficient	6.00E-06
Grain Thermal Conductivity	3.05 W/m K	Fracture Toughness	0.72E6 Pa $m^{0.5}$

In April 2022, the FORGE team implemented a 3-stage fracture stimulation program (Forbes et al., 2019) (McLennan, 2022):

1. **Stage 1:** Involved identifying potential fracture initiation sites through jagged pressure patterns and microseismic event analysis, indicative of fracture activity.
2. **Stage 2:** Employed slickwater at a maximum rate of 35 bpm (5.56 m^3/min), monitored formation breakdown pressure, and conducted a hard shutdown to evaluate fracture behavior. This stage included flowback analysis at 4 bpm (0.64 m^3/min), with wellhead pressure dropping to 0 psi.
3. **Stage 3:** Utilized crosslinked polymer fluid at similar pump rates to Stage 2, introduced microproppant to enhance fracture geometry and sustain fracture conductivity. Microseismicity data from this stage provided critical insights into the fracture network's behavior.

The simulations, focusing on hydraulic fracture growth across all three stages, employed the EG-phase-field framework within the MOOSE platform to accurately capture the dynamic evolution of the fracture network. Figures 3 to 6 offer insights into the simulation of the fracture propagation and pressure responses during the hydraulic stimulation stages of the FORGE geothermal project. Figure 3 illustrates the refined finite element mesh used in the simulations, which captures the complexity of fracture propagation, particularly around the injection points, ensuring an accurate representation of the evolving fracture network. It shows how modeling FORGE reservoir mesh (multiple kilometers scale) is refined to capture the natural fracture network (sub-meter scale). Figures 4 and 5 compare simulated and observed pressure responses during the three-stage hydraulic stimulation program. The simulations accurately capture the pressure step-up and step-down responses, despite an acceptable degree of misalignment.

Noting that the recorded shut-in pressure is set to be zero after each stage and concatenated for simpler visualization versus a stabilized simulated reservoir pressure after each stage. The pressure misalignment is caused by grid resolution (the finer the mesh, the better the match) and operational differences such as the sudden pump shut-in during Stage 2 also. This misalignment is also referred to the idealized injection schedules used in simulations versus the actual injection procedure. The simulated pressure data are colored with the phase field variable, in Figure 4, indicating the extent of fracture opening at the injection nodes, providing a clear visual correlation between pressure

changes and fracture propagation. Figure 5 provides a 3D representation of the fracture initiation at Stage 1, the activation of natural fractures during Stage 2, and the development of a purely hydraulic fracture in Stage 3. Figure 6 showcases the correlation between the simulated fracture propagation and the recorded microseismic events for each stimulation stage. The fracture mesh propagating in the yellow grid aligns precisely with the locations of the recorded microseismicity for the three stages, validating the model's ability to predict fracture growth patterns accurately. In Stage 1, the initiation and final extension of fractures are clearly depicted, while Stage 2 shows the extension of fractures activated during Stage 1. Stage 3 demonstrates further hydraulic fracture propagation, closely matching the microseismic data. This rigorous validation against microseismicity and pressure data confirms the model's accuracy in predicting reservoir behavior under field-scale operational scenarios. By providing a reliable predictive tool, this model significantly enhances the efficiency and effectiveness of EGS development, enabling informed decision-making and optimization of stimulation strategies.

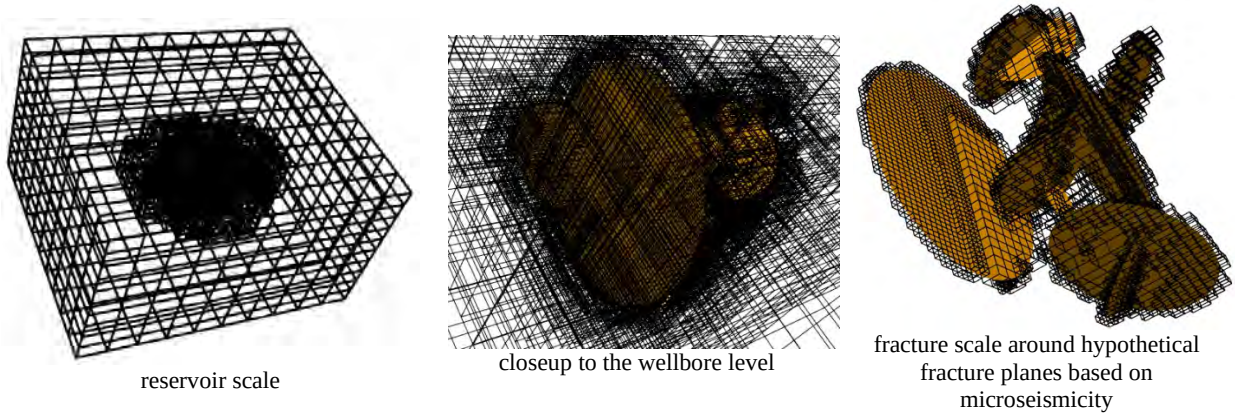


Figure 3: Refined finite element mesh from reservoir-scale to fracture-scale employed for the coupled thermo-hydro-mechanical modeling of the FORGE EGS reservoir.

4. Conclusion

This study presents a novel phase-field finite-element framework for modeling field-scale Enhanced Geothermal Systems (EGS), addressing the challenges of complex fluid flow, heat transfer, and rock mechanics interactions. By incorporating a diffusive thermoporoelasticity formulation, enriched Galerkin discretization, and field-scale phase-field modeling, the framework accurately captures fracture propagation and its impact on reservoir behavior. The successful application to the FORGE geothermal project, validated against analytical solutions, laboratory experiments, and field data, demonstrates the framework's effectiveness in simulating fracture initiation, propagation, and interaction. The integration of a fixed-stress split decoupling technique and localized mesh refinement further enhances computational efficiency, making it a valuable tool for large-scale EGS simulations. This research contributes to advancing EGS technologies by providing a robust and efficient modeling approach for optimizing reservoir performance and geothermal energy extraction.

ABSTRACT

A recent study identified topography (land surface elevation above sea level) as an important input dataset (feature) for predicting the location of hydrothermal systems in the Great Basin in Nevada. Yet, topography is generally a result of more than one geological process and may consequently contain multiple distinct signals. For example, the geologic evolution of the Great Basin has produced both crustal thickening (i.e., regional-scale trends in elevation) and thinning via Basin and Range extensional faulting (i.e., valley-scale topographic relief). We postulate that these geologic processes may affect the occurrence of hydrothermal systems differently. Therefore, we separate the regional trend from the valley-scale signal in the Great Basin, and then use them separately to evaluate the importance of each as predictors for hydrothermal favorability.

Our prior work applying supervised machine learning (ML) using the data from the Nevada Machine Learning Project demonstrated that employing a training strategy that randomly selects negative training sites produces better performing models for predicting hydrothermal favorability than a training strategy that used expert-selected negatives. The models created using both training strategies exhibited a west-east geographic trend in the predictions for the favorability of hydrothermal resources. These models generally predicted higher favorability in western Nevada

and lower favorability in eastern Nevada. This west-east trend in predicted favorability correlates with elevation across the Great Basin, which trends higher from west to east.

By separating the original elevation feature into distinct features for *elevation trend* (i.e., regional-scale topography) and *detrended elevation* (i.e., valley-scale or local relative topography), we find that models using the separated topographic signals consistently outperform competing models that use the original elevation feature. Although western Nevada still exhibits higher favorability than eastern Nevada, using separated signals for regional elevation and local structure reduces the west-east prediction trend in the region and emphasizes structures associated with hydrothermal upflow. This work emphasizes how carefully engineering features to represent geological conditions relevant to hydrothermal systems allows ML algorithms to detect important patterns for predicting hydrothermal resource favorability and leads to better model performance.

1. Introduction

Hydrothermal systems in the Great Basin, a prominent extensional province in the western United States, are generally controlled by basin-bounding faults located in actively subsiding basins (Faulds et al., 2011; Faulds and Hinz, 2015) with many systems having no easily identifiable surface manifestations (i.e., many systems are *blind*; Coolbaugh et al., 2007). Yet, changes in valley-scale topography (i.e., relative positions of basins and adjacent mountain ranges) serve as an indicator of geologic structures that may be associated with hydrothermal upflow.

The Nevada Machine Learning Project (NVML; Brown et al., 2020; Faulds et al., 2021a; Smith, 2021; Faulds et al., 2024), aimed to identify hidden geothermal resources in the Great Basin. Using datasets compiled under the Nevada Play Fairway Analysis (Faulds et al., 2017; Faulds et al., 2021b) as well as data collected specifically for NVML, NVML fit an artificial neural network (ANN) to predict the presence or absence of hydrothermal resources. The NVML research team labeled 83 of the 1,728,000 250-m square cells as positive (i.e., as having a known hydrothermal system) and 62 cells as negative (i.e., as not having a hydrothermal system). The remaining cells were unlabeled (i.e., the presence or absence of a hydrothermal system was and remains unknown). Eleven 250-m resolution evidence layer grids were used as input features (i.e., predictors or unassociated datasets) to the NVML ANN. Ten of these 11 input features consisted of quantitative data (e.g., elevation, strain rate, heat flow, and gravity). One of the 11 input features was engineered by experts as ellipses that were drawn around favorable structural settings. By using expert-knowledge to address fundamental challenges (e.g., selecting known sites without hydrothermal systems), the NVML project demonstrated that machine learning methods can be successfully used in geothermal resource evaluation.

Mordensky et al. (2023) conducted a similar study to predict hydrothermal favorability in the western United States, using data-driven ML approaches and data from the most recent U.S. Geological Survey (USGS) Geothermal Resource Assessment (Williams et al., 2008). Of the approximately 700,000 2-km square cells, 278 were known positives, but there were no known negatives provided in the Williams et al. (2008) data. Because hydrothermal systems are inherently sparse (i.e., < 99.9% of the study area), Mordensky et al. (2023) recognized that a random sample of the unlabeled cells could be labeled as negative with high confidence; therefore, they implemented a training strategy that treated a random sample of the unlabeled cells as negatives during the training process. The random selection of negative cells from unlabeled cells also addressed the mathematically problematic condition of severe class imbalance (i.e., having many

more sites without hydrothermal systems than with hydrothermal systems) that mired the ML algorithms. Mordensky et al. (2023) estimated the natural positive-negative ratio as approximately 1:700, thereby identifying the number of randomly selected negatives needed during fitting. Mordensky et al. (2023) demonstrated that data-driven ML algorithms could be used successfully to remove or minimize the need for expert feature-weighting decisions used previously in Williams et al. (2008).

Recent work by Caraccioli et al. (2023) compared the results of the NVML ANN to other less-complicated ML models (logistic regression and eXtreme Gradient Boosting [XGBoost; Chen and Guestrin, 2016]) using different strategies for selecting negatives (i.e., NVML versus Mordensky et al., 2023) and nearly the same input features. The single difference between the input features used in NVML compared to those in Caraccioli et al. (2023) is that Caraccioli et al. (2023) did not use the ellipses that were drawn around favorable structural settings. Caraccioli et al. (2023) elected not to use these expert-crafted ellipses which tended to dominate ML models because the NVML team had drawn the ellipses around the majority of the positives, arguably engineering each ellipse as a fuzzy (i.e., mathematically vague or imprecise) positive. The influence of the ellipses on the NVML ANN can be seen in Fig. 1.

By comparing the NVML strategy of expert-selected negatives to the strategy of randomly selecting negatives from Mordensky et al. (2023), Caraccioli et al. (2023) demonstrated that employing a training strategy that randomly selects negative training sites consistently produces better-predicting models when using the XGBoost algorithm, which is mathematically simpler than an ANN. Caraccioli et al. (2023) hypothesized that using only expert-selected negative sites may impart bias towards one or two types of negatives while there are really many conditions that can cause hydrothermal systems to be absent. Central to the work described herein, Caraccioli et al. (2023) identified elevation as the most important feature in the best-performing model; however, a low-high, west-east trend in elevation dominated the signal of that feature and contributed to similar favorability predictions at the tops of mountain ranges in the west as in the valley floors in the east. This finding seemed contrary to the geologic interpretation that proximity to relative valley-scale structure controls deep circulation pathways. As a result, Caraccioli et al. (2023) postulated that the contribution of the valley-scale topographic signal in the elevation feature was negligibly small compared with the regional signal. To allow for the possibility that valley-scale topography contains an important signal, we herein use the separate regional trend and valley-scale topographic data from DeAngelo et al. (2023) as separate features to test the importance of local topographic relief when predicting hydrothermal systems.

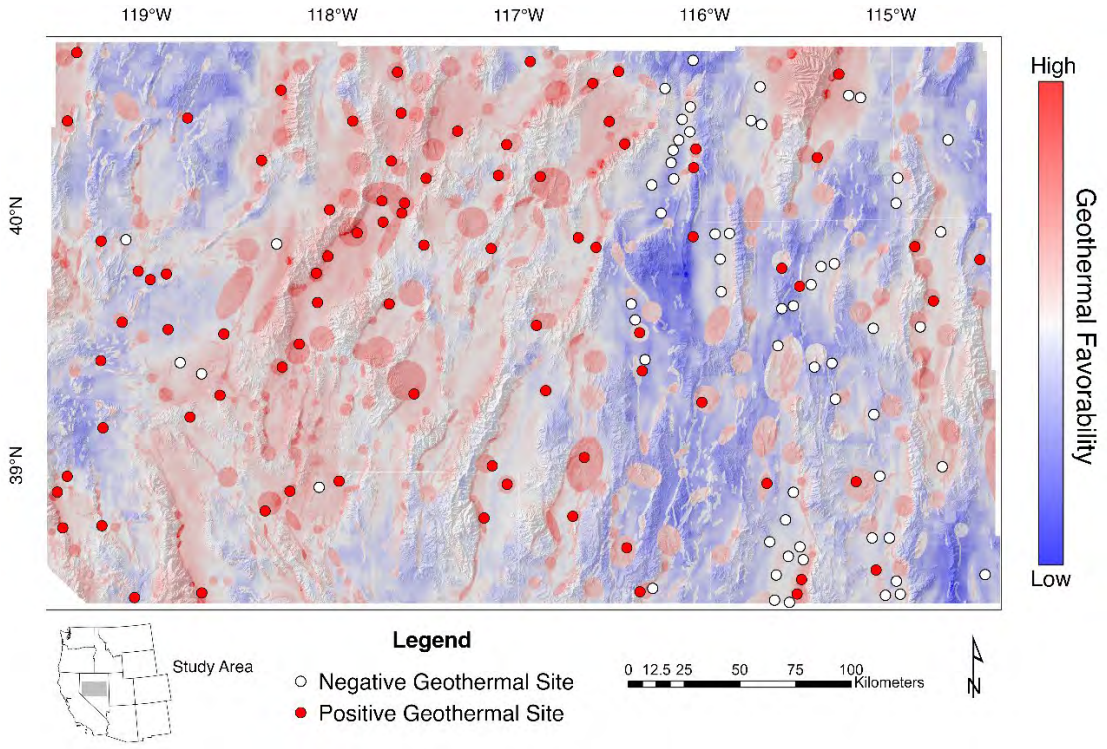

Figure 1: Nevada Machine Learning project (NVML) favorability map from Faulds et al. (2021a). White points are negative training/testing sites defined through expert selection. Red points are the positive sites (i.e., known hydrothermal systems). Favorability scores from the artificial neural network (ANN) have been normal score transformed for easy comparison with the results below from our study. Hillshade from USGS 3D Elevation Program (U.S. Geological Survey, 2019).

2. Methods

We compare XGBoost ML models using the original NVML features with models that replace the original elevation feature with two separate features (i.e., *elevation trend* and *detrended elevation* from DeAngelo et al., 2023). That is, although *elevation trend* and *detrended elevation* sum to the original elevation feature, we consider these two topographic features as two unique signals that we separate to inspect their value as predictors.

XGBoost is a boosted decision-tree ML algorithm in which a series of decision trees (i.e., estimators) predict probabilities for a cell being a positive or negative site (Chen and Guestrin, 2016). The cells are then formally classified as positive or negative by specifying a probability decision threshold. We use the commonly chosen decision threshold of 0.5 (see generally Fernández et al., 2018). ML algorithms (e.g., XGBoost, ANNs) calculate probabilities differently. Therefore, to allow the comparison of the new models with the NVML ANN, all favorability maps presented herein are the normal score transform (see generally Pyrcz and Deutsch, 2018) of the model predictions. Because the normal score transform preserves quantiles, the transformed prediction values are plotted as hydrothermal favorability, allowing for an easy comparison of regions of highest and lowest favorability.

In the remainder of this section, we briefly describe the data processing, exploratory data analysis, training strategies, hyperparameter optimization, and our method for comparing model performance.

2.1 Feature Selection

We use the features from the original NVML project and the separated regional and valley-scale elevation features engineered in DeAngelo et al. (2023). The original NVML ANN used 11 features. Ten of the 11 features were derived from interpolated maps of the following geologic properties: elevation, strain rate, slip rate, fault recency, gravity, slip and dilation tendency, seismic density, heat flow, magnetics, and distance to the nearest fault (Fig. 2). The eleventh feature was created by defining ellipses that contain geologic structures deemed by experts to be favorable for the occurrence of hydrothermal systems (i.e., known favorable structural setting; Fig. 3). Because the experts drew ellipses around known positives, the ML algorithms associate all areas within the ellipses with the occurrence of a hydrothermal system; therefore, the structural ellipses impart an implicit bias. The goal of this study is to predict favorable structural settings where a geologist has not had occasion to draw an ellipse, thus we remove the dataset with the structural ellipses.

Using the features from NVML and then by replacing the original elevation feature with the two separated elevation features from DeAngelo et al. (2023), we create two feature sets that can be compared. The first feature set (the Original Elevation Signal feature set) contains the same input features used in Caraccioli et al. (2023), corresponding to the 10 interpolated maps from NVML (i.e., original elevation, strain rate, slip rate, fault recency, gravity, slip and dilation tendency, seismic density, heat flow, magnetics, and fault). The second dataset (the Separated Elevation Signal feature set) replaces the original elevation feature with *elevation trend* and *detrended elevation*.

2.2 Exploratory Data Analysis

As part of exploratory data analysis, we inspect the linear correlation of the features using the Pearson correlation coefficient (see generally Lee Rodgers and Nicewander, 1988). Comparison of correlation allows us to see the pairwise linear relationships of the features (i.e., if the feature is unique or strongly correlated with one or more other features) and establish if two features represent similar signals. The Pearson correlation is a statistical measure that quantifies the linear relationship between two variables by providing values between -1 and 1, where -1 indicates a strong negative correlation, 1 indicates a strong positive correlation, and 0 indicates no correlation.

For each input feature, we compare the distributions of feature values for the NVML-labeled (i.e., positive and negative) sites to the full range of input-feature values to see if labeled sites mostly have low, intermediate, or high values relative to the unlabeled sites. To allow for an evaluation of whether labeled data are in discrete intervals within the larger range of the input feature values, we plot a cumulative distribution function (CDF) for every combination of features and labels (Fig. 4). When randomly sampling negatives and handling class imbalance, the CDF of the randomly sampled negatives should look similar to the CDF of all values of the input feature, because we are sampling most of the map area except the sparse positives.

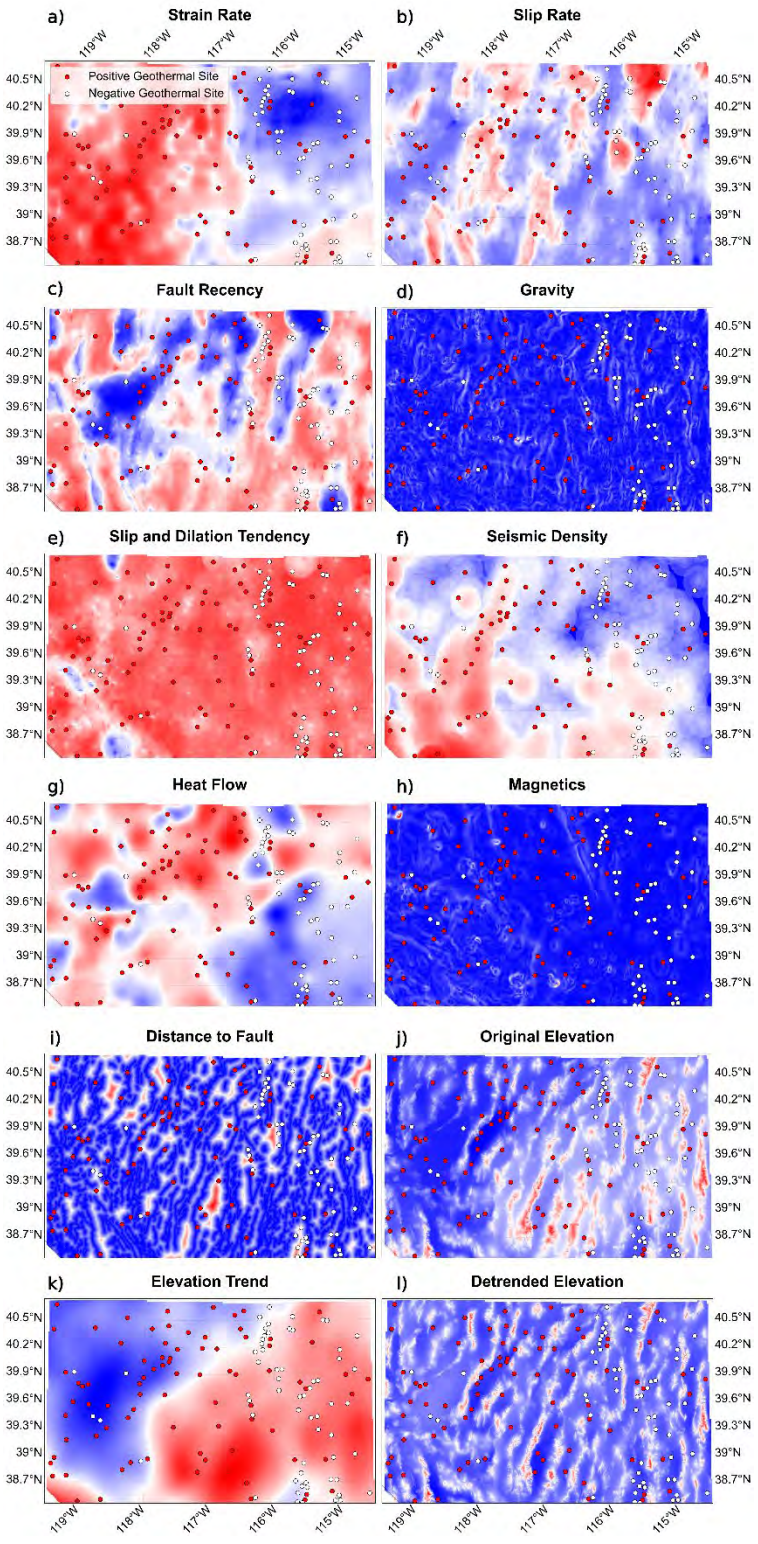

Figure 2: Maps of the ten standardized (i.e., unitless) Nevada Machine Learning project (NVML; Faulds et al., 2021a) features (a-j) and the DeAngelo et al. (2023) separated elevation input features (k, l) used for analysis herein. Blue depicts low values in the unitless scale. Red depicts high values in the unitless scale. White points are negative training/testing sites defined through expert selection. Red points are the positive sites (i.e., known hydrothermal systems).

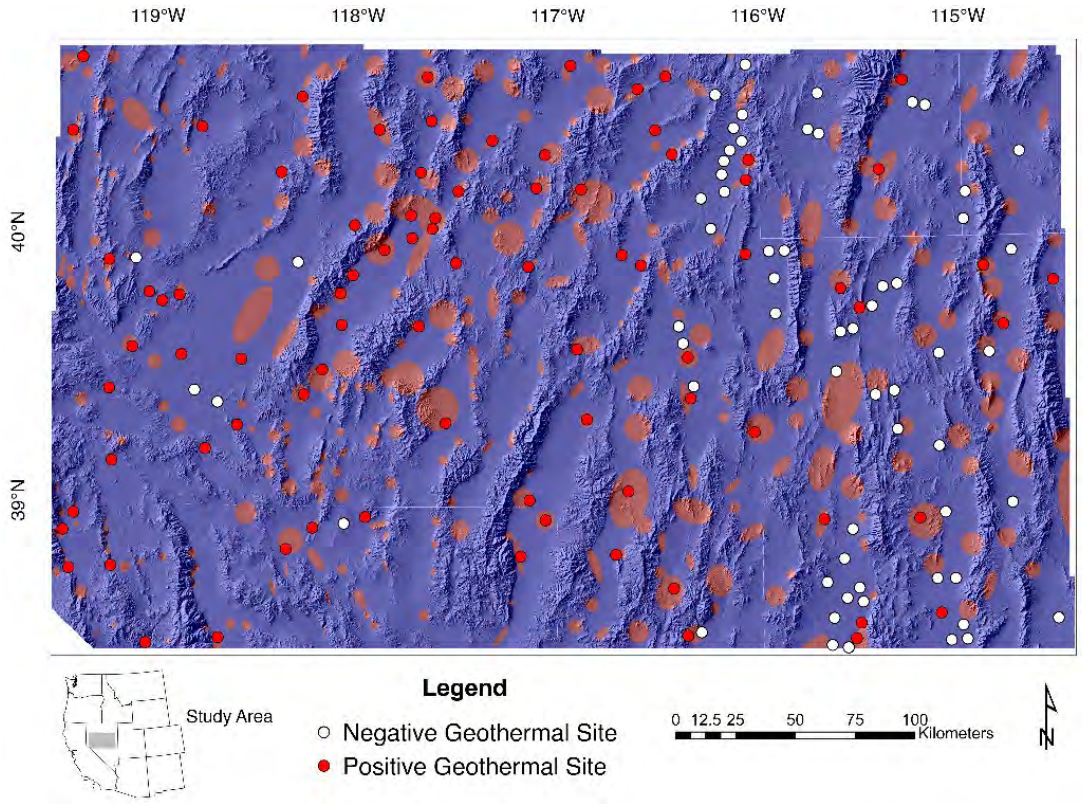

Figure 3: Map of the eleventh Nevada Machine Learning project (NVML) feature (favorable structural setting ellipses [red areas] from Faulds et al., 2021a) used for the artificial neural network (ANN) model (Fig. 1), but not used as an input feature for analyses herein. For strategy subsampling negative sites from unlabeled sites, negative sites were selected from areas outside of ellipses (i.e., blue area). White points are negative training/testing sites defined through expert selection. Red points are the positive sites (i.e., known hydrothermal systems). Hillshade from USGS 3D Elevation Program (U.S. Geological Survey, 2019).

2.3 Training Strategies

We implement two strategies for each training dataset: 1) the NVML training strategy; and 2) the training strategy from Mordensky et al. (2023) that implements random subsampling of negatives from unlabeled sites and accounts for class imbalance (the Natural Class Imbalance training strategy). The NVML strategy uses the same negative and positive sites from NVML (i.e., 62 negative sites and 83 positive sites). The Natural Class Imbalance strategy uses the same known positives as the NVML strategy, but randomly selects negative sites. Because we would like to minimize the possibility of randomly sampling and labeling an unlabeled positive site as negative, we choose to only select negatives from outside the favorable structural ellipses delineated by NVML (blue area in Fig. 3). We do this under the assumption that the highly sparse systems are less likely to occur without a favorable structural setting. Following Mordensky et al. (2023), we estimate that one in four hydrothermal systems have already been discovered in the study area, thereby approximating a roughly 1:5,100 positive-negative ratio. Although this estimate is approximate, Mordensky et al. (2023) demonstrated that the corresponding model predictions are insensitive within the expected range of uncertainty (see Mordensky et al. [2023] for complete details).

2.4 Hyperparameter Optimization

We optimize prediction performance by tuning four hyperparameters: class weight, number of estimators, maximum depth of estimators, and learning rate. Class weight is a way to correct for class imbalance. The greater the class weight, the greater the emphasis the model imparts on correctly identifying positive labels (i.e., the minority class) as positives at the expense of predicting negative labels as negatives (i.e., the majority class). The number of estimators specifies the number of decision trees (i.e., estimators). The maximum depth of estimators determines the number of levels in the estimators. The learning rate controls the amount of information communicated from a previous estimator to a new estimator. We leave the other parameters on XGBoost at the default settings found in the Python XGBoost, version 1.7.3 module as they have only a modest impact on performance (Chen and Guestrin, 2016).

We optimize the hyperparameters using the F1 score (Equation 1), a recommended metric for binary positive-unlabeled classifications (Bekker and Davis, 2020). We minimize bias resulting from any singular train-test split by conducting 60 80:20 train-test splits with five-fold cross-validation. For the Natural Class Imbalance strategy, we select new random negatives with each train-test split. We fit a final model using all the labeled data, the median optimal hyperparameters from the 60 train-test splits, and one last random sample of negative sites for the Natural Class Imbalance strategy.

$$F1\ Score = \frac{True\ Positives}{True\ Positives + \frac{1}{2}(False\ Positives + False\ Negatives)} \quad (1)$$

To test and prevent overfitting, we impose generalization loss early stopping (see generally Prechelt, 2002) in the validation subset of the training data during the five-fold cross-validation. With generalization loss early stopping, the fitting of new estimators stops immediately after the loss (a function that is penalized by decreased model performance) increases. We train a final model for each approach using the median estimator at which early stopping is engaged from the 60 train-test splits.

2.5 Measures of Feature Importance

For every modeling approach, we measure the relative importance of each input feature in making predictions using three measurements of feature importance: 1) sensitivity analysis using an F1 score; 2) sensitivity analysis using the area under the receiver operating characteristic curve (i.e., ROCAUC), and 3) Shapely Additive exPlanation (i.e., SHAP) values (see Mordensky et al. [2023] for a more detailed summary). To allow comparison between the different measures, each measure is min-max normalized to a zero-to-one scale. Using three different measures allows us to explore the variability between the measures.

2.6 Comparing Model Performance

To compare model performance, we perform a normal score transform on the predictions for each approach and compare the transformed distribution of predictions for the known positives with the transformed distribution of predictions for the unlabeled sites (see Mordensky et al. [2023] for additional details). Approaches with greater overlap in the distributions of predictions for known

positives and unlabeled sites indicate lower predictive skill than approaches with distinct distributions of predictions for the known positive and unlabeled sites.

3. Results

In this section, we briefly describe the input feature data, present favorability maps, and plot feature importance. We provide the median optimal hyperparameter values in Appendix A.

3.1 Exploratory Data Analysis

CDFs of feature values for the positive, NVML negative, and remaining unlabeled sites (essentially the distribution of a random sample of negatives) are shown in Fig. 4. The separation of cumulative distribution functions show that distributions are markedly different. The CDFs for the positive and negative sites generally bound that for the unlabeled sites with strain rate, seismic density, heat flow, fault distance, and slip rate, indicating that the corresponding features may have more value for separating positives from NVML negatives when used as predictors. Conversely, the CDFs for positive and unlabeled data show a greater difference in distribution for fault recency, fault distance, original elevation, *elevation trend*, and *detrended elevation*.

The Pearson correlation coefficient (Fig. 5) shows various degrees of correlation among the features with values from 0.78 to -0.59. Overall, strain rate is the feature most correlated with the greatest number of other features (e.g., *elevation trend* and seismic density; -0.59 and 0.64, respectively). *Elevation trend* and *detrended elevation* are minimally correlated. *Elevation trend* has similar correlation to the original elevation. *Detrended elevation* has poor correlation with all other datasets other than the original elevation.

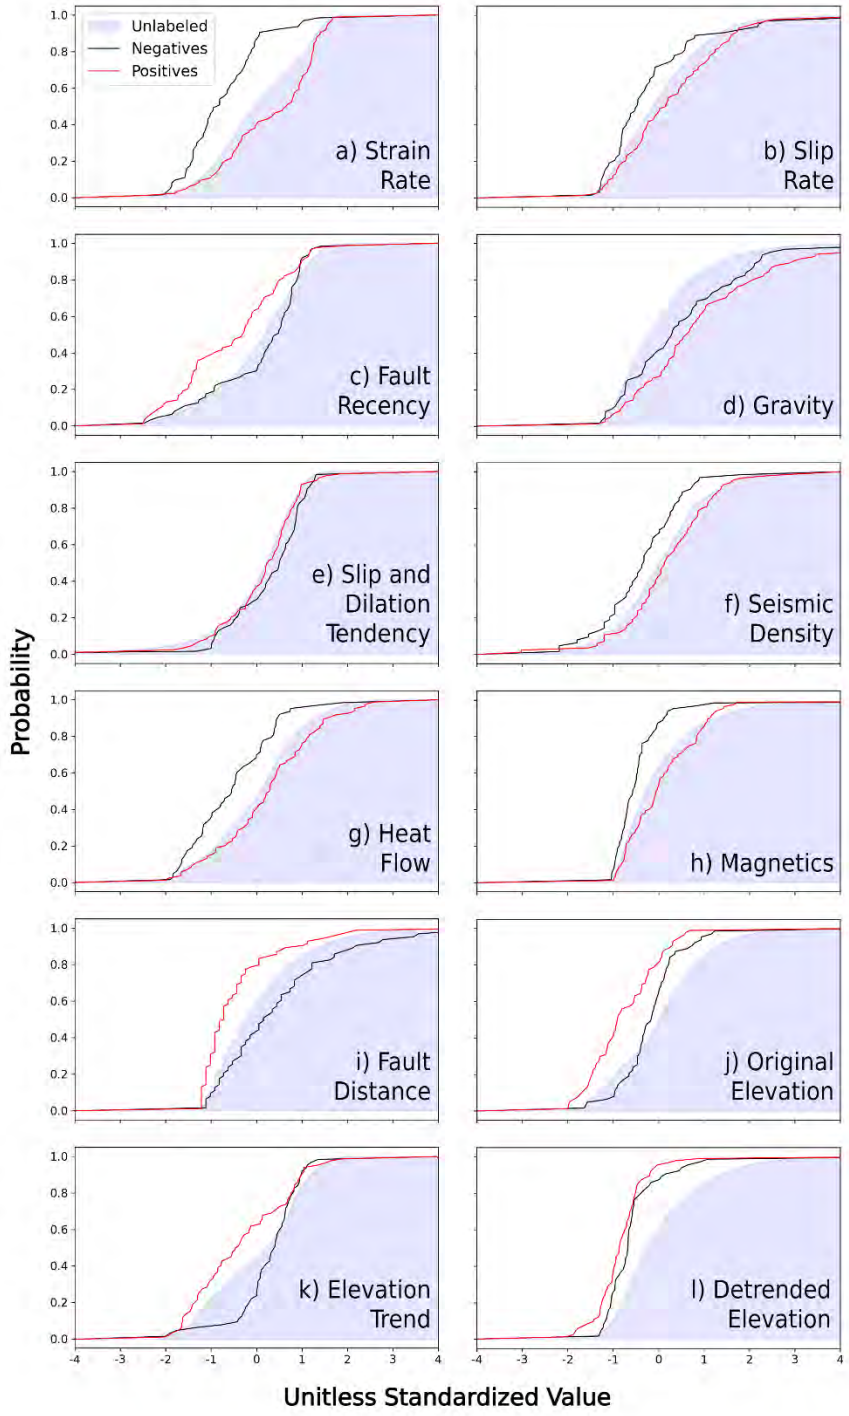

Figure 4: Cumulative distributions of the standardized features for the ten Nevada Machine Learning project (NVML) features (a-j) and the DeAngelo et al. (2023) separated elevation features (k, l). The shaded blue area corresponds to the unlabeled sites in NVML. The red line corresponds to positive-labeled sites in NVML. The black line corresponds to the negative-labeled sites in NVML. Separation of cumulative distribution functions show that distributions are markedly different, so a difference between the positive and negative lines implies the feature may be useful for discriminating between the positive and negative training sites.

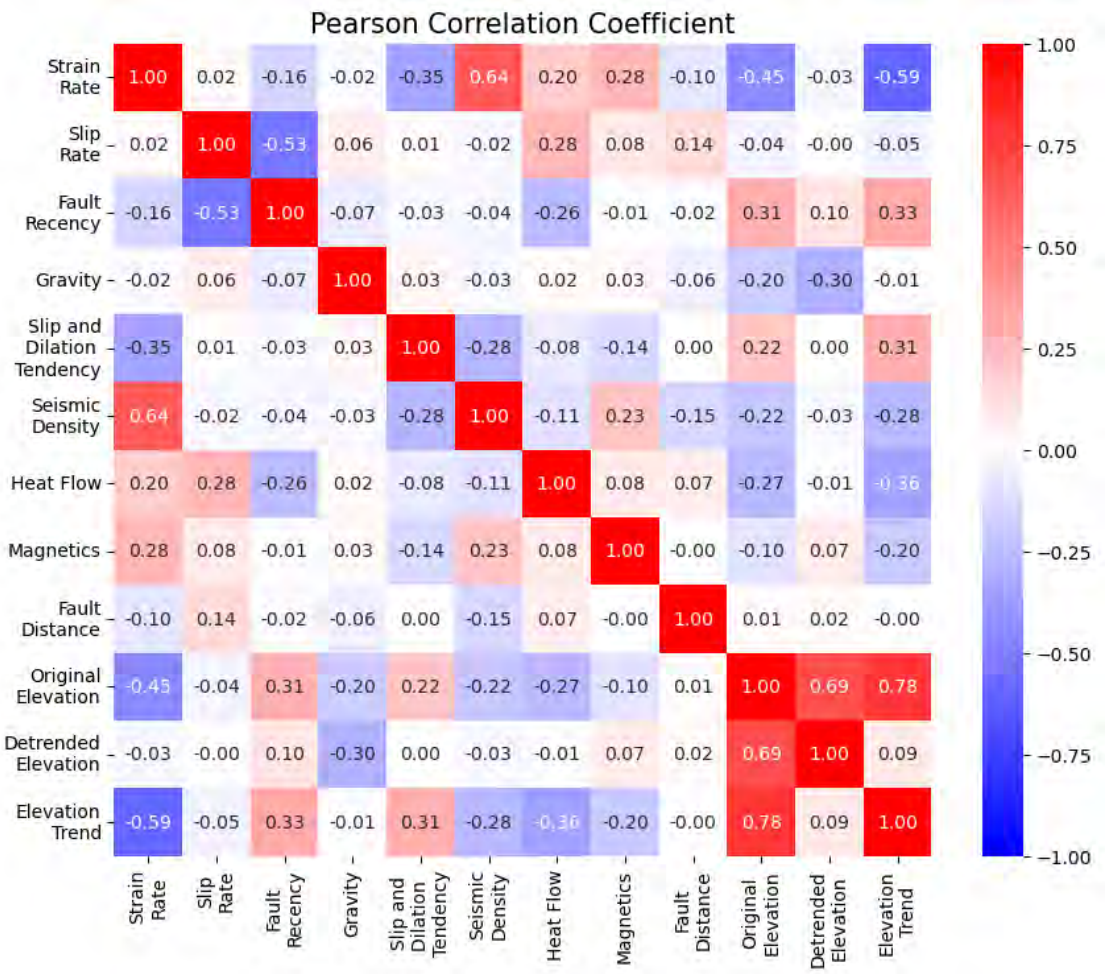

Figure 5: Pearson correlation matrix of the different features for all examples (i.e., sites or cells). Brighter colors indicate a higher absolute correlation between feature pairs. Blue indicates a negative correlation, and red indicates a positive correlation.

3.2 Favorability Maps

When using the Original Elevation Signal feature set there is a greater west-east trend between high and low favorability (compare Fig 6a to 6b, and 7a to 7b) in the models produced by both the strategy that used expert-selected negatives (i.e., NVML; Fig. 6) and the strategy that used randomly selected negatives (i.e., Natural Class Imbalance; Fig. 7). The model using the Separated Elevation Signal feature set and the randomly selected negatives (Fig. 7b) places greater emphasis on low relative topography (i.e., basins) when predicting high favorability.

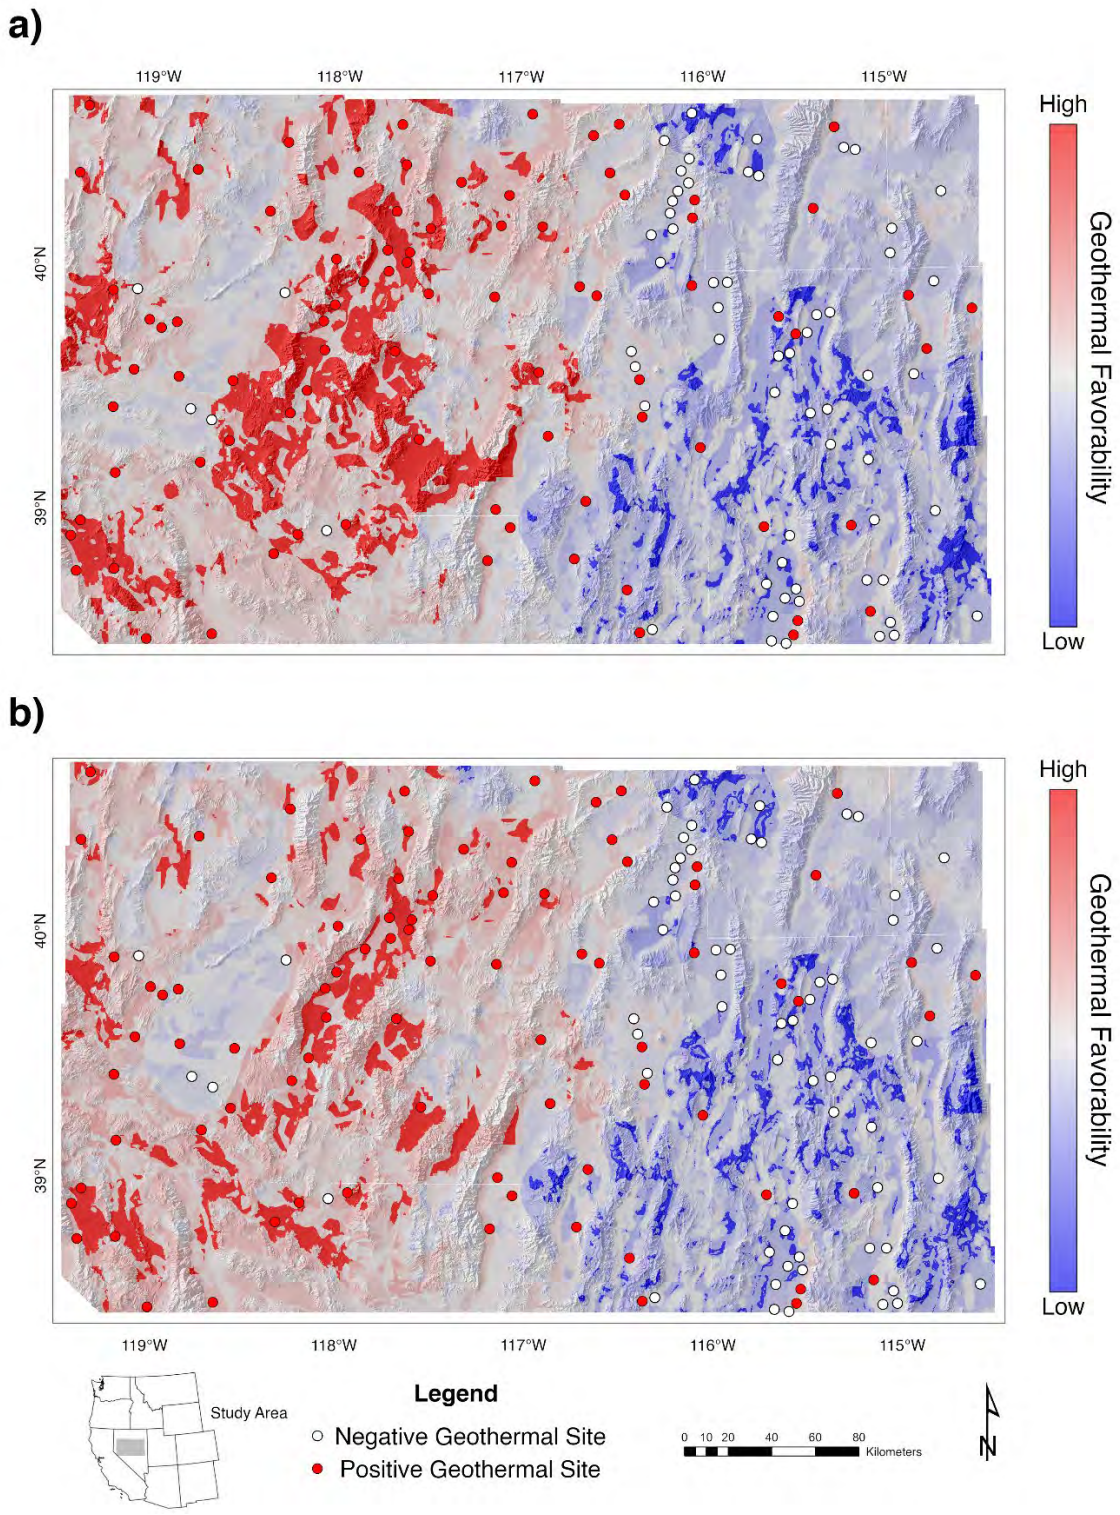

Figure 6: Geothermal favorability maps using the NVML negatives with a) the Original Elevation Signal feature set; and b) the Separated Elevation Signal (separated regional-scale and valley-scale elevation) feature set. Geothermal favorability is the normal score transform of XGBoost-computed probability. Hillshade from USGS 3D Elevation Program (U.S. Geological Survey, 2019).

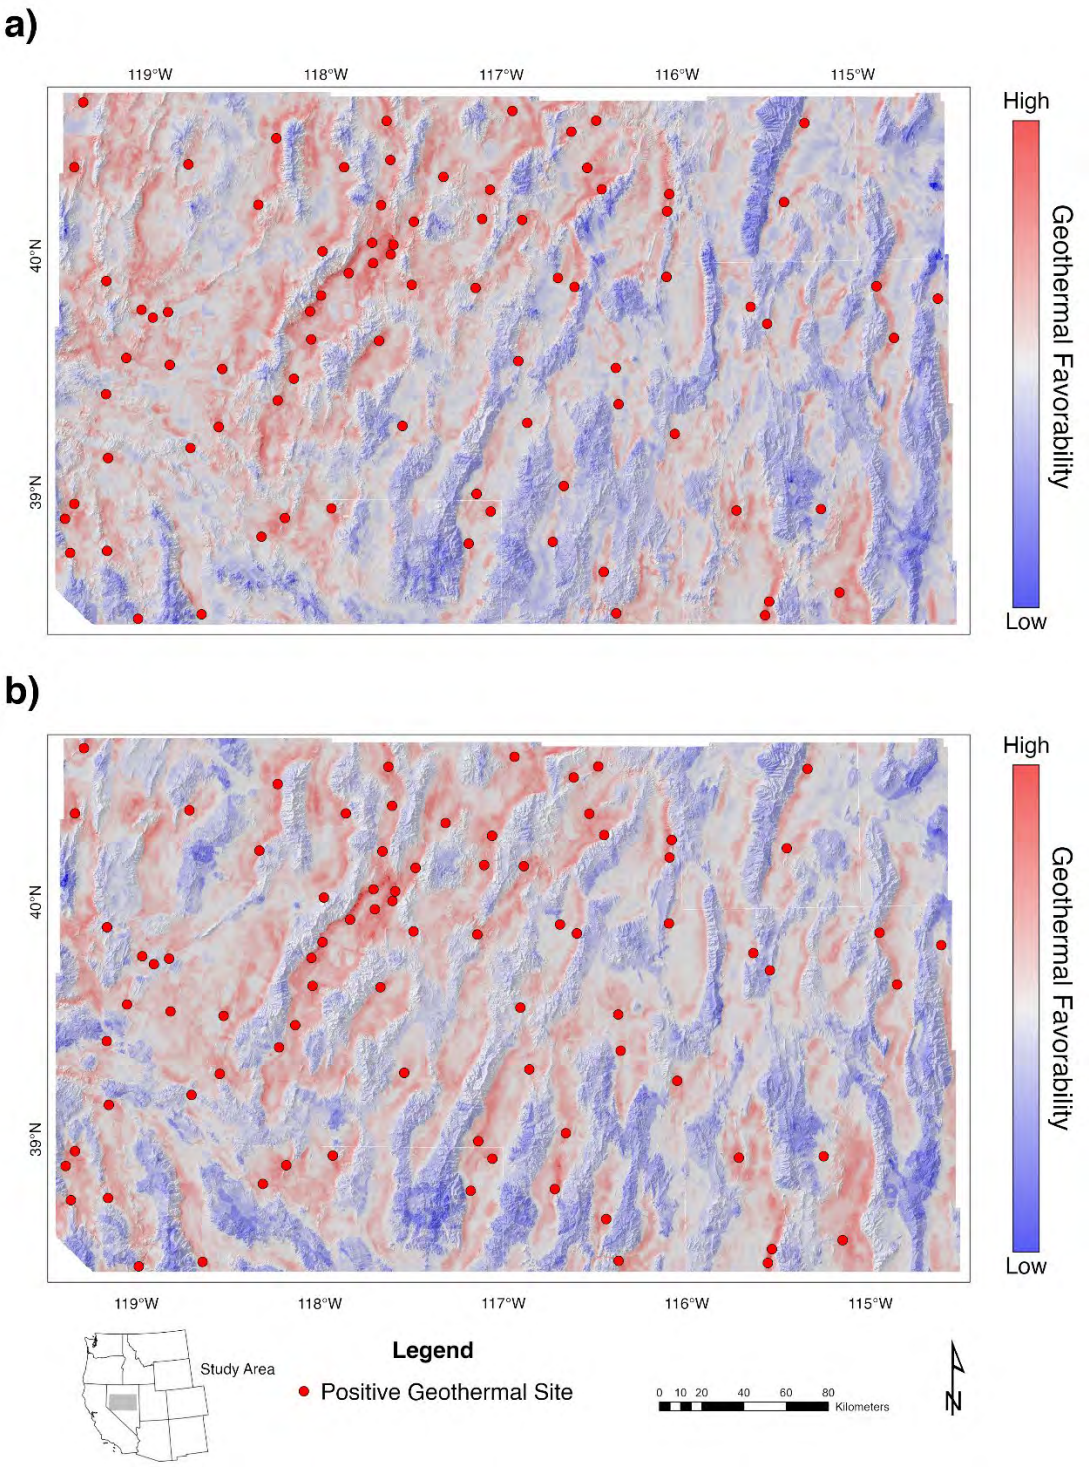

Figure 7: Geothermal favorability maps using random negatives and accounting for Natural Class Imbalance with a) the Original Elevation Signal feature set; and b) the Separated Elevation Signal (separated regional and valley-scale elevation) feature set. Because each random sampling produces different negatives, negatives are not shown. Geothermal favorability is the normal score transform of XGBoost-computed probability. Hillshade from USGS 3D Elevation Program (U.S. Geological Survey, 2019).

3.4 Feature Importance

The relative ranking of feature importance by different measures (Fig. 8) shows that models are primarily dominated by five features (i.e., strain rate, original elevation or *detrended elevation,* fault distance, and heat flow). For the NVML strategy (Figs. 8a, 8c), strain rate is the dominant feature for both models, regardless of the topographic dataset used. For the Natural Class Imbalance strategy (Figs. 8b, 8d), the most important feature varies depending on the input features used. If the model is trained using the feature set containing the original elevation, then the original elevation is the most important feature. Similarly, if the model is trained using the dataset containing *detrended elevation*, then *detrended elevation* ranks as the most important feature.

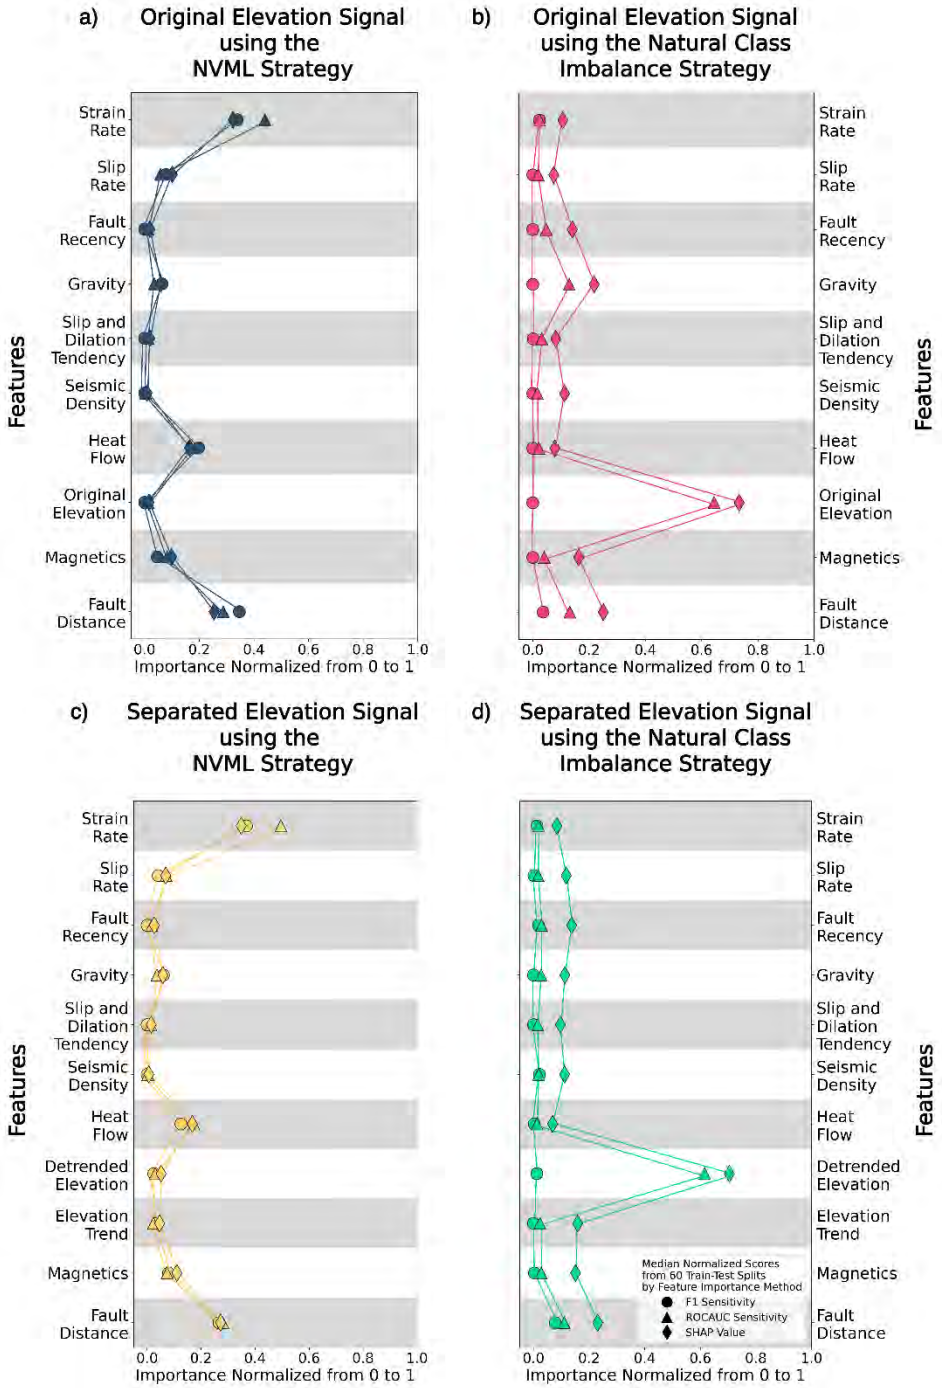

Figure 8: Median normalized feature importance values from the 60 train-test splits using a) the Original Elevation Signal feature set using the Nevada Machine Learning (NVML) strategy (blue); b) the Original Elevation Signal feature set using the Natural Class Imbalance strategy (red); c) the Separated Elevation Signal feature set using the NVML strategy (yellow); d) the Separated Elevation Signal feature set using the Natural Class Imbalance strategy (green). Abbreviation: ROCAUC (triangle) – Area Under the Receiver Operating Characteristic Curve; SHAP (diamond) – Shapely Additive explanation. The legend shown in 8d also applies to 8a, 8b, and 8c.

4. Discussion

All the resulting resource favorability maps (Figs. 6, 7) exhibit some degree of a west-east trend in favorability predictions, but the models using the separated signals for regional elevation and valley-scale elevation (Figs. 6b, 7b) fit models with spatially narrower predicted zones of high hydrothermal favorability that correspond to low relative topography and reduce the west-east trend in predicted favorability regardless of the dominant signal in the model (i.e., Fig. 8c, 8d). In the context of resource assessments, these narrower highly favorable areas minimize exploration efforts to smaller regions.

Recognizing that hydrothermal systems are sparse, we postulate that the models with the most known positives in the smallest area with the highest favorability are the best-performing models. A CDF of predictions for known positives serves as a summary of this information, such that CDF curves of predictions for known positives further to the right indicate that the predictions for the positives have higher favorability scores (Fig. 9). The models from each training strategy using the separated topographic features (i.e., *detrended elevation* and *elevation trend*) consistently outperform the models using the same respective training strategy and the original elevation. Despite the increased model performance when using separated topographic signals, utilizing a training strategy that randomly selects negatives (i.e., the Natural Class Imbalance strategy) rather than using expert-selected negatives (i.e., the NVML strategy) has a greater impact on improved model performance than using the Separated Elevation Signal feature set rather than the Original Elevation Signal feature set. The improvement in performance when using the Separated Elevation Signal feature set may be because adding a *detrended elevation* feature (i.e., valley-scale topographic signal) isolates relevant basin and range structural patterns and may contribute to the algorithm capturing patterns indicative of hydrothermal upflow (Faulds et al., 2011; Faulds and Hinz, 2015). We note, however, that in systems where basin and range faulting is not a controlling feature for hydrothermal circulation, detrending elevation may not be necessary or the scale of the trend may need to be tuned.

The models using the Natural Class Imbalance training strategy outperform NVML ANN regardless of which version of the feature is used, even though XGBoost is mathematically simpler than an ANN. The most important feature in the top-performing approach (i.e., *detrended elevation* in the approach using the Separated Elevation Signal feature set and the Natural Class Imbalance training strategy) shows that the most important signal for predicting hydrothermal systems we use is valley-scale topography. That signal is partially obfuscated when in the original elevation feature because of the inclusion of the signal for regional trend. The second-best performing model (i.e., the approach using the Natural Class Imbalance with the Original Elevation Signal feature set), assigns greater importance to the original elevation and gravity features compared to the top-performing model. This difference may arise from the higher pairwise correlation between gravity and *detrended elevation* (-0.3; Fig. 5) used in the top-performing model compared to the correlation between gravity and original elevation (-0.2; Fig. 5) used in the second-best performing model. Because *detrended elevation* better partially captures the signal for gravity than the original elevation feature, the model using the separated topographic signals lessens the overall contribution of gravity to the model. As the importance of gravity decreases when going from the approach using detrended elevation to the approach using original elevation, the importance of fault distance increases in two of the three metrics of feature importance, emphasizing the importance of local structure for predicting hydrothermal systems (Fig. 8b vs 8d). Hence, the mixed signal in the feature for original elevation with higher elevation in the east and lower

elevation in the west combined with the geospatial distribution of known positives (being primarily in the west) biases the model, causing the model to fail at identifying local topographic signals and predict high favorability at high local elevation (on ranges; Fig. 7a).

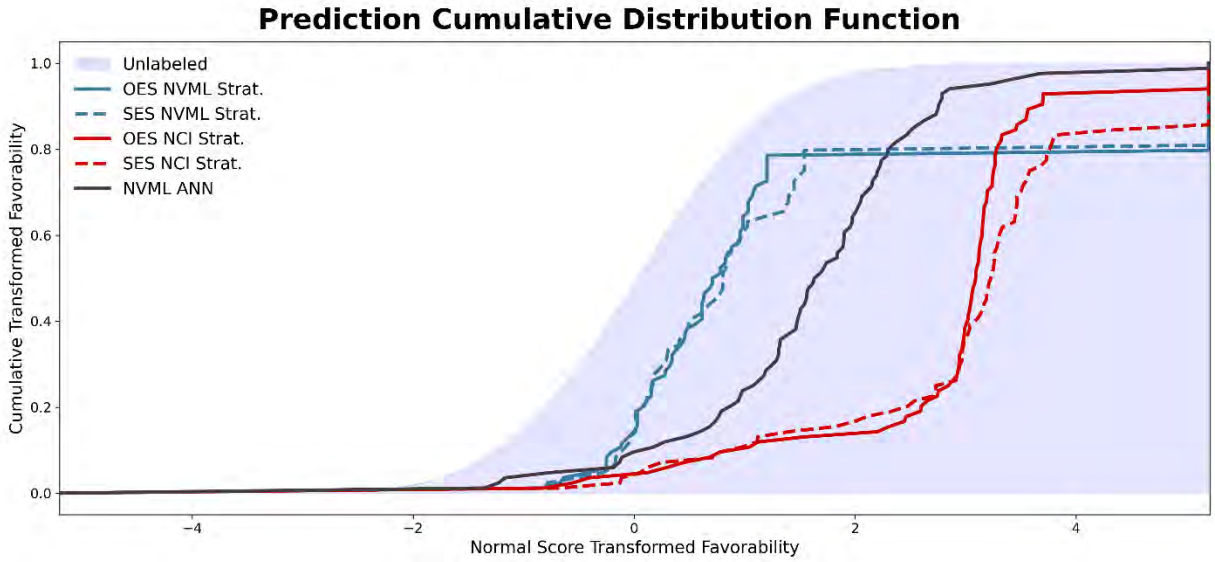

Figure 9: Cumulative distribution function (CDFs) of favorability scores for known geothermal systems relative to other map locations (i.e., unlabeled sites). Shaded blue provides the cumulative distribution of predictions for unlabeled sites. Lines represent the cumulative distributions of predictions for positive-labeled sites from the different approaches. Abbreviations: OES NVML Strat. (solid blue line) – Original Elevation Signal feature set using the Nevada Machine Learning strategy; SES NVML Strat. (dashed blue line) – Separated Elevation Signal feature set using the Nevada Machine Learning Strategy; OES NCI Strat. (solid red line) – Original Elevation Signal feature set using the Natural Class Imbalance; SES NCI Strat. (dashed red line) – Separated Elevation Signal feature set using the Natural Class Imbalance; NVML ANN (solid black line) - Nevada Machine Learning Artificial Neural Network.

The most important feature in the models using the NVML training strategy is strain rate, but adding the *detrended elevation* feature lessens the intensity of the west-east trend in the predicted hydrothermal favorability (Fig. 6). Although both models using the NVML training strategies rank last (Fig. 9), adding the *detrended elevation* feature improves model performance, demonstrating the importance of engineering input features that emphasize relevant geological information.

5. Conclusion

In this study, we evaluate the importance of regional-scale and valley-scale topographic relief as separated input features used to fit models that predict hydrothermal favorability. Separating the topographic signals allows the machine learning (ML) algorithm to fit better to the geological structures associated with hydrothermal systems in the Great Basin as evidenced by the models fit using the separated topographic signals consistently outperforming the models fit using the original topographic feature with the combined signals. Separating the topographic signals into two features also lessens the intensity of a west-east trend in the hydrothermal favorability maps. Hence, careful feature engineering through domain expertise with geothermal ML can deconvolute signals in geologic datasets and consequently improve model performance when predicting

favorability for hydrothermal resources. We explore the impact of separated topographic signals using two training strategies: 1) using expert-selected sites with no hydrothermal systems; and 2) using randomly selected sites from unlabeled sites as having no hydrothermal system. As is consistent in our prior works, the approach using randomly selected sites as having no hydrothermal system vastly outperforms the approach using expert-selected sites with no hydrothermal systems.

Drilling Optimization, Confining Pressure, Machine Learning in Drilling, Hard Rock ROP Model, Geothermal Drilling

ABSTRACT

It is crucial to comprehend how drilling efficiency changes as operating parameters and confining pressure environment change since this can enable improved drilling performance and optimization. The rate of penetration (ROP) and torque (T) required to penetrate hard rock significantly impact the efficiency of the cutting action of the Polycrystalline Diamond Compact (PDC) cutters. As the incremental weight of bit is applied, the drilling process undergoes three different distinct drilling efficiency phases, Phase 1, inefficient drilling, Phase II, efficient drilling where weight on bit (WOB) and rotation per minute (RPM) are strongly correlated to ROP and T, and Phase III where ROP and T are limited with incremental weight on bit and rotation per minute. This study analyzed the different efficiency phases for a PDC bit design under different pressure environments and applied parameters with resulting T and ROP. An in-house rig was utilized for the testing, with the capability of collecting data at frequencies of 200 Hz. Tests were performed in Sierra White Granite (SWG) with a 3 ¾" bit design. The operating parameters applied were rotation per minute (80-160 RPM), weight on bit (0-6 klbs), and confining pressure (0-2,000 psi). The rotation per minute was set constant during all the tests, and the weight on bit was incrementally increased stepwise for data collection at each step. For each weight on bit range and step, heat maps were created showing the correlations between all the different parameters (applied and resultant) to inform the machine learning (ML) feature selection method. Distinct correlations between applied and resultant parameters were seen in the different drilling efficiency phases and within the different phases for different applied parameters. The potential application of this method in a real-time drilling environment shows promising results in identifying the most efficient drilling parameters to obtain optimal drilling.

1. Introduction

It is widely accepted that confining pressure plays a substantial role in determining the mechanical properties of rocks during drilling. It affects the efficiency, cost-effectiveness, and bit wear of drilling operations. Increasing confining pressure increases the lateral stress around the drill bit, resulting in greater resistance and the required force. Evidence shows that higher confining pressure significantly impacts rock energy variation, with higher pressures resulting in increased energy transmission and reduced energy release (Zhou et al., 2021). With the increase of rock's stress, the rock becomes more resistant to being fractured and cut by the drilling equipment. Moreover, specific energy and rate of penetration of laser-perforated (a non-explosive technology) oil and gas wells are significantly affected by confining pressure, with disparities observed between 8 and 16 MPa (Ahmadi et al., 2012). Therefore, higher thrust forces, torque, and penetration depths are necessary to remove the rock material effectively. It is noted that higher confining pressures lead to reduced cutting tool performance, particularly with a diamond bit impregnated with titanium. Drilling efficiency can be significantly improved by incorporating the effects of confining pressure into drilling models and operational strategies (Zhou et al., 2021).

It is typical for the geothermal energy sector to drill through hard rock such as igneous and metamorphic rock formations (Akhtarmanesh et al., 2021). Properly selecting a bladed bit significantly enhances hard rock drilling efficiency by reducing drilling costs, enhancing penetration rates, and minimizing non-productive time (Kouzaiha et al., 2022). A polycrystalline diamond compact bit (PDC) excels in hard rock drilling due to its superior cutting structure and enhanced performance capabilities. It is designed with strategically arranged cutters, alternated back rake angles, and innovative cutter configurations. This bit type helps to manage the depth of cut (DOC) effectively, reduce torsional instability, limit torque fluctuations, and increase the rate of penetration (ROP) (Hababi et al., 2023). PDC bits offer high wear resistance, making them ideal for challenging formations and enhancing drilling efficiency (Yang et al., 2022). To achieve a higher efficiency and ROP in drilling operations, numerical simulations are conducted to optimize the interaction model between PDC cutters and rock (Ahmad et al., 2023). It is also important to note that PDC bits are designed to reduce vibrations caused by torsional vibrations, thereby ensuring maximum penetration speed and drilling efficiency in hard rock. PDC bits can be made more productive and durable by implementing improvements such as cone-shaped or rotating cutters in hard rock drilling applications (Hareland et al., 2009).

Drilling hard rock, especially in geothermal reservoirs, is challenging due to low penetration rates and high bit wear. Advanced bit technology is required to work with hard and abrasive rocks at high confining pressures. Because geothermal drilling poses unique challenges, developing a model capable of predicting the ROP of these types of rocks is imperative. Several ROP models have been developed for PDC bits for various sedimentary rock formations. Based on the geometry of single-cutter rock interaction, the lithology coefficient, and bit wear, Hareland and Rampersad (1994) developed a model for drag bits. To scale up the ROP model from a single cutter to a full bit, they introduced the concept of equivalent bit radius and dynamic cutter action. (Hareland and Rampersad, 1994). The ROP model developed by Motahhari et al. (2010) calculates how a single PDC cutter interacts with rock. In 2014, another ROP model incorporated operational parameters, cutter back and side rake angles, bit hydraulic function, and bit wear function (Kerkar and Hackbarth, 2014). A PDC hybrid drill bit was developed by Wang et al. (2020) to navigate hard and abrasive formations. Wear flat area and interfacial friction angle concepts were incorporated into Atashnezhad et al. (2020) ROP model for PDC bits in hard rocks.

The two phases of drilling efficiency were defined by Akhtermanesh et al. (2021) focusing on the rate of penetration (ROP) in relation to the weight on bit (WOB). This study was conducted particularly for drilling with PDC bits. Phase 1 is marked by insufficient WOB. Due to low WOB, the depth of cut (DOC) is minimal, increasing friction and reducing the ROP. This scenario results in a less effective drilling process with scraping mechanism with low ROP, where the bit does not penetrate deeply with each rotation. On the contrary, phase 2 occurs when WOB is adequately increased (a more efficient drilling process). Higher WOB enables multiple cutting mechanisms, including chipping, crushing, and scraping. These mechanisms effectively reduce and allow for a deeper penetration. ROP is high in this phase, indicating effective operation compared to Phase 1. Phase 3 occurs when WOB exceeds Phase 2's optimal range. There may even be a decline in ROP in this phase. Identifying the transition between phase 1 and phase 2 is critical. Operating within Phase 2 ensures optimal drilling efficiency, reduced operational cost, and minimum bit wear (Akhtarmanesh et al., 2021).

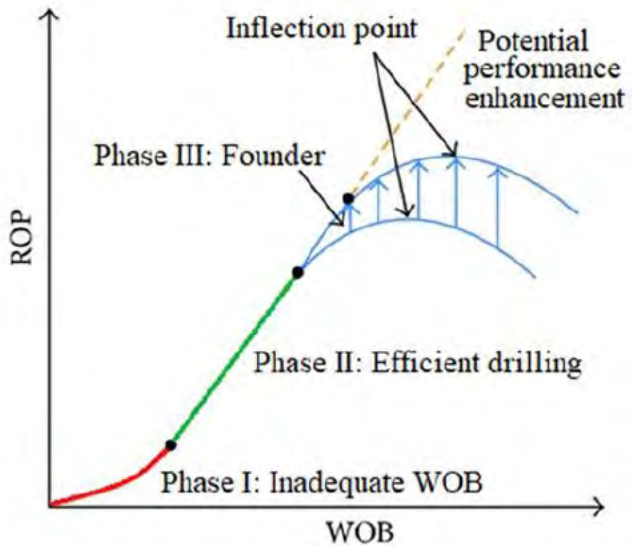

Figure 1: Different phases of drilling (Akhtarmanesh et al. 2021)

Various research papers indicate that machine learning plays a significant role in optimizing Rate of Penetration (ROP) models in drilling operations. ROP predictive models have been successfully constructed using a variety of machine learning algorithms, including Random Forest, Gradient Boosting, Extreme Gradient Boost, and Adaptive Boosting in Southern Iraq oil field (Al-Sahlanee et al., 2023). Machine learning techniques such as Support Vector Regression and Gradient Boosting Regression have also been evaluated for predicting ROP in areas such as Troll West (Liu et al., 2023). Global ROP optimization utilizing deep neural networks for ROP modeling also emphasizes the importance of machine learning concerning making real-time decisions for drilling operations (Brenjkar and Biniaz Delijani, 2022). Tests conducted in areas like Northeastern British Columbia, Canada, and offshore drilling operations in West Africa and Malaysia have demonstrated that machine learning can optimize ROP, reduce drilling costs, and improve operational efficiency (Robertson et al., 2023; Al-Riyami et al., 2023). In this study, machine learning techniques have been applied to understand the transition from the inefficient drilling phase to the efficient one under myriad key operating conditions.

Although significant advancements have been made by the above-mentioned researchers in developing ROP models for PDC bits, it is crucial to create a specifically designed model dedicated to geothermal drilling applications. The impact of confining pressure on rock deformation has been previously extensively studied. Still, the effect of confinement on hard rock drilling efficiency phase change and ROP had not been fully examined. This research aims to understand how changes in confining pressure alter the forces required for efficient drilling. The transition point, where Phase I shifts to Phase II in Figure 1, of WOB and ROP between phases was accurately determined. The detection of the transfer point is complex and is affected by some key drilling parameters, bit design, and cutter geometry. However, the transition point is fundamental to optimizing drilling in hard rock. This is the first attempt to determine this point using laboratory data which could potentially be used in a real-time automated system. This will lead to enhancing operational decision-making in geothermal drilling applications. This work is crucial for optimizing parameters such as drilling speed and bit design to increase drilling efficiency.

2. Methodology

2.1 Experimental Test

An indoor full-scale rig was used to test the Sierra White Granite (SWG) rock sample. The rig consisted of an 8-foot (2.45 m) long hydraulically driven drill string with an outer diameter of 6 inches (15.24 cm). A 559 kW (750 hp) direct-current electric motor was used to supply hydraulic power to rotate the drill string. The SWG core with a diameter of 9 inches (22.86 cm) was inserted inside the pressure cell. The sample's unconfined compressive strength (UCS) was 193,053 kPa (28,000 psi), its Young's Modulus was 4.14×10^7 kPa (6×10^6 psi), and its bulk density was 2650 kg/m^3. The permeability and porosity of SWG are negligible. Drilling parameters and wellbore pressures were reproduced using the drilling system. As the drilling fluid, water was used at a rate of 6.3×10^{-3} m^3/s (100 gal/min) at 15.6 °C (60 °F). The fluid was circulated through the drill string and bit, under the drill bit and out of the pressure cell until the desired confined back pressure was achieved. Sensors placed in the drill string monitored the weight on bit (WOB) and the rotational speed of the bit in a feedback loop. The bit ROP was recorded and analyzed with the drilling parameters controlled.

Figure 2: Drilling facility with rock sample (Reza et al. 2021)

PDC bit with a diameter of 95 mm (3-3/4" inches) was utilized for the experiments. As shown in Figure 2, the bit has four blades and 11 face cutters with a 13 mm cutter diameter.

Figure 3: 4 bladed PDC bit

Three confining pressures were tested: 0 kPa, 6895 kPa, and 13,790 kPa (0 psi, 1000 psi, and 2000 psi). The tests were conducted at 8.4 rad/s and 15.7 rad/s (80 RPM and 150 RPM), with the WOB gradually increasing. In the atmospheric tests, samples were taken at 100 Hz, whereas in the confined tests, samples were taken at 200 Hz. Figure 4 depicts a sample of raw measurement data for the 4-bladed PDC bit at 8.4 rad/s (80 RPM). The ROP was calculated based on the penetration range and measured time for each WOB step (Mayibeki et al., 2023)

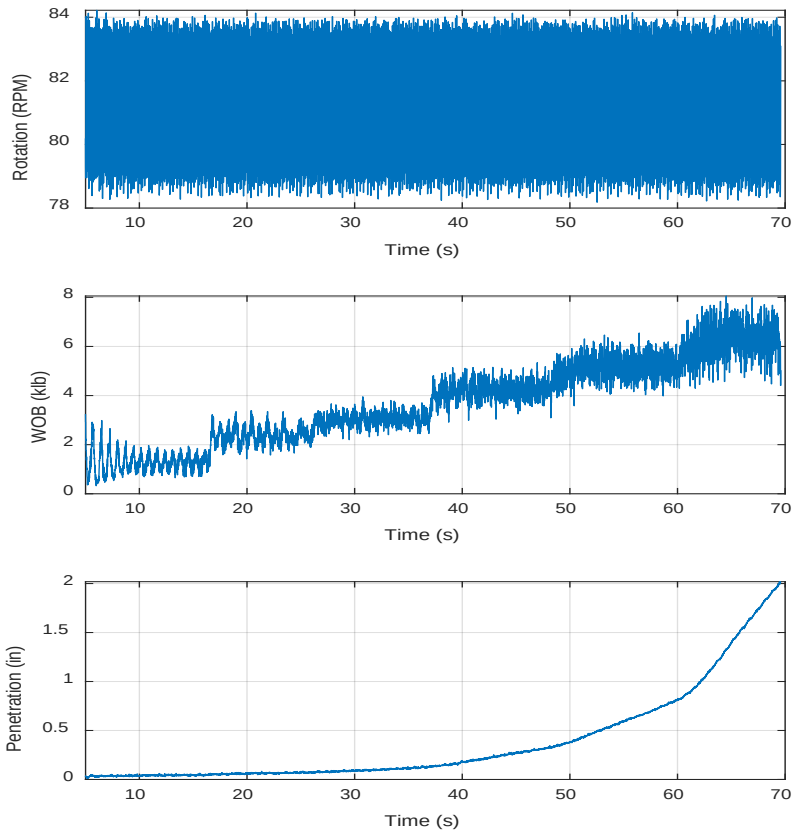

Figure 4: Raw measured drilling data with 4-bladed PDC bit at 80 RPM under atmospheric conditions

2.2 Phase-Driven Variability in Drilling Parameter Correlations Model

Using a comprehensive methodology, this study analyzes the efficiency of a four-bladed PDC bit across two distinct drilling phases. Figure 5 illustrates the method for developing the phase-driven variability model. Initially, the methodology involved loading data followed by rigorous preprocessing, including standardization and splitting. It is crucial to standardize the feature scales to minimize bias caused by varying scales and normalize the influence of each parameter. With this preprocessing step, the subsequent analytical techniques operate optimally, improving accuracy and reproducibility. Based on the standardization of our drilling data, a Random Forest regression model was developed, which was fine-tuned specifically for the drilling data. The decision was based on the model's ability to handle non-linear relationships and its robustness against over fitting, making it an ideal choice for our complex geological data. As the model's evaluation metrics, MAE (Mean Absolute Error), MSE (Mean Squared Error), and R squared score were determined. The MAE represents the average magnitude of the errors in a set of predictions, without considering their direction. The MSE measures the average of the squares of the errors, thereby giving more weight to larger errors. The R^2 score indicates the proportion of the variance in the dependent variable that is predictable from the independent variables. This random forest model provided a baseline predictive framework, crucial for subsequent analyses. To increase the granularity of our analysis, a Cubic Spline interpolation was used to transform the discrete dataset into a continuous one, ensuring smooth transitions. A practical application of the PELT algorithm,

a Pruned Exact Linear Time algorithm that identifies significant shifts in operational efficiency, required this interpolation. Based on the PELT algorithm's sensitivity and efficiency in detecting these change points, the critical transitions in drilling performance were identified. These were then quantitatively analyzed to determine their effects on overall drilling efficiency. Additionally, this methodology provided a robust statistical basis for assessing the impact of different drilling parameters on the efficiency of the 4-bladed PDC bit.

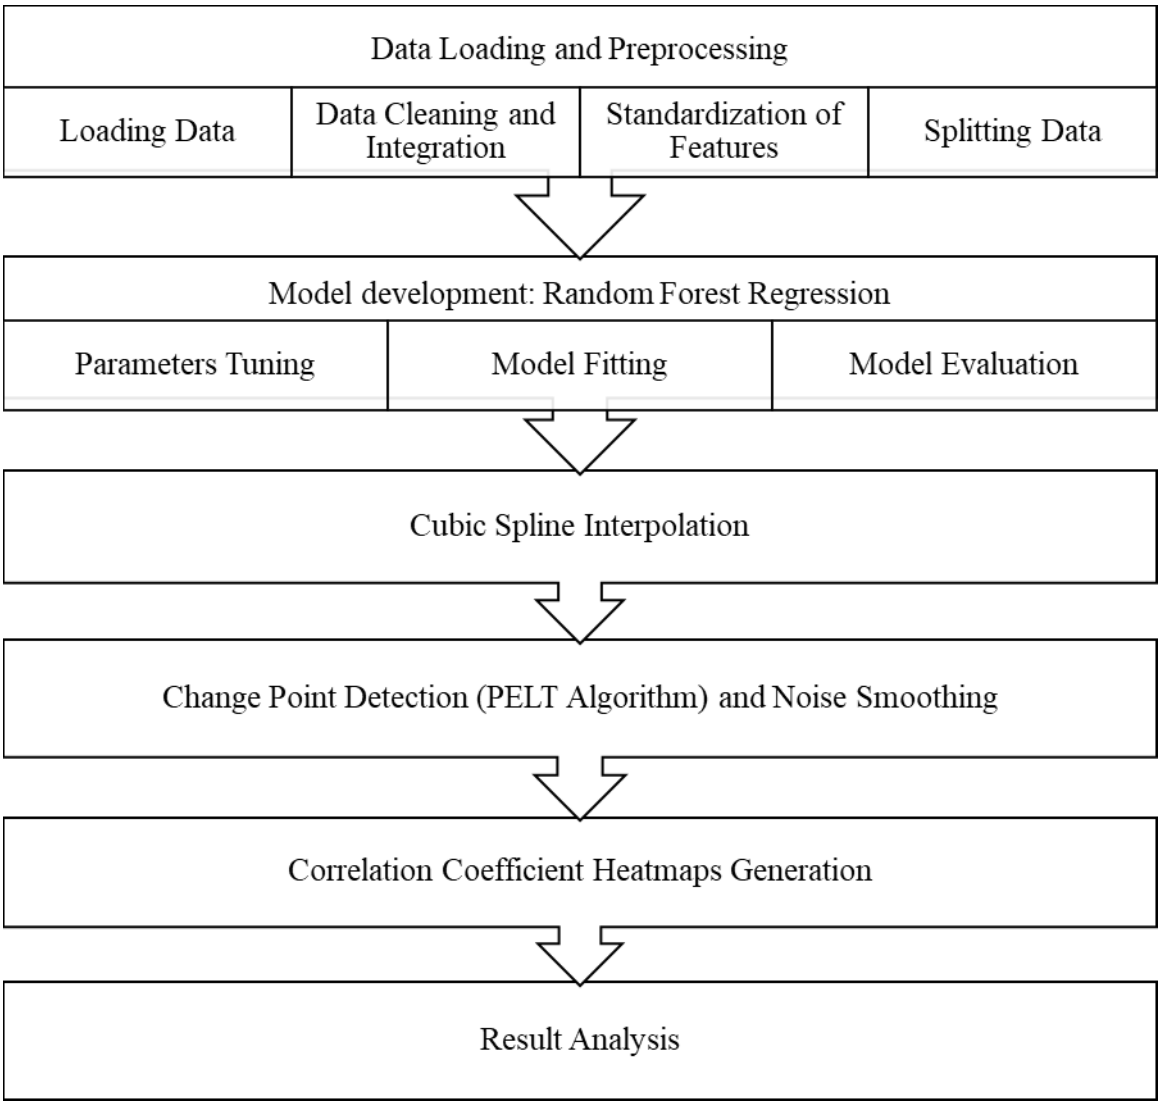

Figure 5: Methodology of the phase-driven variability of the drilling parameters model

3. Result and Discussion

3.1 Transition point of WOB and RPM measurement

For a 4-blade drill bit configuration, a Random Forest regression approach was utilized in conjunction with Cubic Spline interpolation and PELT change point detection. The relation of

WOB and ROP at various confining pressures at various RPM settings was studied. The model captures significant shifts in drilling performance across different operational settings. Figure 6 illustrates the model's effectiveness in capturing ROP behavior. The 4-bladed drill bit is presented operating at 80 RPM under varying confining pressures. Panels (a) through (f) depict actual versus predicted ROP values against the weight on the bit and interpolated data that identifies critical change points. This structured visualization facilitates the understanding of the relationship between WOB, ROP, and operational efficiency under different subsurface pressure conditions.

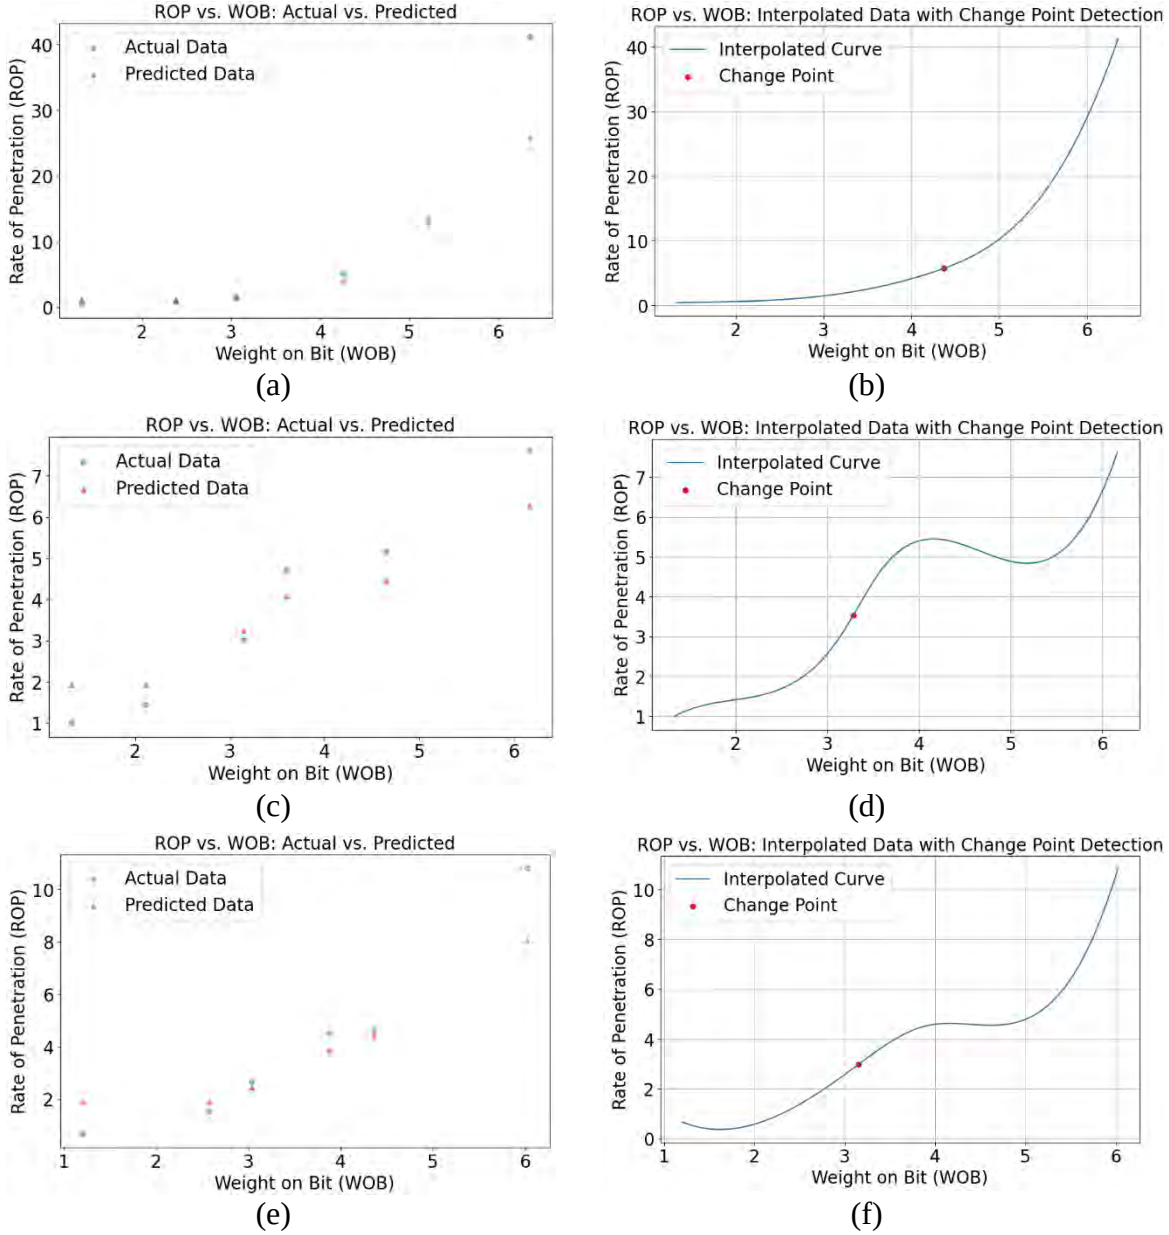

Figure 6: Random Forest model fit on the data to determine the transitional (or change) WOB and ROP point for 4 bladed bit at 80 RPM (a) Actual vs. predicted data at 0 psi confining pressure (b) Change point at 0 psi confining pressure (c) Actual vs. predicted data at 1000 psi confining pressure (d) Change point for at 1000 psi confining pressure (e) Actual vs. predicted data at 2000 psi confining pressure (f) Change point at 2000 psi confining pressure

Table 1 depicts the evaluation metrics of the random forest model at different confining pressures running at 80 RPM. This table provides information regarding the accuracy and goodness-of-fit of the model. The metrics include Mean Absolute Error (MAE), Mean Squared Error (MSE), and the R-squared (R^2) score. It offers a comprehensive assessment of the model's performance.

Table 1: Model evaluation metrics for 80 RPM

Confining Pressure	MAE	MSE	R^2 Score
0 psi	0.79	0.64	0.98
1000 psi	0.82	0.69	0.84
2000 psi	0.70	0.77	0.80

The MAE of the developed model is lowest at 2000 psi (0.70), suggesting that predictions are most accurate at this pressure level. In terms of penalizing larger errors, the model exhibits the lowest MSE at 0 psi (0.64), indicating that the model performs best under these conditions. The model occasionally produces larger errors than predictions made at lower pressures, with the MSE slightly higher at 1000 psi (0.69), and highest at 2000 psi (0.77). Lastly, the model shows excellent fit at 0 psi, with an R^2 of 0.98, which indicates it explains 98% of the variance. As confining pressure increases, the R^2 drops to 0.84, and 0.80 at 2000 psi, suggesting the model's explanatory power decreases. Even though the MAE is not the lowest at 0 psi, the combination of high R^2 and low MSE demonstrates superior accuracy and consistency. It is evident from the R^2 scores that the model has an impaired ability to explain variance at 1000 and 2000 psi, with the highest predictive accuracy (lowest MAE) at 2000 psi despite a higher MSE. According to this discrepancy, while the model predicts more accurately on average at 2000 psi, it is more susceptible to errors.

Figure 7 shows that the random forest model is developed and applied to detect the change points at a range of confining pressures at a speed of 150 RPM. The figure shows the actual data compared to the predicted data for each case. Then, the change point on the interpolated curve of the dataset is pointed out as well.

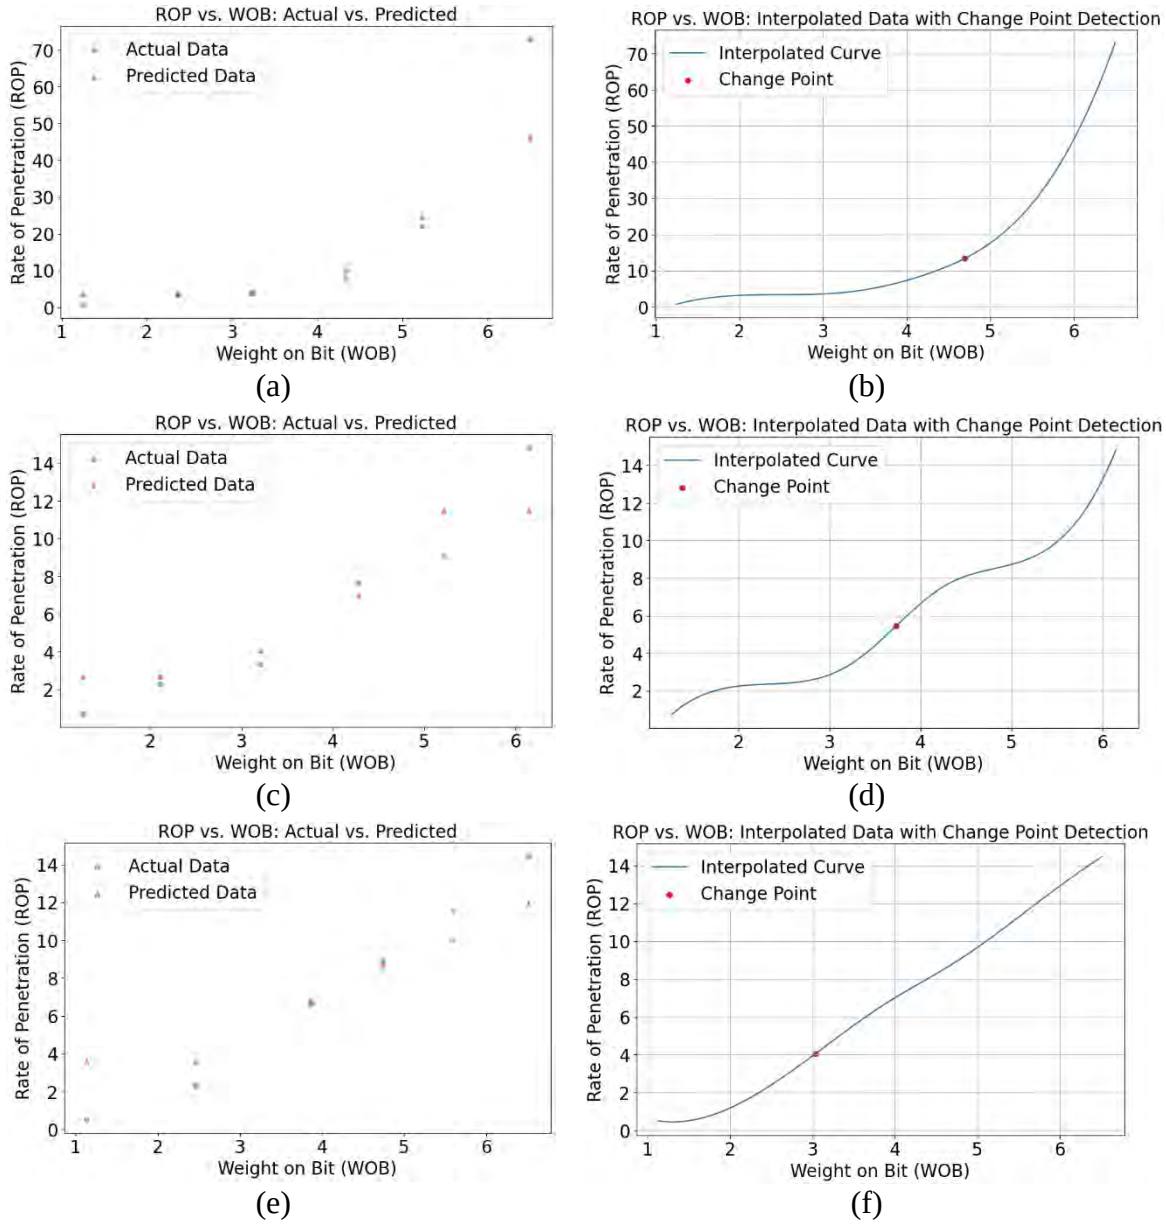

Figure 7: Random Forest model fit on the data to determine the transitional (or change) WOB and ROP point for 4 bladed bit at 150 RPM (a) Actual vs. predicted data for at 0 psi confining pressure (b) Change point at 0 psi confining pressure (c) Actual vs. predicted data at 1000 psi confining pressure (d) Change point at 1000 psi confining pressure (e) Actual vs. predicted data at 2000 psi confining pressure (f) Change point at 2000 psi confining pressure

Table 2 shows that the random forest model is evaluated at a speed of 150 RPM. The same metrics (MSE, MAE, and R^2 score) as the 80 RPM model are calculated based on a range of confining pressures. This table is indicative of the performance of the model.

Table 2: Model evaluation metrics for 150 RPM

Confining Pressure	MAE	MSE	R Squared Score
0 psi	2.75	7.59	0.93
1000 psi	2.19	4.84	0.72
2000 psi	2.29	5.88	0.81

At 0 psi, the model has the highest R^2 score (0.93), indicating excellent explanatory power. However, the MAE (2.75) and MSE (7.59) are the highest. Thus, while the model fits the overall data well, its predictions are less accurate and prone to larger errors on average. At 1000 psi, the model achieves the lowest MAE (2.19) and MSE (4.84), indicating the highest predictive accuracy and the smallest average errors. Despite this, the R^2 score is the lowest (0.72). This suggests that while the individual predictions are more accurate, the overall fit is not as strong. At 2000 psi, the model balances predictive accuracy and explanatory power. The MAE (2.29) and MSE (5.88) are moderately low, and the R^2 score (0.81) is relatively high, indicating a good compromise between fitting the data and maintaining predictive accuracy. In short, at 150 RPM, the model performs best in terms of predictive accuracy (lowest MAE and MSE) at 1000 psi, but it explains the most variance (highest R^2) at 0 psi. The results suggest a trade-off between the accuracy of individual predictions and the model's overall fit, with 2000 psi providing a balanced performance.

Table 3 provides a summary of the transition points between ROP and WOB for a wide range of rotational speeds and confining pressures. Based on the results, it is evident that transition points vary suggestively with fluctuating operating conditions. A thorough understanding of these insights is crucial to drilling performance in diverse drilling operations.

Table 3: Transition point of ROP and WOB for varying RPMs and confining pressures

4 Blade Bit			
RPM	**Confining Pressure**	**$WOB_{transition}$**	**$ROP_{transition}$**
80	0 psi	4.37 klbs	5.73 ft/hr
80	1000 psi	3.28 klbs	3.53 ft/hr
80	2000 psi	3.15 klbs	2.97 ft/hr
150	0 psi	4.69 klbs	13.34 ft/hr
150	1000 psi	3.73 klbs	5.43 ft/hr
150	2000 psi	3.03 klbs	4.05 ft/hr

Firstly, from Table 3, it is noticed that, at 80 RPM, the WOB transition decreases from 4.37 klbs at 0 psi to 3.15 klbs at 2000 psi. Whereas, at 150 RPM, the WOB transition shows a similar trend, decreasing from 4.69 klbs at 0 psi to 3.03 klbs at 2000 psi. At both 80 RPM and 150 RPM, the WOB transition decreases with increasing confining pressure. Higher confining pressures require lower WOB to transition, possibly due to increased resistance from the surrounding rock formation.

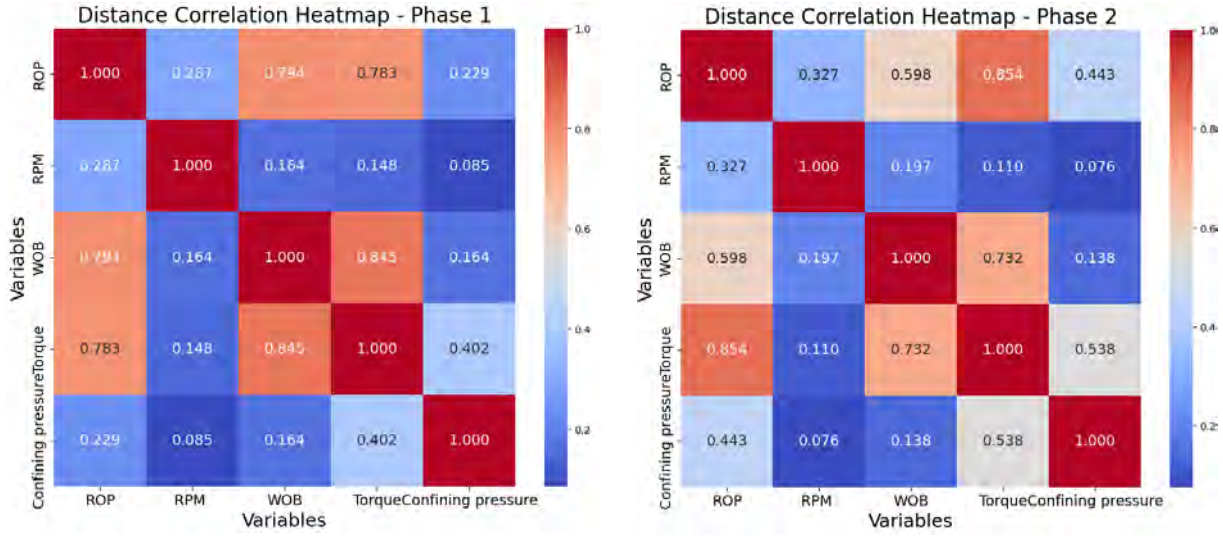
Secondly, at 80 RPM, the ROP transition decreases from 5.73 ft/hr at 0 psi to 2.97 ft/hr at 2000 psi, as seen in Table 3. At 150 RPM, the ROP transition is significantly higher at 0 psi (13.34 ft/hr)

compared to 5.43 ft/hr at 1000 psi and 4.05 ft/hr at 2000 psi. It concludes that the ROP transition also decreases with increasing confining pressure for both RPM levels. Higher confining pressures seem to slow down the rate of penetration, indicating more resistance to drilling.

Finally, at 0 psi, increasing the RPM from 80 to 150 results in a higher WOB transition (from 4.37 klbs to 4.69 klbs) and a significantly higher ROP transition (from 5.73 ft/hr to 13.34 ft/hr) as noted in Table 3. Higher RPM improves the drilling rate significantly in the absence of confining pressure. At 1000 psi and 2000 psi, the trends are consistent but less pronounced. For instance, at 1000 psi, WOB transition increases from 3.28 klbs to 3.73 klbs and ROP transition increases from 3.53 ft/hr to 5.43 ft/hr with higher RPM. At 2000 psi, the WOB transition decreases from 3.15 klbs, while the ROP transition is at 4.05 ft/hr. This suggests at higher RPM, the drill bit performs slightly better. This is due to the improved cutting action of the bits against the hard rock formation.

3.2 Efficiency mapping of Phase 1 and Phase 2

The distance correlation coefficient analysis provides a robust quantitative framework to evaluate the interdependencies among drilling parameters. By comparing the coefficients across two efficiency phases, the key variables that contribute to enhanced drilling performance can be identified. Figure 8 shows the distinct correlation coefficient heat-maps for Phase 1 and Phase 2 of drilling efficiency. These heat maps describe the strength of the correlations between several drilling parameters: ROP, RPM, WOB, Torque, and Confining Pressure. The phases have been distinguished based on the change point detected listed in Table 3.



(a) (b)

Figure 8: Distance correlation heat map of 4 bladed bit (a) inefficient drilling phase: Phase 1 (b) efficient drilling phase: Phase 2

In Phase 1 (Figure 8a), WOB and ROP showed a moderate correlation (0.794), indicating a role for WOB in influencing ROP. As a result of this sub-optimal correlation score, the WOB was not effectively translated into penetration efficiency. This could be the result of poor bit-to-rock

interaction. WOB and torque correlate more strongly (0.845) than ROP and torque (0.883). A higher WOB generally results in a deeper cut per revolution, which typically requires a higher torque. According to the correlation between RPM and torque (0.148), there is little to no synchronization between bit rotation speed and mechanical torque. The reason for this is often a mismatch between the drilling parameters and the rotary system, which results in inefficient energy transfer. A minimal correlation was observed between confining pressure and torque (0.402), indicating that changes in confining pressure did not significantly alter torque requirements, possibly due to insufficient hydraulic power.

In Phase 2 (Figure 8b), WOB and ROP correlation significantly strengthened (0.598), indicating effective transmission of WOB to penetration through the rock. This improvement was observed due to the increase in drilling efficiency. The strongest relationship of ROP is with Torque (0.854) in this phase. Higher torque means better engagement of the bit's cutting elements with the rock, increasing the ROP. The confining pressure also strongly affects the ROP in this phase (0.443 compared to 0.229), as confining pressure makes the rock more resistant to the mechanical force applied by the bit. The WOB and torque demonstrate a similar relationship to Phase 1. RPM and torque demonstrated a similar correlation to Phase 1, suggesting no efficiency improvements in the rotary drive system. Confining pressure and torque show an increased correlation (0.538), which could reflect better adaptation to varying geological pressures.

Table 4 shows the difference in the distance correlation coefficients of Phase 1 and Phase 2. The heat maps reveal higher correlation coefficients in Phase 2 than in Phase 1. This suggests that the operational parameters are more interdependent and possibly better optimized in Phase 2. The stronger correlations indicate more cohesive interactions among variables such as WOB, RPM, Torque, and Confining Pressure. These parameters could contribute to improved drilling performance. Changes in the drilling environment (more precisely, applying more confining pressure) affect the efficient phase more than the inefficient phase. The slight changes in correlations involving RPM indicate that RPM's role remained relatively consistent across phases. As seen from the differences of ROP-torque and torque-confining pressure in Table 4, torque became a more critical factor in the drilling process in Phase 2. A possible explanation for this is the changes in bit design, drilling fluid properties, or formation characteristics.

Table 4: Distance Correlation Differences between Phase 1 and Phase 2 (Phase 2 - Phase 1)

	ROP	**RPM**	**WOB**	**Torque**	**Confining Pressure**
ROP	0	0.04	-0.195	0.071	0.214
RPM	0.04	0	0.033	-0.038	-0.009
WOB	-0.195	0.033	0	-0.112	-0.026
Torque	0.071	-0.038	-0.112	0	0.136
Confining Pressure	0.214	-0.009	-0.026	0.136	0

Parameters showing significant correlation increases from Phase 1 to Phase 2 might be targeted for specific adjustments to enhance efficiency. From Table 4, the pairs of ROP-WOB (-0.195), ROP-confining pressure (0.214), WOB-torque (-0.112) and torque-confining pressure (0.136)

are key combinations here that need to be optimized while drilling under varying confining pressure and RPMs. Synchronizing these parameters more closely leads to better performance outcomes. For example, WOB and ROP show a strong correlation in Phase 2. Maintaining or optimizing WOB settings could be crucial for maximizing ROP under similar conditions.

3.3 Discussion

It is important to note that, this model was designed to identify a single detection point. It performs well under atmospheric confining conditions (0 psi). In contrast, for confining pressures of 1000 psi and 2000 psi, there is evidence of an intermediate transition zone as the drilling efficiency phase transitions from Phase 1 to Phase 2. The observed sinusoidal shape of the interpolated line in the graphs for these pressures supports this hypothesis. Figure 9 shows where this transition zone from Phase1 to Phase 2 could exist. In this area, the drilling is not yet efficient, rather transitioning into the efficient phase.

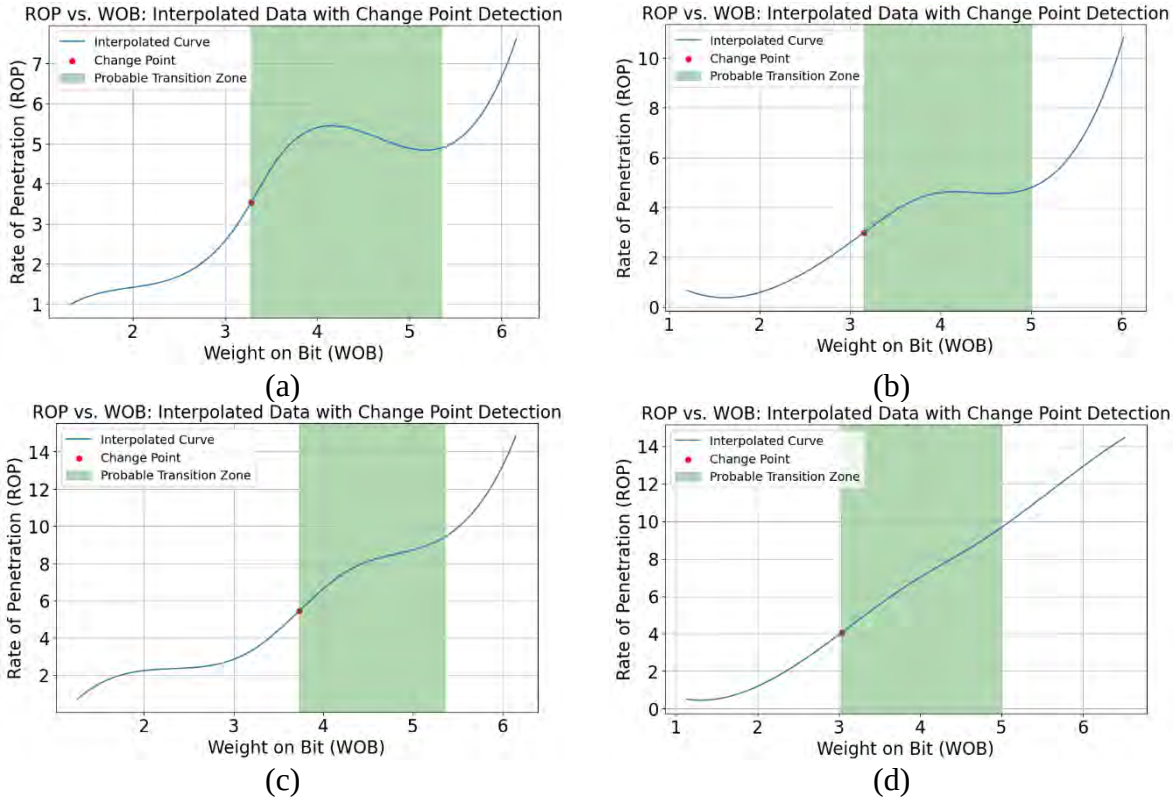


Figure 9: Probable intermediate transition zone from phase 1 to phase 2 for 4 bladed bit (a) 80 RPM at 1000 psi confining pressure (b) 80 RPM at 2000 psi confining pressure (c) 150 RPM at 1000 psi confining pressure (d) 150 RPM at 2000 psi confining pressure

The exact magnitude of this intermediate transition zone remains unknown within the scope of our current study. The authors are precisely detecting and characterizing this region through ongoing research.

4. Conclusion

- This study identified three distinct phases of drilling efficiency for geothermal drilling using a PDC bit under varying confining pressures and operational parameters. During Phase 1, the drilling is inefficient with a low depth of cut and high friction. During Phase 2 the drill is efficient with optimal WOB and RPM leading to effective rock penetration. The correlations between drilling parameters exhibit significant phase-driven variability. As a result of this variability, it is possible to identify which parameters need to be adjusted to improve performance. It also emphasizes the need for synchronized WOB, RPM, and torque adjustments.
- ROP correlation with WOB and confining pressure and torque relationship with WOB and confining pressure are the most significant combinations that can convert the inefficient drilling phase into an efficient phase under increasing confining pressure.
- Random forest regression, cubic spline interpolation, and PELT change point detection, were utilized to analyze the relationship between WOB and ROP. In particular, this approach highlights the model's ability to capture significant changes in performance across various settings. Additionally, it gives a nuanced understanding of how operational parameters affect drilling efficiency.
- The random forest model demonstrated high predictive accuracy, as indicated by low MAE and MSE values and high R-squared scores under various operational conditions. The predictive capability of this system will enable proactive adjustments to be made to drilling performance.
- The distance correlation coefficient heat maps were generated for Phase 1 and Phase 2, considering the change points detected as the transition point. However, in future research works, if the intermediate transition zone between these phases is detected, the heatmaps would be different for Phase 2 (efficient phase). That might also reveal other striking correlations among the drilling parameters leading to an optimized drilling operation.
- Confining pressure had a significant impact on drilling operations. High confining pressures increase resistance around the drill bit, requiring higher thrust and torque forces to remove rock effectively. ROP and torque are affected the most due to confining pressure in the efficient drilling phase. Incorporating confining pressure effects into drilling models could significantly improve drilling efficiency.
- The transition points of ROP and WOB were quantitatively determined for different RPM settings, which provides an essential benchmark for optimizing drilling operations. However, with little to no effect of RPM on transitioning the drilling phase in efficient one concludes that changing RPM is of the least importance to get better results. To maintain drilling within the efficient phase, this insight is crucial for making real-time adjustments to operations.

5. Limitation and Future Recommendation

In this study, we employed Random Forests (RF), which typically assume independent and identically distributed inputs (IID). Due to the temporal dependencies inherent in drilling operations, adjacent data points tend to be correlated based on the input data, which is a time-series measurement. Therefore, the model may be affected by the violation of the IID assumption. A potential improvement would be to incorporate lag features or hybrid approaches (e.g., to combine RF with time-series models, such as Long Short-Term Memory (LSTM) networks).

Furthermore, this modeling effort is based solely on a single rock type, whereas in practice, drilling operations often encounter varying formations, which may have an impact on parameters such as weight on bit (WOB), torque, and rate of penetration (ROP). These changing formations should be incorporated into the model in future work. Finally, although adjusting WOB in real-time can offer insights, drastic changes to WOB for model training could pose risks such as bit failure. It is important to consider controlled, incremental changes, along with historical data from different WOB levels, in order to avoid damage to the equipment.

A broader range of confining pressures and RPM settings should be considered for future studies to refine efficiency models and better understand the limits of PDC bit performance under extreme conditions. Implementing the machine learning models developed in this study into real-time drilling operations will enhance decision-making processes. It will allow for dynamic adjustments based on immediate feedback from the drilling parameters. Moreover, it would be useful to investigate the impact of other bit materials and designs (apart from 4 bladed PDC bit) on drilling efficiency, particularly in hard rock geothermal drilling. Furthermore, the authors are developing more complex machine learning algorithms and incorporating additional prediction factors such as bit wear and specific energy.

Predicting Steam Production in Water-Dominant Geothermal Reservoirs affected by Reinjection rate Using Recurrent Neural Networks

Magnus Thor Jonsson and Lilja Magnusdottir

University of Iceland, HS-Orka

Keywords

Recurrent Neural Network, Geothermal Reservoir, Pressure Drawdown, Reinjection

ABSTRACT

This research explores the use of Recurrent Neural Networks (RNNs) to predict pressure drawdown in both water-dominant and shallow steam wells within geothermal reservoirs affected by reinjection practices. Reinjection, a common technique to maintain reservoir pressure and extend the lifespan of geothermal systems, introduces complexities due to the interaction between reinjected and native fluids, significantly impacting steam production rates.

The study aims to develop a RNN model that utilizes historical data on water and steam production, reservoir characteristics, and injection practices to accurately forecast pressure drawdown in both the water part of the reservoir as well as in the steam zone. RNNs, with their capability to retain past information and predict future events in time-series data, provide a promising approach to modeling the non-linear and dynamic behavior of geothermal reservoirs influenced by reinjection.

A dataset generated using a 3D numerical reservoir model, including pressure in water-dominant and steam-dominant wells, as well as fluid, steam, and injection rates, forms the basis for training and validating the RNN model. The model's performance is compared against both measured data and predictions from a lumped parameter model to highlight its forecasting accuracy and reliability.

The results demonstrate that the RNN model outperforms the lumped parameter model in predicting pressure drawdown in water-dominant wells. It also effectively predicts steam pressure drawdown, accounting for the transient effects of reinjection on reservoir behavior.

1. Introduction

Geothermal energy, a sustainable and renewable resource, has the potential to play a significant role in meeting global demands for sustainable energy. Geothermal reservoirs, especially those dominated by water, are essential sources of geothermal energy. In these systems, the production of steam plays a crucial role in energy generation. One common method to sustain reservoir pressure and extend the lifespan of these resources is reinjection. Reinjection involves the process of reintroducing fluids back into the geothermal reservoir after energy extraction. While this practice helps maintain reservoir pressure, it also introduces complexities due to the interaction between reinjected and native fluids. Understanding and predicting the effects of reinjection on steam production in shallow wells is essential for optimizing the management of geothermal energy extraction.

Traditional methods of predicting steam production in geothermal reservoirs often rely either on complex 3D numerical models with many unknown parameters that are difficult to calibrate or on lumped parameters models that may not adequately capture the intricate dynamics of reinjection and its effect on the steam zone in the reservoir. As a result, there is a need for more advanced and accurate predictive tools. Recent advancements in Artificial Intelligence (AI) and machine learning offer promising solutions to address these challenges.

Recurrent Neural Networks (RNNs) have demonstrated their capability to model time series data and complex temporal relationships, making them suitable for predicting steam production in geothermal reservoirs influenced by reinjection practices. Production and injection management is important for optimizing the geothermal resource. Although it is crucial, only limited research on using machine learning has been published in this area. Siler et al. (2022), did a study where machine learning (ML) models were utilized to enhance performance predictions for geothermal reservoirs by combining reservoir modeling with ML to produce accurate predictions of temperature and pressure timeseries for productions wells. More commonly, AI techniques have been used for geothermal potential assessments such as extracting hidden features from hydrological data, generating geothermal potential maps, and identifying production-associated geologic factors (Song et al., 2021; Zhou et al., 2020; Lai et al., 2019; Garcia et al., 2018; Noh et al., 2018).

This research focuses on the application of RNNs to predict pressure drawdown, especially in shallow steam wells, in water-dominant geothermal reservoirs where a steam cap has formed. Shallow wells are particularly challenging due to their susceptibility to changes in reservoir dynamics and reinjection impacts on the steam zone. By leveraging the strengths of RNNs, this study aims to develop a predictive model that can accurately forecast pressure in both the water and steam parts of the reservoir, taking into account the complex interactions between reinjected and native fluids. The objective is to evaluate the impact of reinjection practices on steam production , thereby aiding in the optimization of reinjection strategies.

Integrating advanced AI techniques with geothermal reservoir management, this research aims to enhance the efficiency and sustainability of geothermal energy production. The findings are expected to improve the understanding of reinjection dynamics and boost predictive capabilities for steam production, thereby optimizing extraction processes. This predictive tool can help optimize operational strategies, ensure sustainable reservoir management, and enhance the economic viability of geothermal projects. By offering a novel approach to managing the

complexities of reinjected reservoirs, this study contributes significantly to advancing the field of geothermal energy production.

This paper is structured as follows: Section 2 provides an overview on geothermal energy production, reinjection practices, and the application in geothermal reservoir modeling. Section 3 details the data collection and preprocessing. Section 4 discusses the architecture of the Long Short-Term Memory (LSTM) RNN model. Section 5 presents the results of the study, highlighting the performance of the RNN model in predicting steam production. Finally, Section 6 concludes the paper with a summary of key insights.

2. Geothermal Energy Production

Geothermal energy production harnesses the Earth's internal heat to generate electricity and provide heating. This sustainable energy source is derived from the natural thermal energy contained within the Earth's crust. The process begins by drilling wells into geothermal reservoirs, which are typically located in regions with high tectonic activity. These reservoirs contain hot water and steam, which are brought to the surface through production wells as shown in Figure 1.

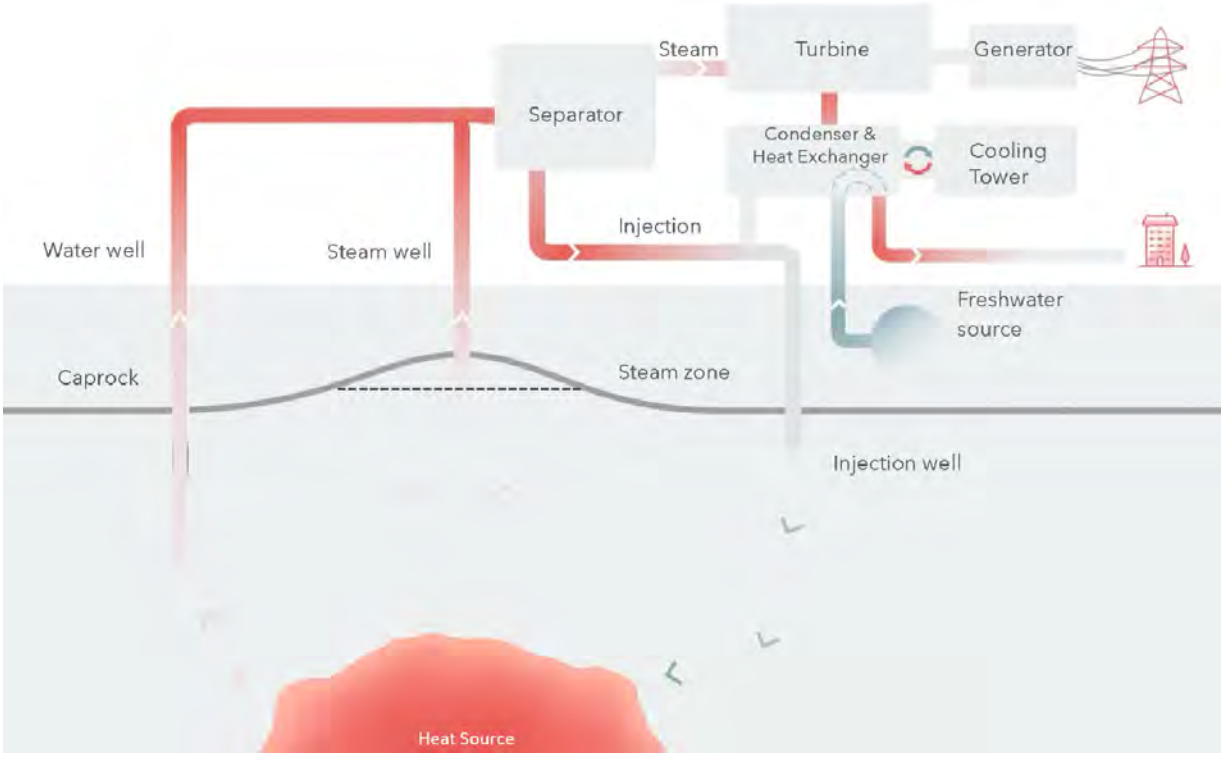

Figure 1: A geothermal power plant producing electricity and hot water from both water and steam wells.

Once at the surface, the hot water and steam are directed to a geothermal power plant. There are three main types of geothermal power plants: dry steam, flash steam, and binary cycle. Dry steam plants take steam directly from fractures in the ground and use it to drive a turbine that generates electricity. Flash steam plants pull deep, high-pressure hot water into cooler, low-pressure water, causing the rapid vaporization or "flashing" of the water into steam, which is then used to drive a turbine. Binary cycle plants transfer the heat from geothermal hot water to another liquid that boils at a lower temperature than water; this secondary liquid is vaporized and used to turn a turbine.

One of the primary advantages of geothermal energy is its low environmental impact. Geothermal plants emit very low levels of greenhouse gases compared to fossil fuel-based power plants. Additionally, geothermal energy provides a stable and reliable power source, unlike solar and wind energy which are intermittent. The continuous availability of geothermal resources allows for consistent base-load power generation, making it a valuable component of the renewable energy mix.

The efficiency of geothermal energy production depends significantly on the characteristics of the geothermal reservoir, including its temperature, pressure, and fluid composition. The energy production involves managing the extracted fluids, which may contain various minerals and gases. The re-injection of cooled geothermal fluids back into the ground helps to sustain the pressure in the reservoir and mitigate environmental impacts. This system ensures the long-term sustainability of the geothermal resource.

Effective management of a geothermal reservoir involves precise control over various operational parameters, such as the wellhead valve openings, production rates for each well site or area, and the injection rates. The complexity of these tasks is compounded by the diversity of wells within the reservoir. Some wells penetrate deep into water-dominated layers at high pressure, while others extend just below the caprock to capture steam, as illustrated in Figure 1.

In conclusion, geothermal energy production is a sustainable and reliable method of harnessing the Earth's internal heat for power generation and heating. With its low environmental impact and potential for continuous energy supply, geothermal energy plays a vital role in the renewable energy landscape. The future of geothermal energy production lies in improving the efficiency of extraction and utilization processes, reducing costs, and expanding the geographical reach of geothermal projects. Ongoing research and technological innovations are essential to overcoming the challenges associated with geothermal energy production and realizing its full potential as a major contributor to global energy needs.

3. Data Pipeline

Effective machine learning relies heavily on the quality and preparation of the input data. Thus, a robust data pipeline is crucial. It encompasses the entire process of collecting, processing, and transforming raw data into a form suitable for use by a machine learning model. This process involves several critical steps: data collection, data preprocessing, data transformation, storage, and workflow management. Effective data preprocessing is essential as it ensures the data is clean, normalized, and formatted correctly, which significantly enhances model performance and generalization. Without proper preprocessing, models may learn from noise rather than meaningful patterns, leading to poor predictions.

In this study, historical data spanning 43 years from various sources, including water wells, steam wells, and injection wells, serves as the foundation for the analysis. Key variables such as date, reservoir pressure, and flow rates were organized in a time-series format. To model the reservoir's response to these operational conditions, a comprehensive dataset is essential. This dataset forms the backbone for training and validating the Recurrent Neural Network (RNN) model, enabling accurate predictions and informed decision-making.

The primary components of this dataset include mainly the production rate, pressure data and injection rates generated using a 3D reservoir model of a geothermal reservoir in Iceland. However, production and injection rates used in the model to simulate the pressure drawdown, were synthetically generated as laws in Iceland prevent geothermal companies from sharing that data. Pressure data is vital for monitoring the reservoir's pressure dynamics, which are influenced by production and reinjection activities, as shown in Figure 2. Records of injection volumes are necessary to quantify the amount of fluid being reinjected into the reservoir. Monitoring injection volumes also aids in assessing the effectiveness of reinjection in maintaining reservoir pressure and prolonging the reservoir's productive life. By correlating steam production records with other dataset components, the RNN model can be trained to predict future pressure and production trends and optimize operational decisions.

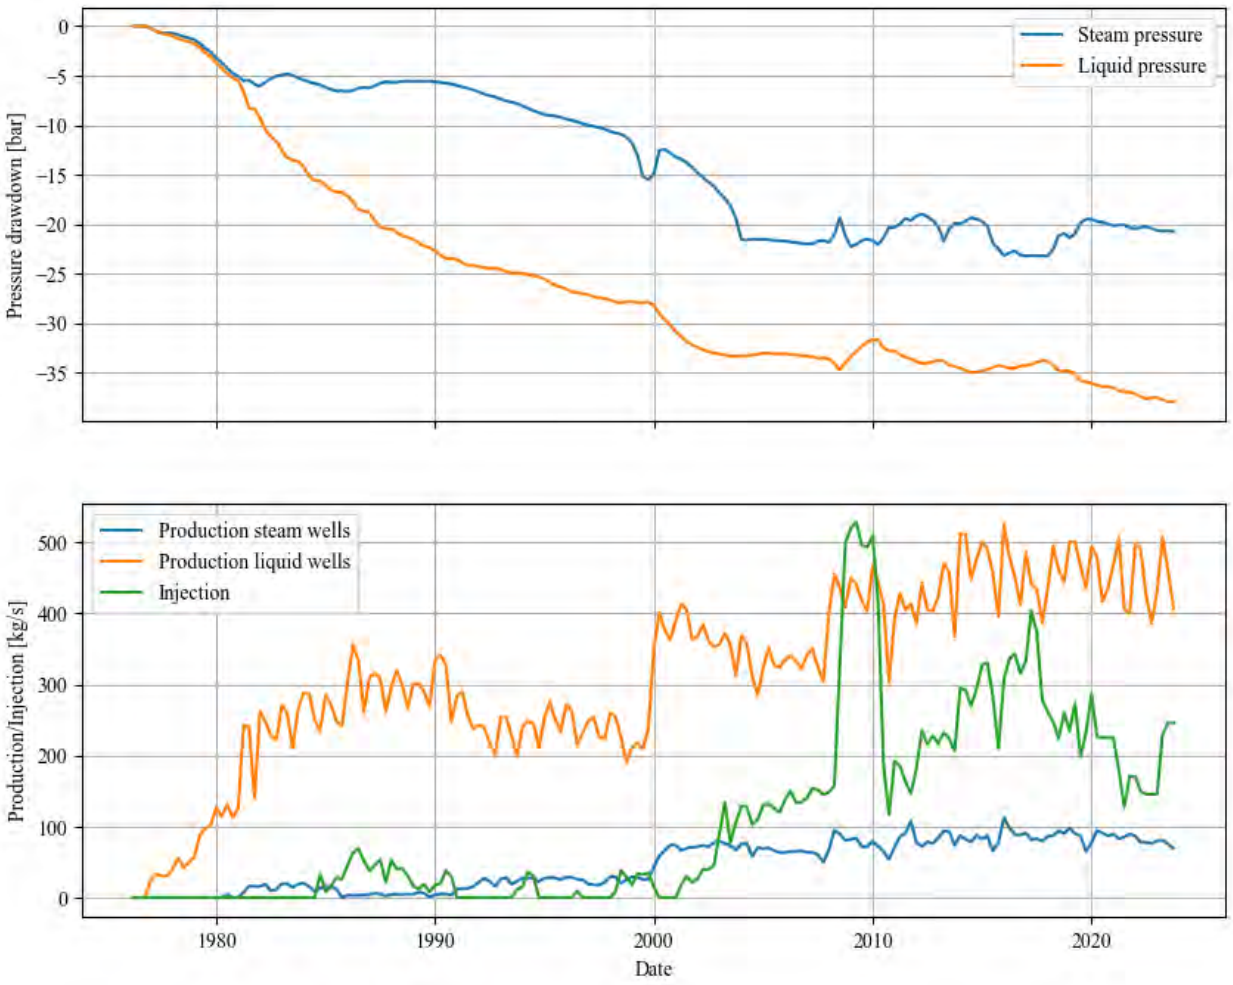

Figure 2: Production and injection rates, and pressure drawdown in both water and steam wells.

The data collection process entails ongoing monitoring and recording of the specified parameters through a network of sensors and measurement devices positioned at various well sites. These devices are calibrated regularly to ensure data accuracy and reliability. The data is then transmitted to a central database for storage and further analysis.

Preprocessing involved handling missing values through interpolation or forward-filling methods, differencing to remove trends, and normalization to ensure the data values were within a suitable range for model convergence. The following subsections will explain the preprocessing steps used to prepare the data for training.

3.1 Differencing

Differencing is the first process in the data pipeline. This procedure not only centers the data but also smooths out fluctuations during model training, resulting in a more stable training process. First-order differencing involves subtracting each data point from the previous one, centering the data and eliminating trends.

3.2 Normalization

Normalization is essential when dealing with multivariate time series of different scales. It involves scaling the data so that the standard deviation of the training data is set to unity and its mean to zero. This is achieved by dividing each value by the standard deviation of the training set and subtracting the mean. To prevent data leakage, the mean and standard deviation are calculated only from the training set. The same normalization transformation is then applied to the test set to ensure comparability.

The normalization formula is:

$$\boldsymbol{X}_{norm} = \frac{\boldsymbol{X} - \mu_{Xtrain}}{\sigma Xtrain} \tag{1}$$

where $\boldsymbol{X}$ is the original time series, $\boldsymbol{X}_{norm}$ is the normalized version, μ_{Xtrain} is the mean of the training set, and σ_{Xtrain} is the standard deviation of the training set. If $\boldsymbol{X}$ is also the training set, then it will be normalized to have a mean of zero and a standard deviation of one.

3.3 Batching

For batch learning with time series data, it is necessary to create fixed-length sequences using a sliding window approach. This involves sliding two side-by-side windows over the dataset, one step at a time. The points inside the first window are collected and stored as a sequence, maintaining their temporal order. This sequence serves as the input for the models. The second window, positioned one step to the right, contains the target data that the model must predict based on the input sequence.

Figure 3 illustrates the sliding window method, where circles represent data points, marked with the first letter of the variable and a subscript denoting their time step. An input window of size I_s and a target window of size T_s are shown side by side, with their subsequent shifted windows.

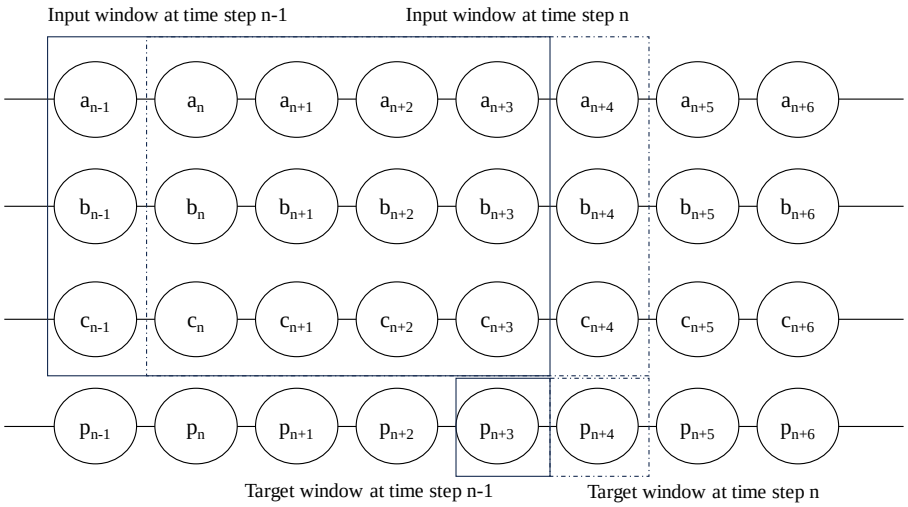

Figure 3: Diagram showing sliding window method

The length of the input sequence, I_s, is a hyperparameter that needs tuning. The ideal input size captures the most significant features of the data while providing the model with the temporal context necessary for accurate long-term predictions.

3.4 Splitting

Evaluating a model's performance requires testing it on unseen data. Typically, data is split into three sets: a training set, a validation set, and a test set. The training set is used for model training, the validation set for tuning hyperparameters, and the test set for evaluating performance on unseen data. Initially, only the train and test sets are necessary. Once the model achieves acceptable performance, a validation set can be introduced to further assess its generalization ability.

For time series data, it is crucial to split the data chronologically to ensure the model is not trained on future data, which could leak information and result in overfitting. This approach ensures the model learns to predict future trends based solely on past data, maintaining the integrity of the predictive process.

In summary, the data pipeline for this study involves careful preprocessing, including differencing, normalization, batching, and proper splitting, to prepare the data for LSTM network training. These steps are essential for ensuring the model can effectively learn and generalize from the historical data, leading to accurate predictions of reservoir pressure drops.

4. Long Short-Term Memory Neural Network Model

Long Short-Term Memory (LSTM) is a specialized architecture within the realm of Recurrent Neural Networks (RNNs), renowned for its ability to address the vanishing gradient problem, as outlined in Pattern (2006). RNNs are designed to handle sequential data by maintaining a hidden state that captures information about the sequence seen so far, effectively serving as a memory matrix. LSTMs enhance this capability by introducing a more sophisticated internal structure compared to standard RNNs.

From a high-level perspective, an LSTM network resembles an ordinary neural network, such as a Multi-Layer Perceptron (MLP), but each neuron is replaced with an LSTM cell, the fundamental building block of an LSTM model. Each LSTM cell contains internal mechanisms called gates that regulate the flow of information in and out of the cell, allowing it to remember or forget information over long periods. This gating mechanism includes three types of gates: the input gate, the forget gate, and the output gate. These gates control how much of the current input and the previous cell states should be updated, retained, or discarded, making LSTMs particularly well-suited for time series data where long-term dependencies are crucial.

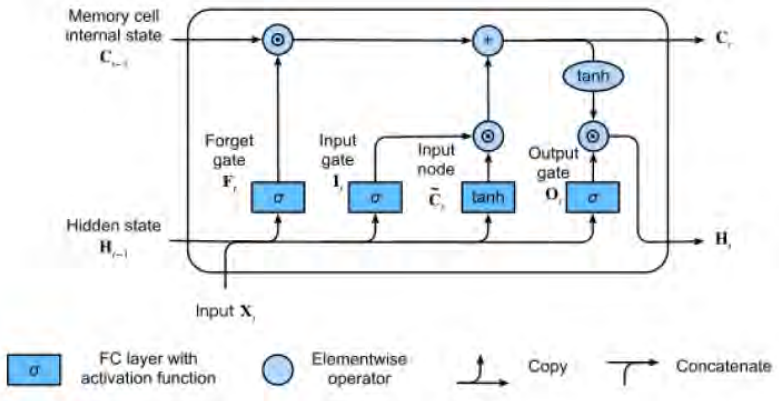

Figure 4: LSTM cell

The input to each LSTM cell at time step t is the concatenated values of the time series at that step, denoted as $x_t = [a_t, p_t, s_t]$, where a_t, p_t, and s_t are individual components of the input series as shown in Figure 4. Additionally, each cell receives the hidden state (h_{t-1}) and the cell state (C_{t-1}) from the previous time step. Each LSTM cell processes this information through its gates:

- Forget Gate: Determines which information from the cell state should be discarded.

- Input Gate: Decides which new information should be added to the cell state.

- Output Gate: Determines the output of the cell, which is based on the cell state.

The internal operations involve matrix multiplications and activation functions, which modulate the inputs through the gates, updating the hidden state and cell state accordingly. These updated states are then passed to the next cell in the sequence.

LSTM cells can be organized in different configurations. In single-layer configurations, cells are aligned horizontally, forming a single chain where the output of one cell becomes the input for the next. In stacked layer configurations, multiple layers of LSTM cells are stacked vertically, allowing the network to learn more complex representations of the input data. In these configurations, the hidden states ($h_i^{(k)}$) of the cells in different layers and time steps interact, with each cell in a layer having recurrent connections to itself over time.

The output from each LSTM cell can be extracted directly from the output gate and typically passes through a fully connected layer to match the desired output shape. This output can be used in

various ways, such as direct prediction for the current time step, as input to the next layer of cells in a layer-wise passing fashion, or for sequence generation tasks where future values in a sequence prediction task are generated.

While theoretically, a sufficiently complex MLP could model any function that an LSTM can, in practice, LSTM networks are more efficient for sequential data due to their recurrent structure and shared weights across time steps. This recurrent nature allows LSTMs to capture temporal dependencies more effectively, making them a preferred choice for tasks involving time series prediction, natural language processing, and other sequence-related applications.

In summary, LSTM networks provide a robust solution for modeling time series data. By leveraging their unique gating mechanisms, they can effectively learn long-term dependencies, address the vanishing gradient problem, and provide accurate predictions. Their architecture, combining hidden states and cell states, allows them to maintain and update information across time steps, making them particularly suitable for complex sequential data analysis.

5. Results

In this study, we employed Recurrent Neural Networks (RNNs), specifically Long Short-Term Memory (LSTM) networks, to predict steam production in water-dominant geothermal reservoirs affected by varying reinjection rates. The dataset used for training and validation encompassed 43 years of historical data, including variables such as reservoir pressure, water and steam flow rates, and reinjection rates. Our model aimed to capture the complex temporal dependencies and interactions within the data to provide accurate predictions of steam production.

The LSTM network was trained on 80% of the data and validated on the remaining 20%. The model's performance was evaluated using standard metrics such as Mean Squared Error (MSE) and Mean Absolute Error (MAE), and Table 1.1 shows the hyperparameters used for the prediction.

Table 1: RNN's model hyperparameters.

Parameter	Symbol	Value
Activation function	*A*	*Relu*
Training loss function	*MSE*	*MSE*
Input length	*I*	*16*
Hidden layers	*K*	*3*
Hidden layers size	*h*	*64*
Learning rate	α	$4\ 10^{4}$
Batch size	*B*	*64*
Number of epochs	*E*	*230*

Figure 5 shows the predicted steam pressure versus the actual values for the validation set. The close alignment of the predicted values with the actual values indicates that the LSTM model effectively captures the underlying patterns and temporal dependencies in the data.

Figure 5: Predicted vs actual steam pressure in a water dominated well.

A lumped parameter model was also set up for this research for the geothermal system in Iceland using the LUMPFIT program to predict the drawdown in the system. In lumped parameter models, two or more tanks are used to simulate the water capacity of the rock layers, and flow resistance is used to simulate their permeability. The models are calibrated based on pressure history and cumulative mass production. Lumped parameter models are much simpler than three-dimensional numerical models and are based on different assumptions. For instance, they do not consider the properties of individual rock layers and cannot simulate phase boundaries or thermal fronts. They are also not useful for determining well locations, such as for reinjection. However, for simple systems, they can be powerful for predicting drawdown trends based on estimated mass extraction.

In the lumped parameter model (LPM) for this research, data from the 3D reservoir model on pressure measurements and mass extraction from 1983 to 2019 were used to calibrate the LPM and calculate the drawdown prediction from 2019 to 2023. The best fit for the data was obtained using a 2-tank closed model. Although the LPM showed an adequate fit to the historic data, the results for the predicted pressure were more accurate using the RNN model, as shown in Figure 6.

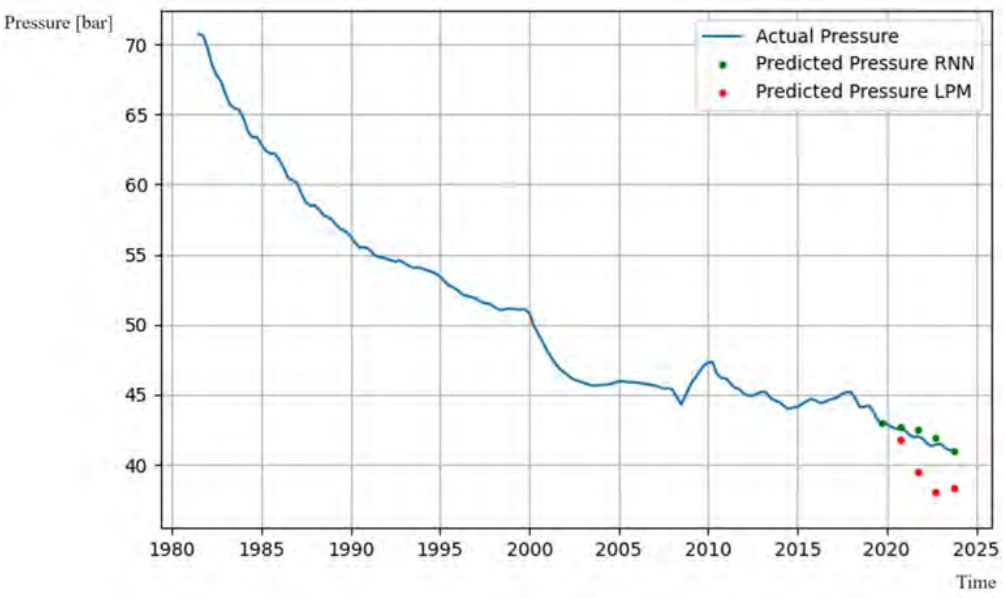

Figure 6: Predicted pressure drawdown using Lumped parameter model and RNN model.

The LPM does not have the capability of simulating the steam zone, only the liquid part of the reservoir. However, the RNN was trained for predicting the pressure drop in a steam dominated well. The fit to the measured stream pressure was good, as seen in Figure 7.

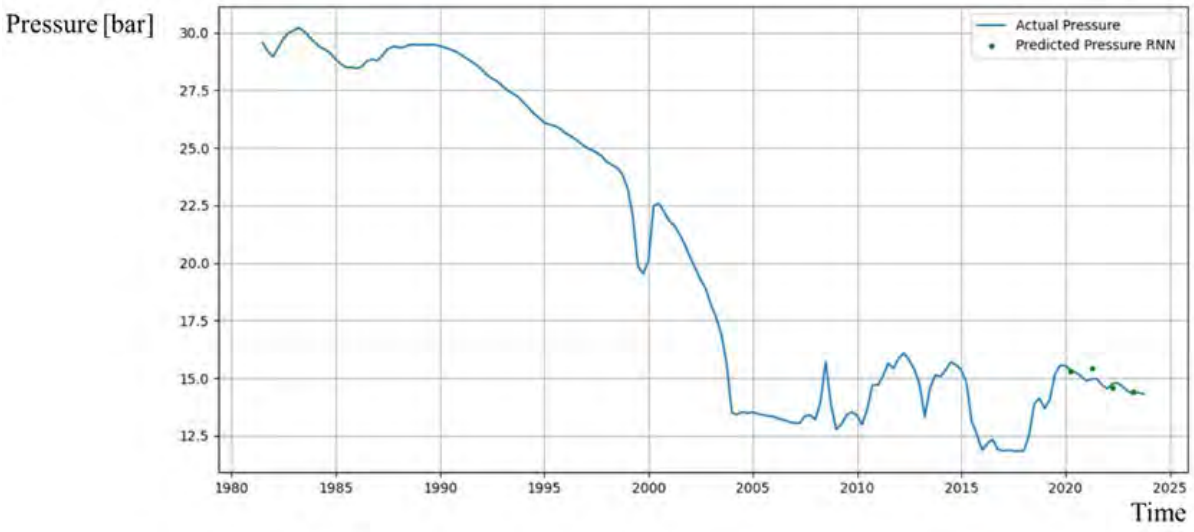

Figure 7: Predicted vs Actual Steam Pressure in steam dominated well

Overall, the LSTM model achieved an MSE of 0.002 and an MAE of 0.015 on the validation set, indicating high accuracy and reliability in steam production forecasting. The possibility of predicting the pressure in the steam zone is crucial to optimize injection strategies and ensuring long-term production from the steam wells.

6. Conclusions

This research demonstrates the efficacy of Long Short-Term Memory (LSTM) networks in predicting steam production in water-dominant geothermal reservoirs influenced by reinjection rates. The ability of LSTM models to capture long-term dependencies and complex temporal patterns makes them well-suited for this application.

The results indicate that the LSTM model provides accurate predictions, closely aligning with the actual steam production values and showing no significant bias. The model's robustness is further validated by its consistent performance across varying reinjection rates, underscoring its potential as a reliable tool for geothermal reservoir management.

The successful implementation of LSTM networks in this study opens up new avenues for predictive modeling in geothermal energy production. By providing accurate forecasts, these models can aid in optimizing operational strategies, enhancing the efficiency of resource utilization, and improving overall energy production management. Future work can explore integrating additional variables and using more advanced neural network architectures to further enhance prediction accuracy and model robustness.

In conclusion, LSTM networks represent a powerful and versatile approach for forecasting pressure drawdown in the steam zones of geothermal reservoirs, offering significant advantages over traditional methods. Their ability to handle complex, sequential data and adapt to varying operational conditions makes them an invaluable asset in the field of geothermal energy management.

Formation temperature, estimation, machine learning, neural networks, geothermal wells

ABSTRACT

This study looks at using artificial neural networks (ANNs) for estimating the static formation temperature (SFT) in geothermal wells. SFTs are conventionally estimated from temperature recovery data using some form of linear regression, such as the Horner method. However, there are a multitude of regression models to choose from, and the optimal one is not settled and may be situation specific. Moreover, commonly used linear regression methods, like the Horner method, require suitably long shut-in periods for their linearization assumptions to apply. As an alternative, machine learning methods have been considered previously to some extent for estimating SFTs. Nevertheless, the development of machine learning alternatives has been limited by available field data and especially accurate SFT data. In this study, we look at using ANNs for estimating the SFT in geothermal wells based on transient temperature recovery data. For training the ANNs, a large set of synthetic temperature recovery data was generated using a wellbore simulator called GEOTEMP2. The GEOTEMP2 simulations describe the temperature in a wellbore during drilling and the following recovery period after drilling. The developed ANN model was evaluated by comparing its estimation accuracy with the Horner method for synthetic validation data. On average, the ANN model provided SFT predictions of comparable quality to the standard Horner method.

1. Introduction

Accurate knowledge of static formation temperatures (SFTs) is important to ensure efficiency and safety when drilling wells in geothermal fields, as well as to determine whether development is possible (Sasaki, 1987). Furthermore, SFT estimates are used to understand the temperature distribution in geothermal fields and as reference data when calibrating geothermal reservoir models. SFTs can only be measured or estimated reliably by drilling wells and measuring temperatures down the wells. Logging equipment is lowered into the wellbore after drilling is completed or paused, and the formation temperature is determined based on temperature data

obtained from the logging. However, wellbore fluid circulation required during drilling shifts the wellbore temperature considerably below the formation temperature. Therefore, since it typically takes many days for the wellbore temperature to equilibrate with the surrounding formation temperature, multiple well logs are generally needed to understand how the wellbore temperature rebounds over time. Assuming negligible internal flow within the wellbore, the wellbore temperature can be expected to gradually rebound towards the SFT state that existed before drilling the well.

To estimate SFTs, analytical methods that are based on physical theory have been used in the past as well as simple empirical equations. The well-known Horner method is one of those methods that is commonly used in practice to estimate SFTs. The Horner method uses an approximate theoretical description of the thermal recovery of the temperature in the wellbore after the completion of drilling. The method requires an estimate of the time that fluid was circulated at the well depth of interest, and multiple bottom-hole temperatures measured at different times after shut in. Until now, the Horner method has been widely used for SFT estimation because of its simplicity, but this method requires sufficient shut-in time and an appropriate number of logging runs, which use up time and resources. A multitude of other SFT estimation methods have also been developed. However, it is not clear from the literature which methods should be preferred as the results appear to be generally inconclusive.

In response to these problems, this study proposes developing a new estimation method that applies machine learning as an alternative approach to SFT estimation. Previously, Bassam et al. (2010) developed an artificial neural network (ANN) model with one hidden layer to estimate SFTs. Their model used only three input values, including a bottom-hole temperature observation, the observation shut-in time, and an estimate of the derivative of the temperature with respect to time. A drawback of their neural network development approach was that the field data they used for training did not include reliable measurements for the SFTs. Because of that issue, they used multiple pre-existing SFT estimation methods to derive the reference SFT values used for training their neural network. Based on that, the training process could have been negatively impacted by inaccurate SFT training data.

As the Bassam et al. training procedure reflects, it is generally difficult to find reliable temperature data for training and validating SFT estimation methods. Therefore, the present study used a wellbore simulator to generate synthetic temperature recovery data to train neural networks. Differently to Bassam et al. (2010) we looked at developing deep neural networks containing multiple hidden layers to achieve better SFT estimates.

2. Methods

2.1 Horner Method

Figure 1 shows a schematic diagram of temperature recovery in a wellbore. The graph shows how the bottom-hole temperature is lowered when drilling fluid is circulated through the well. After fluid circulation ceases and the well is shut in, the well gradually warms up towards the SFT. As it can take a long time for the well temperature to equilibrate, the SFT is usually extrapolated from a series of well temperature logs recorded after shut in.

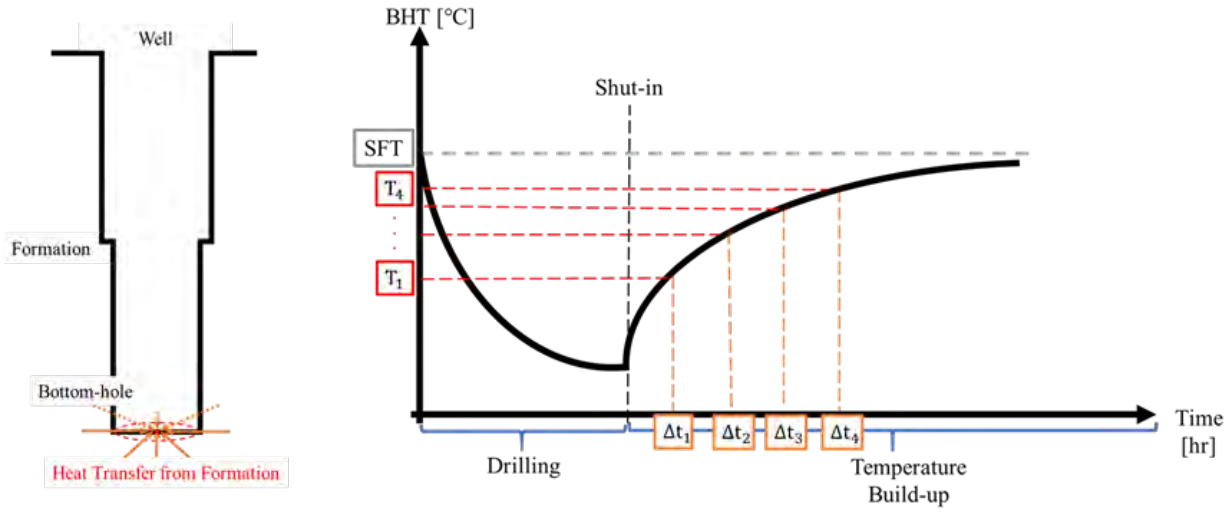

Figure 1: Recovery of bottom-hole temperature (BHT) after shutting in a well.

The Horner method has been widely used to estimate formation temperatures in geothermal wells. In the Horner approach, the SFT is estimated through linear regression by matching the following equation to the recorded temperature history.

$$T_{\mathrm{BHT}} = T_{\mathrm{SFT}} + m \times \log \frac{t_c + \Delta t}{\Delta t} \tag{1}$$

Here T_{BHT}, T_{SFT}, m, t_c, and Δt are the bottom-hole temperature, the SFT, slope, the fluid circulation time at bottom hole, and the elapsed time after shut in, respectively. The assumption is that the downhole temperature changes follow (1) when a sufficiently long time has elapsed.

The Horner plot equation (1) can be derived by describing the well as a line heat-sink drawing in a constant heat flux while the drilling fluid is circulating (see, e.g., (Kutasov and Eppelbaum, 2018)). However, that is a simplification of reality since the temperature conditions and heat flux across the well wall vary during operation. Similar simplifications have been used to derive various other analytical equations for SFT extrapolation. As a result, the applicability of those methods can be limited. Instead of using some of the standard analytical equations, we consider using ANNs to derive an empirical relationship between wellbore temperature recovery data and the SFT.

2.2 Neural Network Approach to SFT Estimation

2.2.1 Neural Network Architecture

This research aimed to develop an SFT estimation model using an ANN algorithm. The neural network model was developed using TensorFlow in Python. The ANN model in this study is a supervised learning model, in which the parameters of the model were adjusted so that it can estimate SFT values by learning hidden relationships between the ANN input data and the SFT values to be estimated.

Figure 2 shows a diagram of the multi-layered feed-forward neural network model developed in this study. The figure shows that the neural network outputs an SFT prediction based on nine model inputs: the circulation time, four observation times, and four corresponding bottom-hole

temperature observations. Figure 1 provides an example illustration of the four pairs of observation times (Δt_i) and temperatures (T_i) that are used as model inputs. In practice, available logging data can be limited and SFT estimation is sometimes carried out based on as few as three or even (with difficulty) two temperature observations. For reliability, however, we suspect that at least four observations might be needed to reveal useful information about the nonlinearity of the temperature transient. The number of temperature inputs were chosen based on that expectation and for the purpose of generating a simple neural network algorithm that would be applicable to cases with observations from only a few well logging runs.

A linear activation function was applied after the output layer of the model and a ReLU (rectified linear unit) activation function was used between all the layers. The number of nodes and hidden layers are not specified in Figure 2 since we tested out different combinations to optimize the ANN design. However, the tested neural networks were constructed with an equal number of nodes in each hidden layer. The following section describes the optimization of the network design.

2.2.2 Optimization of the Neural Network

To optimize the ANN model structure, we trained multiple neural networks using different combinations of layer and node numbers. Those hyperparameters were optimized using simple grid search with the number of hidden layers varied from one to five, and the number of nodes (neurons) in a layer varied from ten to a hundred at intervals of five nodes. The RMSProp (Root Mean Square Propagation) optimization algorithm was used to fit each ANN model to the training data. We chose to minimize the mean squared error (MSE) of the match to the SFT training data while monitoring the MSE of the SFT test data for early stopping. Each optimization run was stopped when the test MSE did not improve for 500 consecutive epochs. The maximum number of epochs was set to 5,000. The combination of network weights, biases, and hyperparameters (number of nodes and layers) that resulted in the lowest mean absolute error for the test data was adopted for the final ANN model. The final model obtained through this optimization process was a network with 3 hidden layers and 30 neurons in each layer. This model was subsequently tested on validation data to check its prediction performance.

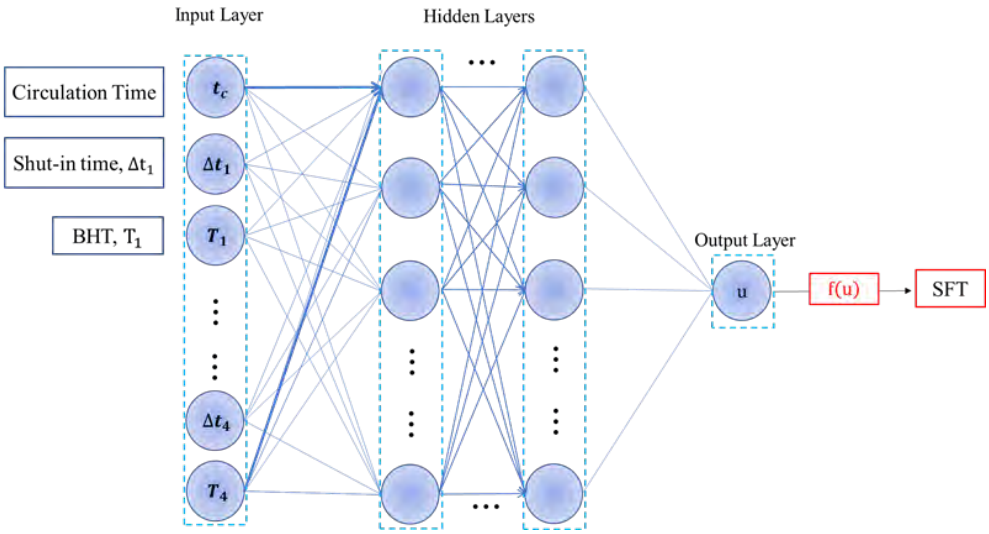

Figure 2: Conceptual diagram of the neural network used in this study.

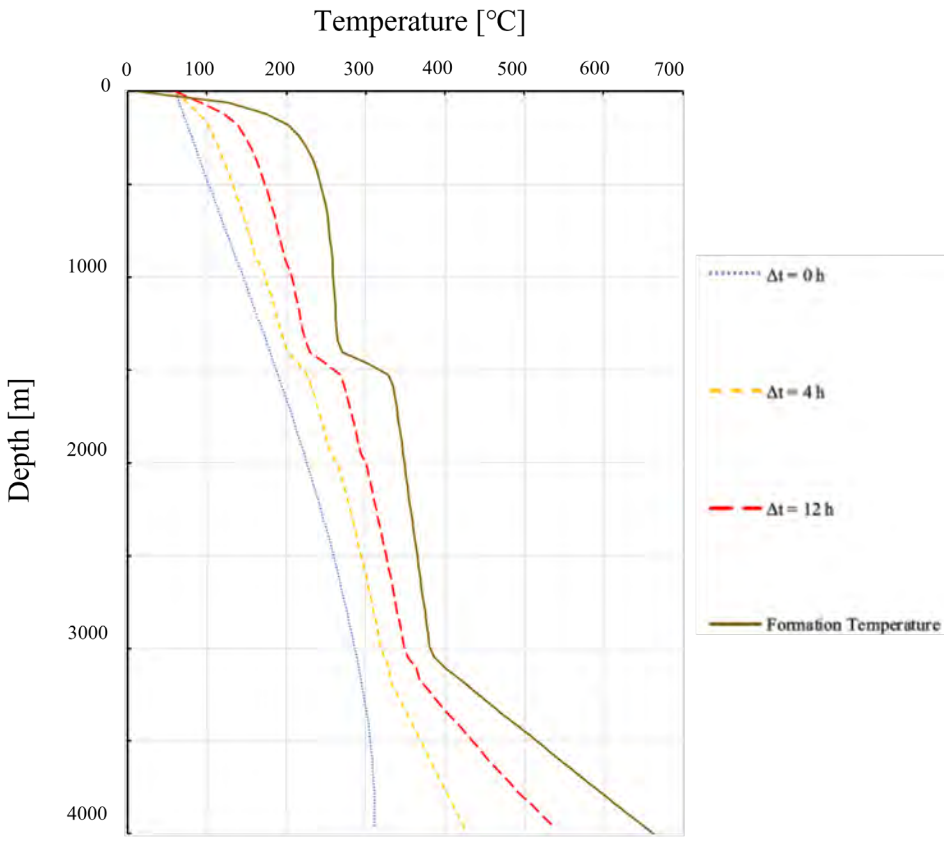

Figure 3: Example GEOTEMP2 simulation results for temperature recovery in a wellbore. Shut in is at $\Delta t = 0$. The static formation temperature shown is based on well WD-1a in the Kakkonda geothermal field, Japan.

2.3 Training Data

2.3.1 Creation of Training Data Using the GEOTEMP2 Well Simulator

The training data used to train the SFT estimation model was generated using a wellbore temperature simulation program called GEOTEMP2 developed at Sandia National Laboratories in the U.S. (Mondy et al., 1984). We used the simulator to model thermal transport within the wellbore for both the drilling period where the well is cooled by drilling fluid circulation and the warmup period when the well is shut in. GEOTEMP2 numerically solves the temperature distribution in a wellbore using a finite volume method for the heat transfer between the downhole fluids and rock formations surrounding the wellbore.

We note that the simulator describes thermal transport caused by both convection and conduction within the wellbore. However, the heat transport within the formation is limited to conduction. As a result, neural networks developed based on the GEOTEMP2 simulations are expected to be mainly applicable for conduction dominated formations.

Figure 3 shows examples of GEOTEMP2 simulated temperature profiles for a well warming up after halting fluid circulation. In this study, GEOTEMP2 was used to assemble a dataset containing multiple series of bottom-hole temperature recovery data. In total, we generated 20,000 instances of thermal recovery data from wellbore simulations. That dataset was used to develop the presented

neural network with 70% of the dataset used as training data and the remaining 30% of the data used as test data. Distinct data series were generated by randomly allocating the formation temperature and well operation conditions.

2.3.2 Range of Input Values for Well Simulations

The performance of a machine learning model depends largely on the quantity and quality of the training data used for the model development. In particular, the ANN generalization ability is expected to be improved by using data obtained from a variety of cases. Therefore, we diversified the training data by randomly allocating input values for the GEOTEMP2 simulations. Variable drilling parameters include the target drilling depth, the fluid circulation time (t_c) after reaching the target depth, and the fluid circulation rate. The target drilling depth varied between 100 and 4,000 m, while the drilling rate was set to a constant 50 m/day for all simulations. Similar drilling rates can be expected for typical geothermal wells. In fact, according to Ong'au (2012), the average drilling rate for wells in Kenya and Iceland is around 50 m/day. The circulation time was allowed to range from 2 to 48 hours, and the flow rate was randomly set to a value between 1,000 and 4,000 L/min (see, e.g., (Ajima et al., 2023; Ishikawa and Naganawa, 2022)).

The drilling fluid was assumed to be injected down the drill string from the surface at a constant temperature of 30°C. In addition, the formation temperature conditions were randomly assigned for each simulation. For simplicity, the temperature with depth profile was assumed to be linear. Thus, we only varied the temperature gradient and the ground surface temperature. This was achieved by randomly varying the surface temperature between 5 and 30°C, and the temperature at a 4 km depth was allowed to range between 100 and 800°C (Figure 4). Note that this SFT-depth profile assumption does not cover all field conditions since actual underground temperature profiles are often nonlinear—influenced by geological structures and groundwater flow. The thermal conductivity of the reservoir formation used in all cases the default value of 1.73 W/m·K in GEOTEMP2. However, we plan to vary the formation thermal conductivity in future work.

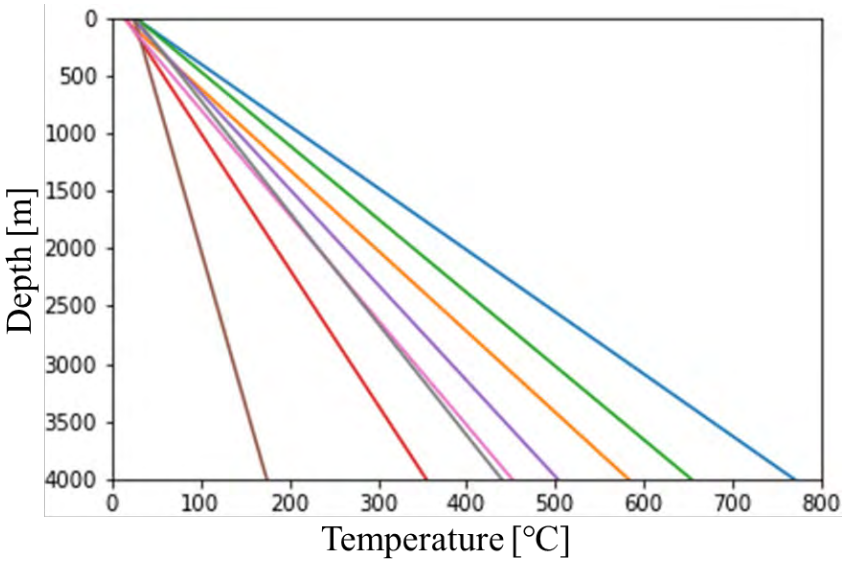

Figure 4: Example formation temperature gradients used for generating training data.

For the temperature observations, the constructed ANN model assumes that data from four logging runs are available. When generating the training dataset, the fourth observation time, Δt_4, was randomly varied from 10 to 250 hours, and the values for Δt_1 to Δt_3 were randomly selected within the range from one to Δt_4 hours. The temperature data obtained at those observation times was used as input into data for training the ANN model. The range of observation times was set to encompass the validation data used in this study.

2.4 Validation Data

The accuracy of the developed ANN static formation temperature estimation model was evaluated using data that is independent of the training data. In this study, the validation data includes synthetic data based on well WD-1a, a super-hot geothermal well drilled in the Kakkonda area of Iwate prefecture, Japan (Ikeuchi et al., 1998). The Kakkonda validation data was generated using the GEOTEMP2 simulator. However, unlike the formation temperature profiles used for training, the shallow Kakkonda temperature profile is characteristic of a convective, high-temperature geothermal field (Figure 3).

Table 1: Synthetic Kakkonda validation data for different bottom-hole depths.

2,000 m Depth		3,000 m Depth		3,700 m Depth		4,000 m Depth	
T_{SFT} = 349.3℃		T_{SFT} = 380.6℃		T_{SFT} = 580℃		T_{SFT} = 670℃	
Δt [h]	T_{BHT} [℃]	Δt [h]	T_{BHT} [℃]	Δt [h]	T_{BHT} [℃]	Δt [h]	T_{BHT} [℃]
46	304.7	5.2	295.8	73.1	561	70.5	647.9
64.3	310.9	24	353.7	75.7	561.5	78.8	649.7
74.7	313.77	113.4	368.9	145.1	568.1	104.9	653.2
86.3	316.33	163.4	371.4	180.6	569.8	132.1	655.7

Table 2: Validation data from the literature (Bassam et al., 2010).

Shen and Beck (1986)		Cao et al. (1988)		Iglesias et al. (1995)		Steingrimsson and Gudmundsson (2006)	
T_{SFT} = 80°C t_c = 5 h		T_{SFT} = 120°C t_c = 5 h		T_{SFT} = 169°C t_c = 5 h		T_{SFT} = 240°C t_c = 2.5 h	
Δt [h]	T_{BHT} [℃]	Δt [h]	T_{BHT} [℃]	Δt [h]	T_{BHT} [℃]	Δt [h]	T_{BHT} [℃]
15	69.6	24	115.8	12	94	30	125
20	71.7	30	117.1	26.57	122	52	158
30	74.1	40	118.4	47.1	139	96	184
40	75.5	50	119.1	95.27	152	242	218

Table 1 summarizes the temperature recovery data generated using GEOTEMP2 based on the temperature profile of well WD-1a in Kakkonda. The fluid circulation time was commonly set to 48 hours for the cooling operation after the target drilling depth was reached, and the simulations were run for four different bottom-hole depth cases. The flow rate was set to 2,000 L/min for all four cases.

Moreover, we also considered validation data used previously by Bassam et al. (2010). Table 2 summarizes this additional validation data. It includes synthetic warmup data reported by Shen and Beck (1986) and Cao et al. (1988). Those datasets have known SFT values that are useful for validation. For real geothermal field examples, we considered well tests reported by Iglesias et al. (1995) for well CH-A in El Salvador and Steingrimsson and Gudmundsson (2006) for well KJ-21 in Iceland. The values reported in Table 2 for those two wells are taken directly from (Bassam et al., 2010). We note, however, that we have not been able to confirm the reliability of those reference values and we consider that the reference SFT values reflect plausible values.

For the datasets taken from the literature, we selected the last four reported temperature observations. An exception is the data from well KJ-21 reported by Steingrimsson and Gudmundsson (2006). For well KJ-21, we ignored data recorded at 556 hours of shut in.

3. Results

The newly developed ANN model was evaluated using the validation data presented in Tables 1 and 2. Figure 5 shows the results of SFT estimation using the newly developed ANN model and the Horner method. The SFT estimates are compared against the reference SFT values for the validation data. The straight line drawn in the figure has a slope of 1, indicating that the closer the data points are to the straight line, the smaller the estimation error. The figure shows for both the ANN model and the Horner method that the estimation errors are within or close to ±5% for all validation data.

Table 3 summarizes the results of Figure 5 in more detail. From left to right, there are the reference SFT values for the test data, the estimated values by the ANN model, the estimated values by the Horner method, the deviation (error) between the ANN model and the reference (true) values, and the deviation (error) between the Horner method and the reference (true) values. The maximum estimation errors of the ANN model and Horner method for all validation data are respectively 8.0% and 6.8%. The average error is 3.2% for the ANN model and 2.7% for the Horner method. The ANN approach, therefore, performed nearly as well as the standard Horner method for the presented test cases.

The maximum estimation error of the ANN model is 0.6% for the Kakkonda synthetic data, which assumes a super-hot geothermal well. This indicates that the developed model can estimate formation temperatures above 400°C, which is considered to be in the high-temperature range, with good accuracy. On the other hand, the ANN approach showed larger errors for the low-temperature data, with a particularly high error for the synthetic dataset from Shen and Beck (1986). The error for the Cao et al. (1988) synthetic dataset is surprisingly high considering that the last temperature observation is within 1% of the true SFT. The Horner method gave considerably better estimates for those two datasets. However, the ANN model markedly outperformed the Horner method for the Kakkonda data. These results suggest that there might be

some features in the Shen and Beck, and Cao et al. datasets that are not reflected in the training dataset. This aspect needs to be explored further in future work.

The ANN estimates for the two geothermal wells (CH-A and KJ-21) appear to be plausible, which is an encouraging result considering that the field measurements are affected by measurement errors. Furthermore, the temperatures in those wells are affected by fluid flow through the surrounding formations, unlike the temperature simulations that generated the training data. Therefore, the ANN approach could potentially be robust to measurement errors and some conceptual differences between the heat transport governing the training data and field data.

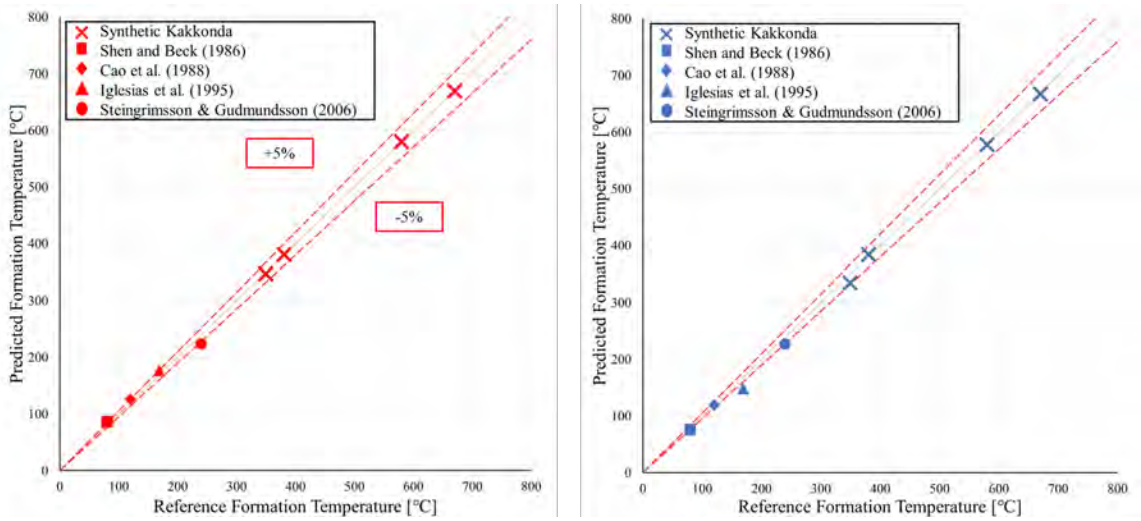

Figure 5: Comparison between reference static formation temperature data and estimated values using the developed ANN model (Left) and the Horner method (Right). The solid diagonal line indicates perfect agreement, while the red dashed lines signify errors of 5%.

Table 3: Results for estimated static formation temperature (SFT).

		Estimated SFT [°C]		Estimation error [%]	
	Reference SFT [°C]	ANN model	Horner method	ANN model	Horner method
Kakkonda 4 km	670	669.7	667.1	0.0	0.4
Kakkonda 3.7 km	580	580.0	577.5	0.0	0.4
Kakkonda 3 km	380.6	380.6	384.1	0.0	0.9
Kakkonda 2 km	349.3	347.3	334.6	0.6	4.2
Steingrimsson and Gudmundsson	240	223.5	223.59	6.9	6.8
Iglesias et al.	169	177.0	158.93	4.7	6.0
Cao et al.	120	126.3	122.5	5.3	2.1
Shen and Beck	80	86.4	79.5	8.0	0.6

4. Conclusions

In this study, we aimed to develop a new method for estimating the SFT in geothermal wells using an ANN algorithm. The neural network method estimates the SFT from transient temperature recovery data recorded while the well warms up after halting fluid circulation. The neural network was trained using a synthetic temperature recovery dataset generated using a wellbore simulator that describes temperature changes caused by fluid circulation during drilling and the following warmup period after the well is shut in.

The ANN estimation errors were found to be within 1% for synthetic validation data generated using the same wellbore simulator as was used to create the training data. However, the ANN errors were around 5–8% for synthetic validation data reported elsewhere in the literature. Moreover, when applied to field data from two geothermal wells influenced by natural convection, the ANN predictions deviated by about 5–7% from the expected reference values. On average, the performance of the ANN approach was similar to the standard Horner plot method. The Horner method resulted in an average percentage error of 2.7% while the average was 3.2% for the ANN approach. A more detailed comparison shows that the ANN method outperformed the Horner method for synthetic datasets generated using the GEOTEMP2 wellbore simulator used in this study. For the synthetic GEOTEMP2 validation data, the average error was 0.2% and 1.5% for the ANN approach and the Horner method, respectively. The ANN errors were noticeably worse for synthetic validation data generated by other means in the literature. This indicates that the data used to train the ANN model may lack relevant features and there is room to improve the training dataset.

Although additional testing is needed, these results indicate that this machine learning approach holds promise for estimating SFTs in geothermal wells. However, improvements are needed to make the presented ANN approach widely applicable. Future work should consider extending the training dataset and other ways of improving the optimization of the ANN model parameters and possible enhancements of the model architecture. The neural network presented here uses a fixed number of temperature inputs. In future work, it may therefore be worth considering extending this approach to allow more flexibility in the number of inputs. Furthermore, we are interested in exploring the potential advantages of this approach for short observation histories for which traditional methods, such as the Horner method, usually fail to deliver good predictions. We also think it is necessary to examine more field data for validation purposes.

ABSTRACT

The Department of Energy's (DOE's) Geothermal Data Repository (GDR) has implemented improvements to both its data lakes and its data standards and automated data pipelines. The GDR data lakes have reduced storage and compute-related barriers to using large geothermal datasets, enabling these large datasets to be accessed by anyone with a modern computer and internet access. More recently, the GDR has been working to further reduce barriers through streamlining the data intake process, educating users on the process and requirements, and helping users access data from the data lakes. These improvements have augmented the quantity of datasets the GDR is able to accept into its data lakes and have enabled users who are new to cloud tools to access these datasets more easily, overall increasing the accessibility of big geothermal data for use in machine learning and other projects. In addition, the GDR now has built-in data standards and pipelines for drilling data, geospatial data, and distributed acoustic sensing (DAS) data. These standardization efforts aim to enhance the real-world applicability of geothermal machine learning outcomes by improving the quality of training data. Specifically, through standardizing high-value datasets, the GDR is reducing project-specific data curation requirements, thus allowing more time for actual research. By automating this process, the burden of standardization is lifted from the user, ultimately increasing the availability of standardized data.

This paper provides an update on recent improvements made to the GDR's data lakes and automated data pipelines, including: (1) streamlining the data lake intake process, (2) better educating users on the process and requirements through a new data lakes page, (3) adding data lake direct access links to GDR data lake submission pages, (4) implementing a DAS data pipeline to convert DAS data uploaded in SEG-Y format to a standardized hierarchical data format v5 (HDF5), (5) extending this pipeline to encompass data in the GDR data lake, (6) adding metadata

requirements for geospatial data, (7) making user interface/user experience (UX) enhancements to the data pipelines' documentation pages, and (8) improving the GDR's data standards and pipelines pages to better guide users in ensuring that their data is standardized by the GDR's automated data pipelines.

1. Introduction

The U.S. Department of Energy's (DOE's) Geothermal Data Repository (GDR) serves as the repository and catalog for data generated by projects funded by the DOE Geothermal Technologies Office (GTO) (Weers et al. 2022). The GDR provides public access to geothermal datasets, which are consistently increasing in variety, size, and complexity. These datasets are becoming increasingly valuable for geothermal machine learning projects. To accommodate this, the GDR is improving its data lakes, implementing new robust data standards, and refining its data pipelines (Taverna et al. 2023(a,b), Weers et al. 2021). Additionally, improvements in user experience (UX) aim to make submitting, accessing, and utilizing datasets more convenient and efficient for researchers. These efforts collectively ensure that the GDR remains a crucial resource for advancing geothermal machine learning and data science projects.

1.1 GDR Data Lakes

As research datasets increase in size, the classic access model of downloading a dataset to a local compute resource becomes less feasible and can result in barriers to access and inefficiencies. Data lakes are a modern approach to data storage and access that provide a solution to these challenges. In the data lake model, especially large or complex (i.e., hierarchical) datasets are housed in a central, public-facing, cloud-based data store (Weers et al. 2021). The GDR data lakes not only enable users to parse or access data without needing to download the full dataset, but they also allow submitters to upload data without needing to rely on the traditional method of uploading data to the GDR submission form. Cloud-based data lakes have made big GDR data accessible to anyone with cloud access, eliminating the need for collaborators to have their own high-performance computing and big data storage solutions (Weers et al. 2021).

The GDR data lakes are currently home to more than 700 TB of public data, including distributed acoustic sensing (DAS), big geospatial data, raw magnetotellurics binary files, and more. Hosting the GDR's big data in the GDR's data lakes has greatly improved accessibility of these datasets and therefore the potential to use them in machine learning and data science workflows. Despite this, there have been challenges surrounding user understanding of data lake access, the data lake intake process, and data lake submission requirements. We have attempted to mitigate some of these challenges through streamlining the dataset intake process, better educating users on the process and requirements, and providing tools on the GDR submission page to ease access of GDR data lake data.

1.2 Data Standardization and Automated Data Pipelines

High-quality data is another key component of machine learning applications. High-quality geothermal datasets are characterized by reliable sensors or devices, frequent measurements, sufficient data points, comprehensive metadata, secure data storage, and effective data curation. Another aspect contributing to data quality is reusability, which can be improved through standardization. Standardizing data ensures consistency in formatting and content across similar

datasets, reducing preprocessing requirements and ensuring that the dataset provides adequate information (Taverna et al. 2023(b)). Currently, the GDR has developed data standards for drilling data in its most common formats (Taverna et al. 2023(a)), DAS data in SEG-Y format (Taverna et al. 2023(b)) using PRODML (PRODML Work Group 2022) and the DAS RCN's metadata standard (IRIS DAS RCN Metadata Working Group 2022), and geospatial metadata. Each standard has an associated page on the GDR to provide additional information on how the standards work. These pages have recently undergone a UX review to improve their usability and accessibility.

The GDR has begun implementing automated data pipelines for certain high-value data types in order to take the burden of data standardization off of the user and ensure that the benefits of data standardization are felt more widely across the GDR (Taverna et al. 2023(b)). These data pipelines align with the data standards. The GDR previously only had one automated data pipeline for drilling data (Taverna et al. 2023(a)) but has since expanded this to include DAS and geospatial data.

2. Streamlining the Data Lake Intake Process

Previously, the GDR data lake submission process was characterized by a lack of consistency, with only a few individuals possessing partial knowledge of the process, confusing conditional and inconsistent requirements, and a heavy reliance on ad hoc communication from curators. This resulted in a lack of standardization in UX and requirements, as well as an outward lack of clarity on how long the process takes and what it entails. The GDR has worked to remedy this problem through streamlining the data lake submission process.

As a reminder, regular datasets should be submitted as normal via the GDR submission form. However, especially large or complex datasets should follow these steps, which are also condensed into the graphic in Figure 1:

1. Create a GDR catalog entry with associated metadata and supporting files. Supporting files may include related publications, readme files, GitHub repositories, a few sample files, or any other information that may help to give context to our curators. Do not try to upload the entire dataset to the submission form. Instead, contact our curation team at GDRHelp@ee.doe.gov and request a data lake resource.
2. Assist GDR curators with public datasets program application requirements. Some data lake datasets may be eligible for free hosting and/or registration in the data catalogs of our cloud partners, such as the Amazon Sustainability Data Initiative. This may include filling out an additional questionnaire to justify the value of your dataset, helping to create a tutorial Jupyter notebook with examples for accessing and using the data, and providing any additional requested resource metadata.
3. Wait to hear back about approval from third-party public datasets programs. The review process is currently quarterly, so please be patient and plan on a few months for this step.
4. Assist data curators with the data transfer process either by making the data available via Globus, FTP, Google drive, or another web-based file-sharing service or by moving the data directly into our staging bucket.
5. When the data have been properly staged and organized, the GDR curation team will ask you to review the data one more time for organization, naming, and completeness. Data will be considered permanent and final after this step unless stated otherwise.

6. Assist curators with any final metadata tweaks. If you are publishing a journal article related to the data, share a preprint with the GDR Team and follow up when the article is published.

Please note that the GDR does not validate or peer review datasets. **All data should be finalized, validated, and peer reviewed by the project team prior to submission to the GDR.** Datasets published to the GDR are considered scientific records, and their data resources are expected to remain unchanged in the same location permanently. Incremental additions can be easily added to existing datasets, including the addition of new versions of previously published data. However, publishing changes to existing data or other major updates to datasets—including data in data lakes—often requires creating an entirely new version of the dataset.

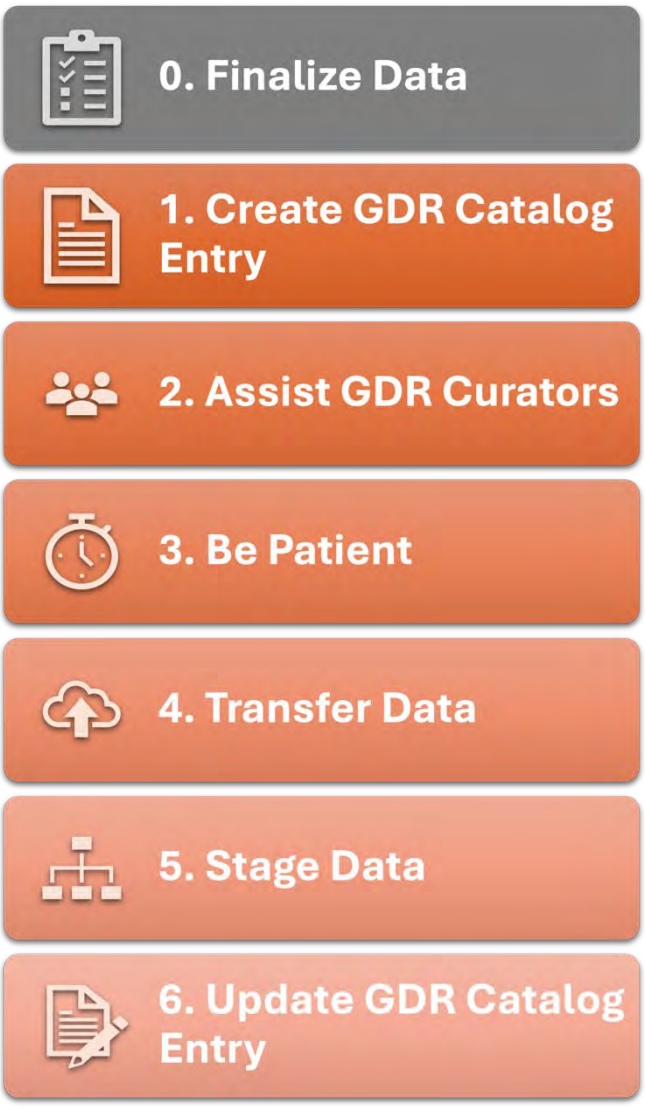

Figure 1: Graphical representation of the streamlined data lake intake process.

This new streamlined process standardizes the UX and makes the intake process more efficient. This has been evident in our ability to scale up data lake data intake to meet the growing demands

of big geothermal data storage. The 475 TB of DAS data currently available through the GDR is a great example of this achievement.

3. User Education and Support

In addition to lacking consistency, the data lake intake process has also lacked transparency. User feedback has relayed that there is a lack of understanding surrounding the submission requirements, the submission timeline, and the GDR's data posterity requirements. To mitigate this issue, the GDR has decided to focus on more proactive education and support. This has included creating a new page on the GDR to describe the data lake intake process in detail, including the graphic in Figure 1, along with more in-depth information about what to expect during the data lake intake process. This has also included work to publish and present on these requirements—including this paper. These steps allow the GDR to clearly communicate the requirements and expectations to potential submitters prior to initiating the submission process.

The impact of this proactive education approach has been observed through an overall decrease in requests that conflict with our policies, an improvement in organization of new submissions, and a reduction in proliferation of largely duplicative versions of data in our data lakes. These factors combined result in higher quality data lake submissions overall.

4. Direct Access Links for Data Lake Data

Users have frequently asked questions surrounding how to efficiently access data from GDR data lakes. In order to make this information more readily discoverable, the GDR has added direct access links to the submission form for data lake resources. These direct access links allow users to easily copy and paste access commands for accessing the data using the Amazon Web Service Command Line Interface (AWS CLI). An example of a direct access link is shown in Figure 2.

Figure 2: Example of a direct access link associated with a GDR data lake resource. Users can use the icon to the right to quickly copy the command so that they may paste it into their terminal for AWS CLI access to the data.

Additionally, the GDR has listed multiple ways to interact with data in data lakes on the Data Lakes page, accessible from the Data drop-down at the top of every page. This list, complete with examples, illustrates how to access GDR data through:

- Jupyter notebooks
- Native cloud query engines like Athena (AWS) and Google Earth Engine
- Native cloud access direct to the public data lakes
- The GDR Data Lake Viewer, a simple user interface that allows users to explore data lakes through their web browser

- Native cloud command line tools, such as the AWS CLI example above
- Mounting the data as a local read-only drive in a cloud-built computer cluster (requires a cloud account in the same availability zone as the data lake.)

5. Implementation of DAS Data Pipeline

To maximize the utility of the large quantity of DAS data stored in the GDR, a data pipeline has been implemented to convert DAS data in nonstandard SEG-Y format to a standardized hierarchical data format (HDF5). The data standard combines aspects of the PRODML raw DAS data format (PRODML Work Group 2022) with the DAS RCN Metadata Working Group's metadata standard (IRIS DAS RCN Metadata Working Group 2022).

This hybridized approach is described in Figure 3 and is described in more detail in Taverna et al. 2023(b). The file structure is hierarchical, broken into two main groups: one for raw DAS data, and one for DAS metadata. The DAS raw data group includes two datasets—one containing a time array, and another containing a raw data array. The metadata group includes two types of subgroups: one for each cable's metadata that contains subgroups for each fiber's metadata, and one for each interrogator's metadata, which is further broken down into acquisition and channel-specific metadata. While the DAS RCN recommends that metadata be stored in a separate JSON file, the GDR standard attempts to store as much of it as possible within the HDF5 file to keep the metadata packaged with the data. Channel location information, however, is stored in a separate channel map file to allow for simplified updates.

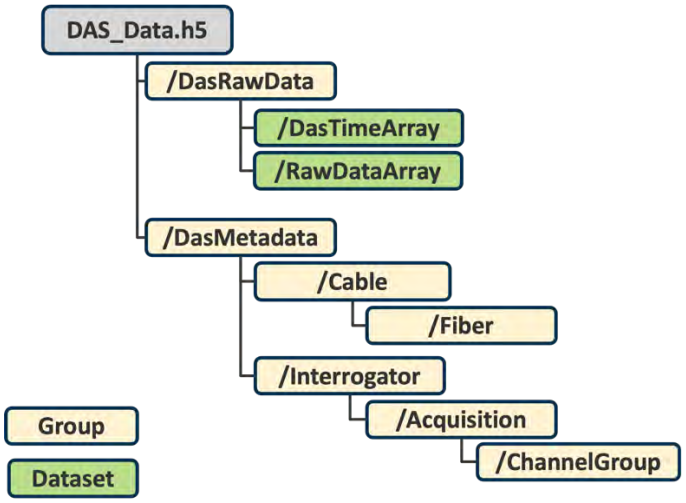

Figure 3: GDR DAS data standard file structure. The GDR standard is HDF5-based, combining aspects of the PRODML format with the DAS RCN Metadata Working Group's metadata standard.

The DAS data pipeline generally operates as described in Figure 4. Metadata are stored in three main locations within a SEG-Y file: The text header, trace header, and binary headers. Because metadata in the text header are not standardized by nature, fuzzy matching is used to identify keywords in the text header, and these keywords are used to extract desired information. Metadata are standardized by nature in the trace and binary headers, so direct translation may be used to extract this information. Extracted metadata are then stored in the associated attributes of an HDF5 file's groups and datasets. This pipeline is not fully automated yet because of the massiveness of

DAS datasets, the diverse ways that GDR DAS datasets are organized, and the frequently incomplete DAS metadata packages.

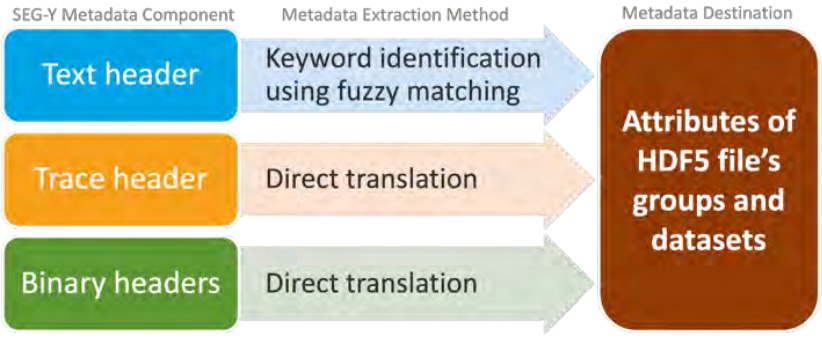

Figure 4: Graphic depicting the general process followed by the DAS data pipeline. Metadata are extracted using a combination of direct translation and fuzzy matching and stored in the associated attributes of the standardized HDF5 file's groups and datasets.

While we are retroactively applying this data pipeline to existing DAS datasets in the GDR, many of these existing datasets have incomplete metadata packages. This is because the most common GDR DAS data format, SEG-Y, is a file format intended for conventional seismic data, not DAS data, meaning that it is not compatible with all of the metadata required for robust DAS data analysis. On top of that, there was no universally agreed on DAS metadata standard until the recent work of the DAS RCN Metadata Working Group (2022). In an attempt to maximize the amount of metadata added to the standardized DAS data files, a metadata template was created to allow data owners to provide additional metadata. GDR curators are actively reaching out to legacy DAS data owners requesting additional metadata via this form.

At the time of this publication, 16.5% of the approximately 287 TB of DAS data in the GDR has been standardized using this method. The remaining data are in formats (non-standardized HDF5, TDMS, and zipped directories) that are not yet compatible with our data pipeline. Future work will investigate the merit of adapting our pipeline to additionally standardize one or more of these formats.

6. Extension of Data Pipelines for GDR Data Lake

The DAS data pipeline is the first to be adapted to work for data in the GDR data lakes. Because DAS data are often on the order of tens of terabytes in size (Trainor-Guitton et al. 2022), they are almost exclusively stored in the GDR data lakes. This means that, in order to be of maximum utility, the data pipeline needed to be adapted to work on data in the data lakes. This necessitated adjustment of the data detector script to detect DAS data files in specific directories in the cloud as opposed to on the GDR servers.

This adaptation will streamline the development of future data pipelines that are compatible with big data in the data lake, which is arguably where data standardization provides the most value. Big datasets require more time-consuming data curation; therefore, standardization of big data results in more significant time savings through reducing the curation requirements (Taverna et al. 2023(a)).

7. Added Metadata Requirements for Geospatial Data

Current storage models often lack the necessary metadata for enabling thorough analyses and reproducibility. Consequently, GDR submissions of geospatial data from GIS nonexperts have frequently lacked complete geospatial metadata (Taverna et al. 2023(b)). To address this problem, a comprehensive review was conducted of proper metadata to be archived alongside geospatial datasets (Taverna et al. 2023(b)). It was decided that the most crucial piece of geospatial metadata is the coordinate reference system (CRS), and hence a required input for CRS has been added to the resource-specific metadata for files with geospatial file extensions (Figure 5). This required input ensures that the CRS is added for every geospatial data file added to the GDR and recommends additional CRS-specific metadata to add to the resource description.

Beyond the CRS, the GDR geospatial metadata standard provides suggestions of which other geospatial metadata is useful to include in your GDR submission, and where to include it in the GDR submission form. These suggestions may be found in Taverna et al. 2023(b) or on the GDR's new geospatial data standard page: https://gdr.openei.org/geospatial_data_standard. The GDR has already seen an improvement in the quality of its geospatial datasets in the short time since this standard and the additional required input have been implemented.

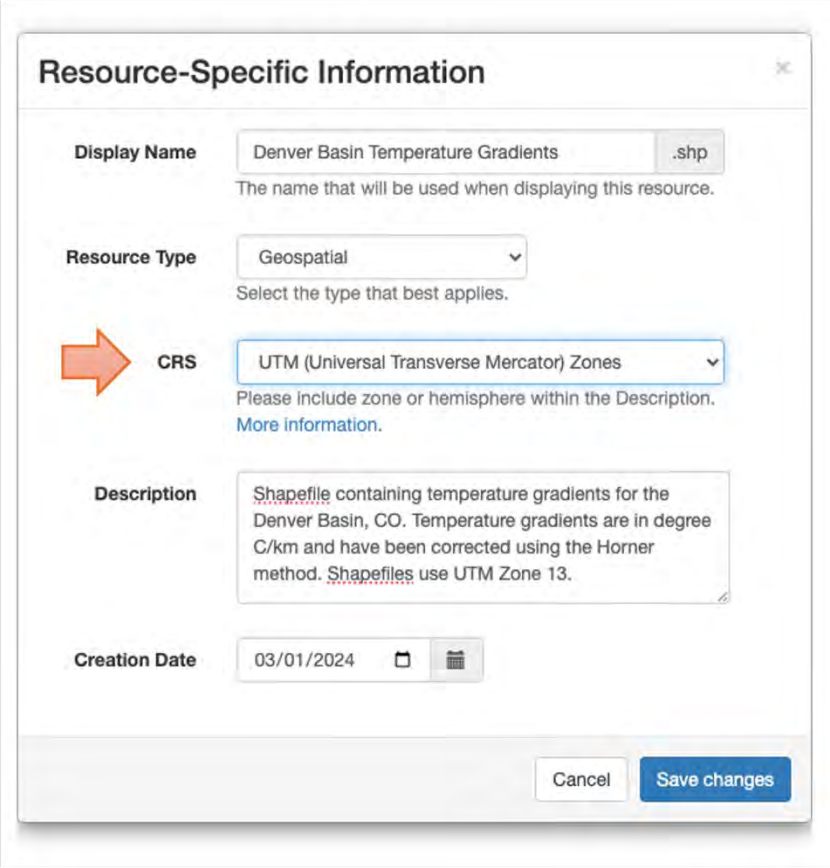

Figure 5: Image of new CRS requirement for geospatial data files uploaded to the GDR. Note the additional CRS-specific metadata suggestion that appears below the CRS field.

8. UX Enhancements

In order to improve the UX associated with the GDR data standards and pipelines, a UX review was conducted on the existing GDR data standard and pipeline pages. This heuristic review primarily focused on the following user-centric design principles: user needs and goals, accessibility, simplicity and clarity, responsive design, feedback and performance, and trust and credibility. This was achieved through revisiting the GDR's data standard and pipeline pages, identifying bugs, confusing wording, and non-intuitive designs; and providing suggestions on how to improve functionality, clarity of information, intuitiveness of navigation, and more.

In this heuristic review, several design principles are recommended to enhance the user interface and functionality of a data table. Key principles include improving navigation by making table headers sticky to reduce scrolling lag and adding a keyword search feature for efficient data filtering. Clear organization is suggested by adding distinct headers for different data sections and creating separate columns for specific data categories. To improve readability, long descriptions should be truncated with an option to expand for more details, and sorting capabilities should be added for key columns. User interaction can be enhanced with icons indicating required fields and maintaining row highlights on hover. Accessibility improvements include ensuring color contrast.

9. Improvements in Data Standards and Pipelines Pages

The input gathered from the UX review was then combined into new and improved data standard and pipelines pages. The key takeaways were then applied to the new data standard and pipeline pages to ensure that they adhered to the same design principles. This included enhancements to design and layout, in addition to pipeline guides and user instructions (i.e., tips to make sure your data are standardized, compatible formats, helpful resources, and how it works). These updates may be found on the data standards and pipeline pages here: https://gdr.openei.org/standards. While it is too soon to tell, the GDR team anticipates that these new pages will have positive impacts on the amount of data that can be automatically standardized, the use of standardized data, and the overall support for the GDR data standards and pipelines.

10. Discussion: Real-World Applicability and Impact on Research

The Geothermal Operational Optimization with Machine Learning project exemplifies how emphasizing data quality through best practices in data curation can significantly enhance the success of a machine learning project (Taverna et al. 2022). Having access to structured and standardized data streamlines data handling by reducing time spent on dataset preparation, enabling efficient assembly of multiple datasets. Having access to especially large or complex datasets through data lakes eases data access, reducing barriers surrounding downloading, uploading, and working with the data. Combined, these features lessen the data curation requirements associated with a project, preserving more time for machine learning and data science experiments.

While it is too soon to see the scale of the impact of the GDR's data standardization efforts, we hope to see growth in the number of geothermal projects using standardized GDR data in their machine learning and data science workflows. We have observed the impact of the GDR data lakes through the sheer number of downloads of our data lake resources.

Table 1 lists the top ten most downloaded datasets of all time, with six of them being data lake resources. This trend is partly due to the nature of data lakes, which often contain especially large and complex datasets comprising numerous files accessed directly from the data lake (i.e., using files in situ instead of a one-time download). Additionally, this highlights the popularity of GDR data lake resources, which significantly enhance the accessibility of extremely large datasets. Notably, the first data lake resource was introduced nine years after the first conventional data resource, which was submitted in 2012.

Table 1: Top 10 most downloaded data submissions of all time as of August, 2024, including information on number of downloads, year published, and dataset storage type.

Rank	Downloads	Year Published on GDR	Title	Dataset storage type
1	5,845,469	2021	PoroTomo Natural Laboratory Horizontal and Vertical Distributed Acoustic Sensing Data	Data lake
2	1,561,471	2021	Brady's Geothermal Field - March 2016 Vibroseis SEG-Y Files and UTM Locations	Data lake
3	1,089,412	2021	Brady's Geothermal Field Nodal Seismometer Data	Data lake
4	728,186	2014	Evaluation Data of a High Temperature COTS (Commercial Off-the-Shelf) Flash Memory Module (TI SM28VLT32) for Use in Geothermal Electronics Packages	Conventional
5	434,950	2021	Brady's Geothermal Field DASH Resampled in Time	Data lake
6	309,362	2023	EGS Collab Experiment 1: Continuous Active-Source Seismic Monitoring (CASSM) Data	Data lake
7	28,441	2014	Project HOTSPOT: Kimama Well Borehole Geophysics Database	Conventional
8	22,472	2023	Imperial Valley Dark Fiber Project Continuous DAS Data	Data lake
9	18,126	2014	Project HOTSPOT: Kimberly Well Borehole Geophysics Database	Conventional
10	12,807	2013	Newberry EGS Demonstration Well 55-29 Stimulation Data	Conventional

This statistic also gives context to the plot in Figure 6, which shows cumulative GDR downloads per fiscal year since the GDR was rolled out more than 10 years ago. Because data lake downloads make up most of the FY24 downloads, it is apparent that the exponential growth in downloads over time would not be possible without the implementation of GDR data lakes.

Figure 6: Cumulative GDR downloads over time, by fiscal year, as of August 2024. This graph demonstrates exponential growth in the number of downloads per fiscal year, enabled by the GDR data lakes (*Graphic by Joelynn Schroeder and Dominique Barnes, NREL, 2024)*.

11. Conclusion

In conclusion, the GDR has made significant advancements in its data lakes, data standards, automated data pipelines, and associated pages to educate users. These enhancements have reduced barriers related to storage, access, and computation, enabling broader access to large geothermal datasets. Recent efforts to streamline the data intake process, educate users, and improve data accessibility have increased the number of datasets the GDR can accept into its data lakes and made it easier for new users to access the data using cloud tools. Introducing standardized pipelines for drilling, geospatial, and DAS data has improved the quality of training data, thereby enhancing the real-world applicability of geothermal machine learning outcomes. Automating

these processes has increased the availability of standardized data, reducing the burden of project-specific data curation on users and allowing more time for research. Overall, these improvements have significantly increased the accessibility and usability of big geothermal data for various projects.

We encourage geothermal data users to leverage the GDR's enhanced data lakes, standardized datasets, and streamlined data pipelines; and to provide feedback on their experience, including both success stories and shortcomings. Your active participation and feedback are crucial for driving innovation and ensuring that future improvements to the GDR align with the needs and wants of the geothermal community and stakeholders. We would love for you to join us in this initiative to make geothermal data more accessible, efficient, and impactful for the entire community.

ABSTRACT

The Department of Energy's (DOE) Geothermal Data Repository (GDR) team has integrated a Large Language Model (LLM) with the metadata and supporting documents associated with GDR datasets to create an Artificially Intelligent (AI) research assistant. By leveraging work done to make GDR metadata machine-readable and an open-source LLM integration model called the Energy Language Model, developed by the National Renewable Energy Laboratory, AskGDR serves as a virtual research assistant to GDR users. It provides answers to a variety of user-provided questions using natural language processing and generative machine learning. Users can get answers to questions about specific datasets, including inquiries about the equipment, assumptions and methodologies used in the origination of the data; or more abstract questions, such as the applicability of data to specific research fields. AskGDR improves the discoverability of geothermal data by helping guide users to datasets beyond simple keyword searches. It enables users to find data based on properties of the data, discover information contained within supporting documents, and explore data from projects related to their research objectives.

This paper will outline the development, integration, output, and efficacy of the AskGDR LLM, including adherence to scientific rigor through improvements designed to increase the accuracy of generated answers, avoid speculation, and provide proper references for all resources used.

1. Introduction

The U.S. Department of Energy's Geothermal Data Repository (GDR) is currently home to 1,209 datasets containing over 5,900 individual resources totaling more than 147 TB of geothermal data. (GDR 2024). Searching on the GDR was previously limited to keyword associations with the provided metadata, facilitating queries analogous to "Show me all the of the seismic data from the PoroTomo project" by executing searches on keywords "PoroTomo" or "seismic", but these types of searches are inherently limited. At best they match all datasets containing those keywords at a superficial level while fundamentally failing to understand the depth of contextual associations in the query itself. Fortunately, as part of the GDR's effort to maximize the utility and discoverability of geothermal data through adherence to FAIR data principles (Wilkinson et al, 2016), each dataset on the GDR includes a comprehensive set of metadata designed to increase the discoverability, accessibility, interoperability, and utility of geothermal data. Furthermore, the GDR strives to adhere to FARR data principles, which combine FAIR with machine readability and AI-readiness, to make geothermal data accessible not only to researchers, but also to machine learning algorithms and artificial intelligence (FARR 2024). These principles laid the foundation for the adaptation of a Large Language Model (LLM) that now powers an Artificially Intelligent (AI) research assistant called "AskGDR", which allows users to ask and receive answers to questions beyond simple keyword searches.

1.1 Adherence to FAIR and FARR Data Principles

A core tenet of the GDRs mission is to make geothermal data universally accessible (Weers et al, 2023). For over a decade, the GDR has strived to achieve the guiding principles of the FAIR data standards: to make data Findable, Accessible, Interoperable, and Reusable. (Wilkinson et al, 2016; Weers et al, 2022). These principles align directly with the U.S. Department of Energy's 2011 Strategic Plan, which states, "Success should be measured not when a project is completed or an experiment concluded, but when scientific and technical information is disseminated." (DOE 2011). Put simply, data and information which cannot be found, accessed, or reused effectively has no value. Previous work done by the GDR team to maximize the value of data submitted to the GDR has laid the foundation for innovation in machine learning (Weers et al, 2022). The GDR team has expanded upon these efforts through the adoption of FARR data principles, which build upon FAIR data principles. FARR data principles include all those in FAIR, plus AI Readiness and Reproducibility. To meet FARR data standards, the GDR team has worked to make GDR metadata machine-readable, rendering it comprehensible by modern AI platforms in addition to meeting FAIR data standards. These efforts enabled AI and Machine Learning (ML) platforms, including Large Language Models (LLMs), to incorporate GDR metadata into their respective knowledge bases to develop smarter search algorithms.

2. Developing a Smarter Search

Building upon recent innovations in LLM research and the GDR's adherence to FAIR and FARR principles, the GDR team began exploring AI-assisted search capabilities with two primary goals:

1) Help users get quick answers to contextual questions about data
2) Help guide users to insights beyond simple keyword searches

2.1 Helping Users Get Quick Answers to Contextual Questions About Data

Every dataset in the GDR contains metadata describing dataset. Good metadata contains sufficient information to understand and properly use the data, including any assumptions, anomalies, and errors incurred while collecting the data (Taverna et al, 2022). Submitters of data to the GDR and the curators who evaluate their submissions each work vigilantly to ensure users of the data have access to all the information they need to properly use and comprehend the included data, it is not always possible to cover every conceivable use of the data. To ensure data reusability in accordance with FAIR data principles, GDR data is curated to promote as many future uses as possible, including potentially unforeseen, novel applications to promote innovation (Weers et al, 2022). However, it's not always possible to anticipate what questions innovators of the future will be asking of the data generated today. As a result, the points of contact listed for GDR datasets often receive unforeseen questions about their data, assumptions, and anomalies incurred during the acquisition of the data. Examples include: "What assumptions were made in the development of this dataset?" or "Does this dataset include an assumption, such as curtailment, in its output?"

The answers to these questions are often buried in supporting documents, published papers, and other materials associated with the dataset. Previously, users had to either read through the supporting materials looking for their answer, or email the Point of Contact (POC) listed on the dataset landing page and wait for a response, sometimes just to find out if the dataset they were interested in would work for them and their research or not. And POCs for popular datasets would often receive the same question(s) over and over, despite having included the answer in the supporting materials. AskGDR instantly devours all the metadata and supporting information associated with a dataset and can provide insight into the assumptions made, equations used, and anomalies detected, saving the dataset POC valuable time and providing the data user with real-time answers to deep technical questions (Sample Question 1 below).

2.2 Helping Guide Users to Insights Beyond Simple Keyword Searches

The primary search interface on GDR relies solely upon keyword matching to produce search results and can quickly find answers to questions like, *"Which datasets include EGS stimulation data?"* through a simple search for "EGS" data, but it cannot answer abstract queries such as, *"Which geothermal technologies have the potential to reduce carbon in the atmosphere?"* (Sample Question 2 below). AskGDR can make the connection between a dataset's characteristics and the potential impact of associated research by incorporating related papers, publications and other supporting documents into the contextual knowledge associated with each dataset.

2.3 Sample Questions

The following questions were input into AskGDR and its responses have been copied here verbatim. Note that some of the links included lead directly to the download of cited resources (i.e., clicking the links may initiate a download).

2.3.1 Sample Question 1: "How was the PoroTomo seismic data recorded?"

Response generated by AskGDR (including format, and cited hyperlinks):

> The PoroTomo seismic data was recorded using a combination of instruments and techniques. The seismic instrumentation included 238 Zland 3-component sensors manufactured by FairfieldNodal, which operated autonomously and continuously with a sampling interval of 0.002 seconds for the entire two-week deployment. The seismic network also included six 3-component seismic stations from the national instrumentation program named Portable Array Seismic Studies of the Continental Lithosphere (PASSCAL). Each station included an L28 model, 4.5-Hertz, 3-component geophone, Reftek RT130 seismograph, and a GPS timing clock.
>
> Additionally, Distributed Acoustic Sensing (DAS) was used, which was the first such deployment in a geothermal field in North America. The "intelligent" Distributed Acoustic Sensing (iDAS) system used a continuous length of fiber-optic cable as an array of seismic sensors. At Brady, the instrumentation included 8700 meters of DAS cable buried horizontally in a shallow trench and 400 meters of DAS cable hanging vertically in Well 56-1. The DAS data were recorded continuously, archived in 30-second files in SEG-Y format.

(End of Sample Question 1 Response)

2.3.2 Sample Question 2: “Which geothermal technologies have the potential to reduce carbon in the atmosphere?”

Response generated by AskGDR (including format, and cited hyperlinks):

> Geothermal technologies that have the potential to reduce carbon in the atmosphere include:
>
> 1. Geothermal power generation: This technology involves tapping into the Earth's natural heat to generate electricity. Geothermal power plants emit significantly less carbon dioxide (CO2) and other pollutants compared to fossil fuel-based power plants, making them a cleaner energy source.

2. Geothermal heating and cooling (GHC): GHC technologies, also known as direct use or geothermal heat pumps (GHP), utilize the Earth's stable temperatures to provide heating and cooling for buildings, agriculture, industrial processes, and other applications. By replacing conventional heating and cooling systems that rely on fossil fuels, GHC technologies can help reduce greenhouse gas emissions.

3. Hybrid systems: These systems combine geothermal energy with other renewable energy sources, such as solar or wind power, to further reduce carbon emissions and increase the overall efficiency of the energy system.

4. Enhanced Geothermal Systems (EGS): EGS involves the artificial stimulation of geothermal reservoirs to increase their permeability and heat extraction capabilities. By expanding the potential for geothermal energy production, EGS can help displace more carbon-intensive energy sources.

By increasing the adoption of these geothermal technologies, it is possible to reduce carbon emissions and contribute to the global efforts to mitigate climate change.

3. Implementation

By leveraging work done to make GDR metadata machine-readable and a prototype LLM called the Energy Language Model (ELM) developed by Pinchuk et al (2024) at the National Renewable Energy Laboratory (NREL), AskGDR serves as a virtual research assistant to GDR users. AskGDR leverages OpenAI's ChatGPT framework to analyze and derive insight from the metadata and supporting documentation associated with GDR datasets. Whenever possible, included ReadMe files and publications are incorporated, along with other metadata provided during the submission process, to create a corpus of knowledge associated with each dataset in the GDR. This corpus is then used to generate AskGDR's response, along with certain limitations put in place to enforce scientific rigor, encourage citation, and promote data provenance.

3.1 Constrained for Scientific Rigor

Unlike conventional LLMs, many of which have knowledge bases that include internet content of unknown or questionable origin, the GDR development team has limited the AskGDR knowledge base to only the data and information provided in GDR data submissions. These data have been curated by the GDR data curation team and vetted for appropriateness, completeness, and relevance. As a starting point, the application has been instructed to act as a librarian maintaining a collection of documents and datasets related to energy and to generate responses using only the context provided. The AskGDR algorithm has been instructed not to deviate from these constraints and will not go to the internet at large in search of answers. AskGDR will not speculate. If the GDR knowledge base does not provide sufficient information for AskGDR to answer a question, it has been instructed to reply that it could not find an answer.

AskGDR has also been instructed to always cite its sources. The datasets and associated publications used to generate an answer are cited below each answer and include links to the relevant datasets and resources on the GDR (see Example Questions 1 and 2). This is important for establishing credibility and a reproducible audit trail of calculated answers in accordance with FARR data principles.

3.2 An AI Research Assistant, Not a Chat Bot

In early planning stages the GDR teams weighed the potential for two very different LLM implementation paradigms: a more traditional, conversational chatbot similar to ChatGPT, and a more constrained, scientific model, which we referred to as an AI Research Assistant. After consulting with industry professionals, potential users, and subject matter experts, we opted for the latter. We determined that adherence to a controlled corpus of knowledge coupled with scientific rigor superseded the conversational aspects of a true chatbot and provided greater value to the geothermal community. As a result, AskGDR is not fully conversational. Each question asked of it is independent of the last. This helps guarantee scientific rigor but limits a user's ability to ask follow-on questions in a natural language syntax. Context can, however, be carried from question to question through careful question engineering, i.e., by embedding the necessary context into subsequent questions.

3.3 Architecture and Flow

AskGDR is an extension of NREL's ELM, which uses Retrieval Augmented Generation (RAG) based on a predefined corpus of knowledge to provide deep insights into text contained within its knowledge base. For AskGDR, NREL's ELM framework has been used to integrate an LLM with the metadata associated with each GDR dataset in addition to supplemental documents including README files, publications, and other PDFs. These documents are parsed into pure text files (AskGDR cannot currently process images or other non-text elements) and then chunked into manageable fragments to optimize information retrieval and the natural language processing (NLP) used to create broader contextual understanding from the text fragments. The chunks are then fed into Amazon Bedrock, a cloud-based framework for building and scaling generative AI applications, which allows for the fine tuning of RAG techniques. Automated build agents in Bedrock convert the text fragments into embedding vectors stored in AskGDR's vector database. When a user asks a question, it is embedded using the AWS Titan model and compared against vectors in the database using cosine similarity. This process returns text chunks from the corpus

that are most relevant to the question and provides that information as context to OpenAI's ChatGPT to produce answers to GDR users' questions.

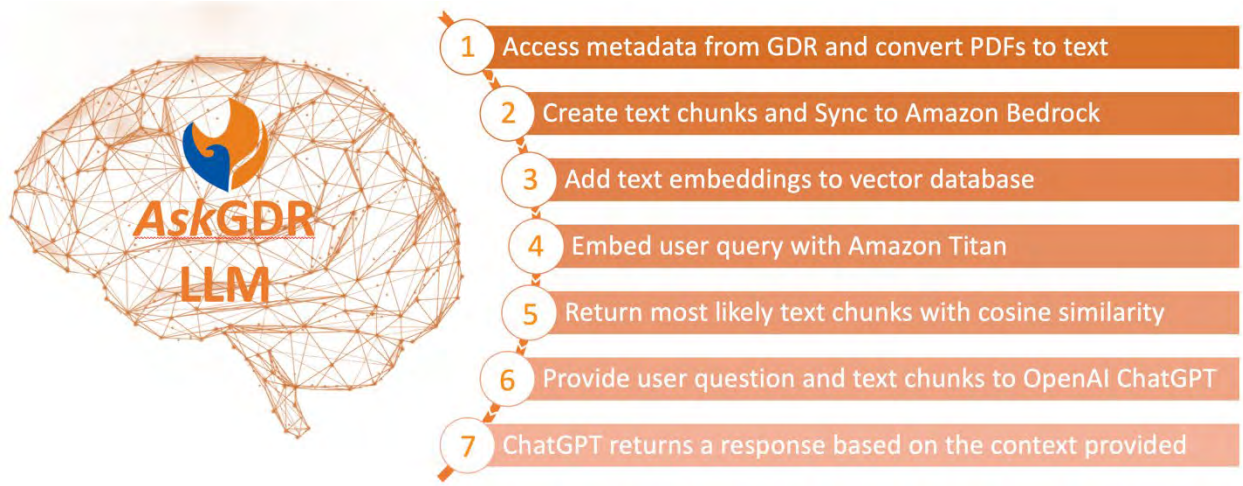

Figure 1 Flow of information from GDR metadata to AskGDR answers.

3.4 Limitations

AskGDR is currently based on ChatGPT 4.0, which produces answers based on the probability of generative text tokens, and not mathematical calculations. As a result, it is not reliable for answering mathematical questions. Similarly, basic ChatGPT implementations are not great at interpreting figures, images, maps, or other visual media. While many extensions exist for ChatGPT that vastly improve its capabilities in these areas, AskGDR has not been programed with any extended capabilities and cannot interpret nor derive insight from images or other visual media within the GDR.

By design, AskGDR is limited to the knowledge and information contained within the GDR. It will not go out to the greater internet nor consult any unapproved sources for answers to user-provided questions. It has intentionally been constrained to the corpus of knowledge that is the metadata and supporting documents associated with curated GDR data submissions. That said, AskGDR can only correctly respond to questions that are answered within the metadata provided by submitters.

Lastly, AskGDR responses are not perfect. Some answers draw upon connections between two datasets that are not actually related, especially when project acronyms are involved. For example, Sample Question 1 above cites a source from the submission titled "Three-Component Long Offset Surface Seismic Survey Data Used to Find Large Aperture Fractures in Geothermal Resources - San Emidio Geothermal Resource Area," which is a seismic dataset not related to the PoroTomo project. This is likely related to the fact that PoroTomo is an acronym, not a real word, and that the project cited has similar text associated with it. Therefore, it is always recommended to fact check responses given by LLMs and chat bots.

3.5 User Interface (UI) Integration

Understanding that the need to ask questions can arise at any time during an exploration of data, the GDR team has devised a UI for AskGDR based on a modal "pop up" that allows it to be accessible from anywhere in the GDR. The AskGDR button (Figure 2, left) opens the AskGDR modal window on any GDR page, allowing users to ask questions without navigating away from their current location.

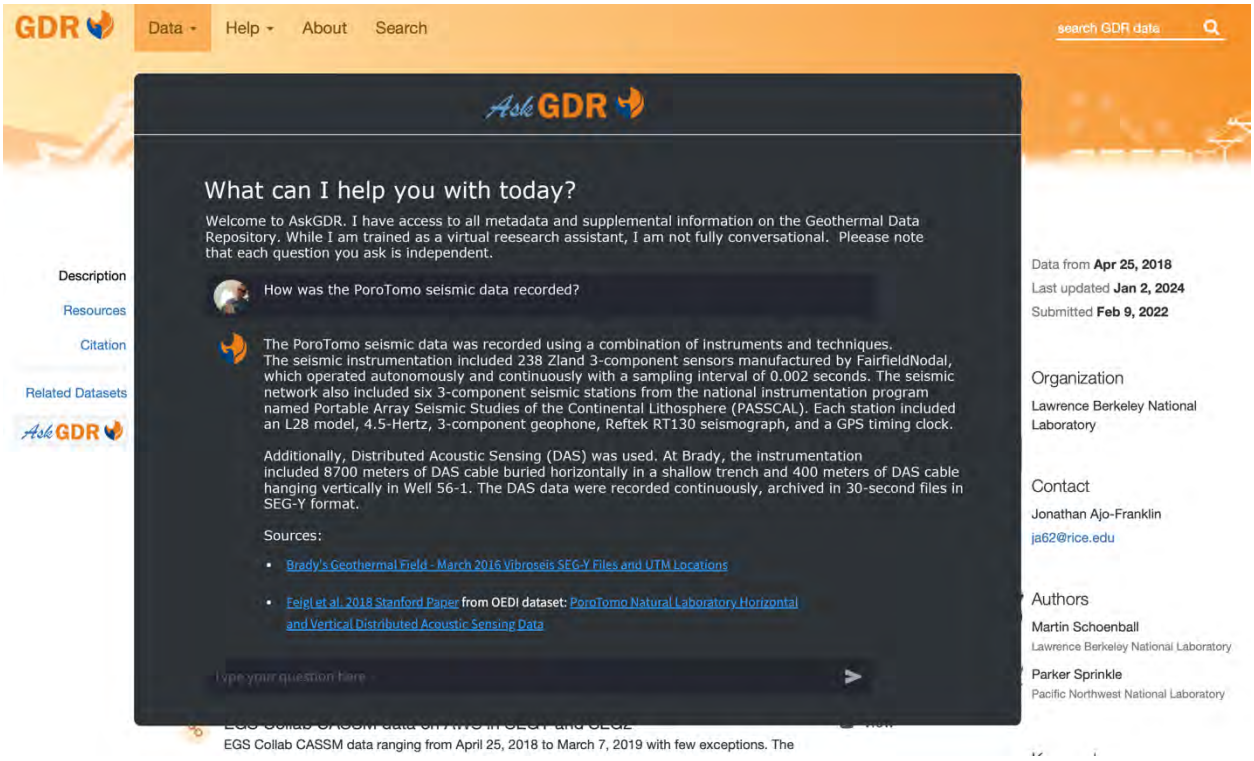

Figure 2 Screenshot showing the AskGDR button (middle left) and the AskGDR pop up (center, black)

The AskGDR button is featured prominently on the GDR homepage, each dataset landing page, and is included under Help in the main navigation.

4. Risks and Uncertainties

AskGDR uses a novel approach that includes several new technologies, some of which come with their own risks and uncertainties, such as cost and quality of generated answers. Additionally, concerns over the legality of AI-generated content have been raised by numerous communities. GDR will continue to monitor these risks and uncertainties and act accordingly to ensure that AskGDR benefits the geothermal community overall.

4.1 Cost

AskGDR utilizes several modern cloud-based technologies, including managed services for its vector database, Amazon Bedrock, and Titan, and OpenAI's API for ChatGPT. Each of these services comes with their own cost, and while the costs of hosting AskGDR have been negligible to date, some of these expenses (e.g. the ChatGPT API) are transactional and will scale linearly with the number of questions asked. Rate limits have been added to AskGDR to prevent users

from asking an unreasonable number of questions per day or mischievously driving up costs for the GDR. These limits are still being fine-tuned by the GDR team in an effort to find an optimal balance between utility and cost but are set high enough that the average user will likely never encounter them.

Other expenses are related to the size of the underlying knowledge base and the computational power required to convert it into a vector database for the LLM to use. These expenses are expected to benefit from economies of scale and should decrease over time. The GDR team is keeping a close eye on these expenses and has already identified several efficiencies that could be implemented to reduce costs, should they become necessary and economical.

4.2 Legality

Concerns have been raised over the legality of AI-generated answers; specifically whether or not these answers constitute plagiarism (Murugesan 2023). These concerns were a factor in our decision to develop AskGDR to function more as an AI Research Assistant than a fully conversational chat bot. AskGDR has been instructed to always cite its sources and will link back to the original source material within each answer, helping to create data provenance and attribute proper credit to the original authors. AskGDR is fully compliant with current DOE and NREL policies on the use of generative AI and the GDR team will continue to monitor these policies as they evolve.

4.3 Quality of Generated Content

One of the greatest risks of generative AI tools like AskGDR is the ability of the underlying LLM to "hallucinate," i.e. recognize patterns in language that result in the generation of inappropriate, nonsensical, or inaccurate outputs (IBM 2024). The GDR team has greatly reduced this risk by instructing AskGDR not to speculate. Rather than attempting to generate an answer from nothing, or reaching out to the internet at large, AskGDR will remain confined to the predetermined, curated GDR knowledge base and will inform the user if insufficient information is available to generate an answer. This reduces the risk of hallucinations but does not eliminate it. The GDR team is keeping track of questions asked by users to monitor the use of AskGDR and the quality of its answers. Questions asked are stored anonymously and are not associated with any user or individual data.

The GDR team is keeping close watch on all of these concerns, collecting data on usage and expenditure, to evaluate the efficacy and impact of AskGDR.

5. Conclusion

AskGDR increases the utility and discoverability of geothermal data by providing the geothermal community with the means to quickly interrogate the methods used to collect data and any assumptions made while also providing the ability to link datasets to abstract concepts aligned with specific research objectives. This new functionality not only saves time for researchers looking to investigate datasets on the GDR, but it also reduces the number of repetitive questions received by data owners and dataset POCs, increasing efficiency and saving time for more critical research activities.

Furthermore, the foundational work necessary to make AskGDR possible, including the prerequisite that GDR datasets adhere to both FAIR and FARR data principles, helps ensure that GDR data is accessible to other LLMs and machine learning efforts. AskGDR enables valuable research done by the geothermal community to be included in the answers generated not only by AskGDR, but also by other generative AI applications, and helps to set a precedent for the availability of scientific information in the world of AI-generated answers.

The GDR provides universal access to data and information and AskGDR helps to further that mission by provide equity in access across diverse communities. It simplifies the interrogation of complex datasets and the insights it provides are free to use for everyone.

Prediction of Formation Properties Based on Drilling Data from Multiple Wells at Utah FORGE Site Using Machine Learning

ABSTRACT

In this study, machine learning methods have been employed to establish relationships between drilling parameters and the formation properties – confined compressive strength (CCS) – in geothermal wells at the Utah FORGE (Frontier Observatory for Research in Geothermal Energy) site. CCS can be considered as a proxy for the ability to comminute rock during drilling. At Utah FORGE, the logging data is available to provide a continuous measurement of CCS, which is then calibrated against the core testing results. Drilling data from four deep wells that used PDC (polycrystalline diamond compact) bits were used to train the machine learning model. The dataset from multiple wells mitigates the risk of overfitting associated with using data from a single well, leading to improved prediction results, especially for the Random Forest (RF) model. For the RF models used to predict CCS, the top four important features are: 1) true vertical depth (TVD), 2) top drive torque, 3) rate of penetration (ROP), and 4) standpipe pressure. Trained by the four-well dataset, the R-squared score of RF model for the training dataset is 0.95 and for the testing dataset is 0.91. RF models are also trained by the three-well dataset (part of the whole dataset). The trend of predicted CCS – by the three-well RF model using the unseen drilling data (the fourth well) – along TVD matches well with the actual value, with a Root Mean Squared Error (RMSE) of 0.10. Thus, the machine learning models are not limited to a single well and hold potential for application to any future wells drilled in this region. This work showcases the utilization of machine learning models to predict formation properties, reducing costs and complexity associated with traditional methods like well logging or core testing.

1. Introduction

Formation properties, e.g. compressive strength, can be obtained through well logging or core testing. However, these procedures are expensive, and implementation can be complex, especially in geothermal wells with high-temperature conditions. Alternatively, predictions of formation properties can be derived from bit-rock interactions without additional operational costs, utilizing machine learning models. To train machine learning models effectively, substantial data is required. Fortunately, at the Utah FORGE (Frontier Observatory for Research in Geothermal Energy) site, five deep wells have been drilled (refer to Figure 1), and each of these wells has well-documented drilling data, a comprehensive suite of well logs, and core testing data. Utah FORGE

is a U.S. Department of Energy funded project for Enhanced Geothermal System (EGS) development (Moore et al., 2019). This rich dataset from Utah FORGE is invaluable in training a machine learning model for predicting material properties in situ.

In this study, machine learning methods are employed to establish relationships between drilling parameters and the formation properties, particularly focusing on the confined compressive strength (CCS). The logging data provides a continuous measurement of CCS (bit face compressive strength under the local effective confining stress regime – mean effective stress), which is then calibrated against the core testing results. CCS reflects the ability to comminute rock during drilling. Phelan et al. (2022) showed the prediction of CCS from a single well, 16A(78)-32 at Utah FORGE. In this study, the dataset from multiple wells that used PDC (polycrystalline diamond compact) bits is investigated. It is beneficial to use multiple wells because it can mitigate the risk of overfitting associated with using data from a single well and increase the overall prediction accuracy for any future wells drilled in this region of Utah FORGE.

The paper first shows how to obtain the "label" – CCS and its calibration. The second part of the paper details the data preprocessing and feature evaluation. Finally, different machine learning models are evaluated, and their performances are discussed.

2. Data Collection

The information of the four wells that used PDC bits at Utah FORGE is listed in Table 1 (Dupriest and Noynaert, 2024). There is only one well, 58-32, which was drilled with tri-cone bits. In this study, only the drilling data from the four wells drilled with PDC bits is used to train the machine learning model. For the machine learning model, the features (input data) are from the drilling data, which include weight on bit, top drive torque, differential pressure, standpipe pressure, top drive rotary, bit RPM, flow rate, and rate of penetration (ROP). True vertical depth (TVD) is also a feature because the rock properties could be different at different depths. The label (output data) is one of the rock properties, CCS. The drilling data (features) can be directly obtained. However, the label, CCS, has to be inferred from the logging data and calibrated by the core testing results.

Figure 1. Utah FORGE site (adapted from Moore et al., 2023).

Table 1. Deep wells drilled with PDC bits at Utah FORGE site

Well Name	Well Type	Drill Bit	MD (ft)	TVD (ft)	Logs	Core testing
16A(78)-32	Deviated	PDC	10987	8559	Sonic log	Yes
16B(78)-32	Deviated	PDC	10947	8391	Sonic log	No
78B-32	Vertical	PDC	9500	9500	Sonic log	Yes
56-32	Vertical	PDC	9145	9145	ThruBit Dipole	No
*58-32	Vertical	Tri-cone	7536	7536	Sonic log	Yes

*Well 58-32 is excluded from the machine learning training because PCD bits were not used.

2.1 CCS Calculation

Continuous CCS along the measured depth (MD) of the four wells was first estimated from analysis of the sonic logs. The method of calculating CCS using logging data is detailed in Phelan et al. (2022). There are core testing results available from three wells, 58-32, 16A(78)-32, and 78B-32, which are used to calibrate the parameters inferred from sonic logs. It is important to note that even though the drilling data of well 58-32 is not used due to different drill bit types, its core testing results can still be used for the CCS calibration. The compressive strength of the core samples under different confining pressure from multiple Utah FORGE wells is shown in Figure 2.

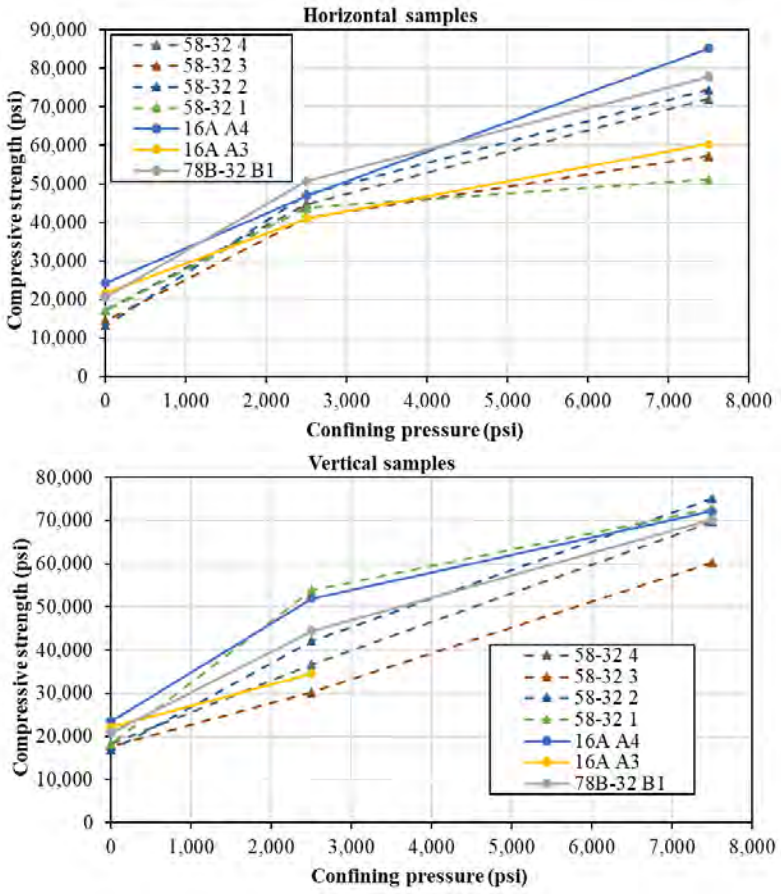

Figure 2. Compressive strength under different confining pressure of the cores from Utah FORGE wells.

During the writing of our previous article (Phelan et al., 2022), the core testing results of well 16A(78)-32 were not available. Consequently, core testing results of well 58-32 were used to calibrate the relevant parameters calculated by logging data for well 16A(78)-32. During this study, core testing results are available from three wells including well 16A(78)-32, 58-32, and 78B-32. Figure 3 shows the comparison of unconfined compressive strength (UCS) and internal friction angle between the inferred values from logs in well 16A(78)-32 and core testing results (including all three wells), which are in good agreement.

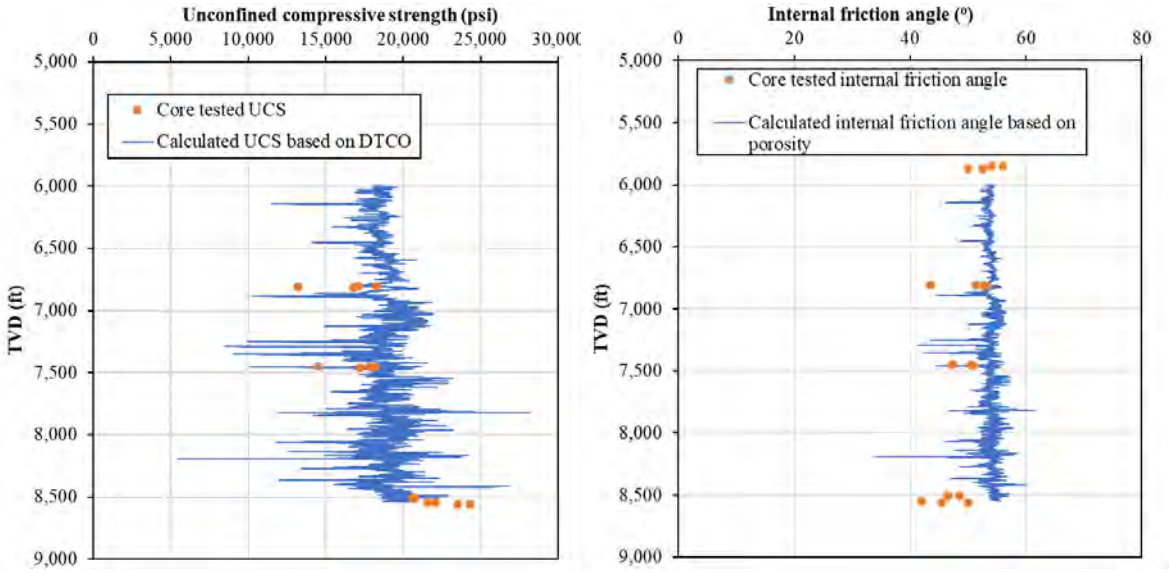

Figure 3. Comparison of UCS and internal friction angle between core testing results and calculated results. The calculated results are from the interpretation of the sonic logs from well 16A(78)-32. Please note the core testing results include wells 16A(78)-32, 78B-32 and 58-32.

The calculated and calibrated UCS and CCS along MD for well 16A(78)-32 are shown in Figure 4. The mud weight is 0.54 psi/ft and the reservoir pressure is 0.433 psi/ft.

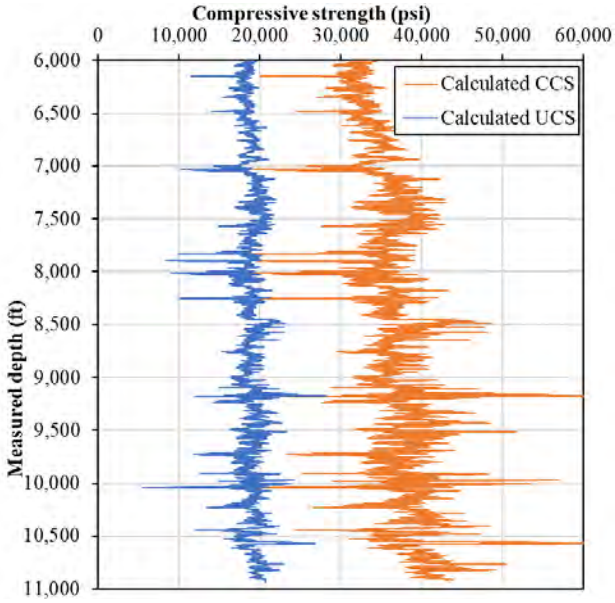

Figure 4. Calculated UCS and calculated CCS along MD for well 16A(78)-32.

3. Data Preprocessing

3.1 Data Filtering

For this research, the area of interest is focused on the reservoir rock, i.e., granitoid and metamorphic rock. Therefore, the data that belongs to the overlying alluvium is deleted. Then, the base filter shown in Table 2 is applied to the features. The data out of the range shown in this table was not reasonable and hence removed and not used. The data with low bit RPM was also removed because its volume is small, and its clustering is different from that of large bit RPM.

For well 16B(78)-32, the available data started from 6000 ft MD, but the selected data for machine learning started from 7600 ft MD (6934 ft TVD). That is because from 6000 ft MD to 7600 ft MD, a Halo Rotary Steerable System was used, which is different from the deeper section and the other wells.

Table 2. Base filter applied to the features

Parameter	Base filter min	Base filter max
Weight on Bit (klbs)	0	200
Top drive torque (kft_lb)	0	100
Differential Pressure (psi)	-8000	N/A
Standpipe Pressure (psi)	0	10000
Top Drive Rotary (RPM)	0	500
Bit RPM (RPM)	0	500
Flow (flow percent)	0	100

3.2 Sliding Section Deletion

The drilling can be classified as rotating and sliding. Rotating is drilling with top drive or rotary table, and the drill string is rotated in order to gouge the hole. Rotary drilling will be used when a straight hole direction is needed. Sliding (orienting or steering) is drilling with downhole steerable mud motor, which does not rotate drill pipe because it uses hydraulic power to drive down the motor and bit. Sliding is used in order to control well direction (DrillingFormulas.Com). When it is sliding, top drive rotary is 0, while there is still a bit RPM.

The purpose of this study is to infer the rock properties from the rock-bit interaction. Rotating is much more reflective of the rock-bit interaction than sliding. Therefore, the sliding section was removed from the dataset. Most of the sliding section is from well 16A(78)-32.

After the data processing (filtering, outliers removal, and sliding section deletion), the maximum and minimum magnitude of the features and label of each well are listed in Table 3.

Table 3. Maximum and minimum value of parameters for each well after pre-processing

Parameter	Max				Min			
	16A(78)-32	16B(78)-32	56-32	78B-32	16A(78)-32	16B(78)-32	56-32	78B-32
Weight on Bit (klbs)	66	82	54	78	0	0	0	0

CCS (psi)	58833	59063	53323	52423	12841	18821	15045	15584

3.3 Feature Evaluation and Selection

The pair plots of features and label after data preprocessing are shown in Figure 5. The pair plot provides a direct view of the relationship between different parameters for different wells. Obviously, bit RPM changes linearly with top drive rotary.

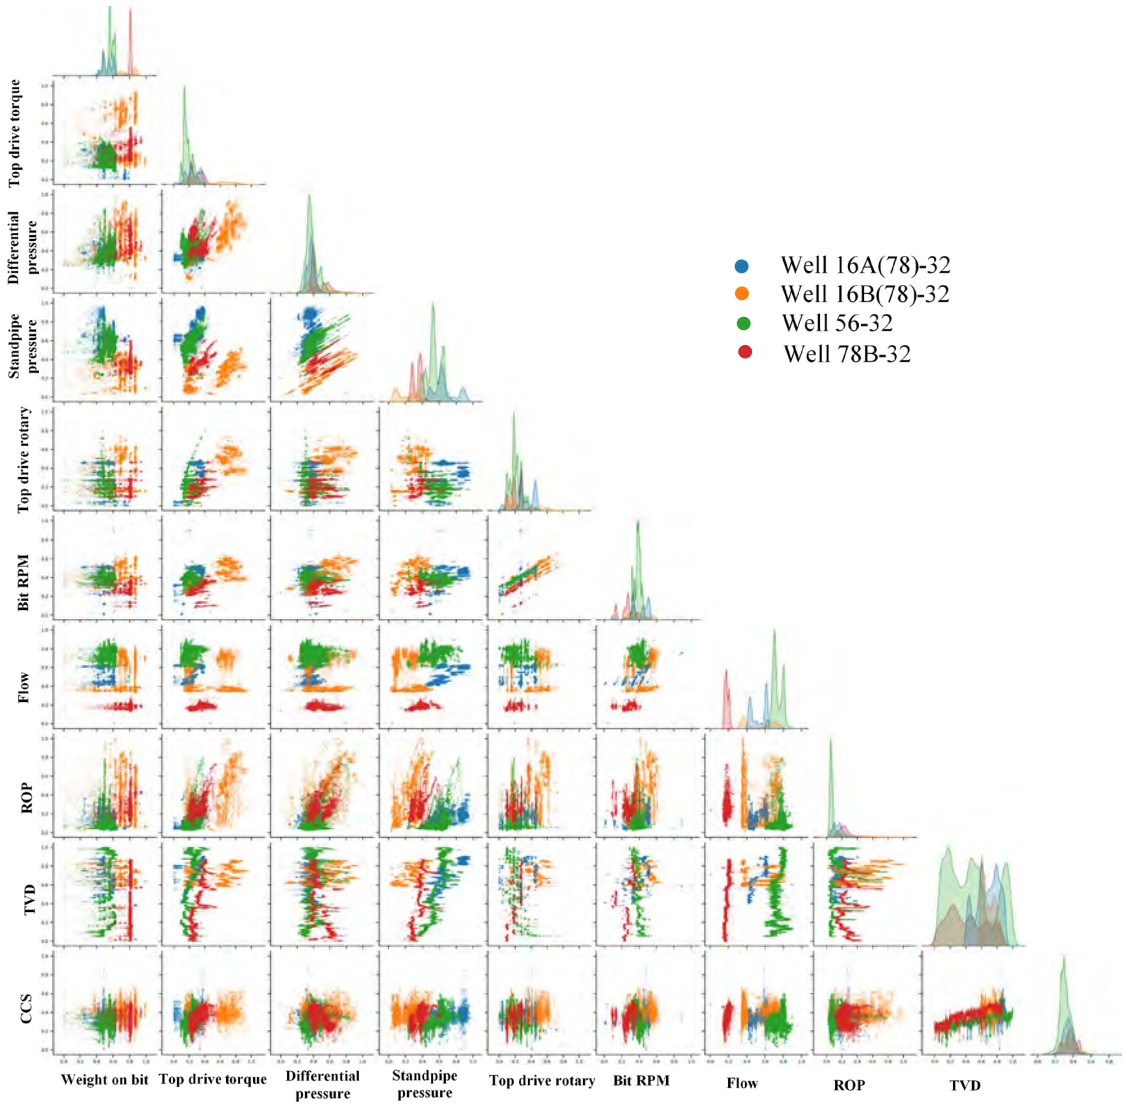

Figure 5. Pair plot of the drilling parameters for the four wells.

Figure 6 shows the correlation coefficients among features and label. The top three parameters that have a high correlation coefficient with CCS are 1) TVD, 2) top drive torque, and 3) ROP.

The top three pairs with a high correlation coefficient are ROP vs. top drive torque, CCS vs. TVD, and Bit RPM vs. top drive rotary. Considering the results of both pair plots (Figure 5) and correlation heat map (Figure 6), bit RPM and top drive rotary are highly correlated, and only the

feature – top drive rotary – is kept. Therefore, the features that are selected for the machine learning model training are: weight on bit, top drive torque, differential pressure, standpipe pressure, top drive rotary, flow rate, and ROP. In addition, to investigate the influence of TVD, the machine learning models are trained with two scenarios: one with TVD as a feature, and the other one without TVD.

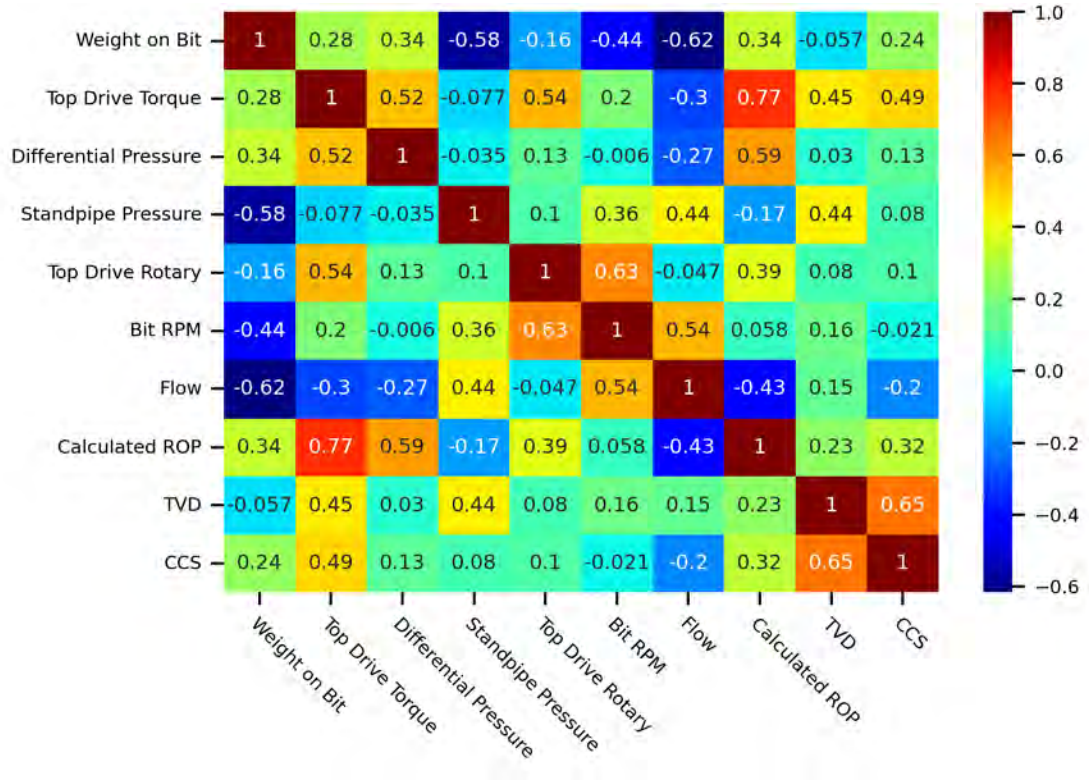

Figure 6. Correlation heat map showing correlation coefficients of the drilling parameters for the four wells.

4. Model Training and Performance Evaluation

After data preprocessing, two types of machine learning models – Random Forest (RF) and Artificial Neural Network (ANN) – are used to build the relationship between drill data (features) and rock CCS (label). Different datasets containing a combination of different wells are used to train the machine learning models. During the training of the dataset containing multiple wells, the features are normalized to the maximum and minimum values of the total dataset (multiple wells together), not to each well. For the prediction of the unseen data, the unseen data was filtered not to exceed the maximum and minimum range of both the features and labels of the "seen" data during the training.

4.1 Machine Learning Model – RF

RF is an ensemble learning method that operates by constructing a multitude of decision trees at training time. For regression tasks, the mean or average prediction of the individual trees is returned. An advantage of the RF model is that it can give feature importance after training.

We first investigate the performance of RF model without TVD and then evaluate its performance with TVD as a feature. In order to reduce the overfitting of RF model, 5-fold cross validation, limiting the maximum tree depth as 20, and setting a minimum number of samples at a leaf node as 5 are applied.

4.1.1 TVD not as a feature

Here TVD is not considered as a feature. Two RF models were trained with different datasets. The two different datasets are: 1) four wells including 16A(78)-32, 16B(78)-32, 78B-32, 56-32; 2) three wells including 16B(78)-32, 78B-32, 56-32 [no well 16A(78)-32]. The four-well model is used to evaluate the performance of the whole dataset, while three-well model is used to test the prediction accuracy of the unseen data, the fourth well. When training the model, the dataset is split into 80% of training and 20% of testing.

The top three important features for the four-well model are: 1) top drive torque, 2) standpipe pressure, 3) ROP, which are the same with the three-well model without 16A(78)-32.

The unseen data set (data from well 16A(78)-32) for the three-well RF model excluding well 16A(78)-32 is also tested. The number of rows in the three-well dataset without well 16A(78)-32 is 76712. 40% of well 16A(78)-32 (7593 rows) was used to test the model trained by the three-well dataset without well 16A(78)-32 is, which is 7593 rows. All of the performance metrics i.e., R^2 (R-squared), RMSE (Root Mean Squared Error), MAE (mean absolute error) are good for the "seen" dataset, including both training (80%) and testing (20%). The RMSE and MAE for the unseen dataset from well 16A(78)-32 for the three-well RF model is good, but R^2 is relatively low (refer to Table 4). Nevertheless, the predicted CCS along TVD matches the actual CCS for well 16A(78)-32 (refer to Figure 9).

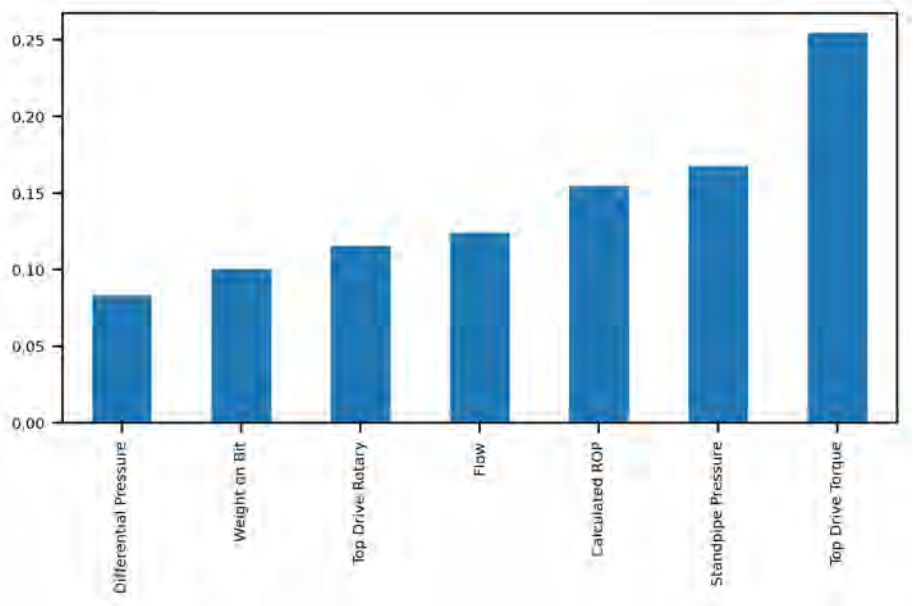

Figure 7. Feature importance of the RF model for the dataset of four wells [16A(78)-32, 16B(78)-32, 78B-32, and 56-32]. TVD is not a feature.

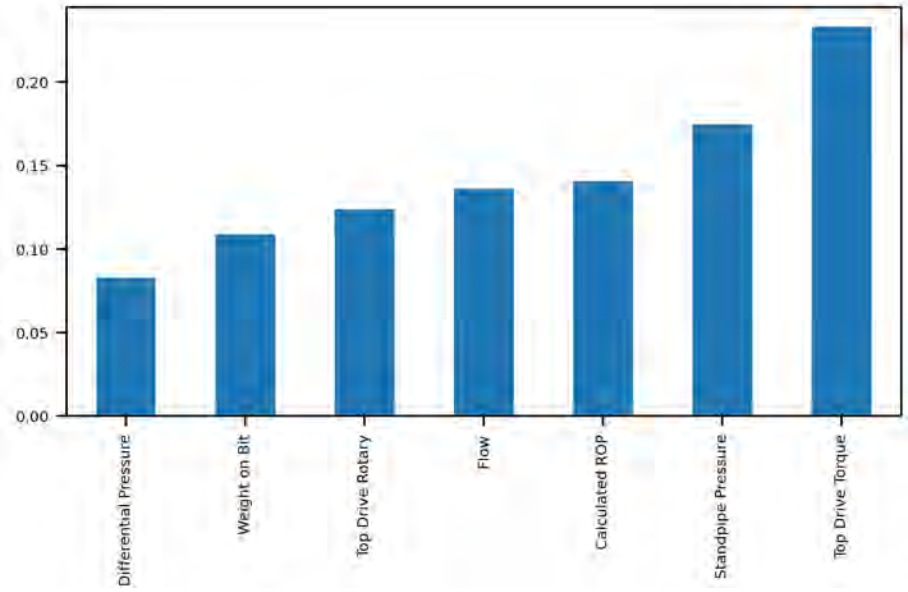

Figure 8. Feature importance of the RF model for the dataset of three wells [excluding 16A(78)-32, including 16B(78)-32, 78B-32, and 56-32]. TVD is not a feature.

Table 4. RF model performance of different datasets (TVD not as a feature)

Model	Train data metrics			Test data metrics			Test new dataset	Test new dataset metrics		
	R^2	RMSE	MAE	R^2	RMSE	MAE		R^2	RMSE	MAE
4 wells	0.91	0.02	0.01	0.84	0.03	0.02	N/a	N/a	N/a	N/a
3 wells (excluding 16A(78)-32)	0.93	0.03	0.02	0.88	0.04	0.02	40% of 16A (7593 rows of 16A)	0.16	0.08	0.06

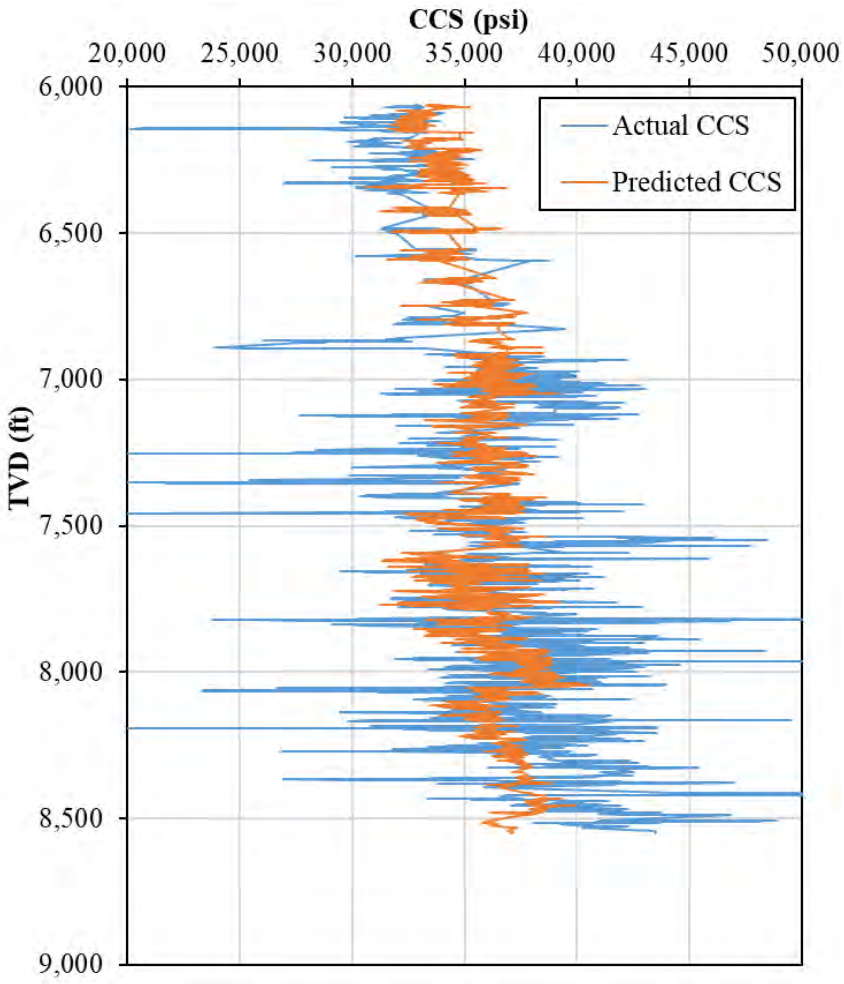

Figure 9. Comparison between predicted value from the three-well RF model and actual value of CCS for well 16A(78)-32. The RF model is trained with the dataset of three wells excluding 16A(78)-32 [including 16A(78)-32, 16B(78)-32, 78B-32, and 56-32]. TVD is not a feature.

4.1.2 TVD as a feature

TVD is added as a feature to investigate its influence. For model training, the datasets are split into 80% training and 20% testing. The feature importance of the four-well RF model is shown in Figure 10. The top three important features are 1) TVD, 2) top drive torque, and 3) ROP, which is the same as the top three features with a higher correlation coefficient with CCS (refer to Figure 6).

The RF models trained with three-well datasets are also investigated. Their feature importance is shown from Figure 11 to Figure 14. For almost all the three-well RF models, the top four important features are the same: 1) TVD, 2) top drive torque, 3) ROP, and 4) standpipe pressure. Only for the model excluding 56-32, flow ranks as the third important feature. This feature importance ranking is aligned with the ranking of correlation coefficient with CCS. Even though standpipe pressure has a very low correlation coefficient (0.08) with CCS, it ranks as third or fourth important feature. Obviously, after adding TVD as a feature, the TVD becomes the first important feature in the RF model. There are two reasons from the point of view of physics: the confining pressure increases with TVD and the rock properties change with TVD.

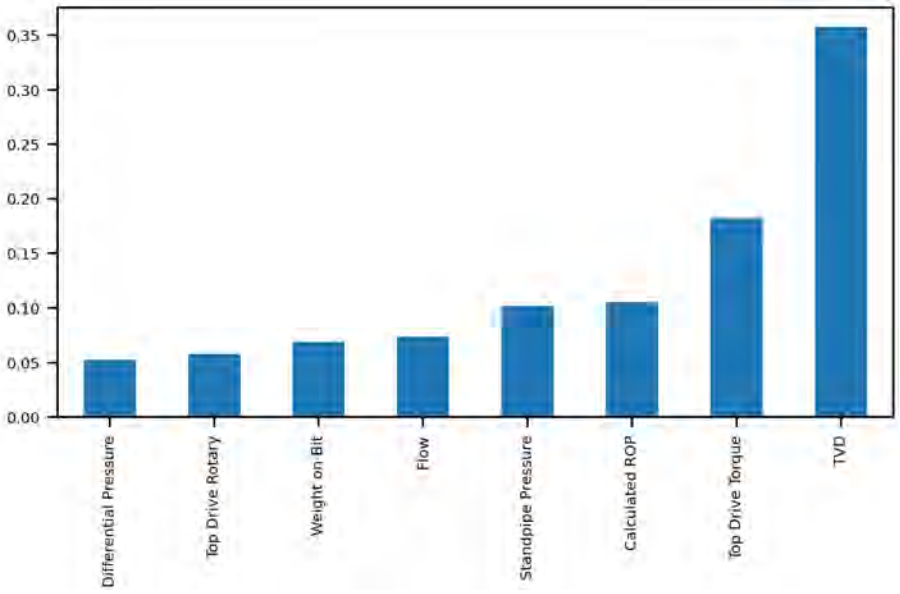

Figure 10. Feature importance of the RF model for the dataset of four wells [16A(78)-32, 16B(78)-32, 78B-32, and 56-32]. TVD is a feature.

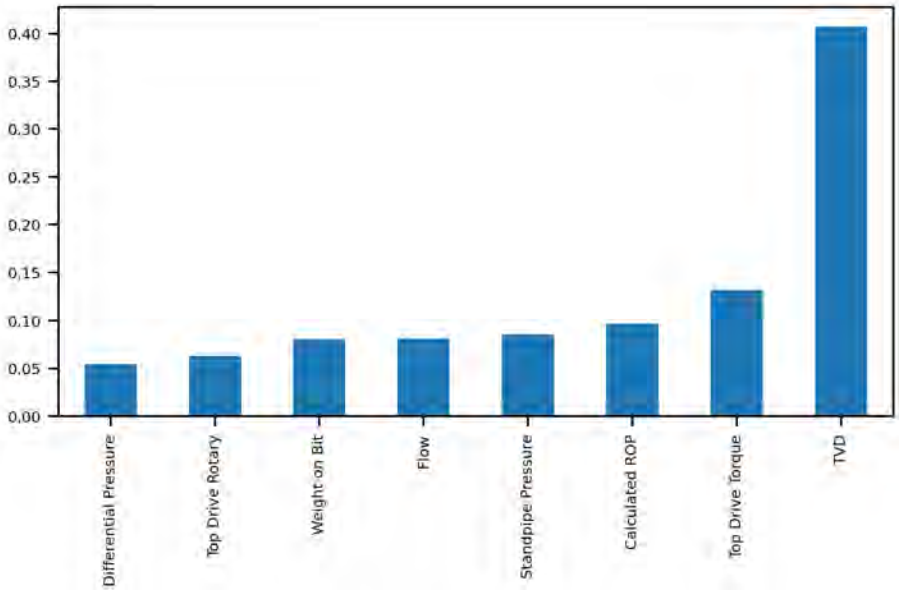

Figure 11. Feature importance of the RF model for the dataset of three wells excluding 16A(78)-32 [including 16B(78)-32, 78B-32, and 56-32]. TVD is added as a feature.

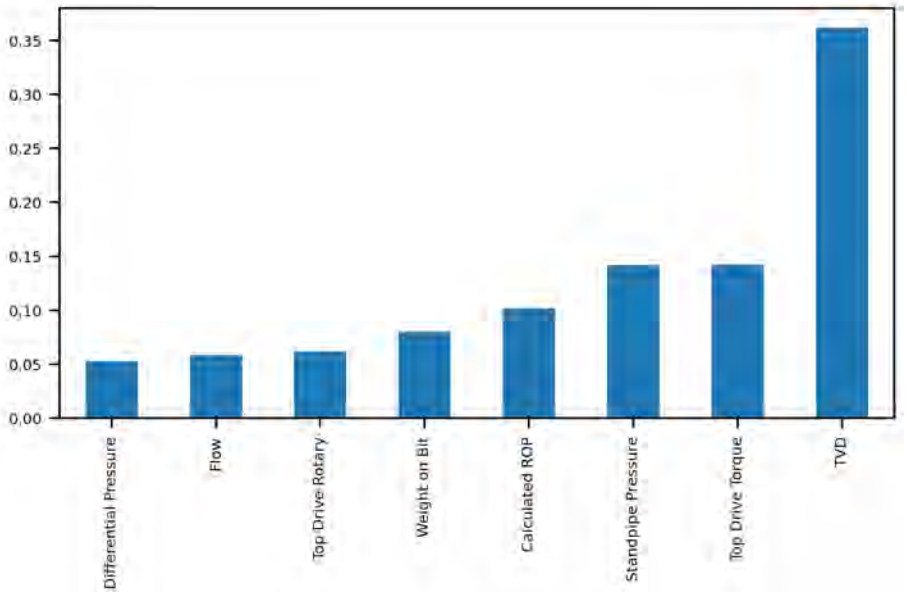

Figure 12. Feature importance of the RF model for the dataset of three wells excluding 78B-32 [including 16A(78)-32, 16B(78)-32, and 56-32]. TVD is added as a feature.

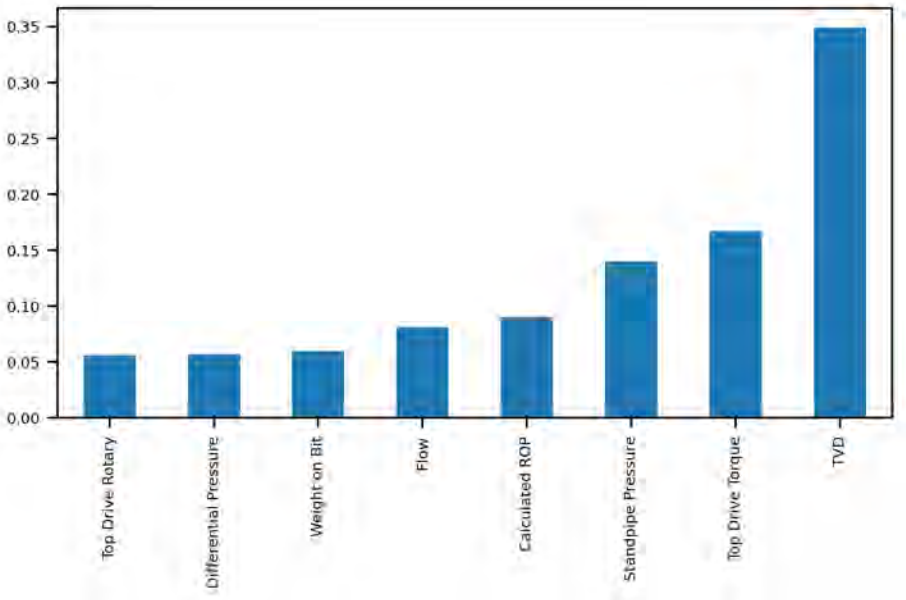

Figure 13. Feature importance of the RF model for the dataset of three wells excluding 16B(78)-32 [including 16A(78)-32, 78B-32, and 56-32]. TVD is added as a feature.

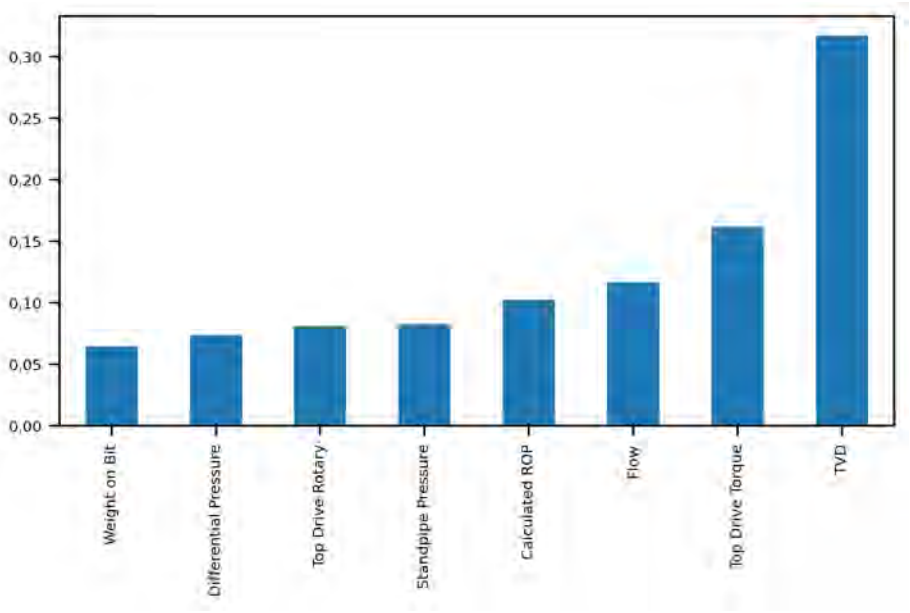

Figure 14. Feature importance of the RF model for the dataset of three wells excluding 56-32 [including 16A(78)-32, 16B(78)-32, 78B-32]. TVD is added as a feature.

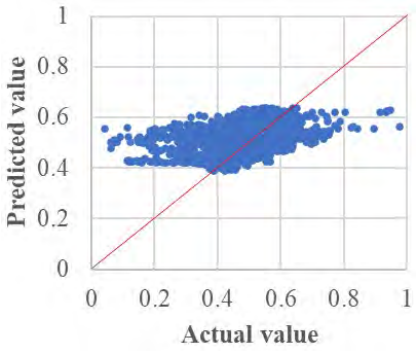
The models' performance is shown in Table 5. The R-square score of the four-well RF model for the training dataset is 0.95 and for the testing dataset is 0.91. The overall RMSE, MAE, and R-squared for prediction using three-well RF models from unseen data are not improved compared to those models without TVD.

Table 5. RF model performance of different datasets with TVD as a feature

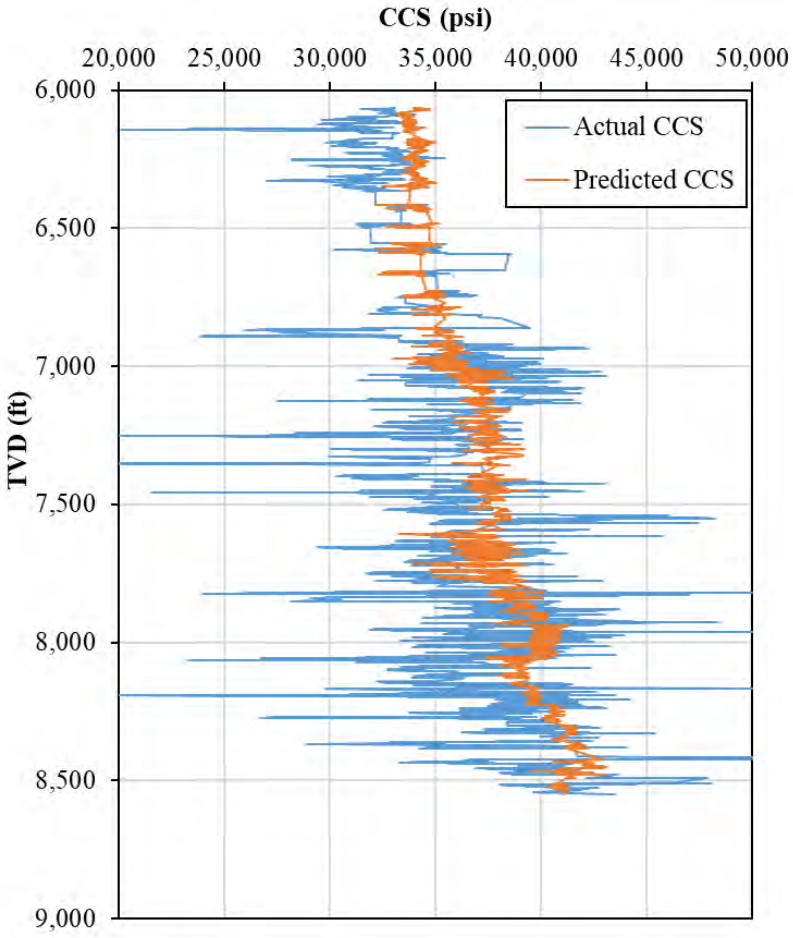
Model	Train data metrics			Test data metrics			Test new dataset	Test new dataset metrics		
	R^2	RMSE	MAE	R^2	RMSE	MAE		R^2	RMSE	MAE
4 wells	0.95	0.02	0.01	0.91	0.02	0.01	N/a	N/a	N/a	N/a
3 wells (excluding 16A(78)-32)	0.95	0.02	0.01	0.93	0.03	0.02	40% of 16A	0.20	0.08	0.06
3 wells (excluding 78B-32)	0.95	0.02	0.01	0.91	0.03	0.02	50% of 78B-32	-0.17	0.11	0.10
3 wells (excluding 16B(78)-32)	0.96	0.02	0.01	0.94	0.03	0.02	90% of 16B(78)-32	-0.10	0.12	0.09
3 wells (excluding 56-32)	0.91	0.03	0.02	0.85	0.04	0.03	49762 vs 43292	0.35	0.07	0.05

However, as shown in Figure 15, the trend of CCS predicted by the model with TVD has a much better match for well 16A(78)-32. Similarly, we also plot the predicted CCS vs. TVD for well 78B-32 and 56-32, and their trends generally match the actual data (refer to Figure 16 and Figure

17). For well 16B(78)-32, since its top drive torque is much larger than that of the other three, and top drive torque is an important impacting factor, the predicted CCS vs. TVD trend is not well aligned with the actual values. It is important to note that in all of these predicted and actual value comparisons, the predicted data is obtained from input drilling data, which is not seen by the corresponding machine learning models before.



(a)



(b)

Figure 15. Comparison between predicted value and actual value of CCS for well 16A(78)-32: (a) normalized predicted value vs normalized actual value, (b) predicted and actual value along TVD. The RF model trained with the dataset from three wells [excluding 16A(78)-32, including 16B(78)-32, 78B-32 and 56-32]. TVD is added as a feature.

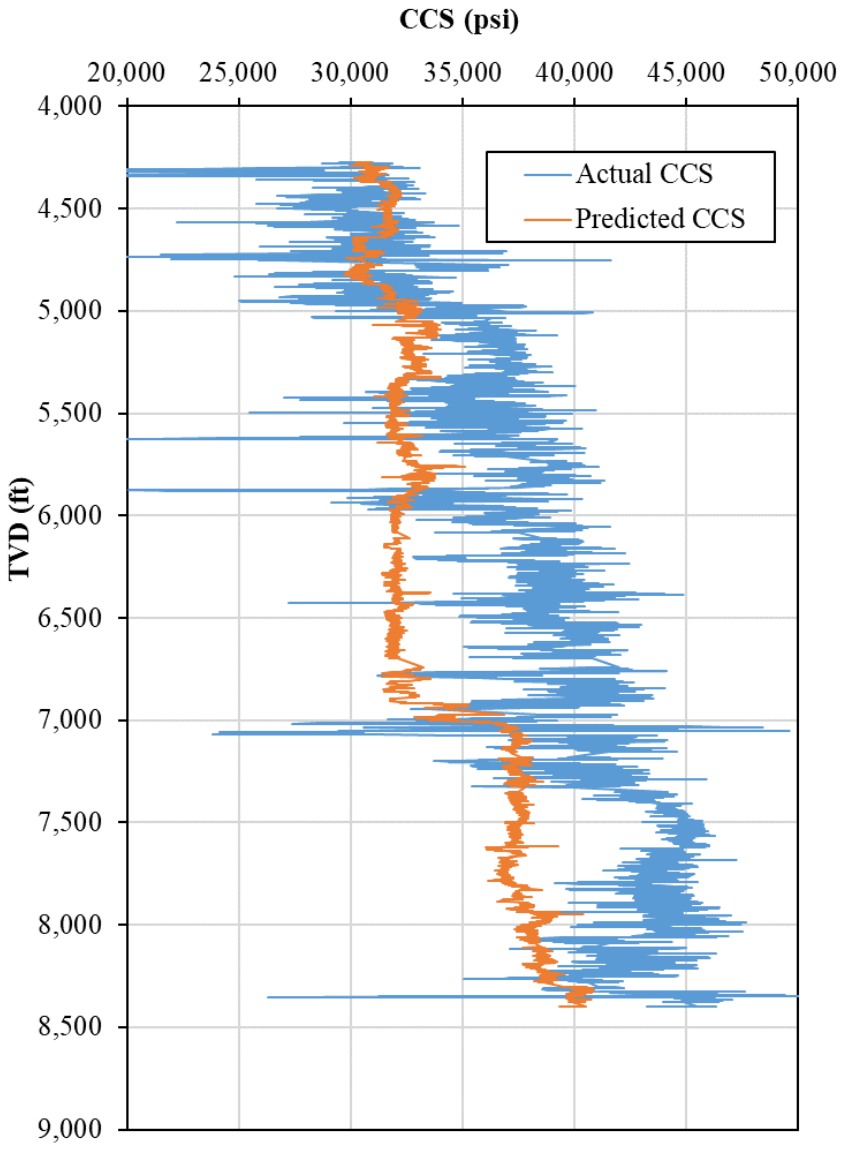


Figure 16. Comparison between predicted value and actual value of CCS for well 78B-32. The predicted value is predicted from the RF model trained with the dataset from three wells [excluding 78B-32, including 16A(78)-32, 16B(78)-32, and 56-32]. TVD is a feature.

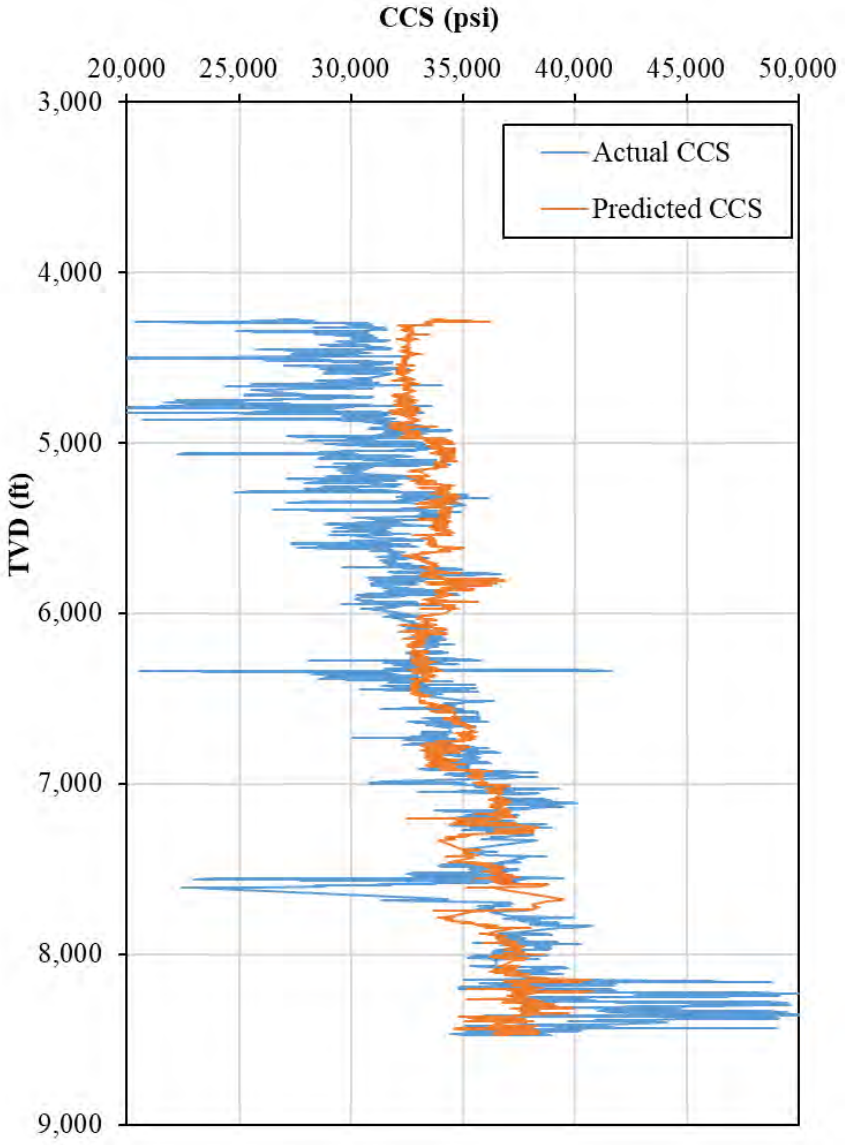

Figure 17. Comparison between predicted value and actual value of CCS for well 56-32. The predicted value is predicted from the RF model trained with the dataset from three wells [excluding 56-32, including 16A(78)-32, 16B(78)-32, and 78B-32]. TVD is a feature.

4.2 Machine Learning Model – ANN

Here we tested the performance of another machine learning model – ANN model. ANNs consist of interconnected neurons, organized in layers. The connections between neurons have associated weights that determine the strength of the signal passing through them. ANNs are typically composed of three types of layers: input layer, hidden layer, and output layer (LeCun et al., 1998).

Table 6 shows the performance of two ANN models trained with 4 wells dataset and 3 wells dataset excluding well 16A(78)-32. TVD is added as a feature during the training of ANN models. The dataset is split into 80% of training and 20% of testing. The overall performance of the RF model is better than the ANN model. The RMSE and MAE of the ANN model are slightly larger than the RF model, but R^2 of the ANN models is much smaller than the RF model. From Figure 18, we can

also see that the variation of predicted CCS vs. TVD for the ANN model is worse than that of the RF model (see Figure 15).

Table 6. ANN model performance of different datasets (TVD as a feature)

Model	Train data metrics			Test data metrics			Test new dataset	Test new dataset (unseen) metrics		
	R^2	RMSE	MAE	R^2	RMSE	MAE		R^2	RMSE	MAE
4 wells	0.66	0.04	0.03	0.66	0.04	0.03	N/a	N/a	N/a	N/a
3 wells (excluding 16A(78)-32)	0.71	0.06	0.04	0.71	0.06	0.04	40% of 16A (7593 rows of 16A)	-0.09	0.09	0.07

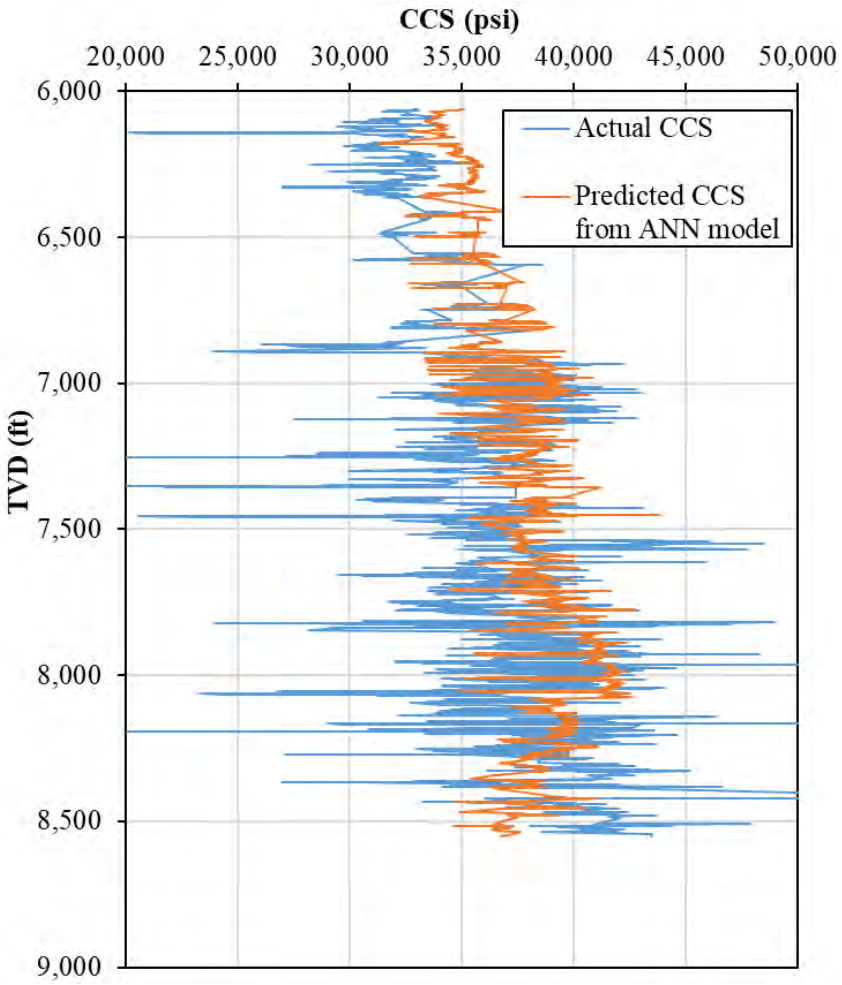

Figure 18. Comparison between predicted value from the ANN model and actual value of CCS for well 16A(78)-32. The ANN model trained with the dataset of three wells excluding 16A(78)-32 [including 16B(78)-32, 78B-32 and 56-32]. TVD is added as a feature.

4.3 Discussion

Based on the above analysis, the performances of the RF model are better than those of the ANN model, both for the training data and unseen data. We also compared the performances between the models with TVD as a feature and those without TVD: the metrics (R^2, RMSE and MAE) are similar, but the trend of CCS vs. TVD for the model trained with TVD as a feature has a better match. The predictions of unseen data have a low RMSE but also a low R^2, which means the models might make accurate predictions but fail to explain much of the variability in the data. Nevertheless, the trend of predicted CCS along TVD by unseen drilling data matches well with the actual value.

The reasons for low R^2 could be due to overfitting, high variance, or inadequate features. During the training of the RF model, K-fold cross validation, was employed along with setting maximum tree depth and minimum number of samples at a leaf node to reduce the overfitting.

In the development of predictive models, particularly in the context of drilling activities, the selection and refinement of features are critical to achieving high accuracy and reliability. One strategy to enhance model performance is the incorporation of additional relevant features. For instance, including the condition of drill bits as a feature may prove advantageous. The state of drill bits can significantly influence drilling efficiency and outcomes, and by capturing this information, the model can better reflect the complexities of the drilling process.

Conversely, the presence of irrelevant or redundant features in a model can lead to high variance. This condition is characterized by the model's excellent performance on training data but poor generalizability to new, unseen data. To address this, it may be beneficial to streamline the model by identifying and removing features that do not contribute meaningfully to the predictive accuracy. Simplifying the feature set not only helps in reducing the risk of overfitting but also enhances the interpretability of the model.

Moreover, expanding the dataset with more comprehensive drilling data from the region could further refine the model’s performance. Additional data can provide a more robust foundation for training and testing, allowing the model to capture a wider array of scenarios and variations within the data. This, in turn, can help in building a model that is both more accurate and generalizable across different drilling conditions and environments.

5. Conclusions

In this study, machine learning methods were employed to establish the relationship between drilling data and CCS of the rock at Utah FORGE site. The training dataset comprised data from four deep wells that used PDC drill bits. The CCS is calculated from sonic logs by empirical formula and calibrated by core testing results.

Initially, data preprocessing involved the removal of outliers, such as exceptionally large values, and sliding sections (where the top drive rotary was zero but the bit RPM was non-zero), ensuring that only rotating sections indicative of bit-rock interactions were analyzed. The analysis identified three parameters—TVD, top drive torque, and ROP—as having the highest correlation with CCS. A further refinement based on pair plots and a correlation heatmap showed a high correlation between bit RPM and top drive rotary, leading to the exclusive use of the "top drive rotary" feature.

The selected features for training the machine learning models included TVD, weight on bit, top drive torque, differential pressure, standpipe pressure, top drive rotary, flow rate, and ROP.

Two types of models, Random Forest (RF) and Artificial Neural Network (ANN), were developed to predict CCS. The RF model outperformed the ANN, consistently showing TVD, top drive torque, ROP, and standpipe pressure as the most influential features. The RF model demonstrated robust predictive ability, with an R-square score of 0.95 for the training set and 0.91 for the test set. The predictions of UCS using three-well RF models using unseen drilling data have a low RMSE (around 0.10). Despite a lower R^2 score indicating limited explanation of variability in unseen data, the model effectively predicted CCS trends along TVD, aligning closely with actual values.

These results suggest that the refined RF model is highly effective for predicting CCS based on specific drilling parameters and can be confidently applied to forecast CCS in new wells within this region. This capability underscores the potential of machine learning in enhancing the precision of geological predictions based on drilling data, thereby supporting more informed decision-making in geological and drilling operations.

Acknowledgements

Funding for this work was provided by the U.S. DOE under grant DE-EE0007080 “Enhanced Geothermal System Concept Testing and Development at the Milford City, Utah FORGE Site.” We thank the many stakeholders who are supporting this project, including Smithfield, Utah School and Institutional Trust Lands Administration, and Beaver County, as well as the Utah Governor’s Office of Energy Development.

Mineral Extraction

Quantifying the Impact of Water Needs for Lithium Production from Geothermal Brines in the Salton Sea KGRA

Shaily Gupta[a] and Margaret M. Busse[a,b]

Keywords

Water Use, Direct Lithium Extraction, Geothermal Energy, Renewable Energy, Salton Sea, Known Geothermal Resource Area

ABSTRACT

Geothermal brines from the Salton Sea Known Geothermal Resource Area (SS-KGRA) are highly saline and contain high concentrations of lithium. These brines are currently brought to the surface, used to produce geothermal energy, and then reinjected into the subsurface to maintain pressure in the geothermal reservoir. Before reinjection, there is an opportunity to extract the lithium. This is promising for securing a domestic supply chain of lithium to help meet energy storage needs for transition to a renewable energy grid. Previous analyses of how much water these processes will require in the region are limited by the lack of data available on freshwater use for both geothermal energy production and direct lithium extraction (DLE) processes. In this work, we develop improved estimates for water use in geothermal energy production and DLE processes. Our findings indicate that the water requirements for geothermal facilities may be higher than previously reported, potentially reaching 46.3 acre-feet per year per megawatt (AFY/MW) in some cases, compared to the average of 16 AFY/MW. For DLE, the ion exchange method is identified as potentially more water-intensive than liquid-liquid extraction. Additionally, the need to reallocate agricultural water to support these processes could strain local water resources and lower the water level of the Salton Sea.

1. Introduction

The surge in demand for energy storage devices has been fueled, in large part, by the rapid progress and widespread integration of renewable energy technologies in recent years. Lithium is highly valued as an optimal battery metal because it is the lightest, naturally occurring metal (Zeng et al. 2024). Lithium is primarily sourced from two types of deposits: hard rock, such as spodumene and lepidolite, and brine deposits. These sources contribute 34% and 66% of the global lithium supply, respectively. Extraction from brine is generally more cost-effective and energy-efficient compared to hard rock mining (Boroumand and Razmjou, 2024).

In the SS-KGRA, there are significant levels of lithium in the geothermal brine, and this brine is already being brought to the surface to produce energy. This provides a readily available source of lithium that can be extracted before the brine is reinjected into geothermal wells. As with any mineral extraction, the processes required consume other valuable resources such as freshwater. For the SS-KGRA, this is important because the region is already experiencing water shortages.

Previous studies have used public data to assess the environmental impacts of geothermal and lithium extraction in the region. These studies found that the growing geothermal/lithium industry would have a minor effect on regional water availability compared to the expected reductions in water allocation from the Imperial Irrigation District (IID). The expected IID reductions are a result of declining Colorado River levels (Busse et al. 2023; Dobson et al. 2023).

In this work, we improve the previous analysis with more up-to-date and detailed understanding of regional water use for geothermal and DLE processes. We collected data from the literature, industry, and patents to create water use ranges for regional geothermal energy production. We also synthesized data on potential DLE unit processes. This approach allowed us to scale potential water use to existing, planned, and maximum geothermal capacities.

2. Methods

2.1 Geothermal Production Overview

A geothermal power plant is typically comprised of a geothermal resource production facility, a power generation facility, and various ancillary installations. In Figure 1, these are indicated by the dashed boxes, and the ancillary installation shown in this instance is a DLE facility for producing lithium hydroxide monohydrate (Figure 1c). High-, standard-, and low-pressure steam is directed from the geothermal resource production facility (Figure 1b) to the power generation facility (Figure 1a) to operate the turbine generator system, producing electricity.

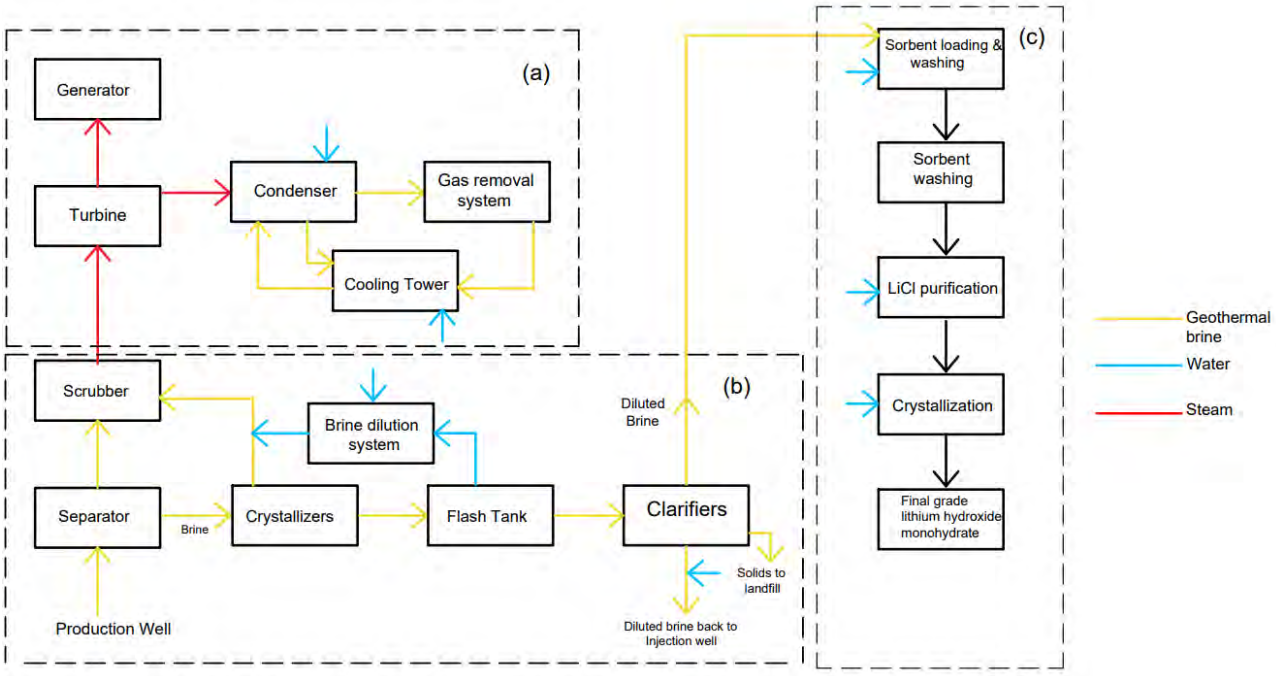

Figure 1. General flow of freshwater (blue lines), geothermal brine (yellow lines), and steam (red lines) through the flash geothermal process in the SS-KGRA.

The resource production facility (Figure 1a) comprises two types of wells: production wells and injection wells. During standard operations, the production fluids are channeled from production wells to the high-pressure separator. The high-pressure separator system divides the production fluid into steam and residual production fluid. The high-pressure steam is sent to the high-pressure scrubber and demister before it reaches the steam turbine. The remaining fluid moves through these same processes at standard-pressure and low-pressure to extract all possible steam for energy production (Figure 1b). The remaining fluid is processed to produce additional steam for energy production and prepare the remaining production fluid for reinjection (Black Rock Geothermal LLC 2023, Featherstone et al., 2020).

2.1.1 Geothermal Freshwater Use

Freshwater is mainly used for dilution and cooling throughout these processes. 29% of the total operating water, is introduced into the system as dilution water for geothermal brine moving from the crystallizer to the scrubber. This water flows through a condenser, mixing with fluid from the flash tank before joining the stream to the scrubber. Remaining production fluid from the flash tank is directed to clarifiers to remove solids before reinjection. This process has two stages: the first removes solids in slurry form, and the second dewaters the slurry. After passing through the secondary clarifier, spent geothermal fluid is directed to the injection wells, and freshwater is added before reinjection to prevent precipitation of solids.

Steam exiting the turbine is condensed in a shell-and-tube condenser, where freshwater is added to support the cooling process. The resulting condensate is piped to the biological oxidizer for hydrogen sulfide removal. The non-condensable gas (NCG) removal system uses ejectors and vacuum pumps to extract gases from the condenser and directs them to the cooling tower basin. Water circulates through the cooling tower, cooled by evaporation and air heat exchange, and is then pumped back to the condenser to condense the steam. This circulating water, which constitutes 70% of the plant's operating water, is managed by vertical wet-pit pumps for both turbine condensers and plant auxiliary cooling needs.

To quantify the amount of water required for geothermal energy production, we extracted information from Environmental Impact Reports (EIRs) that have been submitted by companies in the SS-KGRA. Water use data for construction and operation of geothermal facilities was provided in documentation from Controlled Thermal Resources, Energy Source Minerals, and Berkshire Hathaway (BHER) (Energy Source, 2012; Black Rock Geothermal LLC, 2023; Elmore North Geothermal LLC, 2023; Morton Bay Geothermal LLC, 2023; Controlled Thermal Resources, Inc., 2024).

2.2 Lithium Extraction Process

The conventional method for extracting lithium from brine involves pumping the lithium-rich brine into expansive surface ponds that can cover thousands of acres. In these ponds, lithium and other salts are concentrated through passive solar evaporation over the course of a year or more to increase the lithium concentration to about 6,000 mg/kg (Khalil et al., 2022).

DLE is emerging as a more efficient, alternative to this approach. DLE approaches offer distinct advantages over conventional evaporation ponds and Hard rock mining methods, such as reduced land and overall water usage (fossil and freshwater), faster time-to-market for lithium products,

and lower carbon emissions during operations (Warren, 2021). In broad terms, DLE techniques can be categorized into three main classes: adsorption, ion exchange, and solvent extraction. Regardless of the specific DLE technique employed, either alone or in combination with additional processing steps, these methods must be capable of selectively extracting lithium from chemically complex brines containing high concentrations of various ionic species like sodium, potassium, calcium, magnesium, borates, sulfates. Moreover, for geothermal brines, silica as well as potentially elevated levels of iron, manganese, and other dissolved components, must be considered (Warren, 2021). To quantify freshwater use for various lithium extraction processes, we conducted a literature search and evaluated industry and patent data.

2.3 Local Water Cuts Proposed

In December 2023, the Imperial Irrigation District (IID) (local water authority in the Imperial Valley) with other local water authorities, signed an agreement for water conservation into 2026. The water districts, in return, receive funding from the Inflation Reduction Act to support water conservation efforts. IID plans to focus on agriculture and fund an irrigation efficiency program (Saegert, 2023). In 2023, IID agreed to conserve 100,000 AF. IID is expected to conserve 800,000 AF between 2024 – 2026 (U.S. Department of the Interior, 2023). These additional cuts will be in exchange for $175 million in federal funds for projects at the Salton Sea (IID, 2024b). Conservation measures are to be determined by IID (Garcia, 2024). In previous analysis, we considered at 10% and 40% cut to water allocation for the region (Busse et al., 2023; Dobson et al., 2023). The proposed 800,000 AF over 3 years (Garcia, 2024), if divided equally between each year, represents a 8.6% cut to the 3.1 million AF annual entitlement (IID, 2024a), which is what we will consider herein.

3. Results and Discussion

3.1 Geothermal Water Use in the SS-KGRA

In the United States, there are more than 90 operational geothermal power plants, many of which have been running for over three decades (Robins et al., 2021). The common types of geothermal plants include dry-steam, flash-steam, and binary cycle, with flash-steam plants being the most prevalent in the SS-KGRA. According to historical and estimated water use data, geothermal facilities in the SS-KGRA typically require an average of 16 acre-feet (AF) of water per megawatt (MW) of net generation capacity annually (Dobson et al., 2023). However, water needs can vary significantly across different facilities, ranging from as low as 0.4 AF to as high as 32 AF per MW each year (Dobson et al., 2023).

Here we provide a breakdown of the water use for geothermal facilities in the SS-KGRA that have reported water use for construction (Table 1) and operation (Table 2). Freshwater in this analysis is water purchased from IID. Freshwater required for construction is minimal compared to the freshwater required for operation over the lifespan of the facilities. Operational freshwater use from these facilities ranges from 4 – 46 AFY/MW (Table 2), higher than what was previously reported. It is important to note that the total required water for operation is higher than the freshwater requirement. For example, Elmore North and Morton Bay require twice as much water, but the plant to use steam condensate for the additional water (Elmore North Geothermal LLC

2023; Morton Bay Geothermal LLC 2023). Black Rock Geothermal plans to use 80% steam condensate to meet their total required water need (Black Rock Geothermal LLC 2023).

Table 1. Summary of the construction freshwater use for proposed geothermal facilities in the SS-KGRA.

The average geothermal water use from the analysis in Dobson et al. (2023) was used as a comparison to the water use scenarios identified in Table 2. Figure 2 illustrates this impact across the geothermal production scenarios in the region. The current capacity is 400 MWe, the projected capacity of facilities proposed across the next 3 – 4 years is an additional 520 MWe, and the total possible capacity of the resource is 2950 MWe (Kaspereit et al. 2016).

The maximum water use was identified for Elmore North at 46.3 AFY/MW (57110 m^3/MW) compared to the 16 AFY/MW (19735 m^3/MW) average. If all facilities operated at this water use rate, it would almost triple the impact of geothermal in the region, representing a non-negligible increase in regional water use for geothermal energy production.

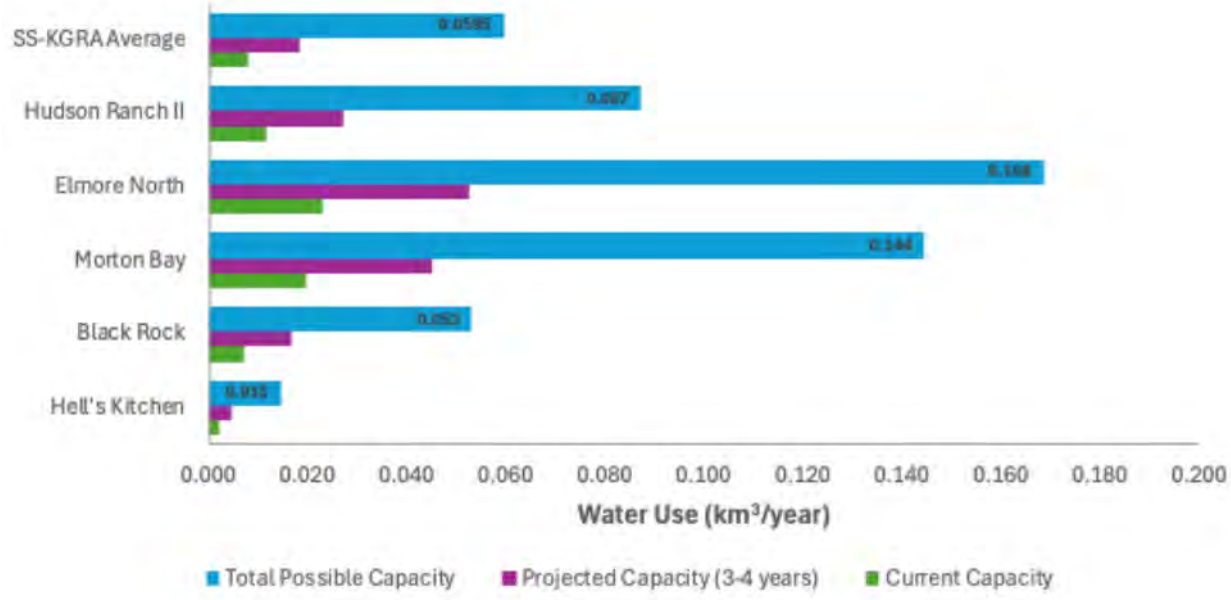

Figure 2. Comparison of how different facility water use projections for geothermal production would compare to the SS-KGRA average water use projections from Dobson et al. (2023).

3.2 Lithium Extraction Water Use

As mentioned previously, the main DLE processes can be categorized as adsorption, ion exchange, and solvent extraction processes. In the SS-KGRA the expected processes are adsorption and ion exchange. Unfortunately, most literature studies we identified did not quantify water use of these processes. Moreover, many did not test their proposed method with brines similar to those in the Salton Sea. Table 3 provides a summary of some of the brines studied at bench-scale for DLE in comparison to the brine composition in the SS-KGRA. Studies that evaluated synthetic brines often did not include fluid composition in this form. For example, Zhang et al. (2024) reported NaCl, LiCl, $MgCl_2$, and $CaCl_2$ concentrations of their synthetic brine. The geothermal brine from Suharyanto et al. (2024) is the most similar we have found to the Salton Sea brines, and this study evaluated an adsorption process, but did not report water use.

Table 3. Summary of geothermal brine composition in the SS-KGRA compared to brine compositions from DLE studies in the literature.

	Dissolved Solids (mg/L)					
Type of Fluid	Lithium (Li)	Sodium (Na)	Magnesium (Mg)	Calcium (Ca^{2+})	Boron (B)	Citation
Salton Sea Brine	211	52,000	160	24,000	350	(Gagne et al. 2015)
East Mesa Brine	6.3	2,600	3.4	130	5.4	(Gagne et al. 2015)
Salt Lake Brine	969	77,650	34,010	176	807	(Luo et al. 2021)
Geothermal Brine	27.02	8,834	422.66	1308.3	86.48	(Suharyanto et al. 2024)

Based on these constraints from the bench-scale literature, we have summarized the water use information we were able to obtain for DLE processes from patents and industry EIRs.

3.2.1 Ion-Exchange

Based on a 2020 patent from EnergySource Minerals LLC, we developed a flow diagram of the proposed process that would exist in an ion-exchange-based DLE facility (Figure 2). This flow includes freshwater flows into the system (blue lines), geothermal brine flow (yellow lines), and process water (brown lines) (Featherstone et al., 2020). For this process, EnergySource Minerals LLC reported the anticipated water use for the entire process at 3400 AFY, but specific allocation of this water was not specified. During normal operation, they also identify a water requirement for fugitive dust control at 56 AFY, which sums up to an operational water need of 3456 AFY at the DLE facility. The estimated duration of the project is 30 years, consuming approximately 102,112 AFY water in its entire duration to produce 17,000 tonne of lithium carbonate equivalent (LCE) (Energy Source, 2012). Though, as mentioned in Dobson et al. (2023), EnergySource has indicated that this may be an overestimate of water use.

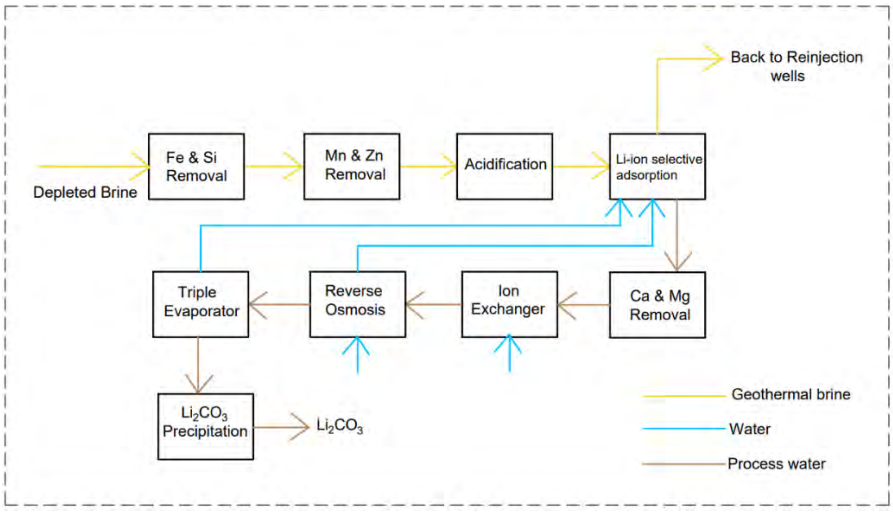

Figure 3. General flow of freshwater (blue lines), geothermal brine (yellow lines), and process water (brown lines) through the ion exchange process as it is often set up in the SS-KGRA (Featherstone et al., 2020).

In their proposed process depleted brine is mixed with limestone to precipitate out iron (Fe) and silicon (Si) compounds, and quicklime is used to remove manganese (Mn) and zinc (Zn) under conditions that do not remove lithium. The addition of these compounds raises the pH of the brine, which is then lowered through the addition of hydrochloric acid (HCl). An aluminum monohydroxide (AlOH)-based cationic resin is used to selectively adsorb lithium ions from the pretreated brine solution. The adsorbed lithium is then stripped from the resin using freshwater, yielding a lithium-enriched solution for further processing. The remaining geothermal fluid is diverted back to the reinjection well (Featherstone et al., 2020).

In the lithium-enriched solution, residual calcium (Ca) and magnesium (Mg) are precipitated out by adding sodium hydroxide and soda ash. An ion exchange step further removes any lingering divalent ion impurities like Ca, Mg and boron (B). To increase the lithium concentration, the solution volume is reduced through reverse osmosis followed by triple-effect evaporation. The triple effect evaporator utilizes steam from geothermal operations and/or a fuel boiler to operate. After processing through the evaporator, the lithium concentration in the product stream is increased from about 5,000 ppm to about 30,000 ppm. Soda ash is introduced to precipitate lithium as lithium carbonate technical grade product.

The precipitated battery-grade lithium carbonate goes through final steps of washing to remove residual impurities, followed by centrifugation to dewater the solid product. The washing fluid is not identified. Finally, the dewatered lithium carbonate is sent to a rotary dryer for complete drying, yielding the final battery-grade lithium carbonate product (Featherstone et al., 2020). A recent study by Schenker et al. (2024) conducted a parameterized life cycle assessment (due to lack of available data) of lithium carbonate production from geothermal brines in the SS-KGRA and Upper Rhine Graben in Germany. They identified that large amounts of freshwater are used in the adsorption process and for regenerating the ion-exchange media. This is in line with where we have identified freshwater inputs in the Featherstone et al. (2020) process.

3.2.2 Liquid-Liquid Extraction

In the liquid-liquid extraction process, impurities are removed from the geothermal brine before lithium is extracted using an adsorption process to selectively bind lithium ions to a solvent. Two streams result from the adsorption process: one returns to the reinjection well, while the purified liquid containing LiCl undergoes further purification. The pH of the lithium chloride stream drops from 5 to about 2.5 before entering solvent extraction process, which occurs in tall, pulsed columns. Here, extraction separates impurity ions in the aqueous phase from lithium ions in the organic phase. Sulfuric acid is used to strip the lithium from the organic phase back into an aqueous solution. The organic phase is then able to be reused. The final purification step involves electrolysis and crystallization to produce dried lithium hydroxide crystals.

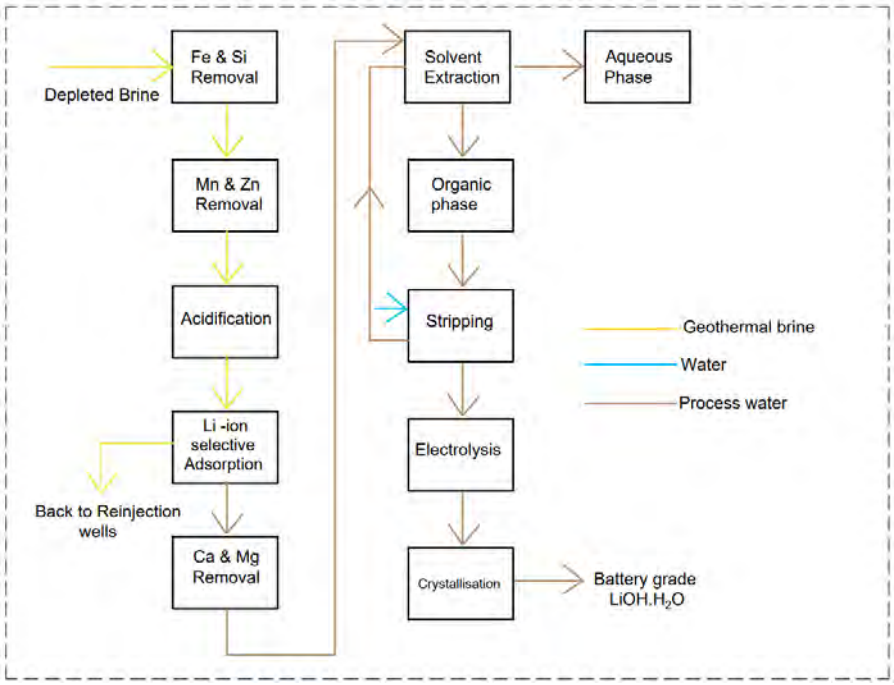

Figure 4. General flow of freshwater (blue lines), geothermal brine (yellow lines), and process water (brown lines) through the liquid-liquid extraction process for DLE (Featherstone et al., 2020; Sun et al., 2021).

We attempted to extract data for freshwater use in liquid-liquid extraction processes from the literature, but we did not find quantitative values for water use. We were able to extract some information on where water is used in the process. This analysis indicated that liquid-liquid extraction may reduce freshwater consumption compared to ion exchange, as it eliminates the need for resin desorption and regeneration, which are major freshwater consumers. Only the stripping step in this DLE process consumes freshwater, as indicated in Figure 4.

3.3 Impact on Regional Water Resources

Due to the lack of quantified water use from applicable DLE processes in the literature, water use for lithium extraction in this analysis remains the same as what was estimated in the Dobson et al. (2023) report. This value is the average estimated water use from three companies – EnergySource Minerals, Berkshire Hathaway, and Controlled Thermal Resources – at 328 m^3/tonne of lithium carbonate equivalent (Paz et al., 2022; Controlled Thermal Resources, Inc., 2024). Based on the agreed upon cuts to water resources in the SS-KGRA (8.6% of the 2022 allocation), we evaluated the possible impacts of geothermal expansion under average and high water use conditions and a scenario of average water use for lithium extraction on the regional water supply (Figure 5).

If the full geothermal field was utilized, the high geothermal water use estimate would require 1.4 times the water allocation for renewable energy compared to the average water estimate. For the planned geothermal expansion, the higher geothermal water estimate would only increase 1.2 times. For context, this additional water equates to a reduction in 2025 acres of land irrigation in the region.

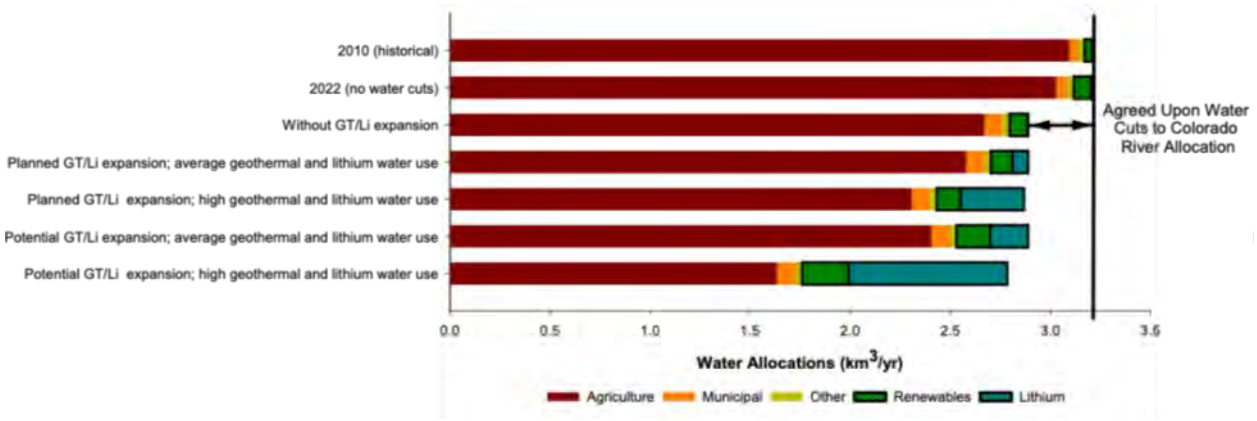

Figure 5. Summary of expected impact of water cuts, geothermal expansion, and DLE on local water availability.

4. Conclusion

This study provides a preliminary analysis of the unit process water requirements for both geothermal energy production and direct lithium extraction (DLE) processes at the SS-KGRA. By developing more detailed water use information, we were able to quantify potential water use scenarios and their impact on the region. Our results show that geothermal facilities in the SS-KGRA may require as much as 46.3 AFY/MW, even though the average reported use in the region is 16 AFY/MW. For DLE processes, we expect the ion exchange method to be more water-intensive than liquid-liquid extraction, with the latter eliminating water needs for resin desorption and regeneration. But from the patents submitted by companies in the region, ion-exchange is likely the process that will be used. Further, we evaluated the potential impacts of the agree upon water cuts (8.6%) along with scenarios for geothermal and lithium production expansion in the region. This analysis indicates that maximizing geothermal and DLE capacity could strain local water resources.

Reducing the available agricultural water in the region by reallocating it to geothermal energy expansion and lithium production has the potential to impact the water level of the Salton Sea, and thus the toxins released to the air because of this decline. This will be exacerbated by current regional efforts to improve irrigation efficiency, which will reduce runoff to the sea. This impact was outside the scope of this work, but it should be evaluated further.

Lithium, Reservoir Simulation, Recovery Factor, Coproduction

ABSTRACT

New methods for extraction of Lithium from Lithium-rich geothermal brines, combined with the increased industrial demand for Lithium for batteries has caused significant interest in using geothermal brine as an economically viable domestic source of Lithium. In initial simulations of co-production of geothermal energy and lithium it was found that well pattern (production and injection well layout) can significantly affect lithium production. A simplified numerical model was constructed that simulates the production of lithium rich brine and injection of lithium depleted brines under several configurations, with the aim of understanding the effect of well patterns on lithium recovery factors. While the interactions of Lithium with rocks and brine are highly simplified pending further research, this numerical model provides a preliminary tool to quantitatively compare lithium production under various scenarios. It was found that lithium production was far more sensitive to well patterns than geothermal.

1. Introduction

In anticipation of making commercial simulation forecasts for the co-production of geothermal energy and lithium, a general non-specific numerical model was developed in TETRAD. The model doesn't represent a particular field or use propriety data and is only intended to provide insight and sensitivity analysis. It is known lithium extraction is being implemented in a geothermal field where the production and injection wells have already been drilled using patterns and concepts applicable to geothermal-only production, and those can't be changed. In that case this preliminary modeling can be used to gain insight into lithium recovery factors. It is also possible that some new projects will start as co-production from the start, and in those cases, the preliminary model can provide insight into the types of well layouts that are advantageous.

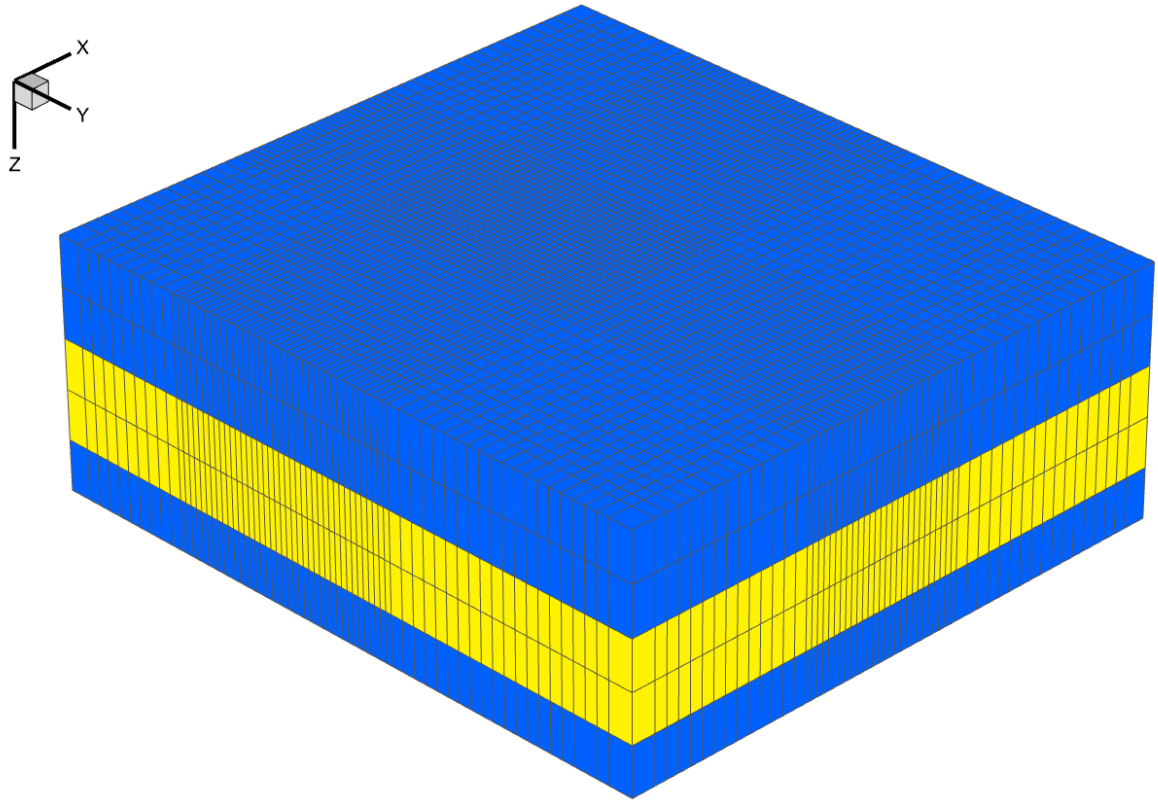

Figure 1: 3-Dimensional view of the model grid

2. Overview of Preliminary Modeling

The model's grid divides each one square mile section into equal sized grid blocks (4x4) and the entire grid covers an area more than 10 by 10 km (Figure 1). The model has the ability after making a run to "blank" peripheral areas and to visualize a focus area Figure 2. This modeling technique allows the model to include simulated interaction with the surrounding resource, which is necessary to properly model effects over time, such as recharge into or outflow from a focus area and adjacent areas.

Figure 2 is the model grid showing the focus at the model's layer 3, which is at an elevation of 1500 meters below sea level. Shown in Figure 3 is the well layout for Scenario as shown in a sample development plan. This plan has three production wells (PW1, PW2, and PW3) and three injection wells (IW1, IW2, and IW3). This figure shows a 2-dimensional representation of two sample parameter distributions (horizontal permeability and estimated lithium concentration). The lithium concentration contours are hypothetical and not based on data.

The model was used to make sample test runs to quantify the effects of different well layouts. The test run supposed three production wells each at 1200 tph for a total production rate of 3600 tph (7920 kph). Within the model the production flows into a separator at 17.2 barg (250 psig) which calculates the flash percentage continuously based on the inflow parameters. The model supposes that injected fluid is the post-flash brine, which is cooled and enriched in chloride with all lithium

removed. This is an assumption because lithium extraction process will remove all the lithium, for the purposes of reservoir engineering and prediction of the possible decline of produced lithium over time, this is the conservative approach

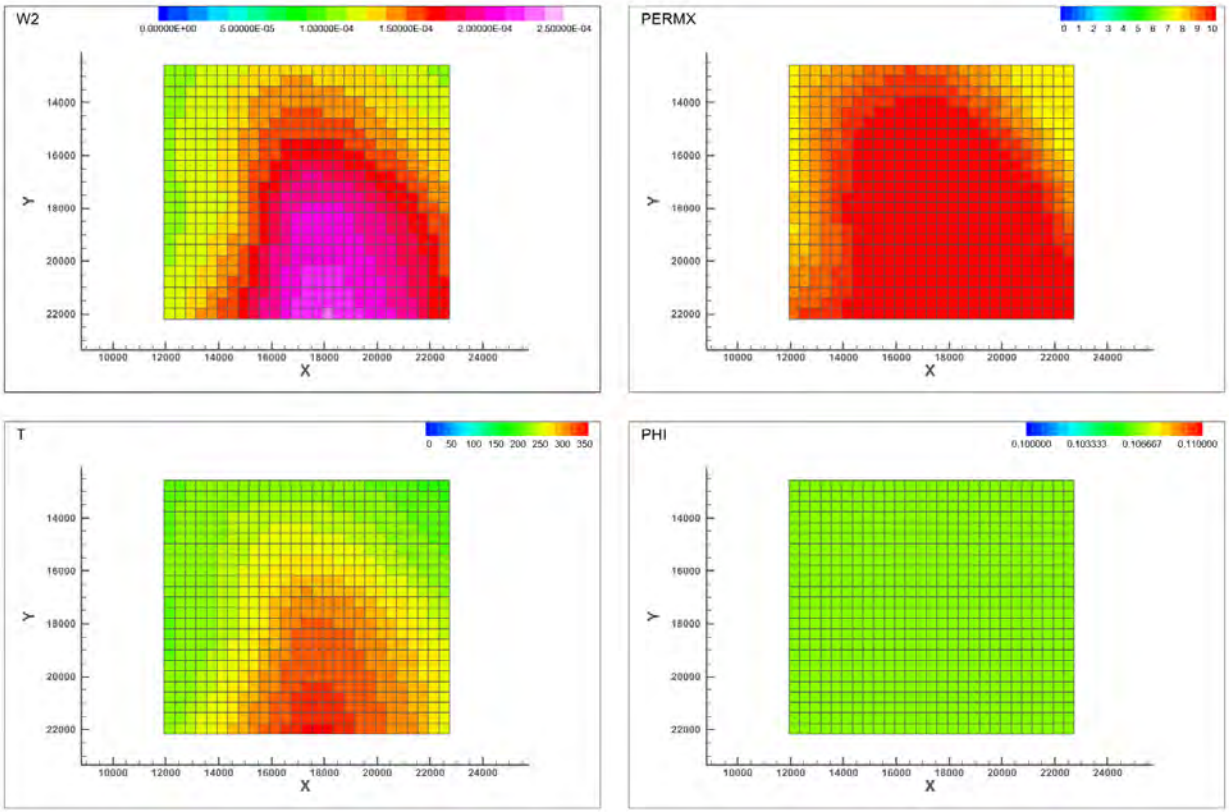

Figure 2: 3-Dimensional view of the model grid

3. Simulation of Full-Field Production with Preliminary Model

The preliminary model was used to model a hypothetical 55 Mwe development as known from published cases. For the simulation, it was assumed that each plant was single flash at 250 psig and required 1100 kph of steam (at 250 psig), which equates to 55 MWe at a consumption rate of 20 kph/MWe. In the model, each plant was configured with 3 production wells and 3 injection wells. In the model, each plant's three production wells were flowed into a simulated separator at 250 psig which automatically calculated the flash at each timestep.

The production flowing into the separators contained TDS including lithium. The result of the simulated flash was steam and brine (with TDS including lithium). The mass of the flashed steam was removed from the model. We assumed that the brine with TDS (including lithium) was then sent through a lithium extraction process which removed the entirety of the lithium and the remaining brine at 210 deg C (with enriched TDS and no lithium) was split into three streams to be reinjected. Note the injection brine is higher in TDS than the produced brine but is devoid of lithium. The assumption that all lithium is removed from the brine creates "worst case" scenario for lithium decline as the injectate has zero lithium. It was found that regarding the forecasted enthalpy, there was low sensitivity to well locations, thus for a geothermal-only development well placement is less important. For lithium production well location was much more important

because relatively small adjustments in well layout can lead to much different lithium recovery versus time, while those same small adjustments had a negligible effect on the geothermal performance (steam flow and enthalpy).

Figures 6, 7, and 8 show the well layout in the simulation grid for Layer 3 (1500mBSL) with respectively; the interpreted initial temperature, horizontal permeability, and lithium concentration. There is some correlation of permeability, temperature, and lithium concentrations but it was not possible to use one overall correlation to generate contours. . Figure 4 shows the results of the test run described above for lithium concentration decline (shown as the percentage of initial concentration) and the average flowing downhole temperature from the production wells over time. This was a 30-year simulated forecast (2025 to 2055). The results show that lithium concentration to be nearly constant in the first 5 years of production, then predicts a gradual decline such that the lithium concentration is 75% of its initial concentration in 2055. The predicted slow downhole temperature decline is near linear and the temperature reduction in 2055 is less than 4 deg C from the initial resource temperature.

The well configuration used was the most optimal plan investigated, especially for lithium production, out of seven tested layouts, the design of which was guided by waterflooding techniques. Further changes may provide better results, and the final layout should be planned in part by the actual parameter distribution found through drilling. Thus, the presented layout and its resulting performance is a favorable layout considering currently known data and current best estimates of the distribution of parameters in the absence of drilling results. Figure 9 shows that with the current interpretation of parameter distribution the full 1100 kph of steam at 250 psig is maintained on all nine of the units over a 30-year period. This is consistent with the historical performance of the Salton Sea geothermal field that has seen long-term production with only minor (or negligible) declines in enthalpy.

Figure 10 shows the forecasted field-wide lithium production versus time expressed as a fraction of initial concentration, assuming that the reinjected fluid is devoid of lithium making the forecast a “worst case” scenario for the given well layout. For the parameter distribution and well layout, the field-wide lithium concentration declines to 62% of its initial concentration after 30 years. As was noted above, lithium production is sensitive to well layout. The lithium production may improve with further changes in the well layout. In general, for geothermal production, most reasonable layouts give a good result. However, for lithium production better results were found with injection wells far away from production wells configured as “injection islands” or as “line drive” configurations like waterflood design in oil reservoirs.

Figure 11 shows the simulated enthalpy of all the production separators on a mass weighted basis. While minor enthalpy decline is forecasted over 30 years full steam flow is maintained in the simulation by gradually increasing the production rate to add 6-7% more flow by the end of the 30-year period to make up for the minor temperature decline. Thus, a 6-7% increase in total flow from the production wells fully counteracts the enthalpy decline and maintains constant full capacity of steam flow.

4. Conclusions

We have full confidence that the field, with the well layout as configured in the simulation, will support full geothermal production and over 70% of the initial lithium production over a 30-year period. Lithium production was found to be more sensitive to well layout than geothermal production. Within limits, the lithium recovery could be enhanced by further experimenting with additional well layouts guided by waterflood techniques in a more detailed reservoir numerical model. Maintaining and continually updating a reservoir model will allow an operator to optimize field development decisions throughout the life of the project.

What's in Your Brine - a Case for Critical Minerals Co-production from Geothermal Brines

Kim Mohler

GLJ Ltd., Calgary, Alberta, Canada

Keywords

Geothermal, Lithium, Brine, Direct lithium extraction, Critical minerals

ABSTRACT

The global demand for production of critical minerals to supply the energy transition away from fossil fuels has been increasing at a fast pace. The cost to produce these critical minerals is typically high, with technology testing and development required to produce critical minerals like lithium with a lower carbon footprint.

Lithium is one of the critical minerals that is required for battery manufacturing, driven mainly by electric vehicle demand increasing globally. The global market for lithium is currently supplied primarily by Australia, China, Chile and Argentina from hard rock mining and evaporation ponds (salars). The current production methods for lithium are environmentally destructive with large surface land impacts and have high operating costs.

The advent of Direct Lithium Extraction technologies has opened the opportunity to produce lithium from deep subsurface brines. The processing technology is being piloted for production of lithium hydroxide and lithium carbonate from deep subsurface brines in Germany, Canada, and the USA. Commercial DLE projects are in development utilizing deep subsurface brines that are from reservoirs that have proven oil and gas production or geothermal heat and power production.

Understanding what is in your geothermal brine through geochemical analysis will define the available concentration of lithium in the brine, but also other potential recoverable minerals and metals. The composition of the brine is important to understand as the DLE process is sensitive to geochemical composition, including components or attributes that can make the lithium extraction process less effective or uneconomic. Equally important to understand are the reservoir conditions including pressure and temperature, in order to define the well network plan, production forecast, and operating plan.

Production of lithium from geothermal brines offers a clean green energy solution utilizing a binary Organic Rankine Cycle geothermal power plant design. The extraction of lithium is an energy intensive process and the use of geothermal energy to power the process provides cost savings, emissions reduction, and a renewable energy source. Many geothermal projects produce brines from the deep subsurface that may have sufficient lithium concentrations to warrant further

investigation and potential development for lithium extraction processes co-produced as a value stream.

This paper will describe the considerations for co-production of lithium from geothermal brines. The paper will include a case study of a lithium enriched geothermal brine project in Germany that is currently in progress. The author is a Competent Person for the Germany project.

1. Introduction

The economies of the largest nations are caught in a wave of energy transition activities, resulting from climate change policies that target reduction of greenhouse gases (GHG). “Energy Transition” is a term used since the 1970’s but more popularized in the last decade, to describe the move away from fossil fuels as primary heating and power generation sources to renewable low carbon intensity sources. Technology development has been underway for many decades to bring renewable power sources like wind and solar to the forefront as options to offset high GHG emission electricity. The market share from renewables has been slow to increase, reported in 2023 to represent 30% (IEA Publications, 2024) of global electricity supply. Geothermal power generation is part of the future for renewable energy sources that have low carbon intensity, however the supply from geothermal is still low at 0.5% of global electricity capacity in 2023 (IEA Publications, 2024).

As part of the global energy transition, the shift to electric vehicles is growing at a rapid pace. The International Energy Association (IEA) estimates that almost one in five vehicles sold globally in 2023 were electric (IEA Publications, 2024), which was up by 14% from 2022. A challenge for the growth of the electric vehicle (EV) sector is supplying all the critical minerals needed for battery manufacturing and other electric vehicle components. One of the critical minerals needed is lithium as the lithium-ion battery is still the main rechargeable battery type used in EV’s, with different chemistries being tested to optimize performance, safety and cost.

Lithium is primarily sourced today from hard rock mining and evaporation ponds (salars) from the top producing countries Australia, Chile, and China. These countries are expected to maintain supplies along with growth in lithium production from Argentina and Zimbabwe in the coming years. The current production methods have large environmental impacts. Hard rock mining of spodumene requires open pit mining methods that cause large land disturbances and require many steps to process a marketable product. Similarly, the large evaporation ponds (salars) used in South America create environmental disturbances which require long periods of time to achieve the desired lithium concentrations before processing. The operating costs for these current extraction technologies are high and with lithium prices softening in recent years, the profit margins are shrinking.

2. Lithium from Deep Subsurface Brines

There is an opportunity for more environmentally friendly lithium production via wells from deep subsurface reservoirs and lithium enriched brines. Several developments are underway utilizing this production method in North America and Europe, applying Direct Lithium Extraction (DLE) technologies for extraction. DLE technologies include sorption, ion exchange, solvent extraction, membranes, and a few other emerging processes, which selectively remove the lithium ions from the brine. The DLE technologies provide a more sustainable and faster method of producing

lithium for feedstock to battery manufacturing and have also been piloted at some salar operators in South America to improve the production timelines.

Deep subsurface brines can be sourced from geothermal aquifers, and oil and gas reservoirs, which in many cases are already delineated so the well data and reservoir rock data can be leveraged for reservoir modeling for lithium enriched brine production. The key factors that need to be understood for development of an economic lithium brine play from deep subsurface reservoirs are rock formation data, fluid data, and flow deliverability.

The geologic characterization of the target formation is key in determining the size and extent of the rock hosting the brine, and then to understand the petrophysical qualities to define the flow characteristics. As well, data on the potential source rock, caprock, and other formations bounding the reservoir are important to understand and include in the modeling. The data required for the static geomodel are comparable to data needed for geothermal or oil and gas evaluations, including porosity, pay thickness, fluid and gas saturations, shale content, and permeability. Further, subsurface pressure and temperature data is needed for flow modeling. In all cases, starting with data from existing wells is a lower cost way of defining the mineral resource and prioritizing for new reservoir data capture through drilling or testing wells, or acquiring and interpreting seismic data.

When existing wells are available, and the target formation for lithium brine production is already producing for geothermal or oil and gas, it is easier to capture produced fluid for geochemical analysis providing the ability to measure the lithium concentrations and other components of the brine. Typically, fluid analysis for these plays includes only standard analysis of trace elements, which may not include lithium and may not provide a full measurement of all ions. In recent years sampling and analytical programs have been undertaken to determine the lithium concentrations in the brines. In Canada and the United States of America (USA), efforts have been made to document the lithium concentrations from geothermal and oil and gas wells, with resulting data shown below for oil and gas field brines in Alberta, Canada, and the Western USA for geothermal brines (Figure 1, Figure 2).

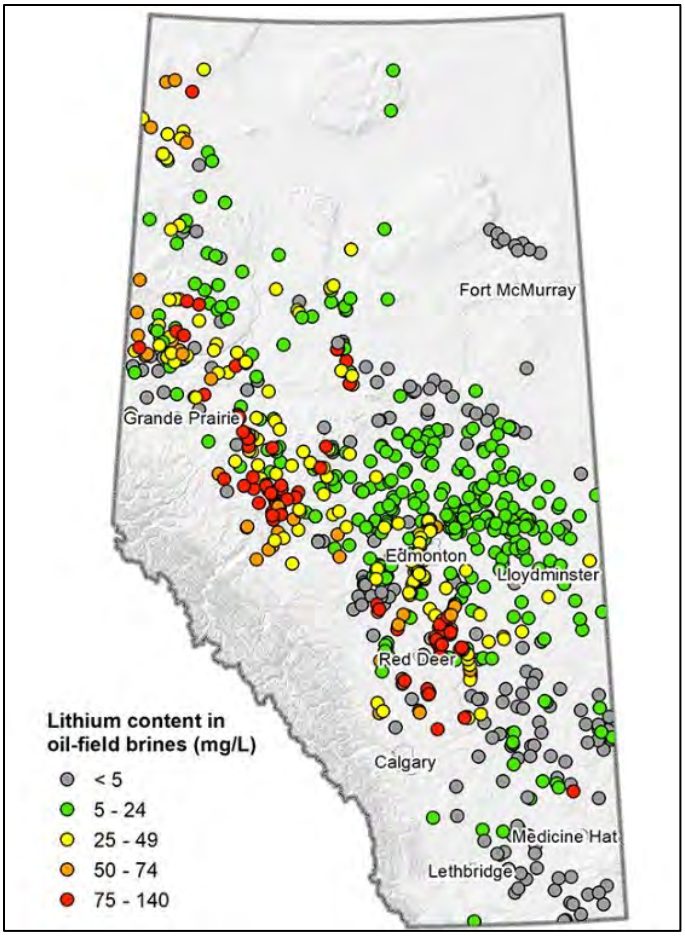

Figure 1: Province of Alberta, Canada, lithium content in existing oil and gas wells in milligram per litre (2024, Alberta Geological Survey, https://ags.aer.ca/research-initiatives/critical-minerals-potential)

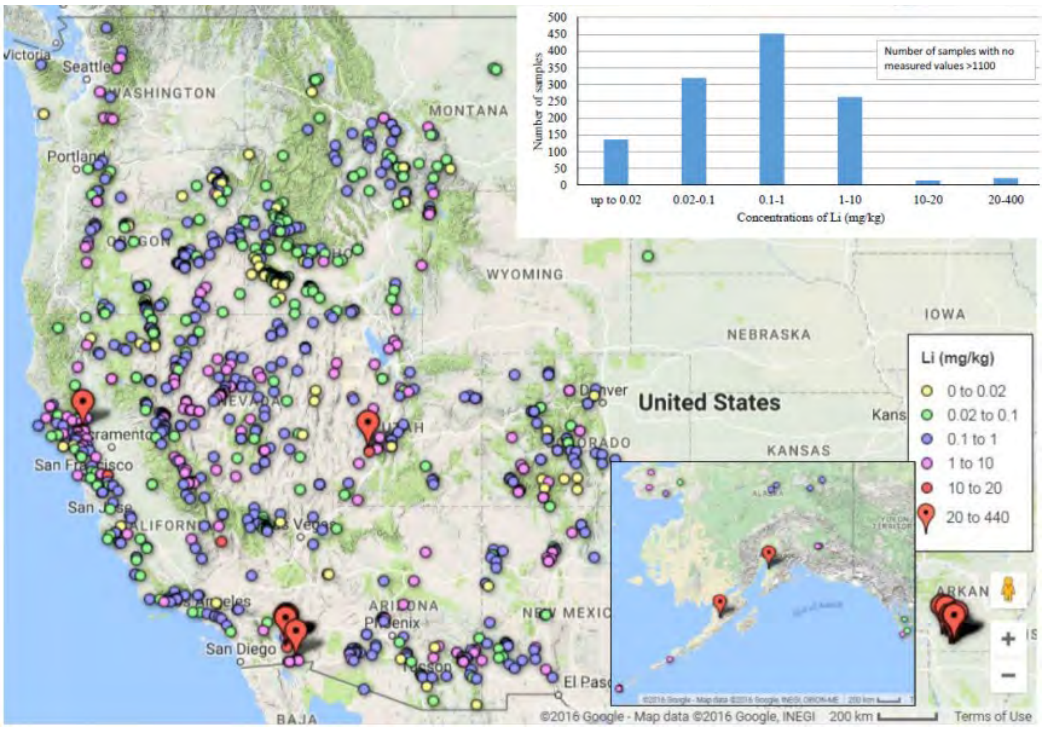

Figure 2: Lithium concentrations in geothermal fluids of Western USA, in milligram per kilogram (NREL Technical Report/TP-5700-79178, May 2021 – Reference: Nupane and Wendt – 2017)

A full geochemical analysis of the brine is required to define the economic potential of the play, and the appropriate DLE technology and other processing that might be required such as pre-treatment. It is possible that other producible minerals are identified in economic quantities like magnesium or bromine, which may require separate extraction and processing equipment and costs.

The geochemical analysis of the brine will provide insights into other physical and geochemical water properties that can impact the efficiency of the DLE process. Some common issues encountered that require pretreatment are high levels of calcium, magnesium, or dissolved organic carbon, which are impurities for most DLE processes. For oilfield brines, any oil and gas must be removed prior to lithium extraction to meet acceptable levels of TOC (total organic carbon) for the DLE technology. For geothermal brines, the issues can be related to the high fluid temperatures and the resulting challenges from dissolved minerals like iron and silica, high TDS (total dissolved solids), and salinity.

Pretreatment is an added cost and large consideration for the project design and economics. As part of the derisking process it is recommended to have an early understanding of the fluid chemistry and metallurgy, which will provide a higher level of certainty early in the project design.

The flow deliverability of the brine is another critical piece of data required to understand the economic viability of the project. Typically, artificial lift, through pumps like line shaft pumps (LSP) or electrically submersible pumps (ESP), will be installed to lift the fluid to surface from the deep subsurface formation for production. The reservoir must have sufficient flow potential to deliver the fluid over the long term to the well, which requires a minimum permeability and porosity in the rock to allow for flow. Each rock and play type will have different minimums,

depending on many factors like well depth, pump type, pump placement, surface infrastructure, areal extent of reservoir, and project costs.

The well network typical for lithium brine projects from deep subsurface reservoirs is similar to conventional geothermal, where production will come from a well or set of wells, and the depleted brine will be reinjected into the same reservoir at a distance away from the production wells (Figure 3). This setup is done to provide pressure maintenance in the reservoir and to avoid brine disposal at surface. The play should be extensive enough to not suffer drawdown from the brine production and allow for the reinjection of the depleted lithium brine to occur at a distance from the production well to mitigate early breakthrough.

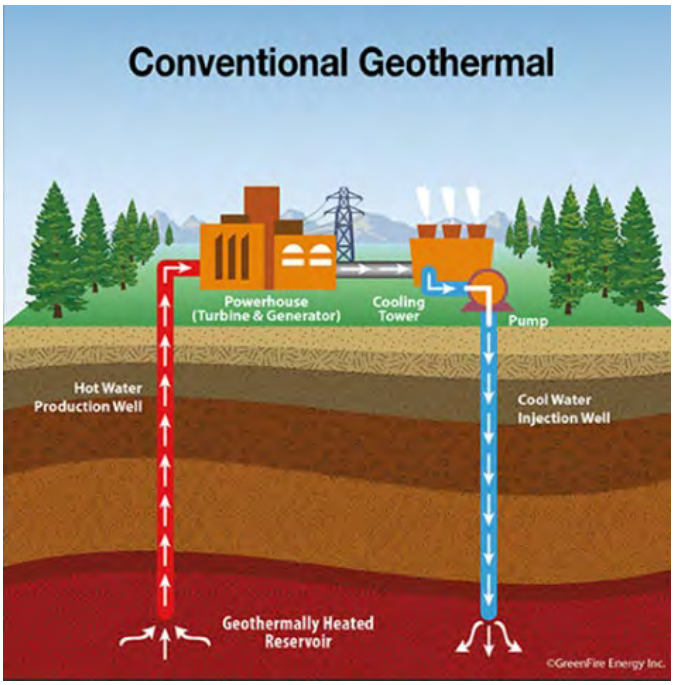

Figure 3: Diagram showing typical conventional geothermal well network with production well and injection well (Greenfire Energy Inc. 2024, https://www.greenfireenergy.com/geothermal-energy/how-does-geothermal-energy-work)

An example is shown below (Figure 4) of a lithium brine project in Alberta Canada, operated by E3 Lithium. They plan to have an array of production wells in one area of the reservoir with reinjection of lithium depleted brine occurring 15 km away from the production well array. They will be using multi-lateral long well drilling techniques to access large areas of the subsurface reservoir with many wells drilled from one well pad.

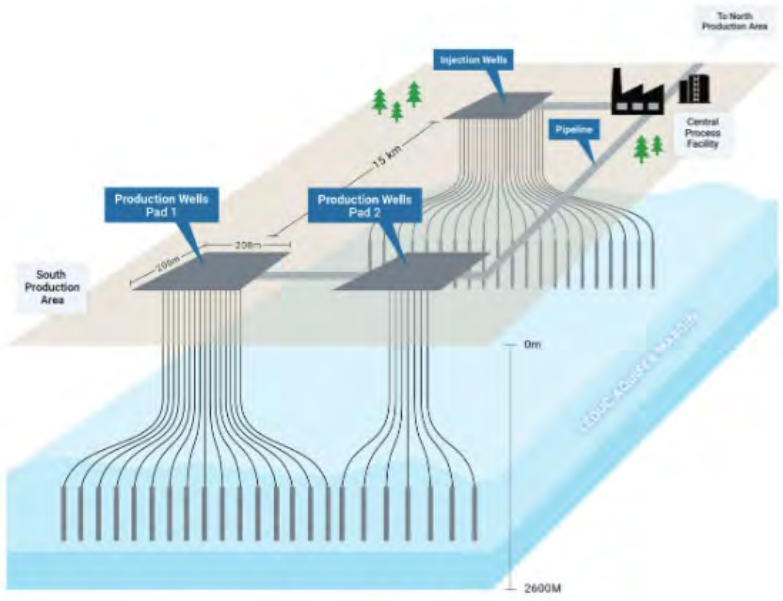

Figure 4: E3 Lithium Conceptual well network layout from report "NI 43-101 Technical Report Preliminary Economic Assessment Clearwater Lithium project Alberta, Canada" dated 12/21/2020 amended 09/17/2021 (E3 Lithium https://e3lithium.ca/our-assets/resources/)

For a geothermal lithium brine project, the spacing between the production and injection wells will have to take into consideration both the temperature breakthrough and lithium depletion. This can be done with detailed reservoir flow models, to optimize the bottomhole spacing for co-production of both products.

3. Reporting of Lithium Mineral Resources and Reserves

The regulatory framework is well established for oil and gas projects and for hard rock mining of critical minerals like lithium from pegmatites, however the regulatory processes for deep subsurface brine projects are still in catch up as regulations for these projects address fluid flow from reservoirs to wells to surface processing facilities. In most jurisdictions, lithium from oilfield or geothermal brines from deep reservoirs is treated as a mineral, under mining industry disclosure standards. The international standards are from CRIRSCO (Committee for Mineral Reserves International Reporting Standards) 2012 (ICMM, 2019). See below for relationship between exploration results, mineral resources, and mineral reserves (Figure 5). This roadmap for transition from mineral resources to mineral or ore reserves is commonly used amongst country standards such as Canada in the NI 43-101 (National Instrument), and in Australia in the JORC Code 2012 (Joint Ore Reserves Committee).

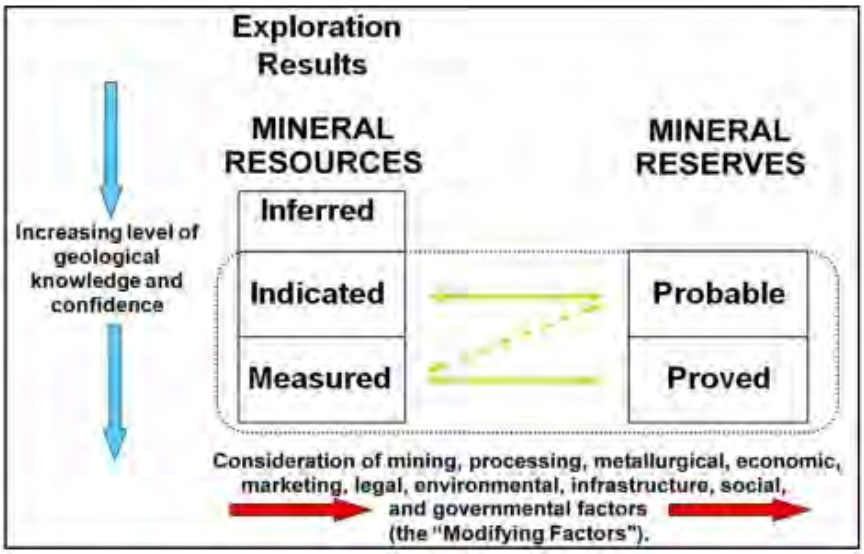

Figure 5: General relationship between Exploration Results, Mineral Resources and Mineral Reserves, CRIRSCO 2019

In the United States the disclosure regulations are established and governed by the Securities Exchange Commission (SEC) under Regulation S-K 1300, where the CRIRSCO framework is applied for applying modifying factors to determine economic viability of a project.

A similar framework and resource reporting process is in place in many jurisdictions for geothermal projects. Below (Figure 6) is the framework from the Australian Code for Reporting of Exploration Results Geothermal Resources and Geothermal Reserves, The Geothermal Reporting code 2010, under the Joint Committee of the Australian Geothermal Energy Group (AGEG) and the Australian Geothermal Energy Association (AGEA) (AGRCC, 2010).

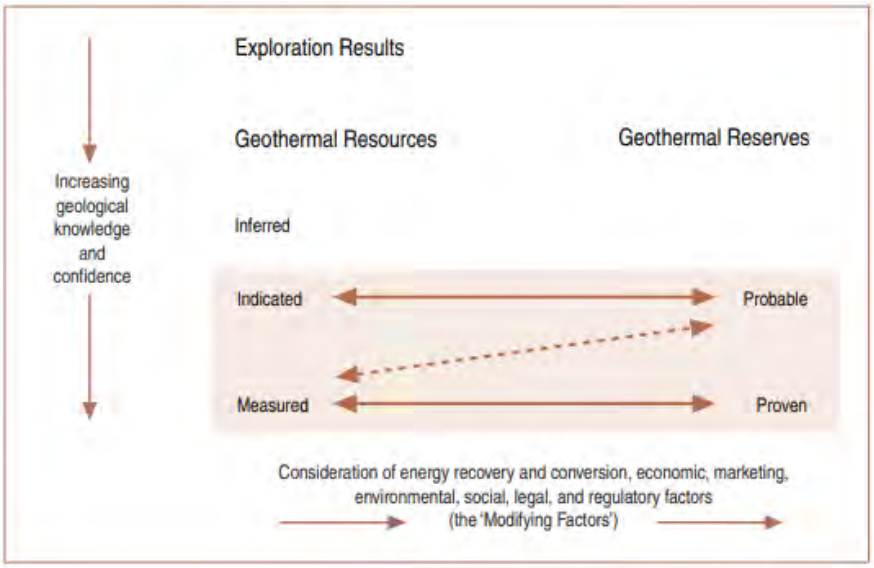

Figure 6: Geothermal Reporting relationship between Exploration Results, Geothermal Resources and Geothermal Reserves, AGEA 2010

In the case of lithium and geothermal resource and reserve reporting, several terms are common, such as “modifying factors” which describe the considerations to convert from resource to reserve and to determine technical and economic viability. They can include mining, processing, metallurgical, infrastructure, economic, marketing, legal, environmental, social, and governmental factors.

4. Geothermal Lithium Brine Project Opportunities, Risks and Challenges

A geothermal lithium brine project from a deep subsurface reservoir may be subject to many risks and challenges, along with the opportunities.

The opportunities to consider may include the following:

- Geothermal reservoir may be characterized and have historical production which reduces project risks and reservoir understanding when adding co-production of lithium.
- Directional drilling techniques of multi-lateral long wells have improved the ability to drill more wells from one wellsite, which allows for smaller surface footprint for the geothermal lithium wells.
- Operating costs can be reduced with geothermal power generation to support the lithium co-production.
- Using geothermal power generation is a low GHG emissions renewable power source.
- Communities could use district heating from the geothermal plant, which may improve stakeholder support of the project.
- It might be possible to produce other critical minerals if they are present in sufficient quantities and can be economically co-produced.

The risks and challenges to consider may include the following:

- Reservoir and Wells:
    - Lithium concentration data might not be available from existing wells within the play area and require drilling and testing of a new well(s), which is expensive.
    - Dissolved gas in the brine may contain toxic gases like hydrogen sulfide (H2S), so well and facility design will require detailed gas and fluid testing.
    - Parasitic load of brine production and injection pumps can be high and should be considered in the net power capacity estimation.
    - Reservoir may not be as extensive as estimated, which can affect long term flow deliverability, where mitigation can be new data from wells and seismic and improved reservoir modelling.
    - Early depletion of heat or lithium if communication between the production and injection wells occurs early, where optimal well spacing at reservoir depth requires good data and reservoir modeling.
    - Corrosion issues due to brine chemistry can impact wells and infrastructure, which can be mitigated with corrosion integrity programs.
- Surface Facility:
    - High geothermal temperatures can result in brine chemistry and physical properties that require additional treatment and processing, increasing capital and operating costs.

    - DLE, lithium polishing, and lithium refining are energy intensive and need to be considered in net power capacity estimation.
    - Operating uptime can be impacted by challenged brine chemistries and well pumping systems.
    - Matching the best DLE technology to the brine and conducting sufficient benchscale and pilot testing before commercial design to optimize cost and operating performance.
    - Location of play with good lithium concentrations and geothermal temperatures may not be proximal to existing power infrastructure or offtake users.
- Market:
    - Lithium pricing has suffered a decline and project may not be as profitable as predicted from studies in last 3 years.
    - Defining the desired end product early in alignment with pricing differentials and possible offtake users for each product type - LiCl (lithium chloride), LCE (lithium carbonate equivalent), or LHM (lithium hydroxide monohydrate) and taking into consideration extra processing to get to more refined products like LHM.
    - EV batteries may move away from lithium as critical component.
- Stakeholders:
    - Community and stakeholders may not support a geothermal lithium project and associated facilities, infrastructure, and operations.
    - Regulatory framework may not provide incentives for geothermal lithium projects.

5. Example of Geothermal Lithium Brine Project

Several geothermal lithium brine projects are in the early development and pilot stages in Canada, the USA and Germany. Notably, Vulcan Energy Resources Limited (Vulcan) has progressed their Zero Carbon Lithium™ project in Germany past the pilot stage to a Lithium Extraction and Optimisation plant (LEOP) scaled up stage. The Vulcan Phase One project is located in the Upper Rhine Valley in south central Germany (Figure 7) and is considered a brownfield development around existing geothermal brine production and geothermal power generation.

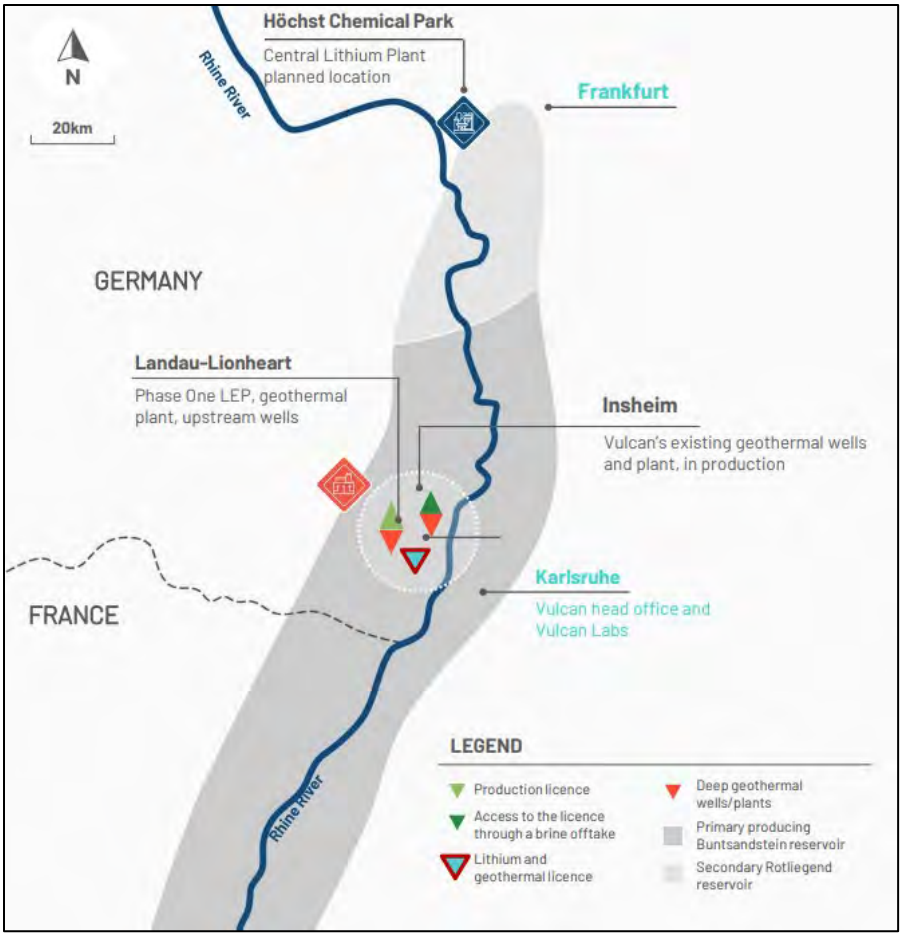

Figure 7: Vulcan Phase One Zero Carbon LithiumTM project location, Upper Rhine Valley, Germany (Vulcan, 2024, https://www.investi.com.au/api/announcements/vul/1e22d4df-e78.pdf)

Vulcan is an Australian based company founded in 2018 that is publicly traded on the Australian Stock Exchange (ASX) and Frankfurt Stock Exchange (FSE). The purpose of the company is to empower a carbon neutral future through the co-production of lithium, heat, and renewable energy from geothermal brine. (Vulcan, 2024). They own and operate a geothermal power plant at Insheim, Germany, called Natürlich Insheim, with capacity of 4.2 MW (Megawatt) that has been in operation for over 10 years. This plant utilizes a binary Organic Rankine Cycle (ORC) for power generation from geothermal brine.

The Phase One development, focused on the Lionheart area, is planned to co-produce the lithium from the geothermal brine, adding new wells to the existing wells in operation at the Natürlich Insheim facility, and adding new facilities to support additional geothermal heat and power, and lithium extraction. See Figure 8 below that shows a representation of the full production process. The Phase One development is targeting a capacity of 24,000 tpa (tonnes per annum) LHM production. The conversion from LiCl to LHM will occur at the planned Central Lithium Plant (CLP) located in Höchst Industrial Park near Frankfurt, Germany, through an electrolysis process.

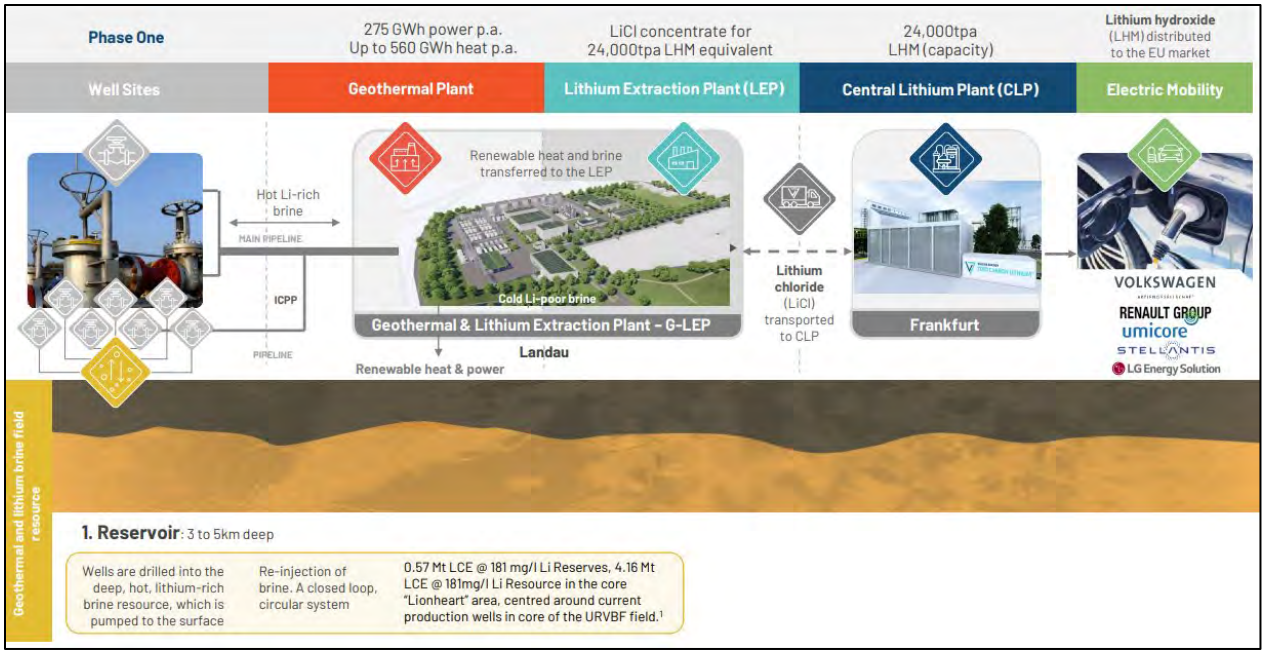

Figure 8: Representation of Vulcan's Phase One development plan (Vulcan, 2024, https://www.investi.com.au/api/announcements/vul/1e22d4df-e78.pdf)

The deep subsurface geothermal reservoir supporting this Vulcan Phase One development is part of the larger Upper Rhine Graben in the aquifers of the Permo-carboniferous Rotliegend Group sandstone, the Triassic Buntsandstein Group sandstone, and the Middle Triassic Muschelkalk formation. The strata are laterally heterogeneous within a structurally complex rift basin (Vulcan, 2023). A high degree of faulting and fracturing exist in the strata which results in some degree of hydrogeological communication with the granitic basement.

The typical depth of the aquifers in the Phase One area is 3,000 m (metre), with bottomhole temperatures of 165°C (Celsius). The geochemical analysis of the producing Vulcan geothermal brines indicates there is a good distribution of lithium enrichment in the brine. The average lithium concentration in the Phase One area is 181 mg/L (milligrams per litre) based on extensive long-term analysis of the brine produced from the six geothermal wells in the region.

Vulcan has reported Mineral Resources (Measured and Indicated) in the Phase One area at 4.16 Mt LCE at 181 mg/L lithium concentration, reported in accordance with Joint Ore Reserves Committee's Australasian Code for Reporting of Mineral Resources and Ore Reserves (JORC Code). They have Proved Reserves of 0.318 Mt LCE and 0.252 Mt LCE Probable Reserves reported for Phase One. The development is based on five new well sites and using two existing well sites, where production and injection wells will be situated. (Vulcan, 2024)

A new geothermal power plant is going to be added to the existing one at Natürlich Insheim, with combined total power capacity of 32 MW and heat capacity of 80 MW, utilizing an ORC plant design.

Vulcan is using an Adsorption-type DLE system where an alumina-based sorbent is used to extract the lithium from the geothermal brine and purify and concentrate in the form of LiCl. Vulcan is using its own tailored sorbent technology referred to as Vulsorb®. The facility where this is conducted is called the Lithium Extraction Plant (LEP). Vulcan has been testing the performance and optimizing with pilot plant operations from 2021 – 2023. In April 2024 they started operation and production from their LEOP located in Landau, Germany. This facility is being used to train staff in a pre-commercial facility to be ready for full commercial operation. This facility produces LiCl, which is to be sent to the Central Lithium Electrolysis Optimisation Plant (CLEOP) to make battery grade LHM. The CLEOP and commercial scale CLP are located near Frankfurt at the Höchst Industrial Park. The CLEOP is expected to start operation in mid-2024 to train staff and optimize before commercial operation of three key processes 1) electrolysis of LiCl to LHM solution, 2) LHM crude and pure crystallization, 3) LHM drying, to deliver battery grade LHM at the 24,000 tpa commercial rate for Phase One, which is planned to start-up in 2026.

The economics of the Vulcan Phase One development have been reported as robust based on an operating cost of €4,022/t LHM and Initial Capital cost of €1.39 B (Billion), with a pre-tax IRR (internal rate of return) of 27.8% and NPV8 (net present value at discount rate of 8%) of €3.9B. The payout period is estimated to be 4 years. See Figure 9 below which summarizes the financial metrics of the project.

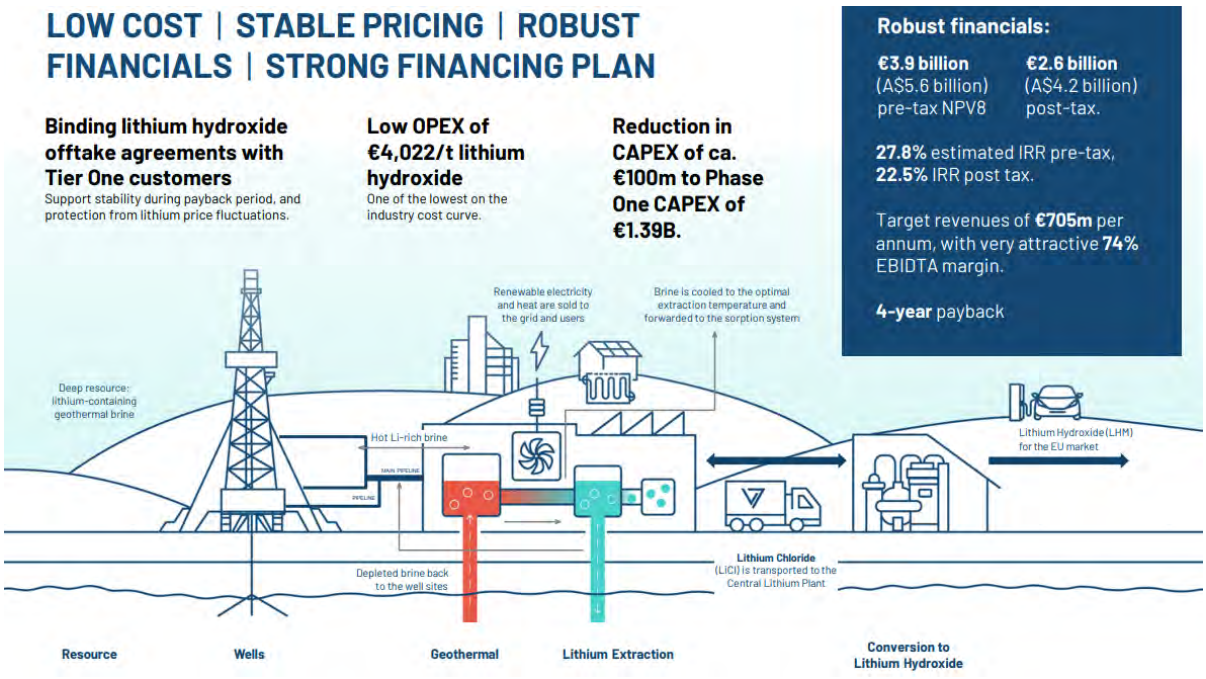

Figure 9: Summary of Vulcan Phase One project plan and economics (Vulcan, 2024, https://www.investi.com.au/api/announcements/vul/1e22d4df-e78.pdf)

What makes this project so unique is the ability to leverage the historical data from long term geothermal production and brine analysis data from the geothermal brine in the Phase One area of development. With the development planned as a brownfield construction, it enables a lower cost solution than many new projects would face. Vulcan is also located near established infrastructure

that supports delivery of the LiCl to the Central Plant in Frankfurt and then access by rail, road, and sea to markets for battery manufacturing. Vulcan has established offtake agreements already with major auto manufacturers, and established strategic supply partners, which allows for improved risk management for pricing.

6. Conclusion

The technical and economic potential for geothermal lithium brine projects is gaining momentum with recent technological improvements in exploration of appropriate aquifers and reservoirs, multi-lateral long well drilling, extraction/refining processes, and battery manufacturing. The increasing demand for lithium is not expected to wane in the upcoming decades with the energy transition to lower GHG emissions. As countries target domestic production of critical minerals and EV manufacturing, the opportunity to develop these projects is improving with potential for government grants and incentives.

In the global market today, ensuring your project considers environmental, social and governance (ESG), is critical to securing stakeholder approvals and financing. The co-production of geothermal brine with lithium extraction not only provides for a green energy solution that has low greenhouse gas emissions, but also reduces operating costs with geothermal power generation. The added benefit to the community of providing district heating can be an additional revenue stream, but also provide an incentive for community involvement and support.

A geothermal lithium brine co-production project from deep subsurface reservoirs is developed with a much smaller surface footprint and environmental impact than the traditional methods of lithium production through hard rock mining and evaporation ponds. Identification of more locations for geothermal lithium projects is possible through leveraging of existing well and seismic data, or supplementing data with new well tests or seismic reprocessing.

Though no commercial scale geothermal lithium brine project exists today from deep subsurface reservoirs, there are several pilots in operation with commercial production to start within 2 to 5 years in Germany, USA, and Canada. These will represent a small portion of the lithium production worldwide but are a step toward critical mineral self-sufficiency for the countries they are located in, and greener approaches to critical mineral production.

Keywords

Lithium, energy transition, net zero emissions, geothermal brine, traditional brine extraction, direct lithium extraction (DLE), adsorption, ion exchange, solvent extraction, CAPEX/OPEX, operating pilot plant

ABSTRACT

Lithium is the cornerstone of energy transition for Indonesia to achieve Net Zero Emissions by 2060 or earlier. This energy transition will drive the Indonesia demand projection for Electric Vehicle Battery and Energy Storage System and in turn will demand much more lithium for this transition effort. Many studies have been conducted to find the sources of lithium, one of them is geothermal brine. Indonesia has enormous geothermal resources, some fields have lithium content that can potentially be extracted. Various methods in the extraction process of lithium from the geothermal brine have been developed, both on laboratory and pilot projects. The geothermal brine is typically pumped to the surface by a geothermal power plant, used for energy generation, and then returned to the underground reservoir via an injection well. Prior to reinjection the geothermal brines contain in the temporary ponds whereas the lithium extraction points may occur here or at any point suitable for the extraction technology. Typically there are three phases in the lithium extraction, like end- to-end process technology solutions, namely **1)** Lithium Brine Extraction- depending on the geothermal brines field compositions, pre-treatment may be employed to remove any contaminants or unwanted constituents from the brines, then selective absorbents are used to separate lithium from other elements **2)** Concentration with membrane system to concentrate lithium at a desired concentration **3)** Deposition using chemical precipitation and purification for

saleable lithium production. This paper reviews traditional brine extraction and direct lithium extraction (DLE) in general and specifically in geothermal brine. The study is based on a desktop study and aims to summarize the knowledge, method, technology, and techniques of lithium extraction from geothermal brine that has already been used and to find out which extraction method is suitable for the Indonesian geothermal field. Our finding indicates the adsorption end-to-end technology process includes pretreatment, lithium extraction, purification, and lithium product production steps such as electrodialysis (a form of ion exchange) and reverse osmosis to yield high recovery rates. The adsorption DLE solution has been used on a commercial scale, in Argentina and China and it has a fifty-year development and implementation history, higher lithium recovery, lower water and chemicals consumption, shorter lead time to production, minimal footprint, potential for no carbon emissions, and an additional revenue stream from unused brine resources for geothermal power producers. The authors have not researched that far for the issue of scaling when the extracted fluid is injected. An important issue that needs to be added to the paper for further research. There is unlikely a one size fits all solution, hence a complete operating pilot plant to simulate the real condition of geothermal field brines is important. The other important points are to keep the project commercial operation date punctuate with faster, cheaper, better and rapid speed of technology implementation.

1. Introduction

Lithium is the cornerstone of energy transition because of the following two reasons, the first reason is that it has the key ingredient in batteries for electric cars and renewable power storage, making it a critical commodity for the energy transition to reduce emissions of greenhouse gases. And the second reason is that Lithium is a big enabler of the energy transition from a battery perspective as we move to electric vehicles and add energy storage to electricity grids, allowing for greater penetration of renewables. As a result, lithium is increasingly being seen as a critical mineral by governments, where they want to secure supplies for that transition, and that has made it an increasingly important commodity. In line with this cornerstone of energy transition, Indonesia is committed to achieve Net Zero Emissions by 2060 or earlier and is beginning to put in place the policies and frameworks that can help reach this target while moving towards advanced economy status.

Lithium is a light and highly reactive metal that offers excellent heat and electrical conductivity. Because of its high reactivity, pure elemental lithium is not found in nature but is instead present as a constituent of salts or other compounds. Lithium is found in three main types of deposits: pegmatites (crystalline hard rock), saline subsurface waters (lithium brines) and sedimentary deposits. The primary commercial sources of lithium are hard rock deposits in Australia and China approximately 60%, and brine deposit in Argentina, Chili, China, and the rest of the world approximately 40%. The three main types of lithium brine deposits include salt-lakes or salt-flats (salars), geothermal, and oil field deposits. Future potential for geothermal brine to supply demand is recognized as an important brine sources of lithium.

For both geothermal and conventional lithium resources, there is interest in developing technology, and processes for the direct extraction of lithium from brines. Unlike conventional methods for producing lithium, the so-called **Direct Lithium Extraction (DLE)**, a potential game changing technology, uses filters, membranes or resin materials to extract mineral from brine water. And as such DLE may significantly increase the supply of lithium, nearly doubling production from same

resource and improving project returns through a process that may be more sustainable. A number of proven DLE technologies are emerging and being tested at scale, with a handful of projects already in commercial construction. While there may still be challenges around scalability and water consumption/brine reinjection. With the ongoing efforts, DLE could be implemented between 2024-2030 in USA and Europe, and between 2025-2030 in both Chile and Argentina.

2. Technology For Lithium Extraction Methods

The following table summarizes the processes for hard rock, traditional brine ponds, and key DLE technologies and their detailed comparisons [1].

Table 1: Lithium Extraction Methods in Hard Rock, Evaporation and Direct Lithium Extraction in Brine [1]

Lithium Extraction Methods	Hard Rock	Brine	
	Mining	Evaporation	DLE
Production Times (Extraction to Production	Weeks to Months	Months to Years	Hours to Days
Lithium Recovery Rates	~60-80% (processing)	~40-60%	~70-90%
Costs Capex Opex	Varied on Grade/ Chemical Conversion	~US$23-34,000tpa LCE ~US$3,300-4,900t LCE	~US$26-34,000tpa LCE ~US$2,800-3,600t LCE
Lithium Product	Spodumene (~5-6% Li_2O)	Lithium Carbonate (Li_2CO_3) Lithium Chloride (LiCl)	Lithium Carbonate (Li_2CO_3) Lithium Chloride (LiCl)
Process	Heating, Cooling, Crushing, and Roasting	Staged Atmospheric Evaporation, Plant Processing	Adsorption (Ad), Ion Exchange (IX), Solvent Extraction (SX), Membrane
Further Process Requirements	Yes	No (subject to end use)	No (subject to end use)
Land Area Requirement	High	High	Low
Weather Dependence	Yes	Yes	No
Water Consumptions	High	Medium-High	Low-Medium
Energy Consumption	High	Low (free solar evaporation)	Medium
Emissions	High	Low	Low

The traditional lithium extraction method from well-established producing countries like from hard rock (Australia & China) and from brines (Chile, Argentina, and China), to countries with recently mapped resources and reserves such as the United States, Europe, Mexico, Canada, Bolivia, and Ukraine, to locations typically not associated with lithium such as United Kingdom, Peru, Siberia, and Thailand, exploration for traditional deposits of “white diamond pearl” is happening globally.

From the nontraditional brines deposits (geothermal, oilfield brines) will come additional brines with grades of 100 to 200 part per million (ppm). The first option focuses on providing both clean geothermal energy and lithium supply. Although nothing has been proven on a commercial scale as yet, there are already financially confirmed projects in Europe and North America sites. With technology development and proof of concepts, more geothermal lithium-brine operations will appear on the global map, with some automotive companies supports like General Motors, Renault, and among others.

2.1 Traditional Evaporation versus Brine Direct Lithium Extraction

Traditionally, lithium produced from brine water is stored in evaporation ponds. As the water evaporates, the other elements of the brine such as magnesium or calcium precipitate out, leaving the brine more concentrated to produce lithium carbonate. The evaporation process, however, yields only 40% to 60% of the potential lithium in the brine. DLE has the potential to yield 80% to 90% or more. It's also much faster. The evaporation process can take nine to 18 months depending on the type of project and weather conditions. With DLE, that process can be shortened to days or even hours. And you do not need all the land for the pond evaporation process. What is more, you can potentially reinject the remaining brine water after the process, which further reduces the environmental impact.

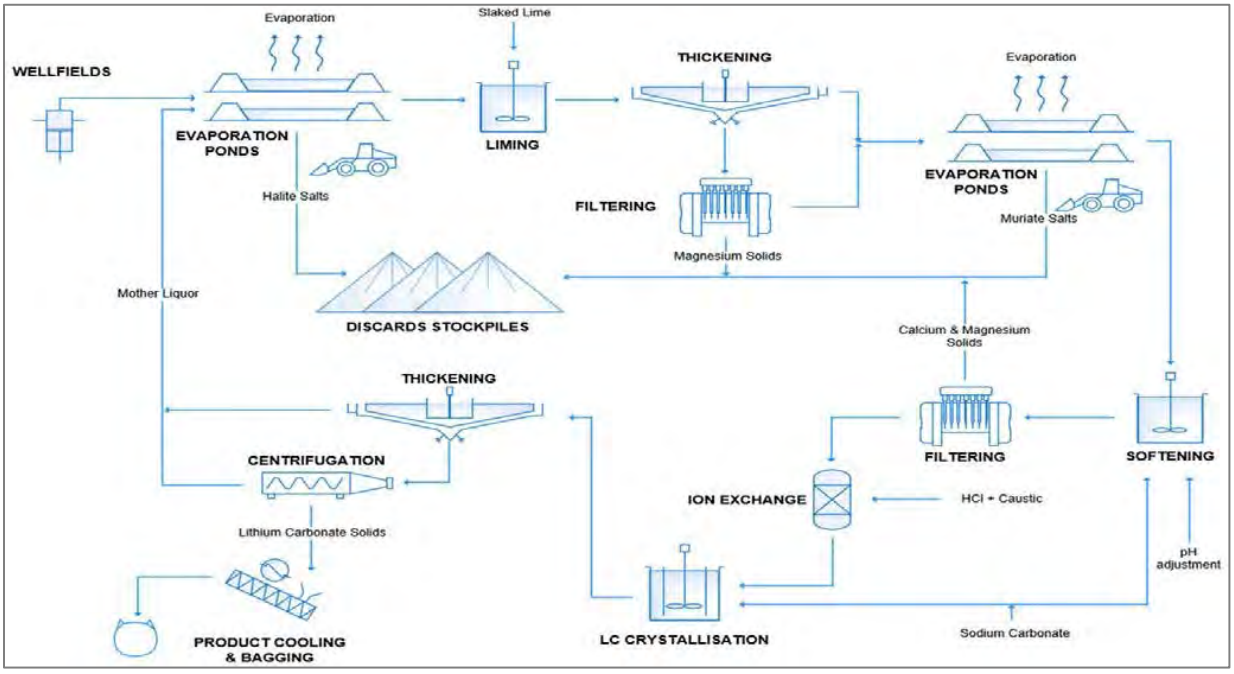

Figure 1: Traditional Brine Pond Flowchart [1]

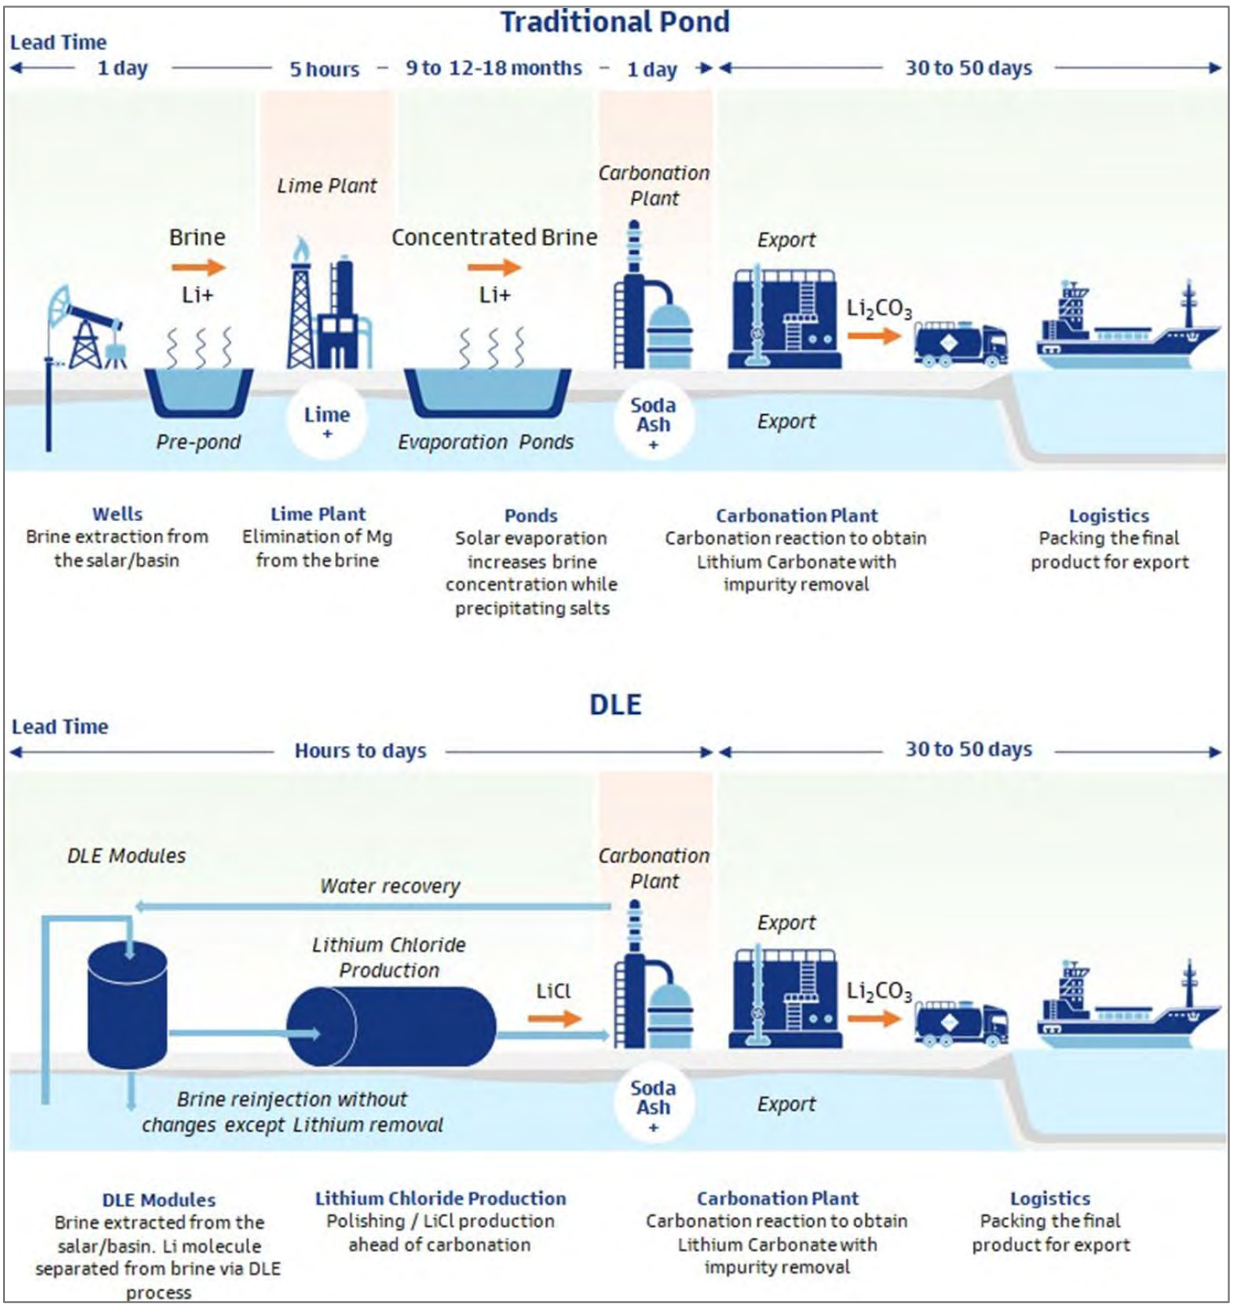

Figure 2: Traditional Process Brine Extraction vs DLE, and Timing of Each stage [1]

Indicative pond process flowsheet based on Sal de Vida flowsheet
Source: Company data, Goldman Sachs Global Investment Research

The following table above outlines 27 global lithium projects that are using or plan to implement DLE, along with a further nine advancing third-party technology developers.

For geothermal or oilfield brines to succeed as a source of lithium supply, a proven process for DLE will be required. There are a number of companies testing various DLE approaches. While their ideas differ, the concept remains the same: letting the brine flow through a lithium-bonding material using adsorption, ion-exchange, membrane-separation, or solvent-extraction processes (Figure 3), followed by a polishing solution to obtain lithium carbonate or lithium hydroxide (Figure 4).

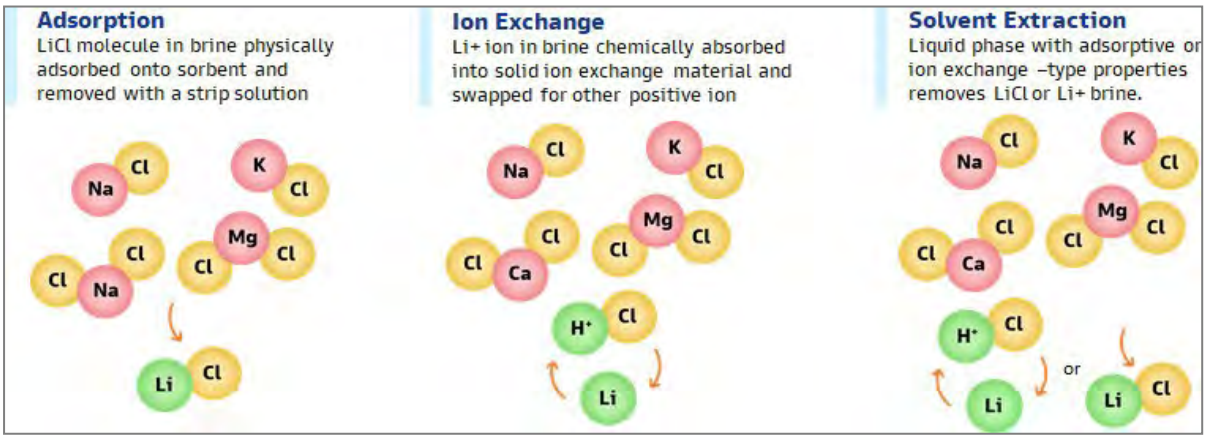

Figure 3: Details of the 3 Different Types of DLE Processes [1]

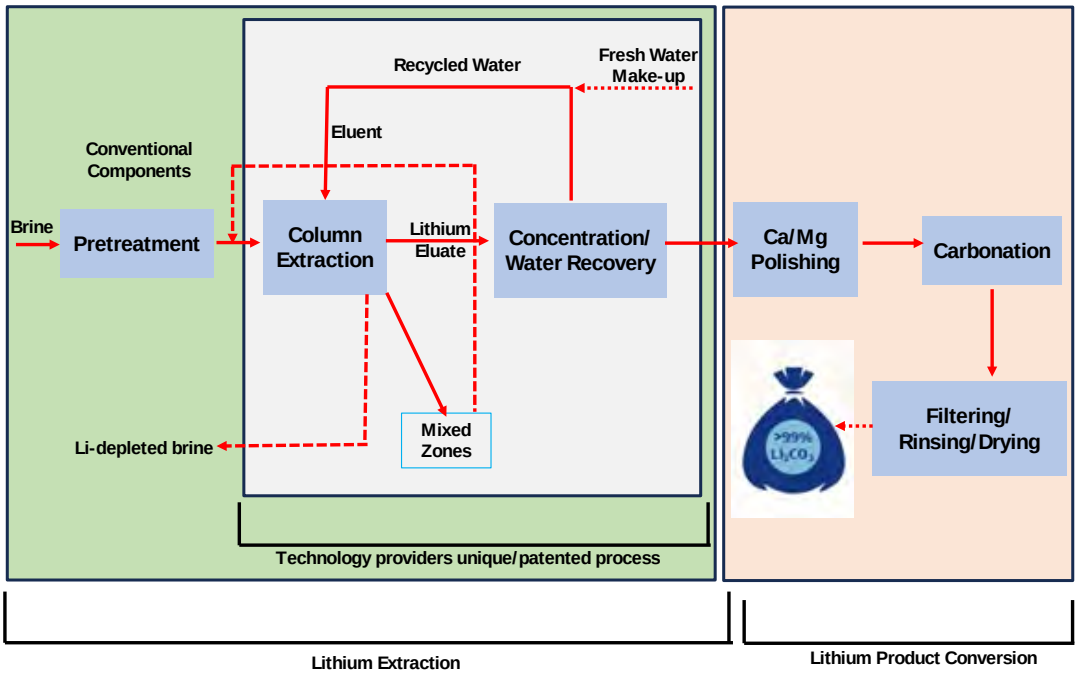

Figure 4: DLE Flow Chart [1]

Adsorption

Adsorption is the most developed DLE technology globally, using adsorbents to adhere to the lithium for selective removal. Some sorbents developed can recover >90% of the lithium present, including recently tested lithium aluminium layered double hydroxide chloride sorbent, or LDH (Lithium-Aluminium Double Hydroxide Chloride). During more recent testing, the LDH sorbent was made by intercalating (inserting) aluminium hydroxide with lithium chloride, which made several $[LiAl_2(OH)_6]$+layers in the sorbent. These layers were separated by water molecules and hydroxide ions that created spacing requirements to allow lithium chloride to enter more readily than other ions, such as sodium and potassium. After the sorbent was loaded with the lithium chloride, it was washed with a diluted lithium chloride stream to remove unwanted ions, then washed a second time to unload the lithium chloride.

The Pros of Adsorption: (i) does not require reagents or solvent extraction, instead water is used to recover lithium chloride with soda ash to convert to carbonate (ii) less impacted by brine composition, weather conditions, with lower waste generation (iii) lithium extraction efficiency of greater than 90% (iv) may combine processing steps such as electrodialysis (a form of ion exchange) and reverse osmosis to yield high recovery rates (v) produce high quality lithium chloride/carbonate.

The Cons of Adsorption: (i) requires temperature lower than 40^0 C (ii) lower eluate (extracting a substance process) LiCl concentration than ion exchange (iii) some implementation may difficult to prevent contamination with the brine (iv) the adsorption equipment can be expensive (high upfront cost).

Ion Exchange

Ion exchange systems separate ionic contaminants from solution through a physical-chemical process where undesirable ions are replaced by other ions of the same electrical charge. This reaction occurs in an IX (ion exchange) column or vessel where a process or waste stream is passed through a specialized resin that facilitates the exchange of ions.

The Pros of Ion Exchange: (i) simple process (ii) high selectivity for lithium and reduced risk of impurity contamination in the product stream (iii) high capacity and high concentration of lithium in the strip solution, can be suitable for low lithium concentration brines (iv) low energy/water consumption (v) continuous operation.

The Cons of Ion Exchange: (i) high upfront cost (ii) high opex due large amount of base and acid inputs (iii) some IX material may degrade in acidic conditions.

Solvent Extraction (SX)

Solvent extraction uses an organic solution containing solvent and extractant to extract lithium from brines. The organic solution comprises of kerosene (or similar material) and an extractant that very high selectivity toward lithium over sodium and magnesium.

The Pros of Solvent Extraction (SX): (i) high concentration of lithium can be produced from brine with high recovery rate, and not effected by weather conditions (ii) low opex costs (iii) lithium solvent extraction is essentially a stand-alone process.

The Cons of Solvent Extraction: (i) less applicable with higher impurity (ii) organic solvents are environmentally challenging (iii) fire risk with high temperature brines (iv) expensive relative to other technologies (v) the residual brine that remains after lithium extraction may require post-treatment to remove leached solvent.

The following figure shows the effectiveness and readiness of direct lithium extraction technologies.

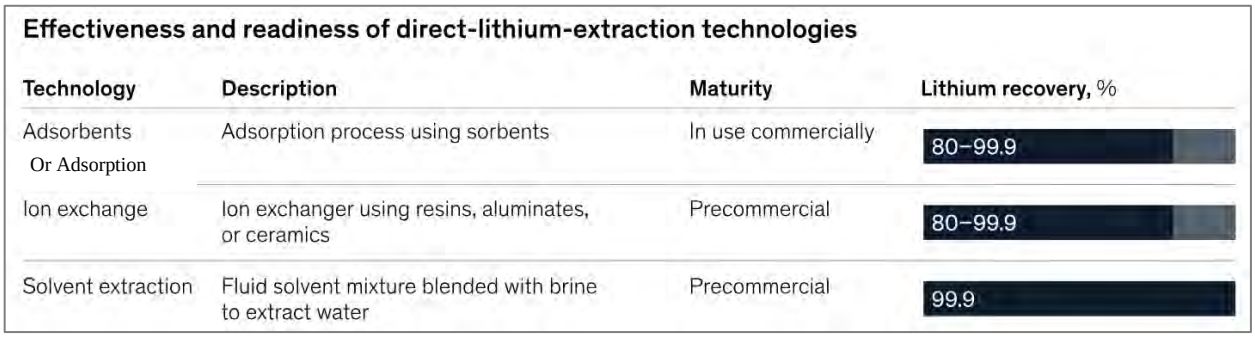

Figure 5: Effectiveness and Readiness of DLE Technologies [2]

Promising DLE technology is currently being considered not only by unconventional players but also by companies that traditionally develop “typical” brine assets. DLE has several potential benefits, including:

1. eliminating/reducing the footprint of evaporation ponds

2. decreasing production times compared with conventional brine operation
3. increasing recoveries from around 40 percent to over 80 percent
4. lower usage of fresh water, which can be one of the deciding factors when applying for a mining concession in a region with scarce water resources
5. lower reagents usage and increased product purity (in terms of magnesium, calcium, and boron) compared with conventional brine operations

To date only adsorption DLE has been used on a commercial scale, in Argentina and China. If DLE can be scaled up and spread across brine assets, it will boost existing capacities via increased recoveries and lower operating costs, while also improving the sustainability aspects of operations.

Figure 6: Modern Li-Brine Projects Choosing Direct Lithium Sorption (DLS) [3]

DLE Adsorption is a commercial technology adapted to the local resource for the following reasons:

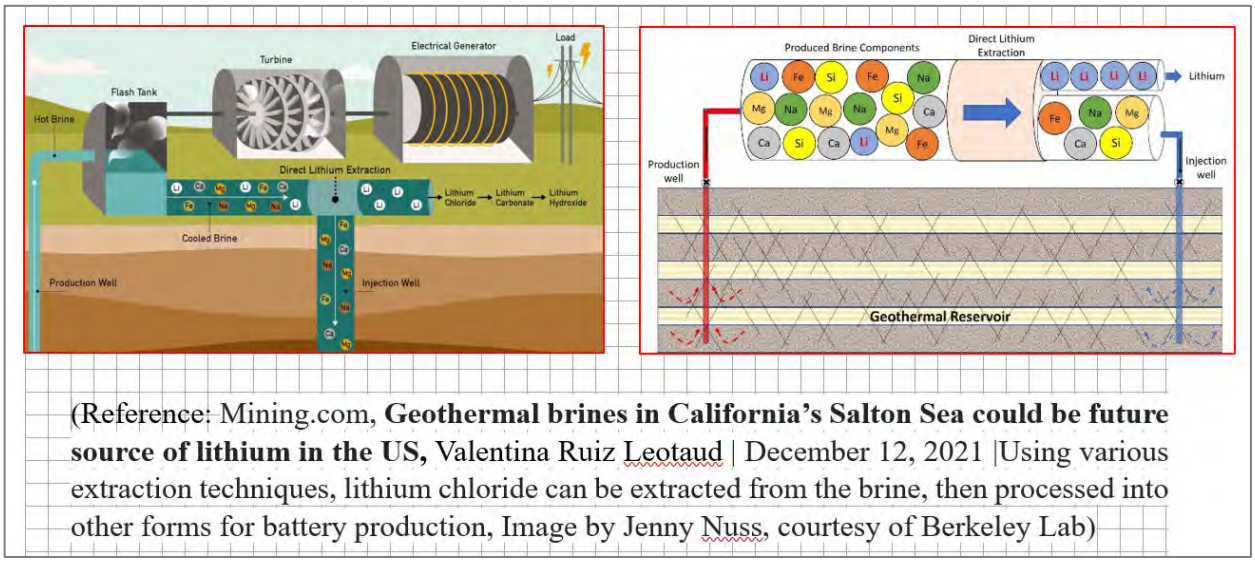
1. DLE using sorption has a fifty-year development and implementation history;
2. DLE Adsorption practiced commercially in South America for 26 years by Livent. More recently DLE Adsorption has been commercially deployed in China;
3. Large investment in DLE projects have recently been made in Argentina by Rio Tinto and Eramet;
4. DLE Adsorption includes several key advantages compared to traditional brine evaporation such as higher lithium recovery, lower water and chemicals consumption, shorter lead time to production, minimal footprint;
5. DLE Adsorption associated with geothermal brine adds the following no need to heat the brine with natural gas, potential for no carbon emissions, additional revenue stream from energy.

2.2 Early Review of Indonesia Geothermal Brine Lithium Extraction

The paper written by Suud et al [4] reviewed the lithium extraction from the geothermal brine by direct extraction methods using solvent extraction, adsorption and ion exchange, membrane, and electrodialysis. Multiple-stages solvent extraction from geothermal brine well in one of Indonesian Geothermal working areas performed by Suud et al demonstrated an extraction efficiency of 94% and indicated an opportunity to be further investigated for lithium extraction from one of the Indonesian geothermal brine.

3. Case Study To Implement Direct Lithium Extraction in Geothermal Brines

Lithium is an alkali metal that typically occurs in brine as LiCl. This LiCl solution is concentrated and purified through various processes and is then converted to high-purity Lithium Carbonate Li_2CO_3 and/or Lithium Hydroxide Monohydrate $LiOHH_2O$ commercial products. In the produced geothermal brines as shown in the following figure, consisted of the following chemical components such as Li, Fe, Si, Ca, Mg, and Na and may include additional components such as K, B, Al, Sr, Mn, Cu, Ba, Zn, Ni, Cr.



(Reference: Mining.com, **Geothermal brines in California's Salton Sea could be future source of lithium in the US,** Valentina Ruiz Leotaud | December 12, 2021 |Using various extraction techniques, lithium chloride can be extracted from the brine, then processed into other forms for battery production, Image by Jenny Nuss, courtesy of Berkeley Lab)

Figure 7: Geothermal Brines in California's Salton Sea [5]

To refresh our memory on these geothermal brine components the following Periodic Table is presented here to comprehend where those brine components located in the Table from US National Institute of Standards & Technology [https://www.nist.gov].

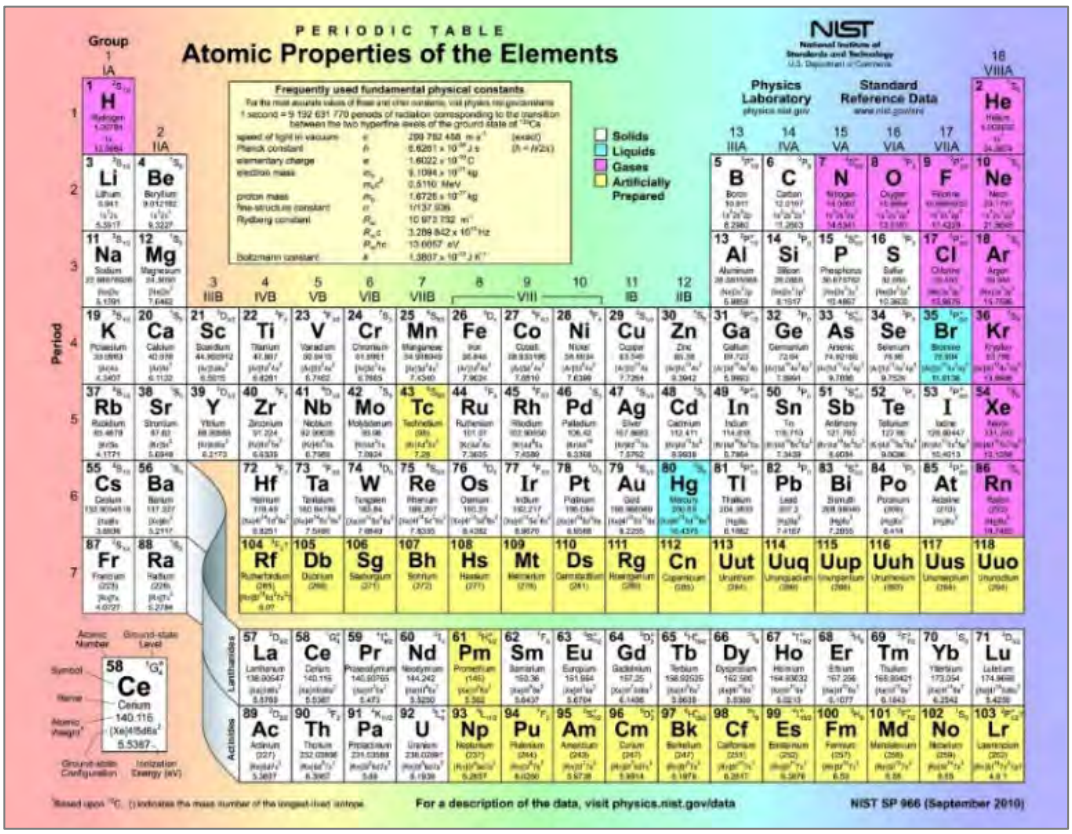


Figure 7A: Periodic Table [https://www.nist.gov]

The most well-investigated and technologically advanced method for direct lithium extraction from geothermal brines from the Salton Sea, with information available in the public domain, is **ILiAD (Integrated Lithium Adsorption Desorption)** [6]. The Iliad process includes pretreatment, lithium extraction, purification, and lithium product production steps. In the ILiAD process, removal of zinc and manganese precedes the lithium extraction process. Iron, silica, and manganese are removed and recovered in sequential steps before lithium extraction. Lithium is removed with AlOH or AlO_x sorbents using continuous bed process. According to the patent, the lithium chloride selective adsorbent may be a resin-based alumina imbibed adsorbent, a lithium alumina intercalate adsorbent, an alumina imbibed ion-exchange resin, or an alumina-based adsorbent. Iron and silica are removed by precipitation and zinc and manganese are removed by solvent extraction with Cyanex 272 or similar solvents using counter-current contactor. Post-extraction purification and processing include processes for removal of calcium and magnesium by ion exchange and further purification of the lithium chloride stream by precipitation and solvent stripping reactions. Lithium hydroxide is produced by electrolysis and lithium carbonate is produced by the addition of sodium carbonate and purified by cycles of crystallization and dissolution. The process is designed to be modular, with each process module sized for production of approximately 3,000 metric tons LCE (Lithium Carbonate Equivalent) per year, depending on brine lithium concentrations. Pilot trials demonstrated the ability to produce high-purity lithium products (>99.9% pure) at a 90% lithium recovery rate.

4. Supply/Demand Implication of New Direct Lithium Extraction Supply From 2025+

The following table shows the global production lithium and in 2022 (Reference: 8) the total global production was 130,400 tonnes. The largest lithium producers are Australia, Chile, and China. The need for lithium has increased significantly due to the growing demand for electric vehicles. The demand forecast for lithium is expected to reach 1.5 million tonnes of lithium carbonate equivalent by 2025 and over 3 million tonnes by 2030 [9].

The new technologies for lithium extraction, such as DLE which extracts lithium from brine, has the potential to revolutionize the production, timing and environmental impact of lithium extraction. While there may still be challenges around scalability and water consumption/brine reinjection. With the ongoing efforts, there will be more brine supply if DLE could be implemented between 2024-2030 in USA and in Europe, and between 2025-2030 in both Chile and Argentina.

5. The Techno-Economic Analysis

Pre-Feasibility Study and/or Pilot Scale in the Technical Feasibility Study of Direct Lithium Extraction (DLE), with reasonable assumptions, can provide guidance for estimating costs of lithium extraction from geothermal brines. The following table summarizes report in National Renewable Energy Laboratory (NREL) US Department of Energy in May 2021 [10] on DLE Project Economics. The main focus of this present study was limited to understanding techniques and costs made publicly available by companies with projects advanced to stages of development and investment that require formal reporting to pertinent institutions. These projects were focused on geothermal, salar (brine from salt-flat or lakebed), oilfield, and evaporite brines, all of which were informative for estimating costs of lithium extraction from geothermal brines. Eventually, a specific geothermal fluid will require a best-lithium extraction processes, or combination of processes, based on fluid composition and physical and chemical requirements related to power generation and reservoir management. The estimated lithium production cost of $ 3,485/mt Lithium Carbonate Equivalent LCE using ion exchange technology.

**Estimated commercial production with costs and performance informed by bench-scale experiments and ASPEN modeling (Ventura et al. 2020).
***Euro to USD exchange rate 1.2; $3,656/mt Li2CO3.
****$4,155/mt Li2CO3

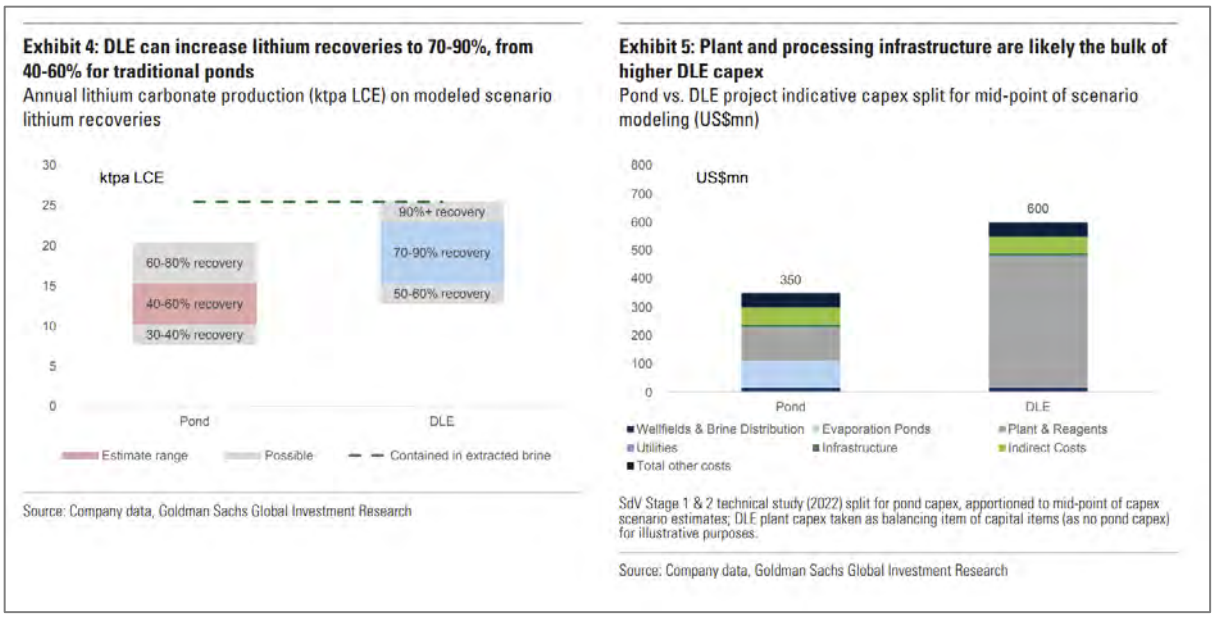

Figure 11: Scenario Economics & Real World Asset Benchmarking [1]

The scenario economics [1] assume a hypothetical brine resource is extracted at the same grade and volume at ~25ktpa contained LCE over a 20-yr production life to produce and sell the same quality of lithium carbonate product, both as a DLE (which ramps up 18 months faster vs. traditional ponds though with higher nominal Capex/Opex) and a traditional evaporation pond project.

The DLE project achieves recoveries of ~70-90% producing ~18-23ktpa LCE, while a traditional brine pond achieves recoveries of ~40-60% producing ~10-15ktpa LCE . The plant and processing infrastructure drive a higher upfront Capex for a DLE project, which more than offsets the lack of traditional pond infrastructure.

6. The Issue of Scaling When The Extracted Fluid Is Injected

The silica scaling can caused a significant cost to the geothermal producer and as such it reduces generation efficiency, and prevents further generation. By removing silica prior to lithium extraction process is beneficial, and in turn it will lower operating costs and generate more power from the same fluid. in the extraction process is beneficial before lithium extraction. Mroczek et.al [11] investigated the potential for extraction of lithium by electrodialysis from the brines at the Wairakei Geothermal Field in New Zealand. The necessitated removal of silica prior to extraction of lithium is beneficial for the extraction process; in particular, lower silica concentrations may decrease pre-treatment costs. Electrodialysis, like Nanofiltration (NF) and Reverse Osmosis (RO), are membrane processes that have been used as an end-to-end technology solution increasingly for the production of "pure" waters from fresh water and seawater. Membrane processes are also being applied in process and wastewater systems. The authors have not researched that far and there have not been any case studies from companies that have researched it to date. It is all still under research. And as such that is an issue that needs to be added to this paper for further research.

7. Lithium Extraction Method Suitable For Indonesia Geothermal Field

The extraction methods for mining geothermal brine for lithium has been recognized for decades, yet many methods and technologies, which are still being tested and have yet to break through commercially, can be inefficient or costly. So which method is suitable for geothermal brine sources in Indonesia? The variations between brine resources such as concentrations of lithium and any other elements or impurity ratios mean there is unlikely a one size fits all solution; however solutions may still offer some transferability of successful direct lithium extraction technologies between resources. There are still some concerns on type of end products (lithium carbonate or chloride), project finishing capacity, scalability, and brine reinjection not dilutive to the resource; in short the implementation of DLE technologies has the potential game changing technology to significantly increase the supply of lithium from brine projects.

One of the methods project and technology providers continue to pursue such as adsorption end-to-end process includes pretreatment, lithium extraction, purification, and lithium product production steps. Adsorption method may combine processing steps such as electrodialysis (a form of ion exchange) and reverse osmosis to yield high recovery rates. To date only adsorption DLE has been used on a commercial scale, in Argentina and China. If DLE can be scaled up and spread across brine assets, it will boost existing capacities via increased recoveries and lower operating costs, while also improving the sustainability aspects of operations.

DLE Adsorption is a commercial technology possibly could be adapted and suitable to Indonesia Geothermal Fields for the following reasons it has a fifty-year development and implementation history, practiced commercially in South America for 26 years and recently in China, higher lithium recovery, lower water and chemicals consumption, shorter lead time to production, minimal footprint, potential for no carbon emissions, and an additional revenue stream from unused brine resources for geothermal power producers.

Lithium extraction from geothermal brines requires complex technologies and systems. The question probably will be: How much does it cost to extract lithium from geothermal brine? Estimating the complicated cost of end-to-end process such as pretreatment, lithium extraction (may combine processing steps such as electrodialysis, a form of ion exchange and reverse osmosis to yield high recovery rates), purification, and lithium product production is difficult. So what are the main factors of lithium extraction system cost?

The main factors of geothermal extraction cost will depend at least on the following twelve (12) factors such as brine contaminants (to remove these impurities first and lithium second, other front-end contaminants such as silica, sulfate, iron, calcium, magnesium, hardness, and any suspended solids), lithium concentration (the less concentration in the liquid stream the more cost to concentrate it), flow rates (the higher the flow rate for lithium extraction and polishing the bigger equipment the more capital cost), up-front planning (concepts, designs, and regulatory requirements), space requirement (the footprint will affect cost), installation rates (installation rates in geothermal fields or consider prepackaged modules vs build-in-facilities), level of system automation needed (higher level of automation with less operators and less human errors or lesser automation with less capital cost), turnkey and prepackaged systems (save time in construction time with about the same cost or less), shipping the system to the plant (factor in freight cost where the system can be constructed near the field), operation cost (factor in system operating costs over

time), other possible costs and fees (hidden costs and fees might be), and treating costs of secondary waste produced by the system.

The bottom line is a complete pilot plant to simulate the real condition of geothermal field brines. A complete operating pilot plant installed may run for 1/10 to 2/10 of the lithium extraction facilities. The most important point is to keep the project commercial operation date punctuate with faster, cheaper, better and rapid speed of technology implementation.

8. Conclusion

Lithium is a big enabler of the energy transition from a battery perspective as we move to electric vehicles and add energy storage to electricity grids, allowing for greater penetration of renewables. That is why lithium is increasingly being seen as a critical mineral by governments, where they want to secure supplies for that transition, and that has made it an increasingly important commodity.

Traditionally, lithium produced from brine water is stored in evaporation ponds and the process can take nine to 18 months depending on the type of project and weather conditions. With Direct Lithium Extraction DLE, that process can be shortened to days or even hours. And you do not need all the land for the pond evaporation process. What is more, you can potentially reinject the remaining brine water after the process, which further reduces the environmental impact.

Various DLE technology consists of the following three (3) methods such as adsorption, ion-exchange, membrane-separation or solvent-extraction processes. The next step is a polishing solution to obtain lithium carbonate or lithium hydroxide. To date only adsorption DLE has been used on a commercial scale, in Argentina and China. DLE Adsorption is a commercial technology possibly could be adapted and suitable to Indonesia Geothermal Fields for the following reasons it has a fifty-year development and implementation history, practiced commercially in South America for 26 years and recently in China, higher lithium recovery, lower water and chemicals consumption, shorter lead time to production, minimal footprint, potential for no carbon emissions, and an additional revenue stream from unused brine resources for geothermal power producers.

How much does it cost to extract lithium from geothermal brine? Estimating the cost of end-to-end process lithium extraction from geothermal brine is difficult but manageable. The main factors of lithium extraction system cost will be depending of the following factors such as brine contaminants, lithium, flow rates, up-front planning, space requirement, installation rates, level of system automation needed, turnkey and prepackaged systems, shipping the system to the plant, operation cost, other possible costs and fees, and treating costs of secondary waste produced by the system.

The authors have not researched that far for the issue of scaling when the extracted fluid is injected.

An important issue that needs to be added to the paper for further research. The bottom line is a complete pilot plant to simulate the real condition of geothermal field brines. A complete operating pilot plant installed may run for 1/10 to 2/10 of the lithium extraction facilities. The most important point is to keep the project commercial operation date punctuate with faster, cheaper, better, and rapid speed of technology implementation.

Resource planning, Power Generation, Capacity Expansion Models, Grid Decarbonization, Utilities

ABSTRACT

Driven mostly by decarbonization goals, geothermal interest in the US power sector has grown considerably, gradually evolving from being considered a niche technology, to being recognized as a viable source of clean, baseload, grid-balancing power, and renewable electric power generation. Furthermore, recent technical advances that could greatly accelerate deployment in the near future, and US federal incentives for low-carbon generation technologies, including geothermal, can enable opportunities for integrating geothermal into utilities resource planning portfolios.

However, in general, utilities do not have in-house expertise to evaluate geothermal technologies and its potential role in helping decarbonize the grid as well as help them achieve their individual decarbonization goals. To date, geothermal is rarely included in Capacity Expansion Models (CEM) which utilities use in their planning activities and resource/technologies prioritization.

To this end, EPRI and NREL are working together in a DOE-GTO funded research project to improve geothermal understanding (opportunities, value, risks) among the power industry to help accelerate geothermal deployment.

In the present paper we describe the approach and preliminary findings of this work, focused on two topics: 1) Expand the degree of understanding on the value, opportunity, and risk of geothermal technologies among utilities and related companies/groups, specifically around geothermal for power generation. 2) Improve representation of geothermal power technologies in capacity expansion models (CEM).

1. Introduction

Given recent studies (Blankenship et al., 2024) and advancements (Fercho et al, 2024), geothermal has become a viable, secure, and flexible clean resource to a much broader geographic area than

previously possible. Given state and utility decarbonization targets as well as federal incentives for low-carbon generation technologies, including geothermal, it is important that power utilities understand the value and risks of geothermal power and its potential role in helping to decarbonize the power sector.

However, utilities often lack in-house expertise to assess geothermal technologies and their potential impact on grid decarbonization. Furthermore, geothermal energy is seldom incorporated into most energy system models, including Capacity Expansion Models (CEM) that utilities employ for resource planning and prioritization.

To address this issue, and help with the overarching goal of accelerate geothermal deployment, EPRI and the National Renewable Laboratory (NREL) are working together in a one-year, Department of Energy (DOE)-Geothermal Technology Office (GTO) funded research project to engage with the power sector, to transferer knowledge (on the opportunities and value of geothermal technologies and how to evaluate and handle risks) as well as to increase geothermal representation in utilities resource planning process. Having a common understanding of how geothermal energy technologies are currently represented in CEM used by U.S. electric and gas utilities and how CEM results inform utility planning activities and priorities will enable opportunities for integrating geothermal energy technologies into a broad range of plant operation and investment decision planning.

2. Approach

The current one-year project is focus on two main topics:

1. Expand the degree of understanding on the value, opportunity, and risk of geothermal technologies among utilities and related companies/groups, specifically around geothermal for power generation, through a “Utilities Engagement Workshop” and the delineation of strategies and best practices for utilities to plan for geothermal build out. The target audience for the workshop are:

    a) utilities’ Resource Planning Groups, which are in charge of evaluating the full range of options (including new generating capacity) for their medium- to long-term planning based on financial, and other considerations, such as decarbonization goals;
    b) utilities’ Technology-Centered Groups, which perform more in-depth technical assessments of emerging or alternative technologies that can be integrated into their portfolio;
    c) other companies/groups that could benefit from geothermal power generation.

2. Implement improved representations of geothermal resources and technologies in EPRI’s capacity expansion model, the U.S. Regional Economy, Greenhouse Gas, and Energy (US-

REGEN), which EPRI[1] utilizes to undertake numerous power sector analysis for their utility members.

This second effort aims at generating guidance for realistic representation of geothermal resources and technologies in utility models since accurate geothermal representations are critical for economic comparisons and valuations. This will be achieved through a phased approach that includes:

a) Assess how/if geothermal is represented in other capacity expansion models used by the power industry in their regional utility planning processes.
b) Generate best practices and guidance for realistic representation of geothermal resources.

3. Utility Engagement

In the past two years, EPRI launched a Geothermal Interest Group (GIG), to engage utilities and other members that would be considering geothermal for replacing their fossil fuel power plants and diversifying their portfolio. In the context of this project, a virtual workshop has been organized to provide opportunities to exchange ideas, challenges and prospects between EPRI, GTO and NREL with participant utilities/companies (particularly those previously engaged in the GIG) to identify barriers and a path forward. The workshop will be centered on geothermal for power generation, which includes Hydrothermal, Enhanced Geothermal Systems (EGS) and Advanced Geothermal Systems (AGS).

The target audiences for this effort are two main groups within the EPRI membership that would have interest in geothermal power:

- Resource Planning Groups in charge of higher-level analysis with financial modeling focus, considering future portfolio including decarbonization goals.

- Technology-Centered Groups in charge of more technical assessments of emerging technologies and R&D efforts.

As part of the workshop planning a Survey was sent out to EPRI and GIG members to understand their knowledge and interest in geothermal technologies and with their input structure the workshop to their needs. The survey questions are presented in Table 1.

[1] EPRI is an independent non-profit energy research, development, and deployment organization, whose membership consist of hundreds of organizations around the world, including the energy sector, academia, and government. In particular in the US, it serves over 100 utilities.

Table 1: Survey Questions

Survey Questions to EPRI members
1. Name 2. Organization 3. Contact Email where you would like to receive updates regarding this workshop. 4. Of the following, what best describes your role in your company. *Business and Strategy, Technical and Operations* 5. Is your organization actively operating, considering or planning geothermal projects? *Yes, No* *Box: If you answered YES please specify, if you answered NO why did you select NO?* 6. What is the level of familiarity you have with geothermal technologies *a. Not at all familiar* *b. Slightly familiar* *c. Moderately familiar* *d. Very familiar* *e. Extremely familiar* 7. If applicable, which activity describes your largest commitment/investment in geothermal thus far *a. Participation in EPRI's Geothermal Interest Group (GIG)* *b. Funding of feasibility studies (internal or contracted)* *c. Partnering in projects* *d. Operating geothermal power plant* *e. Other (Please Specify)* 8. Do you use US-REGEN or other capacity expansion models (e.g. ReEDS)? *Yes, No, Other (Please Specify)* 9. Are you familiar with geothermal costs or resource data? *a. Do you use NREL's geothermal ATB (annual technical baseline) geothermal technology cost data: Yes/No* *b. Do you use proprietary geothermal technology cost data: Yes/No* *c. Other: [fill in]* 10. Are you aware of the incentives that exist for geothermal development? *Yes, No* 11. When evaluating technologies what value has the highest importance? Please select Highest, Medium, Lowest Importance for each of the options below. *a. Resilience* *b. Cost*

c. Capacity
d. Decarbonization
e. Incentives
f. Other: please comment

12. Would you or your organization be interested in participating in a workshop addressing geothermal power production integration in utilities portfolios? (to be held second half of August 2024)
Yes, No, Maybe

13. What would you like to see in this workshop. Your input will help better target the content to current needs.
Fill in

3.1 Survey Results

The survey was delivered to approximately 50 organizations (more than 170 individuals) of which 35 responses were received. A list of the engaged organizations is presented in Table 2.

Table 2: List of survey answering organizations

US-Canada Utilities/Companies	International Organizations
Calpine	CELEC EP
Con Edison	Empresa de Pesquisa Energética
Constellation Energy	Eneva
CPS Energy	Petrobras
CRC	
Fervo Energy	
Hawaiian Electric Company	
Manitoba Hydro	
National Grid	
New York Power Authority	
Southern Company	
SRP	
Tri-State Generation & Transmission Assn. Inc	
Vistra Corp	
Xcel Energy	

3.1.1 Summary of relevant survey information (Questions 4-13, see Table 1)

- 94% of survey participants stated their organizations are actively evaluating the long-term cost effectiveness of geothermal.
- 69% of survey participants stated their organizations are actively operating, considering or planning geothermal projects.

- The average level of familiarity with geothermal technologies of the survey participants is Moderately Familiar, 35%, while 26% are very familiar.
- Almost 80% of participants stated not using capacity expansion models in their planning process.
- Regarding geothermal cost or resource data, 19% indicated the use of NREL's geothermal ATB technology cost data and 26 % indicated the use of proprietary geothermal technology cost data.
- When asked about incentives awareness for geothermal development, participants split almost equally. 48% yes, 52% no. But when considering US only responses, 65% indicated awareness.
- The value that has the highest importance, for participants, when evaluating geothermal technologies is cost, following by decarbonization, resilience, capacity, and incentives. From all the attributes, incentives have a largest range between high to low importance.
- Some organizations (see Table 3) provided multiple responses and in some cases from different type of groups (Business and Strategy and Technical and Operations).

Table 3: Organizations with multiple responses and from different type of groups.

	CELEC EP	**Con Edison**	**Fervo Energy**	**Manitoba Hydro**	**National Grid**	**PETROBRAS**	**Xcel Energy**
Business and Strategy	1	1	2	1	0	0	2
Technical and Operations	2	2	0	2	2	6	0

3.1.2 Full Survey Responses:

The graphics below represent all the answers to the survey (except questions 1-3), including the individual comments that were required in some questions:

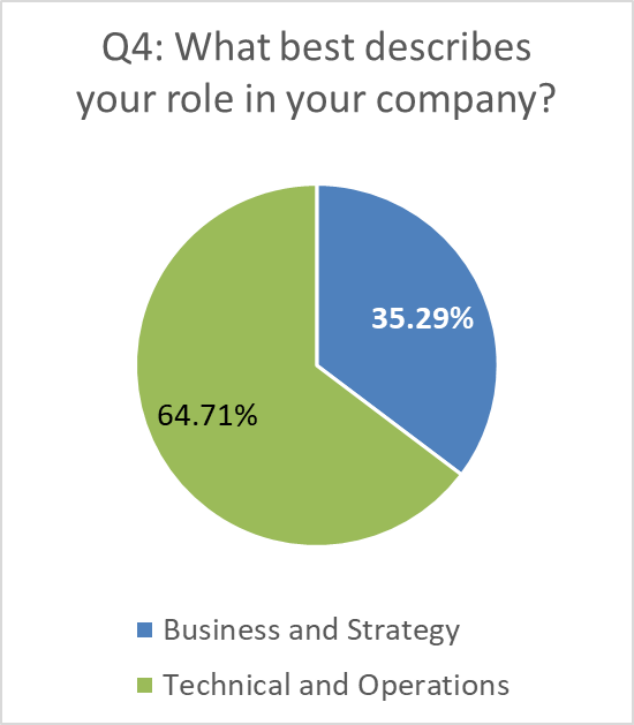

Figure 1.- Distribution of roles among survey participants.

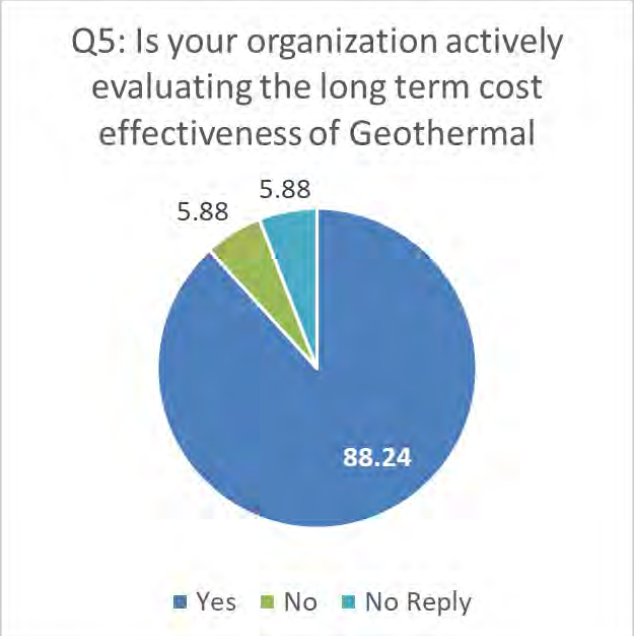

Figure 2.- The survey discussed in this paper was distributed to a diverse group of utilities and companies, primarily EPRI members. Over 88% of respondents indicated they are evaluating the long-term cost effectiveness of geothermal energy; those not considering geothermal were likely not to respond to the survey.

Figure 3.- The percentage of companies that are actively considering, planning, or operating geothermal projects. Additional details about these companies' activities were provided by respondents in some of the comments included in the text.

Participants were asked to provide additional information whether their organization was actively operating or considering planning geothermal projects. Below is the list of provided answers. Specific individual/company information has been removed and comments were grouped by themes:

Monitoring geothermal developments:

- We are a load service entity in CA and will comply with the California clean baseload energy generation requirements.
- We consider geothermal in our long-range planning but it is not economic.
- We aren't yet, but we hope to be
- […] I work for the [an international] government doing research to support energy policies development
- Considering funding feasibility studies

Actively study and/or planning geothermal projects:

- Our organization is in charge of the development of geothermal projects for electric generation. We have around 5 prospects in a study stage.
- Research project with NREL
- We are working on a geothermal plan, an also we are studying (feasibility) the first geothermal project in Ecuador.
- Every energy source and technology is considered in the long term energy planning process.
- We are planning projects across the WECC.

- Planning geothermal projects
- We have done resource studies, waiting for drilling costs to come down to be practical.
- Considering. We are in a phase of diagnosing the possibility of the business, particularly from a geologic evaluation.
- There are a few initial studies in progress about this theme
- We are evaluating the geothermal potential but geothermal projects are not yet part of our Strategic Plan.
- Due to the resource location(s), we do PPAs. We have 167 MW spread over 6 PPA projects.
- I am a venture investor in a closed loop geothermal company.
- As explained in question 7, we have PPAs, all of which were from bi-lateral deals. We do get developers that bid on geothermal projects that could be competitive project pricing, but the transmission wheeling or existing transmission constraint usually makes these projects uneconomical compared to other resources that bid into our RFPs.
- Development of pilot projects

Active developing geothermal projects:

- My company is actively involved with the operation of a geothermal field and looking into opportunities to grow
- Our organization is now in the field development phase with a geothermal project
- We are building a 400 MW next-generation geothermal project in southwest Utah

Thermal Energy Networks/ Direct use: Although the survey is focused on Electricity Generation, several participants highlighted their interest in heating uses.

- We are currently developing three utility thermal energy network pilot projects
- We are keeping an eye on geothermal technology. District heating is of particular interest. In my role, we are assessing how to incorporate district heating with geothermal into capacity expansion modelling.
- 4 Projects under the Utility Thermal Energy Networks and Jobs Act
- We are implementing pilot proposal demonstrations on geothermal based district heating.
- Geothermal heating projects in multiple outlying buildings at existing power plant facilities. No geothermal electrical generating projects at this time.
- Proposed three utility-owned thermal energy network projects in New York State

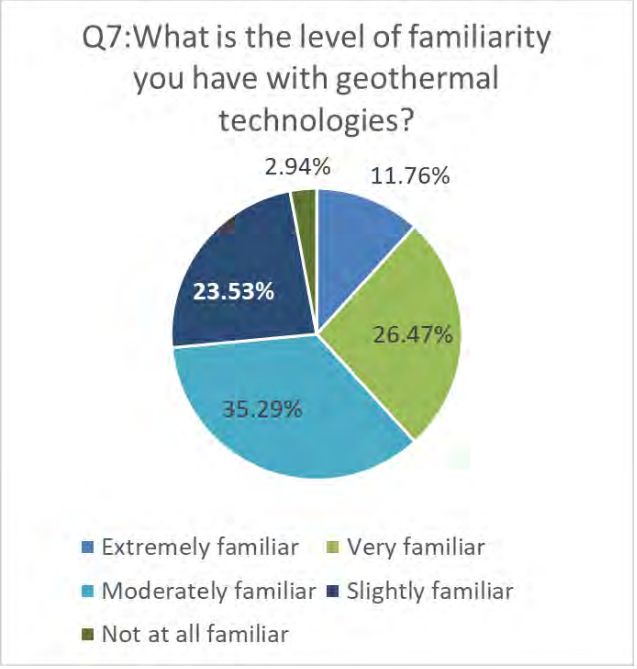

Figure 4.- Level of familiarity with geothermal energy among survey respondents.

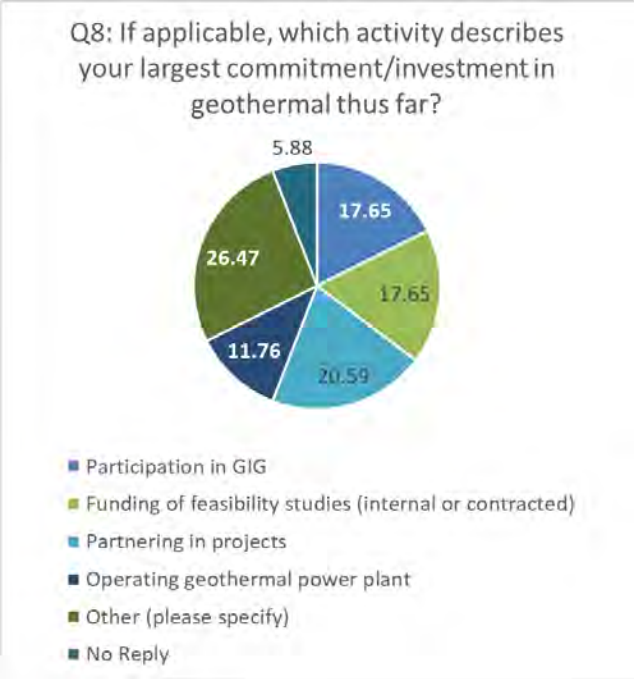

Figure 5.- The distribution of companies' commitment and investment in geothermal energy. Specifically, 17.65% are involved in EPRI's Geothermal Interest Group (GIG) without economic commitment, 17.65% have funded feasibility studies, 20.59% are partnering in projects, and 11.76% operate geothermal power plants. Additionally, 26.47% selected 'other' (with comments provided in the text below), and 11.76% did not respond.

In the case of selecting “Other” participants specified the following:

- Proposed three utility-owned thermal energy network projects in New York State
- I am a venture investor in a closed loop geothermal company.
- [,,,] I work for the [an international] government doing research to support energy policies development
- Participate in EPRI 178B (invite extended through that program) [*note: 178B program is EPRI’s Resource Planning for Electric Power Systems program]
- Development of pilot projects
- Exploration of potential areas.
- Internal evaluations of potential for geothermal
- As explained in question 7, we have PPAs, all of which were from bi-lateral deals. We do get developers that bid in geothermal projects that could be competitive project pricing, but the transmission wheeling or existing transmission constraint usually makes these projects uneconomical compared to other resources that bid into our RFPs.
- considering funding feasibility studies

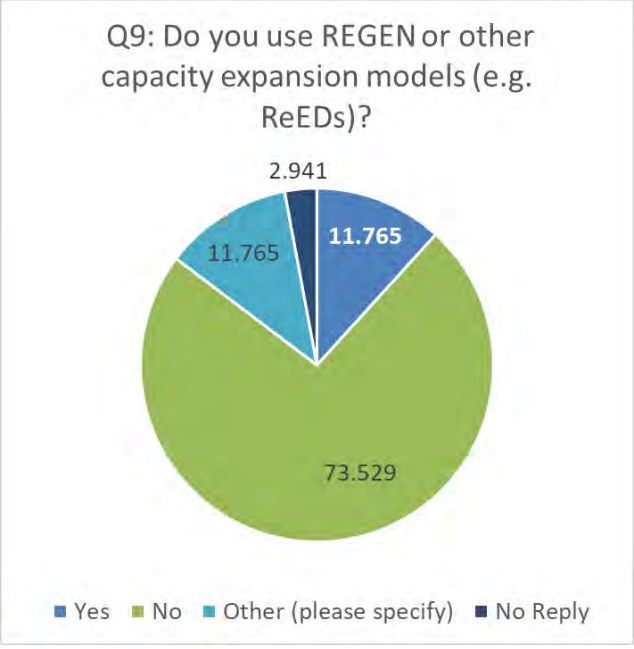

Figure 6.- The percentage of respondents that use and/or know about capacity expansion models (CEM) which is approximately 23.5 %. Of those, half indicated the use of REGEN or ReEDs while the rest mentioned other CEM as listed in the text below.

In the case of selecting “Other” participants specified the following:

- We know about REGEN through EPRI but our company uses PSR software SDDP, OptGen, and NCP.
- Aurora LTC
- Aurora
- Matriz/Encad, developed by Cepel (www.cepel.br)

Q10: Are you familiar with geothermal costs or resource data?

	Yes	No	No. of Responses
Do you use NREL's geothermal ATB (annual technical baseline) geothermal technology cost data?	6	26	32
Do you use proprietary geothermal technology cost data?	8	23	31
No Reply			2
Other			5

Other (please specify):

- It is done by someone else, in another area of my company.
- Still sourcing cost information
- I know the technical-feasibility tool from innerspace
- Not familiar
- Old TAGWeb cases and recent developer RFP pricing proposals.

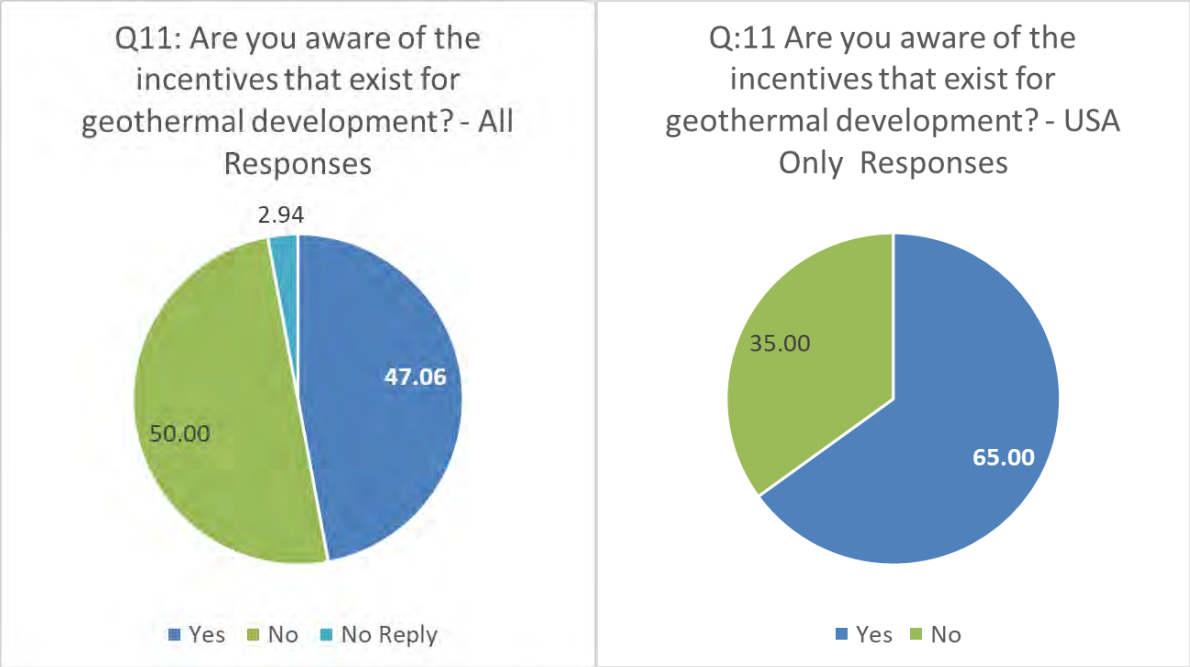

Figure 7.- Percentage of respondents that are aware of incentives for geothermal development. In the USA 65% of respondents indicated awareness.

Q12: When evaluating technologies what value has the highest importance?

	Highest Importance	Medium Importance	Lowest Importance
Resilience	17	15	1
Cost	25	8	0
Capacity	15	16	2
Decarbonization	17	14	1
Incentives	10	15	7

Figure 8.- Distribution of respondents' interest in participating on a workshop on geothermal power production integration in utilities portfolios. The input of the following questions (as described in the text below) was intended to help in the design of such workshop.

Q14: What would you like to see in this workshop. Your input will help better target the content to current needs.

- Utilities and ISOs
- Funds availability for geothermal studies.
- The overview of the entire project phases from scoping through funding approval and permit process thermal conductivity test and test drill safety and EH&S consideration,

drilling process, operation and maintenance, end of life ? Capacity limitation. What could go wrong .... maybe case studies

- My area is focused on networked geothermal systems, also referred to as neighborhood district geothermal. My group is not evaluating geothermal at the power production level.
- I would like to have an open discussion of the many forms of geothermal power coming into the market, including advanced closed loop geothermal, which the DOE's GTO often ignores in favor of enhanced geothermal.
- Technology development, actual costs, incentives.
- We would be interested in understanding opportunities for Geothermal energy in Texas and how to conduct technoeconomic research and analysis.
- Equipment manufacturers, resource assessment, regulations and policies
- Novel applications for geothermal heat
- Would love to see how hourly compliance requirements (for example, slice of day in California) affect planning decisions.
- Challenges in developing geothermal. Community outreach. study/survey potential geothermal site and evaluation of project development
- Technical performance and cost information for district geothermal to support incorporating into a capacity expansion planning model, as well as strategies for modelling.
- Capital costs, O&M, and reasonable cost declines especially with respect to drilling.
- Looking to see what is out there and how to optimize geothermal load balancing for networking purposes.
- Enabling and scaling geothermal based space heating/cooling. Optimization of technology.
- The use of geothermal heating in areas of the country with low potential for use geothermal energy.
- Performance of low-enthalpy geothermal systems.
- Repurposing abandoned oil/gas field to geothermal energy production.
- News about recent years developments in this subject, especially Abou next-generation technologies to enable geothermal exploration at places with medium and low enthalpy
- -The role of O&G industry on that -Possible applications in medium and low enthalpy areas like in Brasil - Estimates of the value of having an increase in Geothermal use in a country that already has an energy matrix with a high percentage of renewables (such as in Brazil) -Regulations (suggestions/examples on how to advance on that subject)
- I'd like to understand the state of the technology emphasizing the recent developments in: - advanced geothermal - geothermal resource assessment - geothermal system configurations and related costs (investment and LCOE) - Operational information: recommended modes of operation and related efficiencies; ramping capabilities; start-up/shut-down characteristics and constraints. - Environmental impacts
- How geothermal can be harnessed in regions with sub-optimal geothermal resources like the southeast USA
- I would like to see deeper dives into the drilling process, derisking of identifying location(s) to drill, specific deep dives into Fervo's technology and their project(s), identify how much potential additional geothermal there is in the Salton Sea region, and closer look into advanced future technologies that will eventually evolve and assimilate into standard designs.

- Ways to help our regulators allow for cost recovery to assess, explore, and build geothermal power plants.
- How to get through the plant development risk/cost portion of a project

4. US-REGEN

The second objective of this project is to develop guidance for improving the representation of geothermal resources and technologies in utility models. This will be achieved by enhancing the geothermal resources and technologies representation in EPRI's US-REGEN model, leveraging NREL's geothermal resource supply curves, technology costs, and modeling approaches from the Regional Energy Deployment System (ReEDS) capacity expansion model (Ho et al., 2021; Pinchuk et al., 2023). US-REGEN is the CEM which EPRI utilizes to undertake numerous power sector analysis for their utility members.

US-REGEN is an economy-wide model developed and maintained by EPRI, that combines a detailed dispatch and capacity expansion model of the United States electric sector with a technologically detailed consumer choice model of end-use service and energy demand as well as a fuel supply model representing alternative primary resources and conversion technologies for non-electric fuels. The three models are solved iteratively to convergence, allowing analyses of policy impacts on the electric sector taking into account electricity demand responses, and conversely allowing analysis of how end-use energy policies and technological improvements impact electric and non-electric demands and load shapes. US-REGEN considers 16 sub-regions of the continental U.S., to account for differences in resource endowments, energy demand, costs, policies, and policy impacts. EPRI has used US-REGEN to undertake numerous analyses for their utility members, including a wide range of environmental and energy policies in both the electric and non-electric sectors. A list of highlighted analyses using US-REGEN can be found at https://esca.epri.com/models.html.

US-REGEN electric sector model is an intertemporal capacity expansion model and can be run separately with higher regional and temporal resolution, or for a single year with hourly resolution and unit commitment constraints. The power generation technologies considered in the electric model are described in (EPRI, 2021: Electricity Generation section). The electric model can be extended to include additional sub-state detail for other states based on the boundaries of independent system operators (ISOs) and regional transmission operators (RTOs). By default, it solves in five-year time steps from 2015 through 2050, but can be configured to use other time-steps and base years. Full documentation of the US-REGEN model can be found in (EPRI, 2021).

Geothermal energy in US-REGEN (Version 2021A) includes only hydrothermal flash technology for power generation; EGS technologies are not considered. New additions of hydrothermal power capacity are constrained based on estimates of discovered and undiscovered conventional sites in the western regions by the U.S. Geological Survey (USGS) in 2008 with total new potential additions amounting to 39 GW (USGS, 2008) by 2050. US-REGEN also assumes an improving capacity factor for geothermal power over time as a result of technical progress, from roughly 50% today to roughly 80% by 2050 with capital costs for new geothermal capacity around $5000/kW today and slightly declining over time.

4.1 Improved representation of geothermal resources and technologies in capacity expansion models

The model structure and complexity determine the level of detail to represent primary resources and power generation technologies. However, general guidelines for the accurate representation of geothermal resources and technologies can be drawn from the enhancement of geothermal energy in EPRI's US-REGEN model, leveraging NREL's ReEDS model. These include:

- *Consistent definition of geothermal resources and technologies across models.* Having a consistent definition of geothermal resources and technologies across different models is crucial for ensuring comparability and coherence in data analysis and decision-making. NREL's definition of geothermal resources, used in this project, include:
    - Hydrothermal
    - EGS-NF (Enhanced Geothermal Systems near hydrothermal fields)
    - Deep EGS
- *Temperature-based representation of geothermal resources*. Geothermal resource quality is directly related to temperature. Adding temperature to geothermal resource classification aligns it with potential assessment structures of other renewables like wind and solar.
- *Disaggregation of supply curves by region, technology type and resource classes*. Breaking down of supply curves by region, technology, and resource class allows for localized insights. However, the model structure, complexity and computational time ultimately define the level of detail for geothermal technologies. For example, ReEDs currently represents 3 geothermal technologies (hydrothermal, EGS-NF and EGS), 10 temperature-based resource classes and 134 regions; the updated US-REGEN represents 3 geothermal technologies, 6 temperature-based resource classes and 48 regions (state-level).
- *Inclusion of range of technology costs and performance*. Modeling several cost scenarios provides a comprehensive economic outlook, helping stakeholders assess risks and opportunities for geothermal technologies more accurately. Based on NREL's ATB, conservative, moderate, and advanced cost scenarios can be included.
- *Integration of discovery rate*. Accounting for the discovery rate reflects potential future resource availability, making models dynamic and forward-looking. This factor ensures realistic projections of geothermal energy expansion, aiding in strategic and sustainable energy planning.

4.2 Next steps

The first phase in this project consisted in updating guidelines and geothermal representation in US-REGEN. A second phase is ongoing, where a series of scenario will be developed to better understand the role and system value of geothermal technologies, particularly in deeply decarbonized futures.

An outcome of this second phase aims at generating guidance for realistic representation of geothermal resources and technologies highlighting system conditions where geothermal becomes attractive and highlight data gaps to achieve a more realistic representation.

Summary

EPRI and NREL are working together in a DOE-GTO funded research project to improve geothermal understanding (opportunities, value, risks) among the power industry to help accelerate geothermal deployment. This one-year project focuses on engagement with national and international utilities/organizations to deepen their comprehension of the value, opportunities, and risks associated with geothermal technologies, particularly in the context of power generation. As well as to enhance the representation of geothermal power technologies within capacity expansion models (CEM) with the objective of facilitating better planning and decision-making in the energy sector.

By collecting input via a 13 question survey, key topics of interest from the surveyed utilities and energy companies were identified: Resource assessment, de-risking, technology innovations (drilling, completion, new technologies), cost, financial incentives, technoeconomic analysis, grid integration and planning, regulation, compliance and policies. This input helped designed the engagement workshop to take place on September 4th, 2024. The key objectives for the workshop include: knowledge transfer, Utilities' experience transfer, and identification of challenges, and opportunities for EPRI-NREL-GTO to help accelerate geothermal technologies in the power sector.

Furthermore, an updated geothermal representation has been implemented in EPRI's US-REGEN model in collaboration with NREL's ReEDS team and leveraging NREL's resource supply curves and technology costs inputs for geothermal power generation technologies. In the second phase of this project, a series of scenario are being developed to better understand the role and system value of geothermal technologies, particularly in deeply decarbonized futures, highlighting how model formulation and assumptions impact geothermal deployment projections in capacity expansion models.

Puna Geothermal Venture, environmental permitting, geothermal, Environmental Impact Statement (EIS), Hawaii Environmental Policy Act (HEPA), Hawai'i Public Utilities Commission (HPUC), State of Hawaii Department of Health (DOH), State of Hawaii Department of Land and Natural Resources, Office of Planning and Sustainable Development (OPSD)

ABSTRACT

The Puna Geothermal Venture Repower Project includes the commissioning of three new efficient generating units and the decommissioning of the old twelve generating units, allowing for an increase of generation up to 46 megawatts. The Repower Project required an environmental analysis and multiple environmental permits to be reviewed and approved by various agencies. The environmental review process began with the Hawaii Public Utilities Commission requiring the review as a condition of the approval of the Amended and Restated Power Purchase Agreement. With no permits to construct the project requiring discretionary review by an agency, the County of Hawaii Planning Department was designated as the authorizing agency. Ormat requested to have the project reviewed under an Environmental Impact Statement, thus maximizing the opportunity for the public to participate in the process. The EIS process took just over two years to complete, including two public involvement periods, with in-person meetings held in Puna. Other environmental permits needed for a successful Project include the Noncovered Source Permit from the State of Hawaii Department of Health (DOH), the Underground Injection Control Permit approvals from the U.S. Environmental Protection Agency and DOH, the Geothermal Resource Permit from the Planning Department, and the Plan of Operations for drilling with the State of Hawaii Department of Land and Natural Resources.

1. Introduction

Puna Geothermal Venture (PGV), a subsidiary of Ormat Technologies, Inc., has operated a geothermal facility on the Big Island of Hawai'i for over three decades. On March 16, 2022, the

Hawai'i Public Utilities Commission (HPUC) approved an Amended and Restated Power Purchase Agreement (ARPPA) between PGV and Hawaiian Electric to provide an additional eight megawatts (MW) of geothermal energy with the PGV Repower Project (Repower Project). The ARPPA would allow for an increase of up to 46 MW. The Project includes the commissioning of new efficient generating units and the decommissioning of the old generating units, allowing for an increase in generation (Figure 1).

Figure 1. Project location and proposed facilities.

As part of the approval of the ARPPA, the HPUC required an environmental review under the Hawaii Environmental Policy Act (HEPA) (Chapter 343, Hawaii Revised Statues, and Title 11, Chapter 200.1, Hawaii Administrative Rules) to be completed before the commencement of construction for the Project. The HPUC, the Department of Land and Natural Resources and the Department of Health Clean Air Branch all declined to be the authorizing agency for the environmental review; therefore, a request was made to the Office of Planning and Sustainable Development (OPSD) to determine the approving agency. OPSD determined that the County of Hawaii Planning Department be designated as the accepting authority for the environmental review because they are responsible for supervising the project through compliance with county

permits that govern the Project. At Ormat's request and after much discussion with agency staff, PGV, and the county, it was determined that an Environmental Impact Statement (EIS) would be the appropriate level of environmental review and would provide the most opportunity for public input.

The PGV facility requires authorization from several federal, state, and county governments to operate. There are six main permits for development. At the county level, construction authorizations for grading and building are required from the Department of Public Works. To comply with the Hawaii ambient air quality standards, amendments to the Noncovered Source Permit (NSP) from the State of Hawaii Department of Health (DOH) must be submitted. The Geothermal Resource Permit (GRP) from the Hawaii County Planning Department is the primary permit, focusing on local land use requirements. In addition, a Plan of Operations (POO) for geothermal well drilling with the State of Hawaii, Department of Land and Natural Resources (DLNR) is also required. Wellfield operations include permits authorized under the Underground Injection Control (UIC) Permit from the U.S. Environmental Protection Agency (EPA) and DOH.

2. Environmental Impact Statement

The EIS analyzed the potential impacts of the Repower Project, which included the replacement of the existing 12 operating power-generating units with four, much more efficient power-generating units. The Repower Project would increase renewable energy production at the existing facility (within the current site fence line) using new, more efficient Ormat Energy Convertor (OEC) units on a co-located smaller land footprint compared to the existing units. The Repower Project would increase power production from 38 to 46 MW in Phase 1, and may further increase production to 60 MW in Phase 2. The overall property size would remain the same, and most of the existing infrastructure and buildings would remain, including administration buildings, the control room, maintenance areas, well pads, and the gathering system. The new OEC units would continue safely supplying reliable power from renewable geothermal resources with more efficient and quieter equipment.

In coordination with the County, Ormat contracted Stantec Consulting Services Inc. (Stantec) to be the third-party consultant preparing the EIS. During the entire EIS process, PGV made all documents available on the project's website (https://punageothermalproject.com/eis/) to keep the public informed of upcoming meetings and the status of the EIS.

The Project's EIS Prep Notice (EISPN) was published on July 23, 2022, which began a 30-day public scoping period. The EIS analyzed the ARPPA-approved Repower Project, which increased power production up to 46 MW (Phase 1). The EIS also analyzed a potential increase from 46 to 60 MW (Phase 2). During the scoping period, the public could submit written comments anytime. As a Hawaii Environmental Review Program requirement, PGV hosted a community meeting during the scoping period. The community meeting was held on August 17, 2022, at the Pahoa Neighborhood Center in Pahoa, HI, with a link for virtual attendance. A one-hour informational open house was held during this meeting, followed by a two-hour period for oral comments. During the scoping period, 29 comments (written or oral) were received regarding the Repower Project.

Once the scoping period was over, Stantec began preparing the Draft EIS document. The public scoping comments were reviewed, with substantial comments received during the scoping period

being addressed in the Draft EIS. The Draft EIS analyzed potential impacts to the following resources: geology, hydrology, air quality and climate change, noise, biological resources, socioeconomics and environmental justice, historic resources, cultural practices, aesthetics, hazardous materials and solid waste, public health and safety, transportation and access, and cumulative effects. The Draft EIS was published on May 8, 2023, beginning a 45-day public comment period. While not required by statute, PGV hosted an open house and public comment meeting on June 1, 2023, where information on the Draft EIS was presented, and the public could provide written and oral comments. The meeting was again held at the Pahoa Neighborhood Facility Center in Pahoa, HI. During the public comment period, 90 comments (written or oral) were received, with more than 1000 individual comments. Comments mainly related to the following issues (not an all-inclusive list): existing operations, hydrology, air quality, cultural impacts, hazardous materials and waste, noise, emergency response, and geologic hazards.

During the preparation of the Final EIS, each comment received during the public comment period was reviewed and responded to, and any necessary changes were made to the final document. The Planning Department accepted the Final EIS on January 22, 2024 and the document was submitted to the HPUC on February 8, 2024; finalizing a two year process from start to finish of the EIS.

3. Operational Permits

Ormat has operated PGV for over 20 years and is committed to providing safe, reliable renewable energy to the grid by operating safely and sustainably. This includes protecting our employees, our environment, and our neighboring communities. PGV recognizes the need to maintain and comply with environmental regulations, and from its inception, the facility has maintained the appropriate environmental permit approvals for operation.

The following section details the types of permits and lead agencies required for the operation of a geothermal facility in Hawai'i. With the completion of the EIS, the timeframe to construct the Repower Project was established by the HPUC at 36 months. This timeframe includes completing the required operational permits and updates. The environmental permits necessary for the operation of PGV are managed at the federal, state, and county levels. Several types of permits are currently needed for operation from these agencies. The Repower Project will require an update to the County GRP, the DLNR POO, and the State and Federal UIC permits. Additionally, an amended permit will be sought for air quality under the NSP program. For construction of the Repower Project, grading, grubbing, and building permits will be acquired from the County Department of Public Works.

3.1 Geothermal Resource Permit

The GRP is managed by the County of Hawai'i Planning Department, with permit approval authority with the East Hawaii Planning Commission. This permit focuses on local land use requirements maintaining home rule. The current GRP allows PGV to increase the power output up to 60 MW, and thus the reason for Phase 2 being analyzed in the EIS. The GRP was initially approved in 1989 and was amended in 2001. Informational updates have been provided to the Planning Department, coincident with changes to PGV's operation.

3.2 Plan of Operation

PGV operates a geothermal wellfield comprised of production and injection wells, which is regulated by DLNR. The POO is PGV's living document that oversees geothermal well development and allows drilling of up to 30 wells and electrical generation up to 60 MW. The geothermal well program is an iterative process that is fit-for-purpose based on geology, resource constraints, land holdings, and regulatory requirements. The Repower Project's new electrical generation units will use geothermal fluid from existing geothermal wells. New wells that are eventually designated as injection wells are also regulated by the DOH and EPA.

3.3 Underground Injection Control

The UIC program at PGV is regulated by both the EPA and DOH. Both agencies have their respective UIC permits for the PGV facility. Well operations are continuous and include testing for integrity and reservoir monitoring programs. The UIC permits include injection pressure limits that are based on formation testing to reduce the potential for the creation of fractures and well construction requirements so that injected fluids do not intersect potential underground sources of drinking water. Continuous monitoring and systematic testing requirements are in place for each injection well, including mechanical integrity tests. Groundwater is monitored to ensure no impacts to groundwater quality occurs from the geothermal operations. The DOH UIC permit is renewed every five years, and the EPA UIC permit is renewed every ten years.

3.4 Noncovered Source Permit

The State of Hawai'i Clean Air Branch manages air quality regulations for PGV by issuance of the NSP for the operation of the wells and geothermal facility. The NSP allows PGV to generate up to 41 MW. The NSP will be amended to add the Repower Project's new electrical generation units and additional MW.

Fugitive hydrogen sulfide emissions at PGV are controlled by capture and treatment with a series of two reactors for chemical abatement. The combustion emissions for current and future drilling are covered in the PGV's existing NSP. No greenhouse gases are emitted from PGV operations. The State NSP is renewed every five years.

4. Conclusion

The PGV facility and the Repower Project demonstrate how environmental conservation and technological advancement can coexist successfully. Currently, all the necessary environmental and government permits to operate the PGV facility are active without any interruptions, ensuring the continuous production of 38 MW of renewable power.

However, as PGV progresses toward the 46 MW Repower Project, and as the State of Hawaii's 2045 mandate to be at 100% renewable energy looms near, everyone is facing complex regulatory challenges involving local, state, and federal authorities. For example, the HPUC's requirement for environmental review of the proposed 46 MW Repower Project, BEFORE any construction could commence, added an unprecedented layer of complexity that is unique in its nature. The Repower Project ARPPA was negotiated and approved between Ormat and Hawaii Electric Light Company (HELCO) in 2019. On December 31, 2019, HELCO submitted the ARPPA to the HPUC for review and approval. The HPUC opened a docket, which followed the PUC procedural

schedule for information requests and responses by all parties from January 2020 through March 2021. On March 31, 2021 the HPUC suspended the docket, pending the completion of an environmental review. The suspension by the HPUC was ordered, AFTER the DOH and DLNR both informed the HPUC that an environmental review was not required. With the docket for the Repower Project in limbo, PGV reached out to the Office of Planning and Sustainable Development for guidance. The result was that PGV was able to designate Hawaii County to be the Accepting Authority for the environmental review. The County's position was that an environmental review was not required, but, to assist with completing the HPUC review and approval of the ARPPA, the County accepted the designation. The EIS took two years to complete, and PGV submitted the Final EIS on December 27, 2023. On February 8, 2024, HELCO filed a copyof the EIS with the HPUC. This filing concluded the conditional approval of the ARPPA, and now allows construction to begin on the Repower Project. For a State in high demand for renewable energy, this process took over four years to get an approval from the HPUC for an additional eight MWs.

PGV's Repower Project is not just about expansion—it symbolizes a commitment. A commitment to responsibly harness geothermal energy, provide reliable and sustainable power, and honor the people and traditions of Hawai'i. By aligning our operations with the regulatory expectations from county, state, and federal agencies, PGV is positioned to enhance its capacity while preserving the delicate balance between progress and conservation.

Creating a Universal Pitch for Geothermal: A Declaration of Communication

Kristina Hagström Ilievska

Baseload Capital

Keywords

Geothermal energy, geothermal industry, geothermal associations, geothermal communications, geothermal messaging

ABSTRACT

Geothermal energy is both a renewable reality and the source of tremendous untapped potential. The energy resource offers an off-ramp for the oil and gas workforce to transition into the clean energy economy and is an essential solution to draw down the climate crisis. Its benefits are clear: stable, baseload power, capable of offsetting regional energy needs through direct use applications and geothermal ground source heat pumps as well as generating electricity on a much larger commercial scale. Yet geothermal is rarely mentioned alongside its renewable counterparts like wind and solar.

Lack of external awareness about the important role that geothermal must play in the transition to a sustainable, green energy future is one of the biggest issues facing the industry. This disconnect between industry knowledge and public perception has been the subject of multiple panels and roundtable discussions at international geothermal gatherings over the past four years. The common theme that emerged from these events was the importance of replacing confusing and disjointed messaging with clear, concise, and cohesive communication.

In late 2023, multiple members of the geothermal community, representing geothermal developers, investors, and associations, convened several workshops to collect data from the industry on how to address geothermal's specific communication challenges. This paper analyzes, categorizes, and distills those insights into a series of actionable recommendations, including:

- Establish one common definition of geothermal energy;
- Tell a simplified story about geothermal in its many applications;
- Employ consistent wording and imagery that focuses on geothermal as a stable, sustainable, and safe source of energy that allows end users to live their normal life;
- Focus on geothermal as a community rather than a group of competitors; and
- Align and coordinate global and regional geothermal events.

1. Introduction

Geothermal energy is an important source of renewable and clean firm energy that has the potential to provide a significant portion of the world's electricity, thermal, and air conditioning needs.[1] Despite its many benefits, geothermal energy has not yet achieved the same level of awareness nor widespread adoption as other renewable energy sources like wind and solar.[2]

One major challenge facing the geothermal industry is the lack of worldwide community alignment on messaging about the merits, benefits, and potential of geothermal energy. This is evident when surveying the websites of international and regional geothermal associations, with each organization employing different terminology, numbers, and even facts. The lack of alignment results in confusion about the definition and uses of geothermal among the general public. For example, the following three questions were posed to the general public via a social media poll in 2023:

1. *What is geothermal?*

   The top three answers: heat, energy, earth

2. *What comes to mind when you think about geothermal?*

   The top three answers: Iceland, volcanoes, hot springs

3. *How could you use geothermal?*

   The top three answers: “no idea,” power, hot water[3]

The disconnect between the real and potential benefits of geothermal and the public perception (or lack thereof) about the technology has been a topic at several international gatherings of the geothermal community. Following the World Geothermal Congress 2021, the International Geothermal Association (IGA),[4] ThinkGeoEnergy,[5] Baseload Capital,[6] the International Renewable Energy Administration (IRENA),[7] and Geothermal Rising[8] agreed that crafting a clear, cohesive, and compelling message that communicates the uses and benefits of geothermal to a global audience was a key step to telling the story of geothermal and garnering increased support.

In 2023, in an effort to address this challenge, they convened communication workshops at two of the world’s largest geothermal industry conferences: the World Geothermal Congress in Beijing, China, and the Geothermal Rising Conference in Reno, Nevada, United States. These workshops brought together leaders in the geothermal energy sector from across the globe to discuss and align on messaging around geothermal energy.

This paper analyzes the data from these workshops to identify patterns, gaps, and opportunities in communication strategies. From these, the authors worked to distill actionable insights, draw conclusions, and present recommendations to be shared with participants and the broader industry.

2. Methodology

2.1 Research questions

At the World Geothermal Congress 2021, held in Reykjavik, Iceland, the issue of communication was raised in a panel discussion. Following that discussion, Baseload Capital convened a communications roundtable with IGA and Think GeoEnergy to discuss data collection. The social media poll and subsequent two workshops in 2023 were the result of that roundtable. Geothermal Rising and IRENA joined the initiative to help further develop a workshop with four specific questions:

1. Where can geothermal associations improve alignment/partnerships?
2. Where can geothermal companies/industry improve alignment and build partnerships?
3. What keywords and images should we use to discuss geothermal?
4. What are the myths and misconceptions around geothermal that we need to dispel?

2.2 Research design

The research questions were deliberately presented in an open-ended manner, in order to a) allow for flexibility and creativity in participant responses and b) generate new ideas and meaningful insights that might not otherwise be captured by close-ended survey data. A thematic analysis was then undertaken to discover and interpret patterns in the data.[9]

This qualitative approach provides more complexity and depth to our understanding of *why*, particularly from sociology and psychology perspectives. As sociologist Kristin Luker argues, "[canonical researchers] are doing a logic of verification study, and [qualitative researchers] are doing a logic of discovery."[10]

Qualitative research complements more abundant quantitative and geoscientific research exploring geothermal energy. It seeks to fill an empirical data gap around how the geothermal ecosystem utilizes marketing and communication to engage and familiarize external audiences about geothermal technologies and applications. This study joins a growing segment of qualitative research that can help us to better understand the energy transition and the role of geothermal in this transition.

Qualitative research scholar Sarah Tracy argues, "Many people erroneously assume that formal generalizability is the only way to achieve resonance."[11] "Resonance" is important because it invites the audience of a study to recognize and apply elements of the study to other academic research and provides practitioners with a practical guide to implement findings from qualitative research. This study seeks to achieve what Tracy calls a "naturalistic generalization," whereby findings from this study aim to influence and affect readers' understanding, routines, and future decision-making and, therefore, produce transferable findings.[12]

2.3 Participants

Participants were attendees of communication workshops held at two of the largest gatherings of the geothermal community. These gatherings, which both took place in late 2023, brought together leaders from industry, academia, finance, government, indigenous communities, research organizations, media, non-governmental organizations (NGOs), and the global community to share scientific and technological achievements and collaborate on solutions to build a sustainable

society. Participants included representatives from the entire geothermal ecosystem, including geothermal ground source heat pumps, direct use and thermal energy networks, and power production.

World Geothermal Congress 2023, Beijing, China

The theme of the 7th World Geothermal Congress (WGC) was "Clean Geothermal, Green Earth." Held at the China National Convention Center in Beijing from September 15-17, 2023, it was China's first time hosting an international geothermal event of this kind. The WGC was attended by more than 1,400 guests from 54 countries and regions. The event consisted of 88 forums and seminars in parallel with a technology and equipment exhibition.

Sixty individuals participated in the communication workshop at the WGC.

Geothermal Rising Conference, Reno, Nevada, USA

With more than 1,700 attendees from 32 countries descending on the western U.S. city of Reno, Nevada, from October 1-5, 2023, the Geothermal Rising Conference (GRC) was the largest annual gathering of the geothermal industry. The event consisted of more than 500 technical, policy, and market sessions, educational seminars, panels, workshops, tours of geothermal and renewable energy projects, and an exhibition hall.

Eighty individuals participated in the communication workshop at the GRC.

2.4 Data collection and analysis

The two workshops were conducted and facilitated in the same manner. The WGC workshop was facilitated by staff from Geothermal Rising and IRENA. The GRC workshop was facilitated by staff from Geothermal Rising and Baseload Capital. Participants at both communication workshops were presented one question at a time and then broken into working groups composed of approximately seven members. They had 10 minutes to discuss each question and record team answers on flip charts prior to reporting back to the larger group. In some cases, groups voted or otherwise indicated support for suggestions with which they agreed by placing a colored sticker "dot" next to the answer.

Recorded answers were photographed by workshop organizers to be compiled and analyzed. The authors of this paper transcribed each written answer into a spreadsheet, along with the question, conference location, group number, and votes received (if any). Results were then coded into broad thematic categories using a bottom-up, or inductive, approach. In other words, the authors had no preconceived notions nor preset categories, but instead allowed the codes to emerge based on what the raw data revealed.

2.5 Limitations

Some participants were invited and others self-selected into the communication workshops. Invitations were issued in an effort to capture a breadth of individuals who otherwise may not have participated and to avoid skewing to one type of perspective, group, or demographic. Those who self-selected to participate likely did so because they had a vested interest in the topic of marketing and communication.

There are not firm non-probabilistic sample size guidelines in a qualitative study such as this, and qualitative research methods suggest study continue until the researchers achieve a point of saturation, meaning no new information or themes are discovered or observed in the data. After two workshops, new findings were still emerging, which suggests there is more data to be uncovered. The authors of this report encourage future studies, perhaps even conducting more workshops using the same process and methodology employed in the two used for this study.

There can be subjectivity in the interpretation and coding of the data. When transcribing the results, every effort was made to decipher the handwritten answers. Approximately 1 percent of the time, this was not possible, either because the answers were illegible, or the photos did not fully capture the data. In some instances – approximately 6 percent of responses – it was not clear to the authors which question was being answered, and thus the data was not coded to a specific question for consideration in the final analysis.

Finally, workshop responses were coded to identify data as it links to, or represents, unique phenomena or "synthesizing concepts."[13] A code is a word or short phrase that symbolically assigns a summative, salient, essence-capturing attribute. In several cases, responses could have fit into multiple, overlapping thematic categories – e.g. "collaboration" and "communication" or "danger" and "environmental damage." Every effort was made to capture the spirit of the responses and acknowledge recurring themes.

3. Overview and Analysis of Data

The communication workshops yielded a data set of over 300 suggestions, including keywords, phrases, questions, and, in some cases, images. Each question was thematically coded independent of the other questions and is considered separately in the analysis below.

3.1 Where can geothermal associations improve alignment/partnerships?

Every group responded to this question, resulting in over 70 suggestions. Participants consistently indicated three overlapping areas where geothermal associations could improve alignment and partnerships:

Collaborate with one another and with outside partners.

There are "many associations, alliances, etc.," wrote one WGC group. "Who do we listen to?" Another WGC group mentioned a need for "global alignment of organizations," including by region and country, and a GRC group suggested "shared memberships between organizations."

Likewise, many groups referenced the importance of coordinating event schedules. "Don't schedule conferences on top of each other," said a group at the Geothermal Rising Conference. This sentiment was echoed by several others, one of whom bemoaned the "cadence of events."

At the same time, participants suggested that geothermal associations should focus on creating partnerships with universities, other renewables, and influencers to help spread the word about geothermal energy.

Establish common definitions and vocabulary for the industry.

Every group mentioned that industry associations should help to better define geothermal. “Define what we are,” wrote one group at the Geothermal Rising Conference. “Align on definitions,” urged a group at the World Geothermal Congress. Several groups suggested developing a glossary of streamlined geothermal vocabulary.

Engage in simplified storytelling.

“K.I.S.S.,”[14] wrote one GRC group, which was immediately followed up by an all-caps demand for “NO NEW ACRONYMS.” Multiple groups used the word “simplify” when talking about messaging and communication with the general public and external audiences. “Improve storytelling (simple illustrations/animations),” wrote one GRC group. Likewise, a WGC group suggested creating simple “models [to] help understand” and communicating at the “grassroots level – how you convey to children/community.”

Participants also thought geothermal associations should “help with framing the message (turn setbacks into positive story – [e.g. a] well with insufficient yield = new data/knowledge)” as well as “share successful stories and policies.”

3.2 Where can geothermal companies/industry improve alignment and build partnerships?

Only groups attending the Geothermal Rising Conference recorded answers to this question, resulting in approximately 50 suggestions. One common theme emerged:

Choose cooperation over competition.

Multiple groups even used similar phrasing when urging industry cooperation; some version of “Bake a bigger pie; don’t fight over the slices,” and “A rising tide lifts all boats,” appeared multiple times.

“Eliminate zero-sum mindset,” wrote one GRC group, and embrace the “mentality that geothermal is for the greater good.” When people do that, it should follow that “what you do in your day-to-day business needs to also promote geothermal.”

To that end, participants also said it was important to “share technical data” and “if you aren’t doing it, give it to another company (the jobs, leads, seismic data).”

3.3 What keywords and images should we use to discuss geothermal?

Every group at both conferences recorded answers to this question. For coding purposes, responses were broken into two separate categories: keywords and images.

There were over 100 responses that fit into the category of keywords; of these responses, approximately one-third were hashtags, and the rest were typically one or two words long. They most commonly focused on three areas:

Stability/reliability/energy security

The clear favorite was #alwayson. Some version of “always on” and “24/7” appeared on nearly every group’s sheet. This also received the largest number of sticker “votes” of any hashtag,

garnering 34 votes from participants at the GRC and eight votes at the WGC. The words “reliable,” “stable,” and “resiliency” also appeared over and over.

Sustainability

Here, #carbonfreeenergy, along with the words clean, green, and renewable appeared in multiple groups’ answers.

Identity

Simply using the hashtag #geothermal or #geothermalenergy (in one case, the “o” was stylized as the earth) also proved popular, showing up in most groups’ recorded answers. Similarly, “geowatt,” “geowhat,” “wearegeo” and “whatisgeothermal” were all suggestions that garnered multiple votes within several groups.

There were 20 “image” suggestions, both descriptive and illustrative. They were primarily – but not exclusively – recorded by groups at the GRC. The plurality focused on the daily, positive experience of end users – “people laughing,” “home showing heat/power/cooking,” “warm house/family dinner, etc.” One group paired a series of images with its own hashtag: “kitchen/light/fridge/family/people – #poweredbygeothermal” or “#energyfromgeothermal.”

The second largest tranche of images focused on the fact that geothermal is earth-friendly and unobtrusive – “beautiful land, nothing to see,” and “invisible” wrote one group. “No steam (except sometimes, maybe),” hedged other participants. Still another group drew earth with a tree, house, and person. “Healthy world,” they wrote.

3.4 What are the myths and misconceptions around geothermal that we need to dispel?

There were approximately 45 responses to this question, with answers clustered relatively tightly around two categories.

Danger and/or negative environmental impact

While the authors initially coded these responses separately, there was sufficient overlap between the two to merit a combined category. “Earthquakes,” “groundwater pollution” and/or “drain[ing] out underground water,” and “steam is often mistaken as pollution,” were the most commonly cited misconceptions, in that order.

Economic feasibility (or lack thereof)

Less commonly cited than myths about environmental impact, but still appearing several times, was the idea of cost. This concern was expressed only in groups attending the WGC, who used words such as “profitability,” “subsidies,” and “economic failure.” “Expensive against wind, gas, solar,” received seven votes from one group. “Expense (high capital cost),” stated another.

4. Conclusions and Recommendations

Data from communication workshops held at the 2023 World Geothermal Congress and Geothermal Rising Conference provide a clear indication that participants would like to see increased alignment among geothermal associations, including coordinating membership and

conferences, standardizing vocabulary across technologies and regions, and taking the lead in communicating the benefits of geothermal to the public and other stakeholders. They want geothermal companies and associations to focus on growing the industry rather than competing with one another. They believe that messaging should emphasize geothermal's reliable, stable, and sustainable nature, with a focus on showcasing the normal, everyday activities made possible by energy from the earth. And they wish to counter the idea that geothermal is somehow dangerous, damaging to the environment, or too expensive to pursue.

Based on these results, there are several opportunities for action, as well as further study. Five recommendations are presented:

- Improve partnerships and share resources;
- Promote a unified industry taxonomy and apples-to-apples comparison;
- Develop a messaging architecture for geothermal;
- Update the visual identity of geothermal to match the messaging architecture; and
- Develop a strategic plan to dispel myths and misconceptions.

4.1 Improve Partnerships and Share Resources

National and international geothermal associations could take this opportunity to reach out to one another when establishing conference schedules to ensure they don't overlap. They could then examine objective data, including attendance numbers, and measure attendee satisfaction by administering surveys after with specific, detailed questions about scheduling. Based on this data, they could consider co-hosting conferences and offering dual memberships.

Likewise, they could collaborate to expand the financial pie. IGA and GR, as the two most impactful and well-known associations, should seek to fundraise and partner in ways that will increase philanthropic funding opportunities. This could be achieved through a joint fundraising position that seeks out donations for the two organizations.

4.2 Promote a Unified Taxonomy and Apples-to-Apples Comparison

The same associations could also take the lead in establishing common definitions, vocabulary, keywords, and images to be used across communication channels. The suggestions provided by participants here could serve as the basis for an industry-wide survey to determine how to best promote geothermal energy in different regions and how these strategies can be replicated and scaled globally.

Additionally, developing a uniform dataset and clear comparison methodology could facilitate apples-to-apples comparison with other renewable energy sources.Transparent and fair methods of comparison could increase industry credibility and attractiveness for investors and partners.

4.3 Develop a Messaging Architecture for Geothermal

In the endeavor to expand the geothermal industry and attract the right investors and partners, it is necessary to redefine the communication strategy and/or create a communication strategy that cuts through the noise.

Instead of relying on traditional sales pitches from individual companies or organizations, associations representing the geothermal industry should consider a common pitch that focuses on solving the problems and meeting the needs of their audience. “Audience” in this context refers primarily to the general public, but could also include more targeted audiences, such as global investors. Creating a strong messaging architecture can guide the entire industry’s communication and allow for increased resonance with a variety of audiences. A potential strategy to achieve this goal is outlined below:

- Understand the audience’s problems: It is vital to first clarify the target audience and carefully research the challenges that the target audience faces. Identifying and addressing these problems allows geothermal to position itself as part of the solution and create a strong connection with the audience.
- Develop a messaging architecture: A common messaging architecture is crucial to deliver tailored messages that are relevant to each stage in the buyer’s journey. (A buyer’s journey describes a buyer’s path to purchase, including awareness, consideration, evaluation, and eventually adoption). Focusing on audience needs instead of company benefits can create resonance and increase industry influence.
- Deploy a common pitch for the industry: Agreeing on a common message around change drivers, choice of category, and choice of subcategory (see Figure 1) could increase geothermal’s visibility and impact in debate and in media. Collaborating with other renewables and including oil and gas in the discussion could also create a stronger position for the geothermal industry.
- Use of Megadeals methodology: Applying the Megadeals methodology and creating a buyer’s journey specific to the chosen audience could optimize communication and increase the geothermal industry’s chances of successful business opportunities. Communicating the right messages at the right time could help build trust and establish long-term relationships with potential investors and partners.

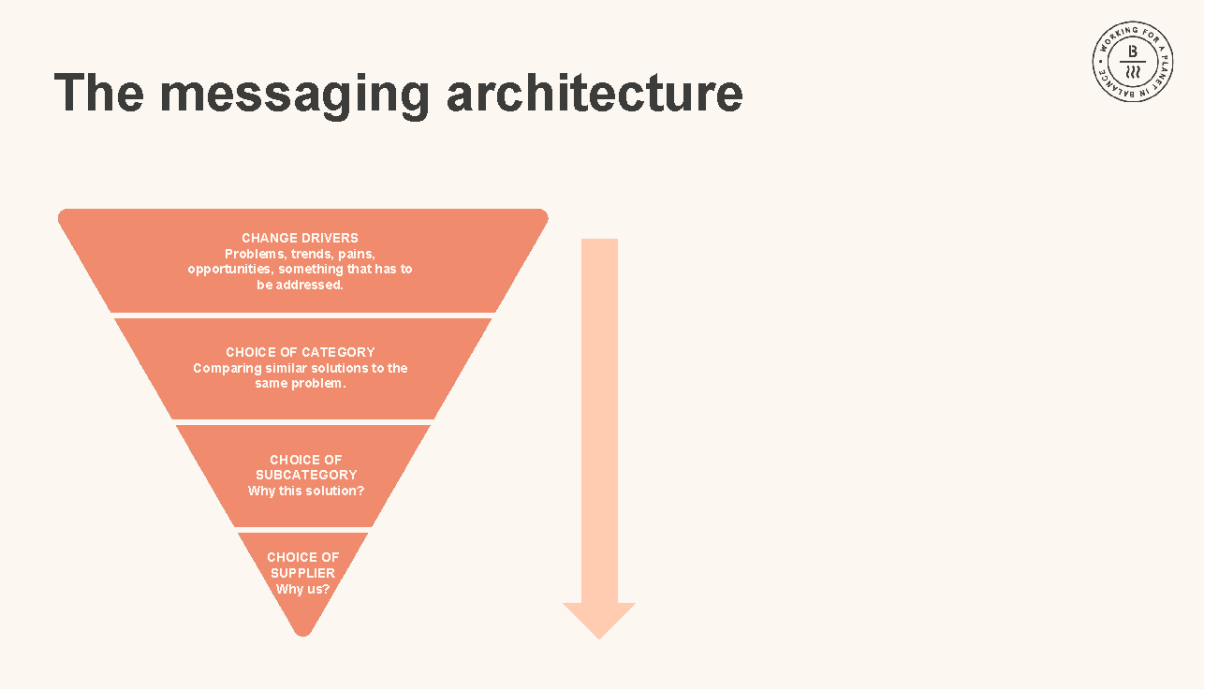

Figure 1: The reverse pyramid shape of messaging architecture demonstrates how focusing on the audience's needs when it comes to energy allows for more salient, persuasive communications on the path from awareness about the benefits of geothermal to eventual adoption.

4.4 Update the Visual Identity of Geothermal to Match the Messaging Architecture

The end user should be the focus of social media and geothermal narratives. Too often the images and marketing employed by geothermal companies, associations, and other organizations are internally focused. Images of cooling towers, piping, boiling mud pots, and geysers appeal to the geoscientists, drillers, reservoir managers, and geologists who make up the geothermal workforce. However, the main audience of images and narratives should be end users – the people who switch on the lights at night or cool down their house in the heat of summer. End users don't understand that the white puffs of smoke coming from a cooling tower are just water vapor. To the external audience, it represents pollution, greenhouse gas emissions, carbon, and climate change.

Other end users are the passionate and well-intentioned advocates of environmental and climate NGOs, policymakers and their staff who change laws, educators who teach the next generation of engineers and marketing professionals, and editors of textbook publishers, to name a few target audiences that the geothermal industry should keep in mind when developing brands, narratives, and marketing strategies.

A good example of a geothermal company taking into consideration the end user are the marketing campaigns of WaterFurnace, owned by the Swedish company NIBE Group and one of the largest manufacturers of geothermal heat pumps. WaterFurnace promotes the individual, the environment, and impacts of policy in its marketing and communications strategies with less focus on infrastructure, geology, and engineering.

4.5 Develop a Strategic Plan to Dispel Myths and Misconceptions

Geothermal associations should develop a high-level strategic communications plan that can be used by the entire geothermal ecosystem. A strategic communications plan could include:

- A geothermal industry public affairs manual;
- Media monitoring and rapid response;
- A daily geothermal clip report;
- A media relations and editorial board/op-ed/letter-to-the-editor strategy;
- A geothermal media-trained member speakers' bureau (expert geothermal talking heads) that can be made available for broadcast opportunities (BBC, DW, CNN, MSNBC, Fox News, VOA, etc.); and
- A crisis communications plan.

This paper's findings demonstrate that the time has come for geothermal associations, companies, and other stakeholders to coalesce around a common message to ensure a global understanding of the important role geothermal has to play in transitioning to a green energy economy and drawing down the effects of climate change.

By working together, using clear, consistent vocabulary and messaging architecture, the geothermal industry can position itself as the preferred solution for investment and partnership. Reshaping the communication strategy for the geothermal industry, focusing on understanding and solving the chosen audience's problems, and dispeling pervasive myths can increase visibility, attract investors and partners, and drive continued growth within the industry.

ACKNOWLEDGMENT

Gathering the research for this paper was truly a team effort and could not have been achieved without the dedication and enthusiasm of many partner organizations, companies, and individuals. The authors wish to acknowledge the members and staff of Baseload Capital, Geothermal Rising, the International Geothermal Association, the International Renewable Energy Administration, and ThinkGeoEnergy for recognizing the importance of this topic and working to convene discussions around the issue of communication within the geothermal industry. Thank you to companies like Baker Hughes, Ormat Technologies, and GeothermEx, which supported the idea from the start. The authors would also like to recognize all the participants who attended the communication webinars, panels, and workshops – your time, energy, and thoughtful insights are most appreciated. And a special thank you goes to Peter Tait, who inspired many conversations along the way.

A Social Science of the Subsurface: Advances in EGS Communication and Engagement Research

Catherine Lambert, Dominic Balog-Way, and Katherine McComas

Cornell University

Keywords

Enhanced geothermal, communication, public acceptance

ABSTRACT

While enhanced geothermal technology is a potentially powerful source of renewable heating and power, it also poses unique challenges for public acceptance. Understanding how the public assesses the risks, benefits, and tradeoffs of EGS projects is crucial for successful development; at the same time, the growth of EGS projects in multiple countries allows for critical comparisons of how public support develops across settings. We present novel findings from a series of studies in Switzerland, the United Kingdom, and the United States on EGS risk perception and public attitudes, with implications for best practices in communication and public engagement. First, a cross-national survey in Switzerland and the United States illuminates how people make sense of an unfamiliar technology like EGS, relying on associations with other technologies, beliefs about the underground, and perceptions of EGS technology as "tampering with nature." Second, a series of qualitative case studies of EGS projects in the UK and the US investigate the role of context-sensitive communication strategies from geothermal developers, in a comparison of projects in the UK and the US. This body of research includes ongoing work as part of the GEOHUB trans-Atlantic collaboration to examine the impact of public attitudes on energy development efforts and how they evolve in real time. A better understanding of critical factors that underlie beliefs and attitudes towards EGS informs evidence-based approaches to the challenge of public engagement, allowing development efforts to better align with societal values and priorities while underscoring the value of social science in global efforts to transition to renewable energy systems.

1. Introduction

The development of Enhanced Geothermal Systems (EGS), a form of deep geothermal energy that relies on creating engineered reservoirs within low permeability rock layers, could potentially expand the use of geothermal resources well beyond the traditional geographic reach of conventional hydrothermal systems. As such, EGS technology could play a critical role in

decarbonizing both heat and power and achieving low-carbon energy transitions. EGS has been described as one of the most benign and low impact options for renewable energy, particularly when comparing issues such as visual impact with wind and solar energy (Stephens & Jiusto, 2010). However, EGS is not without risks, including induced earthquakes, a major source of potential disruption to nearby communities, as well as impacts on water use and potential changes related to traffic, noise and the infrastructure of seismic exploration and drilling (e.g., Ellsworth, 2013; Porter, Striolo, Mahgerefteh, & Faure Walker, 2018; Trutnevyte & Ejderyan, 2018). While addressing the risks of EGS development requires significant technical considerations, successful development also requires the recognition that "a technology's license to operate depends on public acceptance" (Hoşgör, Apt, & Fischhoff, 2013, p.1032).

Public responses to EGS as an emerging renewable energy option have been relatively unstudied, despite calls for increased insight into the risks and social impacts of geoenergy (Giardini, 2009; Knoblauch & Trutnevyte, 2018; Pellizzone & Allansdottir, 2019). Existing research has demonstrated that key concerns often center on seismic risk (Cousse et al., 2021; Dowd et al., 2011; Knoblauch et al., 2019; Stauffacher et al., 2015). Knoblauch et al. (2019), for instance, found that potential earthquakes exerted the strongest influence on acceptance of both EGS and shale gas. Other concerns that have been identified include economic and technological uncertainty (Romanach et al., 2015), as well as procedural fairness (McComas et al., 2016; Song et al., 2021).

Though relatively little research has examined EGS directly, decades of research on risk perception and public acceptance have highlighted a wide range of critical factors, including trust, fairness, and perceptions of risks and benefits (e.g., Balog-way et al., 2020; Siegrist & Árvai, 2020; Wüstenhagen et al., 2007). Research on effective risk communication recognizes the need to move from a one-way communication model to a multi-directional engagement model emphasizing early involvement of stakeholders in the decision-making process (Fischhoff, 1995; Trench, 2008). An engagement-based model recognizes social, cultural and psychological factors shaping lay attitudes and behaviors, and emphasizes engagement through dialogue and deliberation. Through upstream engagement efforts, communicators may define a baseline of public concerns, and perceptions of risks early in the process (Kasperson & Ram, 2013). This allows communicators to stay ahead of problems, demonstrate competence, fairness and openness, and, critically, establish relationships with communities that are built on trust (Besley & McComas, 2014).

Understanding why people support or oppose deep geothermal development requires moving past the dismissal of local concerns as "NIMBYism" (Not In My Backyard) and addressing the underlying drivers of individuals' perceptions of geothermal technologies. Because EGS allows geothermal development outside of areas with conventional hydrothermal resources, it is likely unfamiliar to many in potential target areas. As a result, people are likely to rely on pre-existing associations with comparable industries and technologies to make sense of the new technology. Below, we identify several critical conceptual directions based on the unique characteristics of EGS as a subterranean renewable energy technology. As part of an emerging body of work, we present key findings and implications from two studies of attitudes towards geothermal energy development across three countries. In Study 1, a cross-national Swiss/US survey illuminates how respondents make sense of EGS through associations with the underground and perceptions of EGS as "tampering with nature." In Study 2, case studies of two current EGS projects in the UK and the US investigate the impact of place, culture, and local legacies of extractive industries on stakeholder responses to actual EGS projects in context.

2. Study 1

2.1 Motivation

Prior research has suggested that drivers of attitudes towards EGS may include associations with other subterranean technologies as well as the perceptions that the public has of the deep underground itself. Members of the public have been shown to associate EGS production with fracking and other extractive industries, leading to potentially negative impacts on acceptance (Cuppen et al., 2020, Westlake et al., 2023). The underground nature of geothermal resources, in comparison with more visible renewable energy sources aboveground, may increase this association (Gross, 2013).

Also relevant is the perception of "tampering with nature" (TWN) the belief that humans influence nature in a negative manner through behaviors or use of technologies (Hoogendoorn et al., 2021). Feelings of discomfort with tampering in natural systems can create resistance to technological developments and have been shown to be a strong predictor of public acceptance and risk perceptions for a variety of technologies and behaviors (Sjoberg, 2000; Fritz et al., 2004; Meisenberg, 2009; Corner et al., 2013; Stewart and Lewis, 2017).

The extent to which EGS is perceived as TWN is unclear and may be closely related to whether the underground is viewed as part of nature or not. While underground spaces may be linked with a range of cultural, religious, and spiritual meanings like burial and the underworld (Kearnes & Rickards, 2017), other depictions are of an artificial, inorganic space accessed only through technological interventions (Williams, 1990). Subterranean spaces may be viewed as mysterious and inscrutable (Kinchy et al., 2018; Stewart & Lewis, 2017), or may elicit primordial fears of what lurks in the depths (Giardini, 2009; Gross, 2013) – beliefs which may figure in individuals' assessments of EGS development and whether it constitutes "tampering." Given the associations of EGS with induced seismicity and fracking, it seems plausible that similar associations may apply to EGS.

Drawing on these concepts, Study 1 explores the following research questions:

RQ1: How do individuals perceive the deep underground with respect to EGS development?

RQ2: To what extent do individuals consider EGS to be TWN?

RQ3: To what extent do beliefs about TWN and perceptions of the underground relate to support for EGS development?

2.2 Methods

Survey data collection was conducted in Switzerland and the US in November 2021, with a total sample of 2,031 responses. The sample was nationally representative of age, gender, and education in both countries and by race in the US, and was recruited by two market research agencies, Qualtrics (US) and Intervista AG (Switzerland), using online panels and quota sampling. The questionnaire was translated for Swiss respondents from English into German and French.

2.2.1 Perceptions of the deep underground

We first asked respondents to estimate their familiarity with geothermal energy. Participants then read a one-age vignette about EGS in order to ensure similar baseline knowledge. To address RQ1, we measured perceptions of the underground (i) in general, (ii) with respect to human activities, and (iii) regarding its safety, controllability, and utility for storing. First, we used a free association exercise (Leiserowitz, 2006; Peters & Slovic, 1996; Slovic et al., 1991), in which participants were asked to type the first thought, association, or image that came to their mind when they thought of "the deep underground." They then ranked each association as positive or negative.

Second, a series of semantic differential scales were used to assess what properties respondents associated with the deep underground. These items were developed from prior theoretical and qualitative work on the underground (Gross, 2013; Kearnes & Rickards, 2017; Kinchy et al., 2018; Partridge et al., 2019; Williams, 1990) and consisted of the word pairs shown in Table 1.

Third, respondents indicated agreement with statements about human activity in the deep underground. Two sets of statements were designed to capture 1. whether respondents believed the deep underground was a place for human use and 2. whether respondents believed that the deep underground should be left alone. These items were combined into the scales labelled "Underground as a resource for human use" (α =.87)[1] and "Underground should be left alone" (α = .81). Table 2 lists the items that comprise each scale used in the regression model.

2.2.2 Tampering with nature

To assess perceptions of EGS as TWN (RQ2), we measured whether respondents perceived EGS as (i) unnatural, (ii) disturbing the order of nature, and (iii) contrary to nature. As a comparison, we included the same measures for technologies that previous research has shown are seen as TWN: chemical pesticides and genetically modified organisms (GMOs) (Hoogendoorn et al., 2021; Raimi et al., 2021). Lastly, we measured whether respondents perceive human-induced seismicity as TWN. For each technology, we averaged the three items to form scales labeled "EGS-as-tampering-with-nature" (α = .87), "pesticides-as-tampering-with-nature" (α = .85), GMOs-as-tampering-with-nature"(α=.87), and "induced-seismicity- as-tampering-with-nature" (α = .83).

2.2.3 Support for EGS and related factors

Respondents were asked their general feeling about the implementation of an EGS project in the proximity of where they live on a 7-point scale from "very negative" to "very positive." In addition, we measured factors that previous research has shown as important predictors of technology support: perceived risks and benefits, trust in risk managers, attitudes towards climate change and renewables, and demographics.

2.3 Findings

Results indicate low levels of familiarity with geothermal energy; overall, about 40% of the sample indicated they knew almost nothing or nothing at all about geothermal, and another 40% said they knew just a little about it, with no significant differences between the US and Swiss (CH)

[1] Removing the item "the deep underground is a place to store things" increased the reliability (Cronbach's α) of the "Underground as a resource for human use" scale from .81 to .87, so we removed that item from the final scale.

respondents. We note, however, that responses to the "support for EGS" item indicate generally positive feelings towards EGS (M=4.85, SD=1.75), with no significant differences between the US and Swiss samples.

2.3.1 Perceptions of the deep underground

When rating their free associations, 42% of respondents rated their associations as positive, 28% neutral, and 30% negative. US respondents were more likely than Swiss respondents to rate their associations with the deep underground as positive (M_{US}=4.44, SD_{US}=1.70 versus M_{CH}=4.02, SD_{CH}=1.74, p<.001). In the semantic differential scale regarding perceived characteristics of the underground (Table 1), respondents were more likely to consider the underground as part of nature, mysterious, tangible, clean, bright, controllable, static, predictable, safe, and familiar than the opposing quality (e.g., invisible, dirty, etc.). Swiss respondents tended to perceive the underground as more a part of nature and cleaner than their US counterparts. In comparison, US respondents perceived the underground as more controllable, tangible, and brighter than their Swiss counterparts.

Table 1

Perceptions of the underground – semantic differential items

	M (SD)		t (df=2,029)
	United States	Switzerland	
Separate from nature – Part of nature	3.79 (1.28)	4.09 (1.1)	-5.62*
Comprehensible – Mysterious	3.53 (1.26)	3.34 (1.16)	3.52
Dirty – Clean	3.20 (1.28)	3.40 (1.12)	-3.61
Unstable – Stable	2.92 (1.31)	3.00 (1.19)	-1.43
Uncontrollable – Controllable	2.94 (1.31)	2.61 (1.15)	5.92*
Dangerous – Safe	2.74 (1.34)	2.58 (1.1)	2.97
Unpredictable – Predictable	2.74 (1.35)	2.54 (1.16)	3.65
Unfamiliar – Familiar	2.72 (1.35)	2.52 (1.16)	3.61
Dynamic – Static	2.81 (1.21)	2.61 (1.13)	3.87
Grim – Bright	3.06 (1.26)	2.75 (1.08)	6.05*
Invisible – Tangible	3.34 (1.26)	2.77 (1.17)	10.51*

Note: We used a 5-point scale, anchored at each end by the different items. All of the differences were significant at p<.005, with the exception of dynamic vs. static. We used Cohen's d to examine effect size: * = small effect size (.20 - .45).

Table 2

Perceptions of human use of the underground: Scale items, means, standard deviations, and reliabilities

	M (SD)		t (df=2,029)
	United States	Switzerland	
Underground: Leave alone (α = .81)			
Whatever is below us belongs to the Earth and should be left untouched	3.93 (1.85)	3.7 (1.81)	2.83
Humans should not interfere with Earth's fundamental processes (n.s.)	4.35 (1.78)	4.28 (1.73)	.90
Because processes like EGS are hidden from sight, we won't know about problems until it's too late	4.60 (1.67)	4.33 (1.61)	3.74
The deep underground is a sacred place	4.06 (1.82)	3.25 (1.84)	9.96*
Drilling wells is an invasive way to take something from the Earth (n.s.)	4.38 (1.75)	4.22 (1.66)	2.11
We have no control over what happens in the deep underground (n.s.)	4.64 (1.77)	4.69 (1.65)	-.68
Scale	4.38 (1.36)	4.25 (1.25)	2.36
Underground: Human use (α = .87)			
Exploring the underground is a pathway for new knowledge and discovery (n.s.)	5.27 (1.48)	5.19 (1.47)	1.09
The deep underground below us exists as a resource for humans to use	4.82 (1.63)	4.56 (1.65)	3.52
Using resources from the deep underground can be done safely	4.76 (1.59)	4.14 (1.57)	8.79*
The deep underground is a new frontier for humans to explore	5.05 (1.65)	4.77 (1.63)	1.09
Scale	4.97 (1.38)	4.67 (1.31)	5.15*
The deep underground is a place to store things.ǂ	3.49 (1.83)	3.1 (1.83)	4.83*

Note: Scales ranged from 1=strongly disagree to 7=strongly agree. All items except those marked with n.s. are significantly different between countries at p<.005. We used Cohen's d to examine effect size: * = small effect size. ǂ "The deep underground is a place to store things" did not load on either factor, reduced the Underground: Human Use scale reliability from .87 to .81, and was excluded from further analysis.

2.3.2 Human use of the deep underground

Respondents tended overall to view the underground as a resource for humans to use, with general similarity between the US and Swiss respondents, with two exceptions (Table 2). US respondents were significantly more likely to perceive the underground as "a sacred place," a "place to store things," and that "using resources from the deep underground can be done safely." Comparing the "underground as a resource for human use" and "underground should be left alone" scales between countries, US respondents were significantly more likely to give higher ratings to the items in the "underground for human use" scale at a meaningful level.

2.3.3 EGS as tampering with nature

RQ2 examined whether respondents viewed EGS as TWN. Respondents generally rated the individual tampering-with-nature dimensions slightly above the mean, while US respondents tended to consider EGS as more "contrary to nature" (M_{US}=4.14, SD_{US}=1.85, M_{CH}=3.77, SD_{CH}=1.76), "unnatural" (M_{US}=3.98, SD_{US}=1.91, M_{CH}=3.77, SD_{CH}=1.76), and "disturbing the order of nature" (M_{US}=4.26, SD_{US}=1.88, M_{CH}=4.04, SD_{CH}=1.77) than their Swiss counterparts. Although the differences were significant, only "contrary to nature" had a small but meaningful effect size (d=.21). In comparison with items on pesticides, GMOs, and human-induced seismicity (Figure 1), respondents were more likely to perceive pesticides and GMOs as TWN than EGS and induced seismicity. Induced seismicity was also viewed as TWN more than EGS. While the differences between countries in views about TWN were significant at p<.005, only perceptions of pesticides were meaningfully different (d=-.34).

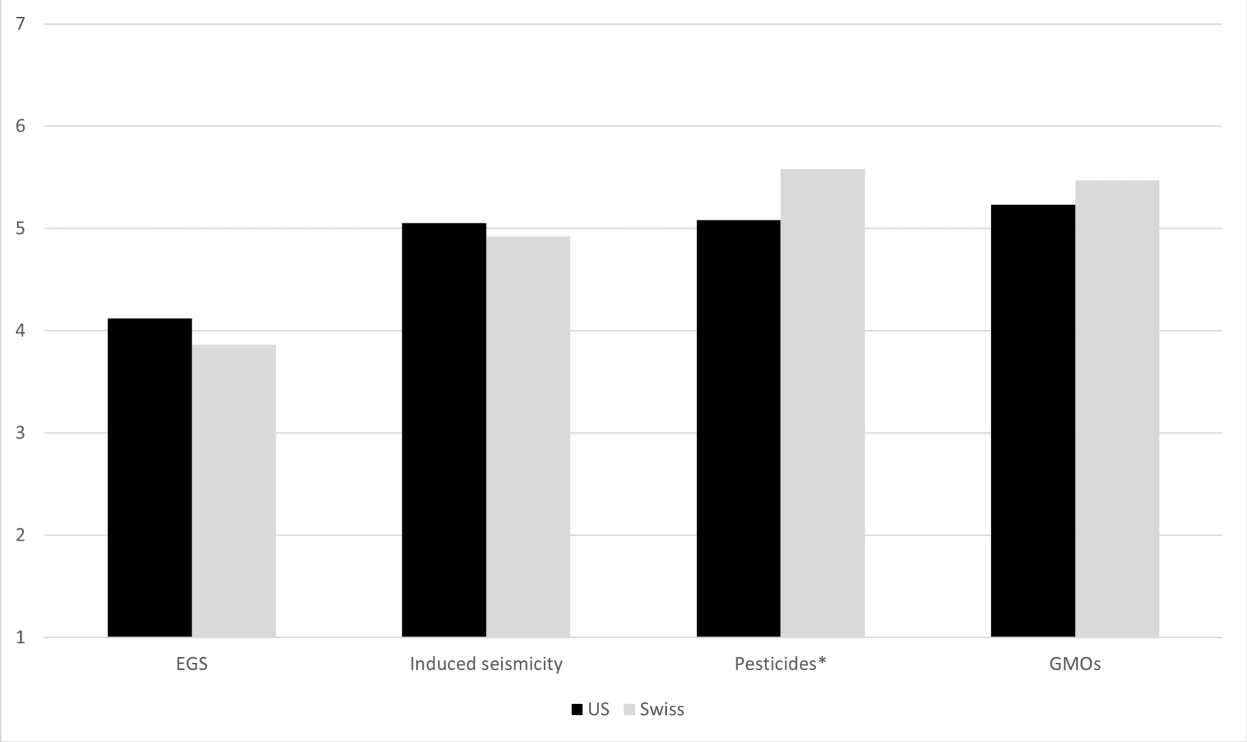

Figure 1. Bar chart showing the mean of perceptions of different technologies as "tampering with nature." While there were significant differences between countries for each technology, an examination of effect size using Cohen's d suggests only the variable *pesticides* was meaningful (-.34).

2.3.4 Factors relating to EGS support

A linear regression was used to measure the influence of different sets of variables on respondents' support for a hypothetical EGS project. We entered four different blocks in order to examine the R square change, i.e., the incremental change of the new addition. Tables 3 and 4 present the final block results for each country.

Table 3

Regression analysis for "What is your general feeling about the implementation of an EGS project in the proximity of where you live?" for US sample (N=989)

						95% Confidence Interval for B	
Variables	B	SE	Beta	t	p-value	Lower Bound	Upper Bound
(Constant)	-.707	.371		-1.905	.057	-1.435	.021
Education (low to high)	-.078	.072	-.026	-1.078	.281	-.219	.064
Gender (female=1)	.029	.081	.008	.357	.721	-.131	.189
Political leaning (Left à Right)	.086	.026	.088	3.320	.001	.035	.138
Age	-.009	.002	-.094	-3.858	.001	-.014	-.005
Location of residence (urban à rural)	.020	.039	.012	.524	.601	-.056	.097
Adjusted R Square .011	ANOVA F(5, 949)=3.019), p=.010						
Underground: Human Use	.301	.041	.243	7.291	.001	.220	.382
Underground: Leave Alone	-.049	.039	-.039	-1.264	.207	-.125	.027
Cum. Adjusted R Square .364	ANOVA F(7, 942)=78.602, p<.001						
Risk-benefit perceptions	.676	.062	.356	10.822	.001	.553	.798
Trust in government regulators	.001	.037	.001	.033	.974	-.071	.074
Trust in private industry	.087	.035	.090	2.452	.014	.017	.156
Climate change concern	.082	.032	.076	2.552	.011	.019	.145
Support for moving to renewables	.205	.033	.185	6.264	.001	.141	.270
Cum. Adjusted R Square .514	ANOVA F(12, 937)= 84.760, p<.001						
EGS as tampering with nature	-.023	.031	-.022	-.758	.449	-.084	.037
Induced seismicity as tampering with nature	.052	.031	.044	1.683	.093	-.009	.112
Cum. Adjusted R Square .515	ANOVA F(14, 935)=72.962, p<.001						

Note: Listwise deletion of missing values.

In both countries, whether respondents perceived the deep underground as a place for humans to use was positively associated with EGS support. However, belief that the underground should be left alone did not significantly influence EGS support in the US or Switzerland at the p<.005.

The third block added risk-benefit perceptions, trust in government and private industry, climate change concerns, and support for moving to renewable energy. Risk-benefit perceptions were significantly related to EGS support, as was support for transitioning to renewable energy. Trust in private industry was significantly related to EGS support for those in Switzerland, but not for the US. Lastly, the fourth block examined the relationship between TWN and EGS support. For Swiss respondents, perceiving EGS as TWN was significantly related to decreased support for EGS projects, which was not the case for US respondents.

Table 4

Regression analysis for "What is your general feeling about the implementation of an EGS project in the proximity of where you live?" for Swiss sample (N=1,027)

						95% Confidence Interval for B

2.4 Study 1 Discussion

Addressing RQ1, respondents tended to perceive the deep underground as a "part of nature." While respondents, on average, have a neutral to positive affective response to the deep underground in relation to the use of EGS, Swiss responses were generally less positive than in the US. This could be linked to two prior EGS projects in Switzerland that caused felt earthquakes in the past and attracted attention nationwide (Stauffacher et al., 2015). Another potential explanation may lie in the US's greater familiarity with industries involving underground extraction.

Respondents tend to perceive the underground as a resource for humans to use, though results are mixed regarding support for specific activities, with low support for the use of the underground to store things, for instance. US respondents are more likely than Swiss respondents to agree that the underground is a space for exploration and a resource for humans, but notably are also significantly more likely to view the underground as sacred, showing that one does not exclude the other.

With respect to RQ2, respondents viewed EGS as somewhat disturbing the order of nature, but perceptions of EGS as TWN were relatively neutral, especially when compared with GMOs and pesticides. Induced seismicity was more likely to be viewed as TWN than EGS itself, despite being a consequence of the technology. Respondents' perceived benefits of EGS may compensate for the perceived negative impacts of induced seismicity. Alternatively, the difference between EGS and induced seismicity perceptions may also be a further consequence of the complexity of "nature" as a construct. TWN can be seen as negative either because nature is vulnerable and needs to be protected, or because nature is threatening and "tampering" with it may lead to unintended consequences. Induced seismicity may suggest a sense of nature "biting back" after being disturbed.

RQ3 investigated how beliefs about EGS as TWN compared with other antecedents in explaining support for EGS development. Beliefs about TWN were associated with EGS support in Switzerland but not the United States. The Swiss results align with past research on resistance to technological developments driven by discomfort with TWN (Corner et al., 2013; Wolske et al., 2019), and support findings from the risk perception literature for technologies such as geoengineering (Siegrist & Árvai, 2020). In addition, that beliefs about human use of the underground greatly matters in explaining support for EGS suggests that pre-existing beliefs about the underground and with subterranean endeavors may be an important contextual factor in responses to deep geothermal development.

In general, support for EGS development was high in both countries, in contrast with numerous case studies which have highlighted oppositional issues with deep geothermal projects (Chavot et al., 2018; Ejderyan et al., 2019). Within our sample, EGS was generally viewed as a positive, renewable form of energy technology, though there are some differences between the US and Swiss samples. Specifically, Swiss respondents who perceived EGS as TWN were much less supportive of the technology, whereas this was not the case for US respondents. Overall, however, there were more similarities than differences between the two countries in the patterns of factors relating to EGS support.

3. Study 2

Study 2 aimed to investigate how public attitudes towards EGS are influenced by contextual elements like sense of place, local histories, and legacies of extractive industries, as well as how geothermal developers adapt to context in their outreach and communication efforts. In comparison to Study 1, which examined attitudes towards EGS technology with reference to a hypothetical project in the respondents' area, Study 2 presents data on community attitudes towards two EGS projects currently in development in the UK and the US, using qualitative case study methods.

3.1 Motivation

Study 2 further examines the role of perceptions of the underground and associations with geothermal energy through the lens of place theory, a conceptual area drawn from human geography and social psychology. The importance of place in shaping responses to energy has received increasing attention in energy acceptance research, particularly as an alternative to the reliance on NIMBY language (Boudet, 2019). A place-based perspective on energy acknowledges that how people interpret new technologies reflects their relationships with place, involving both the physical landscape and the identities, relationships, events, experiences, and history embedded there. Attachment to place can help to reinforce the social construction and amplification of risk, providing a spatial explanation for differences in responses to risky technologies (Masuda & Garvin, 2006). Energy developments that introduce land-use changes and new risks may instigate abrupt disruptions to place attachment, leading to loss of identity and sense of stability (Brown & Perkins, 1992). Disruption itself as well as the perceived risk of future disruption can drive oppositional attitudes towards the cause of the changes (Jacquet & Stedman, 2014).

Place meanings – of place as area of natural beauty or as a community, for example – serve as foundations for the bonds that people feel, and when important symbolic meanings are threatened, people are more likely to take protective action (Stedman, 2002). Perceived contradictions between the interpretations of place and technology lead to opposition, while a perception of "fit" between the place and technology results in support (Devine-Wright & Howes, 2010; McLachlan, 2009). Actors involved in development may attempt to influence perceptions of a project and its impacts by deliberately framing it in ways that emphasize the project's consistency with local place meanings and identities (Jacquet & Stedman, 2014).

Meanings of, and attachment to, place develop over time through the accumulation of experiences, memory, and interaction. Prior research has shown that past experiences with energy industries both contribute strongly to sense of place, and also provide an interpretive lens that shapes perceptions of new energy technologies (Bugden et al., 2017). In the Marcellus Shale, for instance, responses to unconventional oil and gas development were strongly influenced by past experiences with extractive industries (e.g., Brasier et al., 2011; Bugden et al., 2017; Jacquet et al., 2018; Stedman et al., 2012). Regional history with coal mining provided a way for residents to express concerns about the possibility of a similar legacy of environmental problems (Brasier et al., 2011). Given the shared characteristics of EGS development with other subterranean technologies, it seems plausible that community responses to EGS may draw heavily on place identities related to legacies of extractive industries like oil and gas or mining.

In addition, the role of perceptions of the underground and whether the underground is considered a valued part of nature, as explored above, also raises the question of how the underground figures in residents' senses of place. Proponents of geothermal often highlight its underground nature by referring to invisible but limitless "heat beneath our feet" from a featureless and empty territory waiting to be exploited – in essence, positioning the underground as a space rather than a place. As Tuan (1977) describes, "What begins as undifferentiated space becomes place as we get to know it better and endow it with value" (p. 6). Given the findings of Study 1, which suggest that the meanings and interpretations attributed to the underground are varied and potentially strongly value-laden, it seems reasonable to ask whether the underground is considered part of, or separate from, what people consider their "place."

Drawing on these concepts, Study 2 addresses the following research questions:

RQ4: How are residents' evaluations of EGS projects influenced by perceptions of place and the underground?
RQ5: To what extent is "the underground" part of place?
RQ6: How do geothermal developers navigate these dimensions when communicating about EGS?

3.2 Methods

To capture the contextual variables of interest, Study 1 uses a comparative case study approach to understand how contemporary EGS projects have unfolded in real-life contexts, using the comparison of international cases to analyze differences in underlying social and cultural factors. The Cornell Earth Source Heat (ESH) Project in Ithaca, New York is located in the Finger Lakes region of New York and aims to provide district heating to Cornell University's Ithaca campus. A test borehole was drilled in 2022 and feasibility studies are underway. The United Downs Deep Geothermal Project (UDDGP) in Redruth, Cornwall, UK, is being developed by Geothermal Engineering Limited (GEL), aiming to provide 10MW of electricity and 55MW of local heating. Drilling of a well pair was completed in summer 2019 and testing was deemed successful in summer 2022. Each case represents a project in the early stages of development, located within or in close proximity to a host community in a rural region, while allowing comparison between cultural contexts.

Data collection used qualitative methods to evoke attitudes towards EGS and elicit people's embedded experiences with place and energy (Sovacool et al., 2018; Tuck, 2014).These methods consisted of interviews with key actors (local officials, project managers, researchers, and community stakeholders), thematic analysis of publicly available documents (public relations materials, social media content, policy and planning documents, and news coverage), and site and participant observations; community focus groups were also used in the ESH case. Data collection efforts are summarized in Tables 5 and 6.

3.3 Findings

3.3.1 Cornell Earth Source Heat

Public discourse surrounding the Earth Source Heat project (ESH) drew on place in four distinct themes, relating to different scales of place. The project was closely linked to the university's identity as a research institution and land-grant university; rhetoric throughout news coverage,

public relations materials, and planning documents connected the project to an idealized vision of the campus as a "living laboratory," a place for innovation, curiosity, and exploration. Regional and national place identities were also consistently used to frame the project and its projected benefits – for instance, with frequent references to using geothermal heat to defeat the Northeast's cold winters, or embracing EGS as a means to maintain the United States' identity as a technological leader.

A local vision of place was evident primarily in local news coverage, where a sense of identity as a place of sustainability and progressive values was used to promote adoption of EGS: "If New York State is going to [decarbonize], Tompkins County should really be in a leadership position to show how it's done." However, discussion of the project also drew on past experiences, sense of local character, and concerns about impacts to place. This was evident in the interviews and focus groups, where residents' attitudes towards ESH were mixed. For those more positive towards the project, there was a clearly expressed sense of fit with their sense of Ithaca and Cornell as places of innovation and sustainability leadership. As one participant stated, "if it's going to be done anywhere, it should be here."

In contrast, oppositional attitudes emerged from a perceived lack of fit with the area. Participants' views of Ithaca as a place of urgent, pragmatic sustainability leadership were rooted in their experiences with the anti-fracking movement in New York State. As such, some were opposed to an emerging technology that uses fracking and drilling techniques. The uncertain nature of a developing technology was also a major contributing factor; there was considerable concern that ESH did not support local goals for urgent climate action due to the uncertainty of success based on one new technology with high financial costs and technical uncertainty: "all your eggs are in one basket."

An unease with ESH based on similarities with fracking was underscored by perceptions of the underground. Some focus group participants felt protective of the underground as part of Mother Earth: "the image that came out to mind was that Earth is a living organism and we're drilling into it, and the Earth is screaming in pain." Others expressed feelings of unease or dread associated with the general depth of the drilling required, making references to disaster films or joking about the possibility of awakening sleeping threats.

Efforts by university communicators recognized and adapted to these concerns in several ways. In outreach efforts including town hall meetings, visitor hours at the drill site, and online materials, messages were deliberately focused on distinguishing EGS from fracking. This included both technical descriptions and an emphasis on the motives of ESH as a demonstration project generating new knowledge. The framing of the project's test borehole as a "data mine" that only produces information was frequently repeated. As one speaker stated, "We're not producing oil and gas here. We're producing information. The stimulation here is intellectual. There is no [hydraulic] stimulation. There's no fracking." While this approach addresses concerns about similarities with fracking, it overlooks the related concern from residents about the uncertainty of testing a new technology, creating additional dissonance for audience members.

Another prominent communication strategy successfully addressed the challenge of visualizing and contextualizing the project given its invisibility from the surface. To aid visitors in understanding the spaces and depths involved, materials drew comparisons to local settings and landmarks to put the depth of the borehole into perspective. When explaining the different rock

layers that the borehole is passing through, for instance, videos referenced surface contexts like the rock layers visible in the many gorges surrounding the ESH site.

3.3.2 United Downs Deep Geothermal

In Cornwall, discourse surrounding UDDGP drew closely on local and regional place identities rooted in Cornwall's long history of hard rock mining. Rhetoric promoting the project emphasized the revival of the mining industry in the form of geothermal development. At the national level, the project was incorporated into a broader narrative of a "green industrial revolution" in the UK, while regional and local narratives of EGS emphasized the historical identities of Cornwall and the Redruth area as homes of science and invention. News and promotional materials directly connected UDDGP to themes of Cornish leadership, identity, and heritage, with repeated mentions of "a 4,000-year history of mineral extraction and innovation." Cornwall's long history with mining and underground extraction also positions the underground as both a resource for prosperity and as a source of knowledge and discovery.

Residents' responses to UDDGP strongly reflected this sense of fit with place identity, with many participants expressing strong support due to viewing it as an updated form of mining. As one participant stated, "They say, 'Where there's a mine or a hole in the ground, you'll find a Cornishman.'…that's part of our cultural identity. It was born out of the mining industry, and we know the ground very well…So geothermal was built on that, it's mining for heat." However, some negative responses to EGS development in the area included concerns about disruption to the rural character of the area, with potential noise and traffic from drilling viewed as a threat to the historic landscape. For some, this stemmed from concerns about the fragility of the underground given the extensive mining works; one commenter noted "the potential damage both to subterranean and above-ground features" from drilling and induced earthquakes.

Communications from the developer relied on a strong emphasis on geothermal as "heat mining," representing the project as an embodiment of Cornwall's mining heritage, expertise in underground matters, and identity as a home of technology and scientific development. In displays at the visitors center and in social media posts, for instance, the achievements of UDDGP were compared to the work of Cornish historical figures and inventors. This theme was supported with social media and online messaging emphasizing regional themes and imagery like the Cornish flag and the iconic mining landscape surrounding the drill site.

Similarly to ESH, UDDGP materials also use visuals of the local geology and mining infrastructure to contextualize the project; in one video, a staff member is filmed within a mine shaft where water is visibly flowing through fractures in the rock, demonstrating the characteristics of the EGS target reservoir. Another staff member was filmed in front of the surface expression of a fault in the area, explaining what the target fault zone for UDDGP looks like. These tactics both emphasize the localized nature of the resource and provide a concrete model for audiences to understand remote and unfamiliar geological frameworks.

3.4 Study 2 Discussion

In both cases, residents consider the fit of EGS with their conceptions of place, drawing on prior experiences with energy and extractive industries. In ESH, residents evaluated EGS as one option among many for the future of energy in their community, with some finding the ESH project to be

incompatible with the local focus on urgent climate action, due to EGS's emergent nature and perceived similarity with fracking. In Cornwall, UDDGP is evaluated through the lens of local place character and an identification with subterranean expertise and technological innovation, with a strong perception of fit with the mining identity of Cornwall. Perceptions of the underground contributed to residents' perceptions of fit between place and technology, informing whether human use of the underground was viewed as extractive and exploitative, or a source of prosperity and pride in cultural heritage.

Addressing RQ6, communication efforts from Cornell and from GEL drew heavily on place-based rhetoric. In the ESH case, communicators emphasize the campus-level identity of innovation and the pursuit of knowledge to distance the project from comparisons to fracking, while UDDGP emphasizes the alignment between the project and the local, regional, and national visions of EGS. In both cases, geothermal developers made persuasive appeals that are based on local relationships with extractive industries: as "data mining" or as "heat mining."

This research demonstrates the role of place in shaping responses to energy infrastructure and new energy technologies. Perceptions of "fit" between EGS technology and place depend on the nuances of place characteristics; persuasive efforts from each project developer deliberately confront these contextual dimensions, linking the projects to different place-based energy visions and addressing local legacies of extractive technologies. However, the success of these tactics may depend on understanding the importance of competing visions of place in driving opposition, including whether the underground is considered a valued and threatened part of place.

4. Conclusion

In an engagement-based model for geothermal communication efforts, it is critical to understand what the underlying drivers of concern are for public stakeholders, rather than relying on assumptions or assuming a simple lack of knowledge. In this set of studies, we highlight several key findings that inform sources of concern towards EGS.

The results of both studies indicate that people may often view the underground as part of nature, and as such, part of the environment deserving consideration. In some cases such as Cornwall, people may view the underground as part of their "place," attributing value and meaning to subsurface spaces. While the low surface impact of geothermal installations is often emphasized as a benefit, it does not necessarily follow that it is "out of sight, out of mind." Communicators should assess and understand meaningful place characteristics in a community and address potential disruptions beyond simply the visual.

Issues may arise through both concern about the underground itself as a valued part of nature, and concern about the underground as a source of threat not to be interfered with. We recommend that communicators take steps such as focus groups, deliberative workshops, or other participatory engagement methods to understand the prior experiences that a community has with underground extraction and related technologies, such as histories with fracking or mining. Alongside the impact on perceptions of the underground, different contexts with respect to extractive histories may be an important factor in determining the impact of perceived TWN on EGS support, as Study 1 showed.

Study 1 also highlights the fact that people view the deep underground, in and of itself, as more dangerous and unfamiliar than EGS. As such, risk communication about EGS projects could seek to familiarize individuals with current activities in the deep underground before trying to address fears around the use of EGS (e.g., induced seismicity). Contextualizing underground structures and settings using more familiar surface comparisons may also be an effective approach. In addition, although the results found that the US and Swiss public were largely in favor of the underground as a resource for humans to use, respondents also expressed concerns about exploitation (e.g., drilling, storage), as did US and UK participants in Study 2, suggesting that risk communication messages should convey what geothermal managers are doing to mitigate risks and subsurface impacts.

This body of work is part of the GEOHUB trans-Atlantic collaboration between Cornell University, King's College London, University of Edinburgh, and University of Stirling, a research and policy network focusing on deep geothermal energy risk communication. Future work will continue to expand on a "social science of the subsurface," seeking to augment the currently limited literature on the social acceptance of deep geothermal energy projects as well as other subsurface technologies.

Embracing a Circular Model in the Management of Cooling Tower Fill Packs. A Case Study of a Pilot Project Rolled out in Partnership Between Kengen and 'Jua Kali' Entrepreneurs

Rose Mathenge

Keywords

Cooling tower fill packs, circular economy, sustainability, Jua Kali

Entrepreneurs

ABSTRACT

Cooling tower fill packs are an integral part of geothermal power plants cooling tower system systems. The purpose of the cooling tower fill packs is to increase the surface area to allow for maximum contact between air and water to hasten the cooling process. All the power plants and wellheads in the Olkaria geothermal field utilize fill packs which form one of the major wastes generated. During annual inspections of power plants, enormous amounts of cooling tower fill and pack waste are generated. Disposal of the fill packs waste has been a challenge because the waste is mainly hardened plastic and, therefore, could not be disposed of in dump sites. Similarly, efforts to dispose of through incineration proved costly and unsustainable given the accelerated development envisaged in Olkaria. The cost stood at two hundred thousand USD as of the year 2016. Given the above background, since the commissioning of the Olkaria II power plant in 2003, no disposal of the said waste had been undertaken up to the year 2019. Before conducting this study, a large volume of cooling tower waste had been stored at one of the well pads posing a fire risk and halting well monitoring activities for over ten years. To address the problem of disposal of the fill packs, a joint study was conducted between KenGen and" Jua Kali" entrepreneurs. From this study, a potential market for the waste was established. The process entailed shredding the waste at the site to facilitate transport given the bulk nature of the waste, heating and mixing the waste with other additives to produce various products from the waste. The processing was undertaken at the Jua Kali entrepreneurs' sheds in Nairobi.

Establishing a market for the cooling tower fill pack waste is a major milestone as it has created a circular model in managing the waste through reuse to produce products. This is a win-win situation for all: the environment, KenGen, and the entrepreneurs. The breakthrough has reduced the environmental footprint, spurred a secondary market for SMEs, and reduced the disposal cost.

During the pilot study over twenty tonnes of waste were recycled for manufacturing products. The pilot study has saved KenGen about USD Five Hundred Thousand (500,000) and is expected to derive a saving of USD Seventy-Two Thousand (72,000) annually.

1. Introduction

Globally, corporate leadership teams face unprecedented difficulties, including unsustainable natural resource consumption rates. Embracing circularity in value chains in place of a linear model presents an opportunity to create an additional natural resource to address high global natural resource consumption rates.

Circularity means a decoupling of economic growth from resource consumption. It entails reusing, repairing, refurbishing, and recycling existing materials and products. According to Maj et al. (2022), for organization, circularity entails conserving materials, extending a product's lifetime through repair and reuse, and ultimately recycling. According to Zhang et al. (2010), the circularity model's overarching goal is to mimic the natural mechanism of the "producer-consumer-decomposer" system to obtain closed material circulation, multilevel utilization, and the minimum output of waste. Industrial symbiosis can present one of the pathways to achieving the circular economy (CE) and achieving green growth. Industrial symbiosis is a particular kind of synergy, that "engages traditionally separate industries in a collective approach to competitive advantage involving physical exchange of materials, energy, water, and/or by-products" (Chertow, 2000). It proposes to create a system for trading material, energy, and water by-products among companies, usually within a park, neighborhood, or region" (Lowe, 2001). Governments play a key role in rolling out a circular economy model by setting technical guidelines, creating appropriate market conditions, policy, and Institutional and regulatory frameworks. To steer the country towards a circular model, the Government of Kenya has enacted the Sustainable Waste Management Act, of 2022. The Act presents a major milestone, and the expected inherent regulations will offer clarity along this journey. The Act mandates the National Environment Management Authority to develop a database of different waste streams generated by various industries as a focal point for creating industrial symbiosis. Further, the Act obligates producers to bear extended producer obligations to reduce pollution and environmental impacts of their products and waste arising thereof.

To address unsustainable natural resources utilization, circularity represents a strategic issue, which presents an opportunity to cut costs, boost growth, and build resilience. The merit of circularity in any organization is clear. However, the trajectory to a circular business model requires setting up a robust system including building the right cross-functional team to implement a circular strategy and establish measurable goals and target levels of recycled content, reuse, and recycling. In addition to supportive legislation, regulatory framework, and industry standards to help change behavior and strengthen circular economies, establishing partnerships with suppliers and key stakeholders.

Normally, embracing circularity in a process offers several benefits including addressing environmental challenges by reducing material consumption, increasing efficiency, and cutting greenhouse gas emissions, and can set up a strong commercial foundation that is scalable. In addition, it addresses SDGs no 9, 12, and 17 on Industrial, innovation &infrastructure, Sustainable consumption& production, and partnership for the goals which are key pillars in achieving sustainable development.

The current pilot project sought to address five objectives, which were to explore possibilities of recycling cooling tower fill packs, establish a partnership to roll out the pilot research study, demonstrate potential economic and environmental benefits for undertaking the pilot study, document successes experienced along the way and distill lessons learned in the process.

The pilot research study seeks to embrace circularity models in managing cooling tower fill packs instead of linear models to convert cooling tower fill waste into raw materials. The waste forms a major waste from geothermal power plants. It seeks to convert the waste into raw material for other industrial processes. The pilot study seeks to expand the list of materials being recycled in Kenya as the country embarks on the journey to embrace the circular economy model. Currently, there are initiatives underway on recycling and circularity, but it's still not enough to provide the amount of recycled material that the industry will need. In addition, stringent laws are in place to minimize environmental pollution associated with plastics, which the company is required to comply with. For instance, the Sustainable Waste Management Act of 2022 requires NEMA to develop a database on input and type of industrial waste generated countywide as a step towards creating industrial synergies and minimizing environmental risks. Further, KenGen is in the process of setting up a green energy park in Olkaria as a special economic zone, which seeks to create industrial symbiosis for enhancing efficiency in material utilization. The study, therefore, is a step towards embracing industrial synergies to minimize environmental risk and increase resource utilization efficiency. In addition, the study is aligned with international priorities such as the Sustainable Development Goals and climate change mitigation.

To address the four objectives a joint pilot project between KenGen and" Jua kali" entrepreneurs was conducted in the years 2020, and through to February 2024. From this study, a potential market for waste was established. The process entailed shredding the waste at the site to facilitate, heating, and mixing the waste with other additives to allow to produce various products from the waste. The processing was undertaken at the Jua Kali entrepreneurs' sheds.

2. Initial Research and Product Development Process

The research to develop a circularity model in managing cooling tower fills commenced in 2012 and registered a breakthrough in 2020. The research commenced by engaging cooling tower fill manufacturers in discussions on available options for managing the waste. The discussions did not yield any results as manufacturers seemed unaware or rather sent a silent message implying the organization just needs to use the product and then figure out how best to deal with the waste along the way. This was followed by holding discussions with recyclers to explore options for recycling the waste. The first step was marked by holding discussions with water tank manufacturers in the Export Processing Zone Authority zone in Kitengela area in Kenya. This was followed by discussions with Finlays LTD on the possibility of manufacturing recyclable fencing posts from the waste, which proved unsuccessful. This was mainly because the waste exhibits the characteristics of hardened plastic, which charges on being subjected to heat instead of melting. This was followed by visiting the Naivasha Sub County Environmental Office for advice on possible disposal mechanisms. This too was unsuccessful as the county handles mainly the Municipal solid waste category. From the discussion, it was clear that KenGen was therefore obliged to develop a disposal mechanism for any industrial waste related to geothermal development. This was followed by seeking incineration firms to dispose of the waste. However, this though a feasible option turned out to be unsustainable given that KenGen was accelerating

geothermal development in Olkaria. The lowest bidder put a figure of Two Hundred Thousand dollars to dispose of the waste that had been accumulated up to the year 2015. This was followed by a successful step of engaging Jua Kali entrepreneurs to partner in creating reuse of the waste in manufacturing construction industry products. Upon reaching out to the entrepreneurs, it took about two months to make a breakthrough in researching different chemical processing to facilitate the recycling of waste.

2.1 Cooling tower waste generating information

The Olkaria Geothermal field is home to five conventional power plants and seven wellheads. The cooling tower fill packs are estimated at One Thousand Six Hundred tonnes and fourteen tonnes from the conventional power plants and the wellheads, respectively. The replacement frequency of the cooling tower fills is guided by the condition of the fill packs and normally takes about two to four years, with manufacturers recommending three years. In 2023, a new initiative was put in place whereby the removal of cooling tower fill packs is being done per cell while the power plant is operational. This implies that there will be continuous production of waste.

2.2 Initial research and product development process

The research to develop a circularity model in managing cooling tower fills commenced in 2012 and registered a breakthrough in 2020. The research commenced by engaging cooling tower fill manufacturers in discussions on available options for managing the waste. The discussions did not yield any results as manufacturers seemed unaware or rather sent a silent message implying the organization just needs to use the product and then figure out how best to deal with the waste along the way. This was followed by holding discussions with recyclers to explore options for recycling the waste. The first step was marked by holding discussions with water tank manufacturers in the EPZA zone in Kitengela. This was followed by discussions with Finlays LTD on the possibility of manufacturing recyclable fencing posts from the waste, which proved unsuccessful. This was mainly because the waste exhibits the characteristics of hardened plastic, which charges on being subjected to heat instead of melting. This was followed by visiting the Naivasha Sub County Environmental Office for advice on possible disposal mechanisms. This too was unsuccessful as the county handles mainly the Municipal solid waste category. From the discussion, it was clear that KenGen was therefore obliged to develop a disposal mechanism for any industrial waste related to geothermal development. This was followed by seeking incineration firms to dispose of the waste. However, this though a feasible option turned out to be unsustainable given that KenGen was accelerating geothermal development in Olkaria. The lowest bidder put a figure of Two Hundred Million dollars to dispose of the waste that had been accumulated up to the year 2015. This was followed by a successful step of engaging Jua Kali entrepreneurs to partner in creating reuse of the waste in manufacturing construction industry products. Upon reaching out to the entrepreneurs, it took about two months to make a breakthrough in researching different chemical processing to facilitate the recycling of waste.

2.3 Product processing processes

Upon removal of the cooling tower fills from the power plants, the waste is ordinarily stored in an open area within the Olkaria field. The entrepreneurs shred the waste and put it in gunny bags for ease of transportation to Jua Kali industries. At the industries, the shredded raw material undergoes filtration to remove dust. Secondly, the raw material is put in a fine crusher to crush the material

further. Thirdly, the fine material is put in a drier where additives are added to facilitate chemical processing. This is followed by adding heating and compression. This is followed by a tooling process, whereby the product is shaped to the desired shape. The final processes entail cutting the terrazzo strip to the desired size and stacking them into bundles for storage.

2.4 Research approach and methodology

The methodology applied entailed deploying a joint pilot research undertaken by KenGen and "Jua Kali" entrepreneurs. It entailed visiting "Jua Kali" sheds for test running the possibility of recycling the materials and undertaking market surveys. Upon establishing the feasibility of recycling the packs. The approach entailed crushing the waste, chemical processing, heating, compression, and tooling process to facilitate the desired shape of the product.

2.5 Challenges experienced

Just like any new process, diverse challenges were encountered during the joint pilot research study. This included determining the right crushing machine. At first, some of the partners commenced with air-cooling crushing machines, which proved ineffective as they experienced overheating. The team finally settled for water-cooled riser engines to give motion to the machine. Secondly, determining the right licensing requirements for entrepreneurs to facilitate partnerships was a major challenge. This was a critical component to ensure control of the waste from the source to the final site. The team finally settled for licensing from the Association of Recyclers and National Environment Management Authority. Thirdly, the dust accumulated in the cooling tower fills over the years is quite significant, approximately half a tonne for every four tonnes of crushed waste. This meant that the entrepreneurs had to engage more staff to remove soil particles to ensure acceptable quality of raw materials to the recyclers. Fourth, frequent breakdown of crushing machines, which necessitated transportation of the machine to Naivasha town for repair as the site is in a remote area. Fifth, during transportation, the traffic police would impound the waste as they were unfamiliar with the waste. Lastly, the rigidity of clearance at the KWS gate requires that the vehicles transporting waste be cleared in advance, this meant that the entrepreneurs were unable to utilize return trips for general transport vehicles and had to have a dedicated vehicle to transport the waste. This meant a reduced profit margin on their side and increased CO_2 footprint for the transportation of the waste.

2.6 Successes

The pilot study presented varying economic, environmental, and social benefits by turning an environmental problem into business solutions. The project registered numerous successes, Firstly, by creating a circular model for managing waste, created an opportunity to put the materials back into the supply chain, rather than disposing of them as waste. This meant the creation of new a secondary resource for the Small Medium Enterprises (SMEs). Secondly, it has created an employment opportunity for non-skilled and semi-skilled workers in the Jua Kali Industries and at the crushing site. Thirdly, it has created an income for the entrepreneurs, thus improving their livelihood. Fourth, it presented a quality product to the construction industry. In addition, the partnership offers SMEs an opportunity to grow in line with the government's commitment to spurring the growth of SMEs through the Bottom-up Economic Transformation agenda (BETA). Fifth, KenGen has realized cost savings in the form of foregone waste disposal and avoided GHG

emissions to the tune of 2.125 tonnes Co_2e annually. Further, commencing March 2024 the waste will be sold competitively in the market implying a further income to KenGen.

2.7 Lessons learnt

The cooling tower fill pack generation far outstrips the SME market. This is compounded by the slow economic downturn being experienced currently. This saw some of the SMESs closing shops in the year 2023. To address the issue, carrying out market surveys and conducting joint research efforts is critical to create more markets for the waste. Secondly, to reduce operation costs efforts should be geared toward creating linkages with manufacturers to explore options for procuring reusable cooling tower fills. Thirdly, KenGen needs to procure a crushing machine to crush the waste at the generation point. This would reduce the storage area required, transportation costs, and littering experienced during the transportation phase. Lastly, there is a need to identify three storage areas to minimize transportation costs.

3. Discussion

A joint KenGen and Jua Kali entrepreneurs' joint research journey has been presented in this paper. According to this study's results, the research journey was a success marked by leveraging various partners' strengths and a shared vision and goal of a healthier environment, creating a product from waste. The pilot research aligns with KenGen's vision of embracing a circular economic model in the management of the resources at the upcoming Olkaria Green Energy Park. In addition to aligning with the global SDGs particularly SDG no 9, 12, and 17 on Industrial, innovation &infrastructure, Sustainable consumption& production, and partnership for the goals which are key pillars in achieving sustainable development.

The study results demonstrate that the partnership model is a critical aspect in managing various sustainability aspects in geothermal development. Indeed, partnerships can open doors to different business models for organization and stakeholders. Thirdly, to scale up circularity in geothermal development in a strategic manner, there is a need to scan the whole value chain identify opportunities and prioritize as a route to sustainably managing geothermal development. In addition, this can assist in identifying different industrial sectors that have the potential to set up at the green energy park. This can play a critical role in ensuring a wide variety of resource input and output flows available for inter-industry exchanges. Similarly, having companies of varied sizes (including SMEs) can facilitate the development of symbiosis, by offering opportunities for adding value to different volume streams from geothermal processes.

4. Conclusion

The purpose of the paper was to showcase successful joint research between KenGen and Jua Kali entrepreneurs, which created a market for cooling tower fills by converting waste into a product. In addition to offering a platform for piloting a symbiotic link between KenGen and relevant Jua Kali entrepreneurs. The pilot study has demonstrated environmental and economic benefits to the company, community, and entrepreneurs. The research is a story of resilience and applying innovation in managing waste sustainably. Secondly, it is a step in the operationalization of industry symbiosis envisaged in the upcoming Olkaria Green Energy Park. Third, the research

demonstrates the need to embrace partnerships to derive value for various processes in geothermal development. Fourth, the research is a major win for the environment as it allows the waste back to the value chain instead of disposing of the waste. Finally, to optimize circularity in the processes, it is critical to map the potential for circular flows in the company's existing value chain, select the options that create the most value, and start scaling a circular business.

5. Recommendations

Based on the research findings and the evolving regulatory framework requiring the country to embrace a circular model in managing waste, KenGen needs to set up a multi-disciplinary team to identify possible waste that can move to the circular economy, serve structures, and roll out the circular economy for the company different categories of waste.

ABSTRACT

Diesel generators and oil-fired boilers are the main energy systems for many remote communities in Canada and worldwide. This unsustainable energy framework has been creating a cycle of energy insecurity and poverty that communities have a desire to break. Geothermal energy resources, due to their base-load nature, versatility, and the fact that they are produced locally, could be one of the options for improving the energy sovereignty of remote communities. To find out whether geothermal energy is an option for remote communities, the first step is to carry out a resource assessment. The objective of this study was to evaluate the geothermal resource potential of Baker Lake, Nunavut, a typical remote community located in the northern Canadian Shield region where heat flow is usually low (<50 mW m^{-2}). The results of this study indicate, however, that Baker Lake has a greater heat flow, ranging from 68 to 78 mW m^{-2}. This suggests that geothermal resources could be exploited for space heating applications, and our analysis indicates that a depth of 4 km is required to have a high probability (>90%) of meeting the community's ~77 GWh annual heat demand. A depth of 8 km is required to have a high probability of generating electricity. Cogeneration potential also suggests that waste heat from electricity production can significantly support heating needs. Although these results are promising, exploiting geothermal resources in remote areas is particularly risky due to the scarcity of geothermal data. A way to de-risk geothermal projects at an early stage is to identify the sources of uncertain information that have the greatest impact on resource evaluation. The Monte Carlo-based sensitivity analysis carried out as part of this work revealed that, given the existing information, the recovery factor and reservoir volume are the main sources of uncertainty. Future research should focus on reducing the uncertainty of these sources to fully assess the potential for geothermal energy use at Baker Lake.

1. Introduction

Off-grid communities, characterized by their lack of connection to national electricity grids or natural gas networks (Royer, 2011), are prevalent in remote regions such as northern Canada. These communities face major energy challenges due to their isolation and reliance on diesel for space heating and power generation (Pinto and Gates, 2022).

Baker Lake, located in the hinterland of Nunavut (Figure 1.1), is a pertinent case study of the difficult energy situation faced by these northern communities. Reliance on diesel presents environmental risks, including greenhouse gas emissions and the risk of fuel spills, which can have detrimental effects on the Arctic ecosystem (Byrne, 2018). Aware of the need to find sustainable energy solutions, various levels of government, energy companies and research institutions have launched efforts to explore alternative energy sources (QEC, 2018).

Geothermal energy has gained attention as a promising option, offering several benefits for off-grid communities (Minnick et al., 2018). Unlike fossil fuels, geothermal energy offers a renewable, local, and environmentally friendly alternative with minimal carbon emissions. Additionally, geothermal power plants operate continuously, providing a stable and predictable source of electricity and heating regardless of weather conditions.

Enhanced geothermal systems (EGS) offer the potential to develop geothermal energy for electricity and/or heat use in locations without conventional hydrothermal (i.e., convective) resources (Sircar et al., 2022). An EGS is a technology for harnessing geothermal energy from subsurface reservoirs that require artificial stimulation methods such as hydraulic fracturing to enhance the permeability of the reservoir host rocks (Sircar et. al, 2022). For example, the Rittershofen EGS Project (Baujard et al., 2016) in the French Upper Rhine Graben has provided heat for industrial proposes with an installed capacity of 24 MW_{th} to the Beinheim Starch plant since 2005. The system has a depth of 2500 m and utilizes fractured sandstone and carboniferous granite where the 3-well bottom-hole temperature is 177°C. The Soultz-sous-Forêts EGS power project, operational since 2009, can generate 2 MW of electricity via a binary cycle power plant from heat produced from crystalline basement rocks at 5000 m depth (Koelbel and Genter, 2017). Challenges associated with this technology include efficiently stimulating reservoirs without causing significant microseismic activity, managing injected fluids, and developing accurate simulations for reservoir characterization and description (Sircar et al., 2022).

The Government of Nunavut and Nunavut's power utility company, Qulliq Energy Corporation (QEC), are committed to exploring the potential of EGS to provide a sustainable energy alternative for remote communities such as Baker Lake, Nunavut (QEC, 2018). In this framework, Minnick et al. (2018) conducted a preliminary study to assess the regional geothermal potential of Nunavut. The study determined there was insufficient data to accurately assess Nunavut's geothermal potential and recommended more data be collected, including drilling boreholes in a few targeted communities, including Baker Lake.

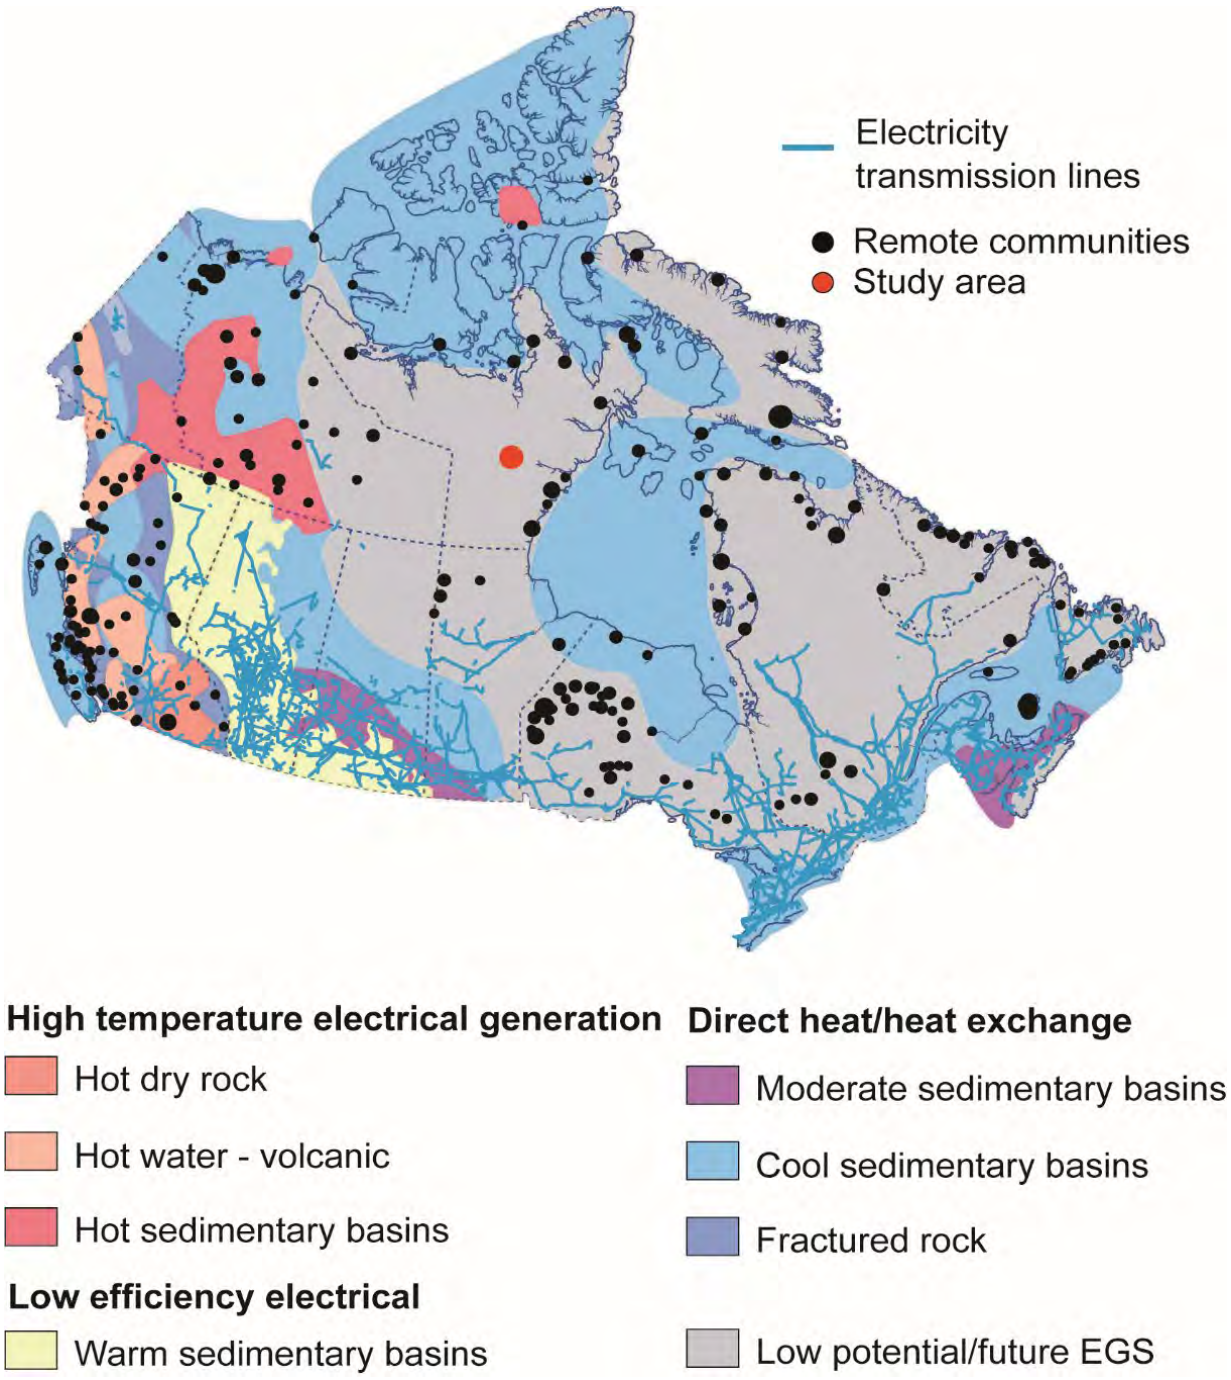

Figure 1.1: Geothermal potential of Canada estimated by Grasby et al. (2012) with location of remote communities taken from Arriga et al. (2017) and modified by Miranda (2021). The red dot represents the municipality of Baker Lake, which is the geographic center of Canada.

In support of this recommendation, a 500 m-deep borehole was cored in Baker Lake in late 2022 and instrumented with a thermistor logging cable. Gold et al. (2023) previously used this data to evaluate various technologies to mitigate the melting of permafrost considering the development of a borehole thermal energy storage system. Using available rock and temperature data, this study builds on the work of Minnick et al. (2018) with the objective of evaluating the deep geothermal

potential of Baker Lake. An EGS would most likely be required to develop geothermal energy in the region given the relatively low geothermal gradient and low permeability of the crystalline bedrock found at depth. As such, our study employed a data-driven Monte Carlo-based approach to assess the feasibility of generating electricity and producing heat at depths from 1 to 10 km. The EGS Resource Assessment Protocol, or Beardsmore Protocol (Beardsmore et al., 2010), was adapted to the arctic context of the region in this study to estimate the thermal energy available to the end user. Additionally, this study aims to rigorously assess the uncertainties associated with the input parameters. By taking these uncertainties into account, this study aims to provide a more robust understanding of Nunavut's theoretical deep geothermal potential.

2. Geological Setting

The community of Baker Lake lies on the Precambrian basement (Figure 2.1) of the Western Churchill Province in the Canadian Shield. Although in close proximity to the Baker Lake Basin (Figure 2.2), the lithology beneath the community of Baker Lake is Archean meta-granite gneiss, and some intercalation of rhyolite and granite rock types. The overburden is thin (0.2 to 2.0 m thick) and mostly composed of gravel to silty sand.

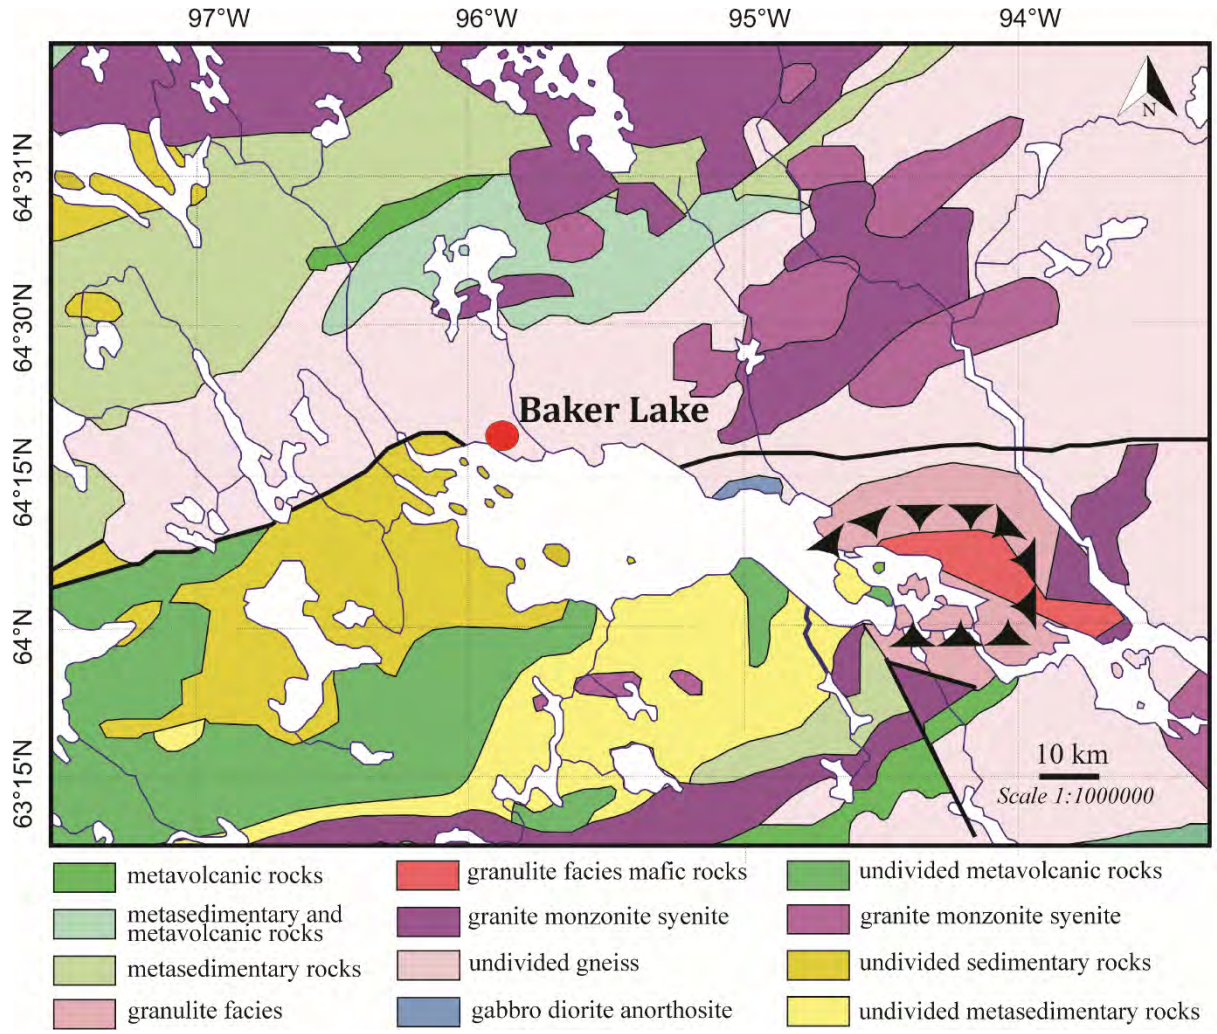

Figure 2.1: Extract of the regional geological map of Nunavut, focusing on the surface geology surrounding Baker Lake. (adapted from Kemp et al., 2006).

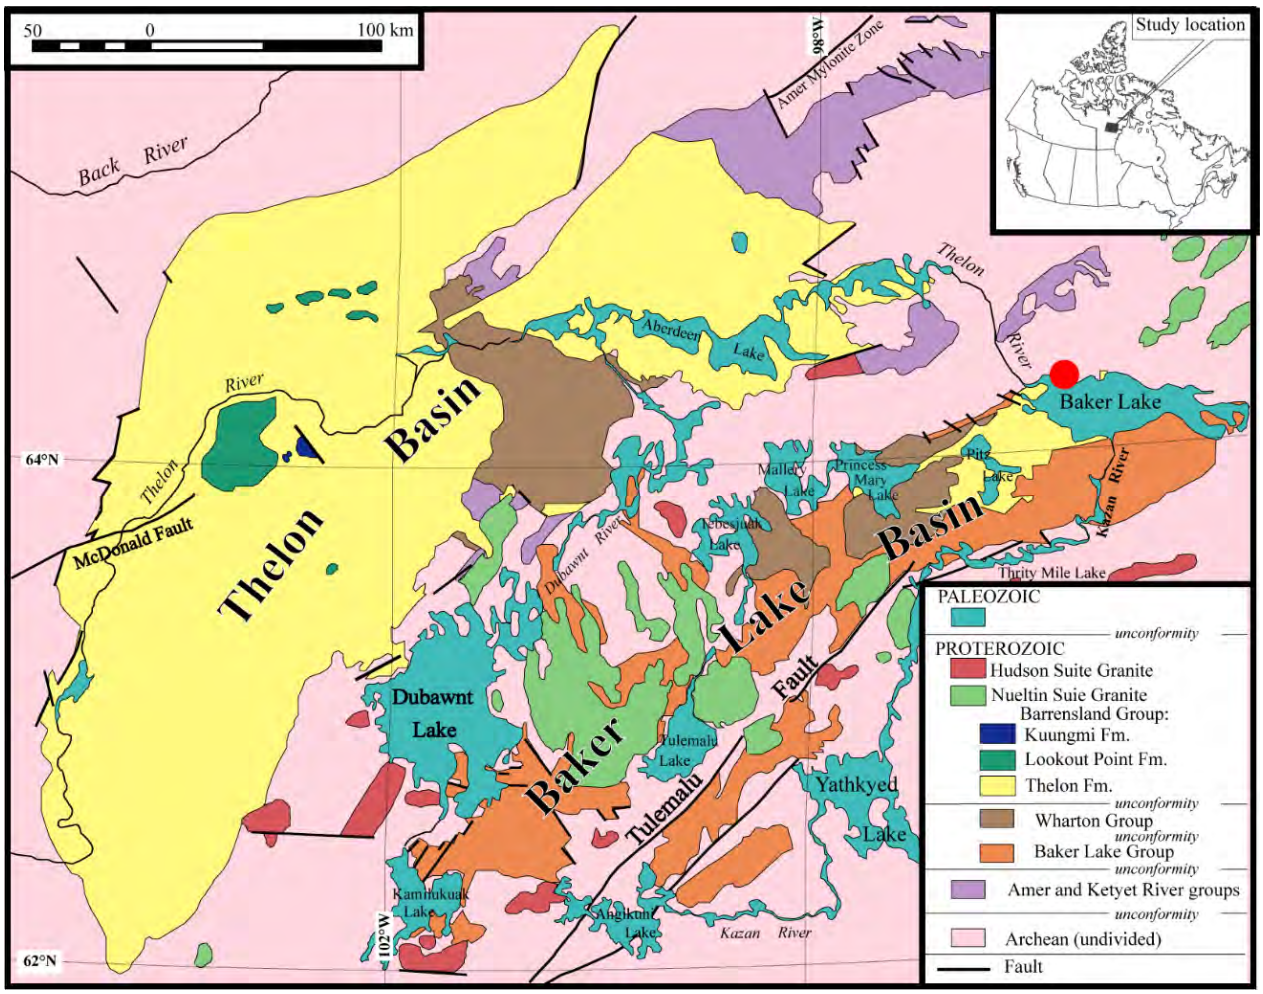

Figure 2.2: Geological map of the Thelon and Baker Lake basins (modified from Rainbird et al., 2003). Baker Lake community is represented by the red dot. The lithostratigraphy of the Baker Lake is composed of the Dubawnt Supergroup. This supergroup comprises the Baker Lake, Wharton, and Barrensland formations (Rainbird et al., 2003; Hadlari et al., 2006). Among these stratigraphic units, the Wharton Group is characterized by the presence of sub-arkosic sandstones, volcaniclastic sandstones, volcaniclastic conglomerates, and rhyolite flows, thus illustrating an advanced phase of basin development. The Barrensland Group is represented by quartzose sandstones of the Thelon Formation. Finally, the Baker Lake Group consists primarily of various sedimentary and volcanic rocks. Concerning the specific lithology of the Baker Lake Basin, it is primarily characterized by the presence of siliciclastic and volcanic rocks. The Hudson granitoids (1850-1810 Ma) are voluminous late to post-orogenic monzonites to granites, while the Nueltin granite (around 1750 Ma) is a rapakivi granite accompanied by porphyritic rhyolite, formed after the Hudson granitoids (Peterson, 1999). The Amer Group is correlated with the Ketyet River Group, which consists of thin metaconglomerate overlain by orthoquartzite and gray pelitic schist (McEwan, 2012). The Archean basement is primarily composed of undivided gneiss, representing the oldest rocks of the continental crust.

3. Materials and Methods

The Beardsmore protocol et al. (2010) is a systematic method for assessing the deep geothermal energy potential of a region to a depth of 10 kilometers and the feasibility of producing heat and or electricity via an EGS.

The protocol begins by modeling the vertical temperature distribution based on thermal properties (conductivity and heat generation), surface heat flow, and average surface temperature as starting points. Next, the protocol evaluates the theoretical and technical potential for energy production at various depths. The theoretical potential assumes that all available heat can be converted into energy. The technical potential considers practical constraints such as terrain accessibility and drilling depth limitations and is thus less than the theoretical potential.

In this article, we used the Beardsmore protocol to assess the deep geothermal potential of Baker Lake and the feasibility of developing a deep EGS for heat and/or power generation. We incorporated paleoclimatic events in the model we used to determine the vertical temperature distribution and heat flow to generate realistic results. This approach is detailed in this section, along with an explanation of our resource assessment method.

As the input parameters are uncertain, the resource assessment relied on the Monte Carlo method. The software @Risk was used for this purpose. The goal is to assess the probability of meeting the community's demand, assessed at 14 GWh for electricity and 77 GWh for space heating. Sensitivity analyses based on the Monte Carlo method were conducted to identify key geological and technical uncertainties.

3.1 Temperature Survey

A digital temperature cable with thermistors was installed in the borehole after drilling was completed. The sensors operate within a range of -55°C to +125°C, with an accuracy of ±0.1°C from -10°C to 30°C, and a resolution of ±0.063°C. Temperature recordings began on December 14, 2022, and ended on April 23, 2023. The last temperature profile recorded was used for the vertical temperature profile model to ensure that the temperature was in equilibrium and not affected by the drilling operations.

3.2 Thermal Properties and Radiogenic Heat Production

Twenty-six core samples were collected throughout the drilling process. The thermal properties of these samples, such as thermal conductivity, diffusivity, and heat capacity, were measured using a thermal conductivity scanner (TCS; Popov et al., 2016). The radiogenic heat production (A) was calculated based on Rybach’s (1998) empirical function, using concentrations of uranium (U), thorium (Th), and potassium (K) obtained through ICP-MS/OES analyses.

Given the lack of more detailed geological information at greater depths, we assume that the reservoir is a heterogeneous rock medium with properties equivalent to those observed in this 500-meter core sample characteristic of basement rocks. Although individual samples exhibit varying properties, these differences contribute to the overall variability of the reservoir's properties. Monte Carlo simulations were employed to incorporate this variability into our calculations.

3.4 Heat Flow Estimation

The heat flow in Baker Lake was estimated through an optimization simulation utilizing the subsurface temperature distribution. To account for the Arctic condition of the study area, a method that incorporates paleoclimate influence has been adopted. The shallow subsurface had been affected by paleoclimate events, which was reflected in the logged temperature profiles in boreholes. Consequently, this data could not be directly used to calculate the heat flow. To address this challenge, we developed a heat conduction analytical model that integrates the thermal properties of the roc and uses historical surface temperature steps. The simulated temperature profile was matched with the measured temperature profile by adjusting the basal heat flux under a given surface temperature scenario based on the understanding of the region's climatic history.

The general mathematical formulation of the 1D inverse heat conduction problem (ICHP) to estimate heat flow is:

$$\frac{\partial}{\partial z}\left(\lambda\frac{\partial T}{\partial z}\right)+A=\rho c\frac{\partial T}{\partial t} \quad \text{in} \quad 0<z<z_{\mathrm{n}}\ 0<t\leq t_{\mathrm{n}} \tag{1}$$

$$-\lambda\frac{\partial T}{\partial z}=Q=\text{unknow} \quad \text{at} \quad z=z_{\mathrm{n}} \quad t=t_{\mathrm{n}} \tag{2}$$

$$T=T(t) \quad \text{at} \quad z=0\ 0<t\leq t_{\mathrm{n}} \tag{3}$$

$$T=T(z)=T_0\ \frac{Q_0}{\lambda}z\ -\ \frac{A}{2\lambda}z^2 \quad \text{for} \quad t=0 \quad 0\leq z\leq z_{\mathrm{n}} \tag{4}$$

where T (°C) is temperature, Q (W m^{-2}) is the heat flow, ρc (J m^{-3} K^{-1}) is the volumetric heat, z (m) is the spatial variable and t (s) is time. The thermal conductivity λ (W m^{-1} K^{-1}) and the radiogenic heat production A (W m^{-3}) were assumed uniform and constant with the time.

The analytical solution of the 1D ICHP stated above is:

$$T\,(\,z\,)=\ T_0\ +\ \frac{Q_0}{\lambda}z\ -\ \frac{A}{2\lambda}z^2+T_t(z) \tag{5}$$

where $T_t\,(z)$ represents the variation of the surface temperature in time by considering a literature-based paleoclimate history (Table 3.1), and is defined as (Birch, 1948):

$$T_t(z)=\sum_i(T_v)\times(\mathrm{erf}\left(\frac{z}{\sqrt{4\alpha t_{i_1}}}\right)-\mathrm{erf}\left(\frac{z}{\sqrt{4\alpha t_{i_1}}}\right)) \tag{6}$$

where T_{v} (°C) is the average temperature variation between the climatic event and today, *erf* is the error function, α (m^2 s^{-1}) is the thermal diffusivity of the rocks, and t_{i1} and t_{i2} (s) are the end and beginning of the climatic event.

T_0 represents the initial temperature condition, which was assumed to be equal to the ground surface temperature T_{g} (°C) (Ouzzane et al., 2015):

$$T_{\mathrm{g}}=17.898+0.951T_{\mathrm{amb}} \tag{7}$$

where T_{amb} (K) refers to the surface air temperature. Using the surface air temperature from the 1981-2010 climate normal period (-11 ºC; ECCC, 2022), the reference ground surface temperature was calculated to be -6 ºC.

Table 3.1: Literature-based paleoclimate history and uncertainty (Miranda et al., 2020 and references therein).

Epoch	Climate event	Time step (years B.P.)	Temperature scenario		
			Cold	Average	Warm
Late Pleistocene	Nebraskan (glacial period)	300,000 – 265,000	-10	-5	-1
	Aftonian (interglacial)	265,000 – 200,000		0	
	Kansan (glacial period)	200,000 – 175,000	-10	-5	-1
	Yarmouth (interglacial)	175,000 – 125,000		0	
	Illinoian (glacial period)	125,000 – 100,000	-10	-5	-1
	Sangamonian (interglacial)	100,000 – 75,000		0	
	Wisconsinan (glacial period)	75,000 – 11,600	-10	-5	-1
Holocene	Holocene (interglacial)	11,600 – 7,000		0	
	Holocene Thermal Maximum	7,000 – 5,800	+1	+1.5	+2
	Holocene (interglacial)	5,800 – 3,200		0	
	Roman & Medieval warm periods	3,200 – 1,000	+1	+1.25	+1.5
	Holocene (interglacial)	1,000 – 500		0	
	Little Ice Age	500 – 270		-1	
	Pre-Industrial & Industrial Revolution	270 – 77	+1.4	+1.7	+2
	1946-2022	77 – 0	+3	+3.5	+4

The heat flow in equation (9) was adjusted to minimize the sum of squared differences (RSS) between the measured and simulated temperatures. This was accomplished using the least squares method in conjunction with a Generalized Reduced Gradient (GRG) solver (Lasdon et al., 1974).

$$RSS = \sum[T_{measured} - T_{simulated}]^2 \quad (8)$$

As literature-based paleoclimate history is uncertain, three scenarios were established to evaluate heat flux and assess the imposed uncertainty.

3.5 Temperature In-Depth

Once heat flow was found, the temperature profile to 10 km depth was estimated using the analytical solution of the 1D heat conduction equation (5).

A Monte Carlo-based sensitivity analysis was used to calculate the in-depth temperature distribution, taking into account the uncertainties and variability of the parameters. While assuming that the thermal properties are consistent with depth due to lithologic coherence, variations in the analyzed values along the column are observed. To model this variability, a triangular distribution is used, encompassing the minimum and maximum values found in all samples, along with the average of the entire column. Additionally, the heat flow value is estimated using a triangular distribution, accounting for warm, cold, and mean climate scenarios (Table 3.2). This approach provides a probabilistic solution, yielding the most probable outcome and two least probable outcomes (minimum and maximum).

The choice of distribution type for each parameter is based on its variability and uncertainty. For T_0, a single value is used because it depends on a linear equation whose unknown has a unique value found in the literature. A triangular distribution best represents the variability in λ and A with the minimum, average and maximum values measured in the laboratory. Q_0 is also represented by a triangular distribution, considering the uncertainty of the calculations related to the paleoclimatic correction, with a warm, cold, and average scenario giving the minimum, average, and maximum Q_0 values. Finally, a single value for the depth z is used because the objective is to calculate the temperature at specific depths.

Table 3.2: Distribution of variables in IHCP equation

Symbol	Description	VariableType	Distribution
T_0	Surface temperature		Single value
λ	Thermal conductivity	Continuous	Triang(min,mean,max)
Q_0	Surface heat flow	Continuous	Triang(min,mean,max)
z	Depth		Single value
A	Radiogenic heat production	Continuous	Triang(min,mean,max)

3.6 Resource Assessment

The available thermophysical data along with Monte Carlo simulations were utilized to estimate the geothermal potential beneath Baker Lake (Table 3.3). First, the available thermal energy for space heating and electricity generation was estimated with the volume method (Beardsmore et al., 2010).

$$H = V \ \rho c \ (T_{\text{res}} - T_{\text{ref}}) \ R \quad (9)$$

where H (J) is the thermal energy, V (m³) is the volume of the reservoir, T_{res} (°C) is the reservoir temperature, T_{ref} (°C) is the abandonment temperature of the reservoir, and R (%) is the recovery factor representing the fraction of thermal energy in a reservoir that can be feasibly extracted for power generation.

For space heating, a reservoir abandonment temperature between 30 and 50 °C was defined (Lindal, 1973; Sarmiento et al., 2013). The potential for electricity generation was assessed using a binary geothermal power plant technology suitable for Arctic conditions, and assuming a reservoir abandonment temperature of 120 to 140 °C (Tomarov & Shipkov., 2017).

Using the waste heat from the power plant for heating purposes is termed cogeneration, or combined heat and power (CHP), and this scenario was also considered in our study using the same electrical system and parameters as described above.

The recovery factor was defined to be between 2 and 20%. The conversion of thermal energy to potential heat and power output P (GWh) was calculated with (Miranda et al., 2020 and references therein):

$$P = \frac{H\,\eta_{\mathrm{th}}}{F_{GPP}\,t} \tag{10}$$

where P ($W_{th,\,e}$) represents the power, F_{GPP} (%) is the geothermal power plant or surface facilities factor related to its availability throughout the year, t (years) represents the project lifetime, and η_{th} (%) is the cycle efficiency calculated as follows (Miranda et al., 2020 and references therein):

$$\eta_{\mathrm{th}} = 0.0935T_{\mathrm{res}} - 2.3266 \tag{12}$$

Table 3.3: Distributions of Variables in Power Output Equation

Symbol	Description	Variable Type	Distribution
V	Reservoir volume	Continuous	Uniform(min,max)
c_p	Heat capacity	Continuous	Triang(min,mean,max)
T_{res}	Reservoir temperature	Continuous	Triang(min,mean,max)
T_{ref}	Reservoir abandonment temperature	Continuous	Uniform(min,max)
R	Recovery factor	Continuous	Uniform(min,max)
F_{GPP}	GPP factor	Continuous	Uniform(min,max)
η_{th}	Thermal efficiency		f(T)
t	Project lifetime	Continuous	Trinag(min,most,max)

4. Results

4.1 Thermal Conductivity and Radiogenic Heat Production

The data obtained from the analysis of samples from the 2022 drilling program reveal that the meta-granite gneiss samples analyzed have a thermal conductivity varying between 2.1 and 2.9 W m^{-1} K^{-1} while the rhyolite samples have a thermal conductivity ranging between 2.2 and 2.4 W m^{-1} K^{-1}. The granite sample analyzed has a thermal conductivity of 2.3 W m^{-1} K^{-1}. The average thermal conductivity of the core samples is 2.4 W m^{-1} K^{-1} (Figure 4.1). The thermal

diffusivity of the meta-granite gneiss samples was evaluated to vary between 1.2 and 1.9 $mm^2 s^{-1}$, while the thermal diffusivity of the rhyolite samples ranges between 1.2 and 1.3 $mm^2 s^{-1}$. The granite sample revealed a thermal diffusivity of 1.3 $mm^2 s^{-1}$. Volumetric heat capacity, defined by dividing thermal conductivity by thermal diffusivity, varied between 1.3 and 2.0 MJ $^{-3} K^{-1}$. The rhyolite samples had a volumetric heat capacity of 1.8 to 1.9 MJ $m^{-3} K^{-1}$, and the granite sample was 1.8 MJ $m^{-3} K^{-1}$.

The meta-granite gneiss samples are characterized by a Th concentration ranging between 2.14 and 8.31 mg kg^{-1}, a U concentration varying between 1. 24 and 9.79 mg kg^{-1}, and a K concentration of 1.88% and 5.43%. The radiogenic heat production in these samples spans from 0.734 to 1.604 µW m^{-3}. For rhyolite samples, Th concentrations vary between 1.71 and 16.1 mg kg^{-1}, U between 1.38 and 9.69 mg kg^{-1}, and K between 1.19% and 4.91%. The radiogenic heat production of the rhyolite samples ranges from 3.384 to 4.198 µW m^{-3}. The single granite sample analyzed has a Th concentration of 3.03 mg kg^{-1}, a U concentration of 0.95 mg kg^{-1}, and a K concentration of 2.49%, with a radiogenic heat production of 1.204 µW m^{-3}.

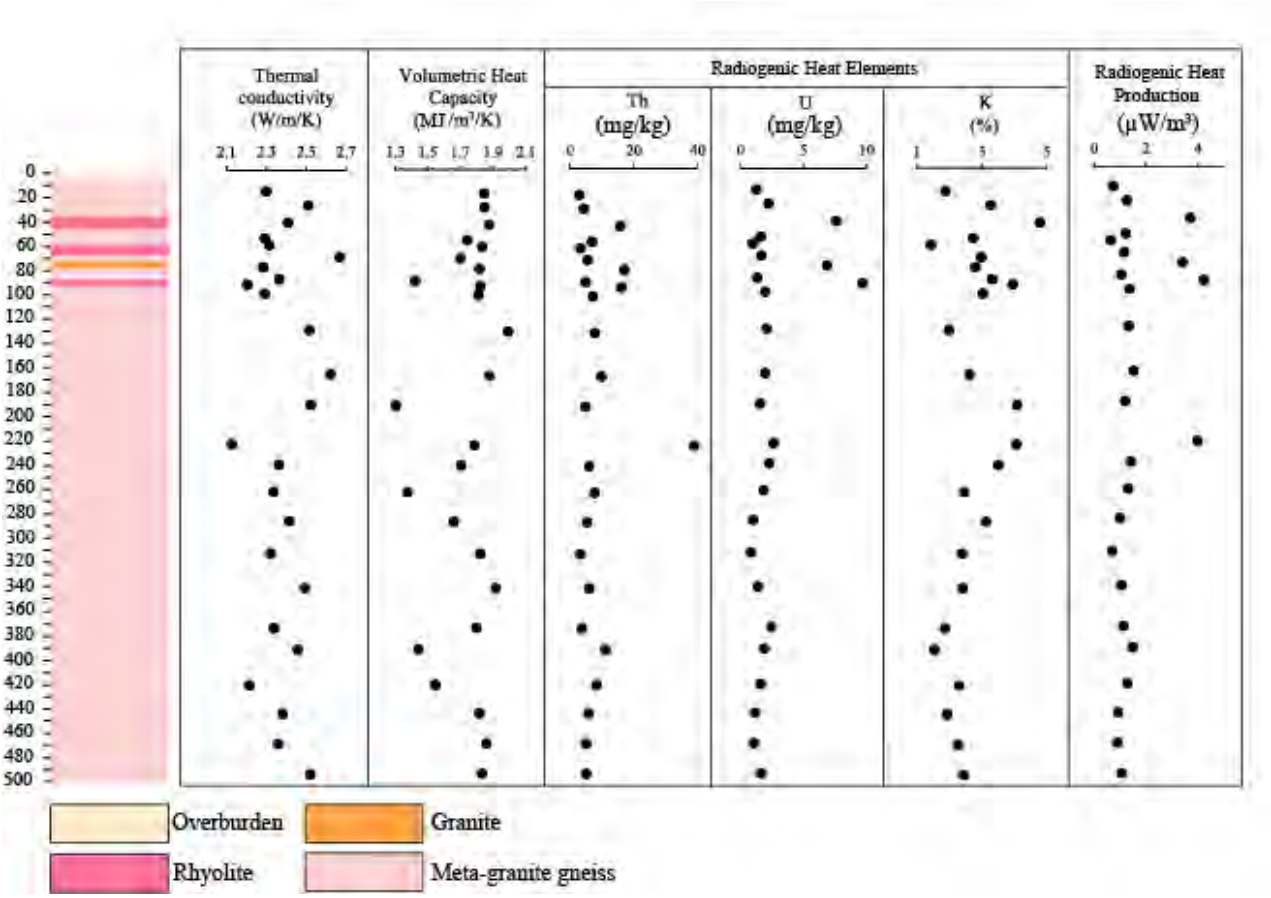

Figure 4.1: Graphical well log illustrating the lithologies observed, and the laboratory data profiles.

4.3 Heat Flow

The temperature profile measured in the Baker Lake well reveals the typical gradient inversion caused by paleoclimate events (Figure 4.2). Below a depth of approximately 100 m, the temperature profile shows a consistent linear temperature increase with depth, suggesting a conduction-dominated heat transfer medium.

The optimization approach used to estimate the heat flow took into account past climatic variations and assumed homogeneous thermal conductivity and radiogenic heat production. As previously mentioned, three probabilistic climate scenarios were defined—cold, average, and warm scenarios. The heat fluxes estimated for the cold, average, and warm climate scenarios are 78 Mw m^{-2}, 73 mW m^{-2}, and 68 mW m^{-2}, respectively (Table 4.1). The RSS values, which measure the deviation or error in the data and indicate the model's fit, are 0.53 for both the cold and average scenarios and 0.52 for the warm scenario. These RSS values are very similar across all scenarios, indicating a consistent level of fit or error among the different probabilistic scenarios.

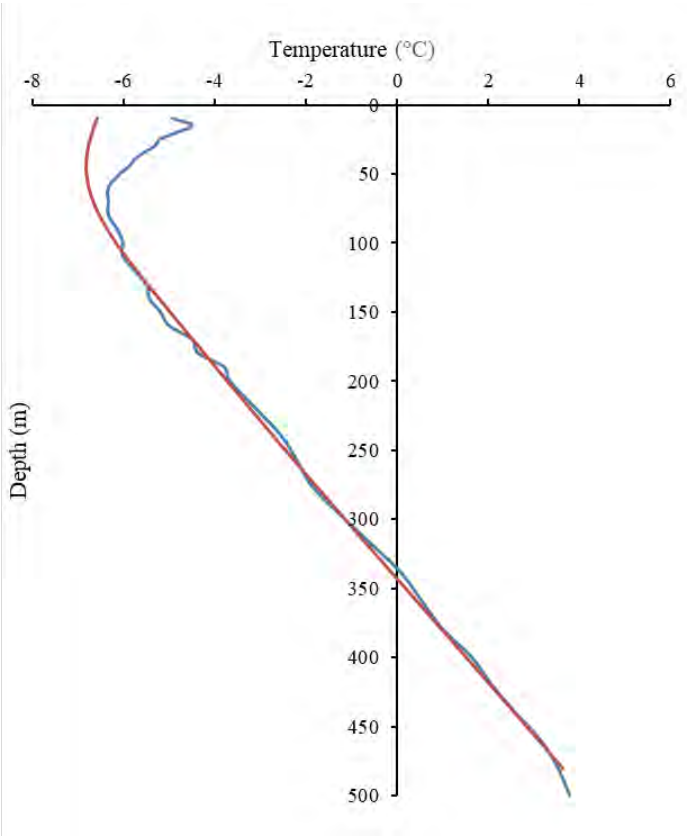

Figure 4.2: Observed temperature (in blue) compared to compute temperature (in red) after optimization.

Table 4.1: Comparison of heat flow and sum of squared residuals across cold, mean, and hot scenarios.

	Cold scenario	Mean Scenario	Hot scenario
Heat Flow (mW m^{-2})	78	73	68
RSS	0.53	0.53	0.52

4.4 Subsurface Temperature Predictions

According to the estimates carried out, minimum temperatures suitable for direct use of the geothermal resource (i.e., 40 °C), may be found starting at a depth of 2 km (Figure 4.3). For electricity production, and assuming that temperatures above 100 °C would be needed, the conditions are met at a depth starting at 5 km. At this depth, the temperature ranges from a minimum of 109°C to a maximum of 170°C, with a most likely value of 139°C.

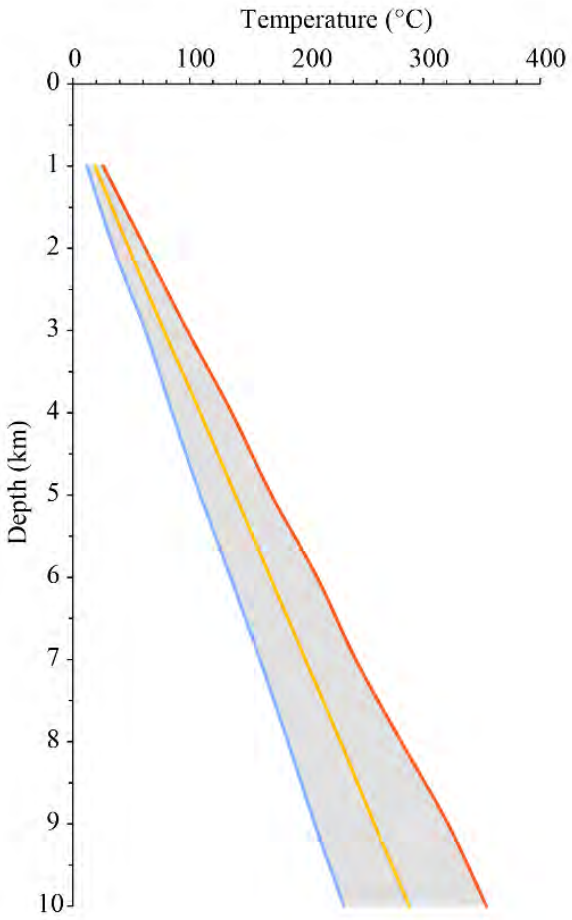

Figure 4.3: This figure shows the average (orange), minimal (blue), and maximal (red) temperatures at depths between 1 and 10 kilometers.

4.5 Resource Assessment and Risk Analysis

4.5.1 Heat Production

The data-driven Monte Carlo-based approach used in this study suggests that at a depth of 1 km, there is a 0% probability of meeting the community's estimated annual average heating needs (i.e., 77 GWh; Figure 4.4.a). However, as the depth increases, the likelihood of achieving the energy target rises significantly. At 2 km depth, this probability increases to 15% (Figure 4.4.b). At 3 km depth, the probability is 76%, and at 4 km, it increases to 91% (Figure 4.4.c,d). At 5 km depth, the probability climbs to 96%. The probability reaches a 100% chance of fulfilling the community heating needs at depths of 6 km and below (Figure 4.4.f-i).

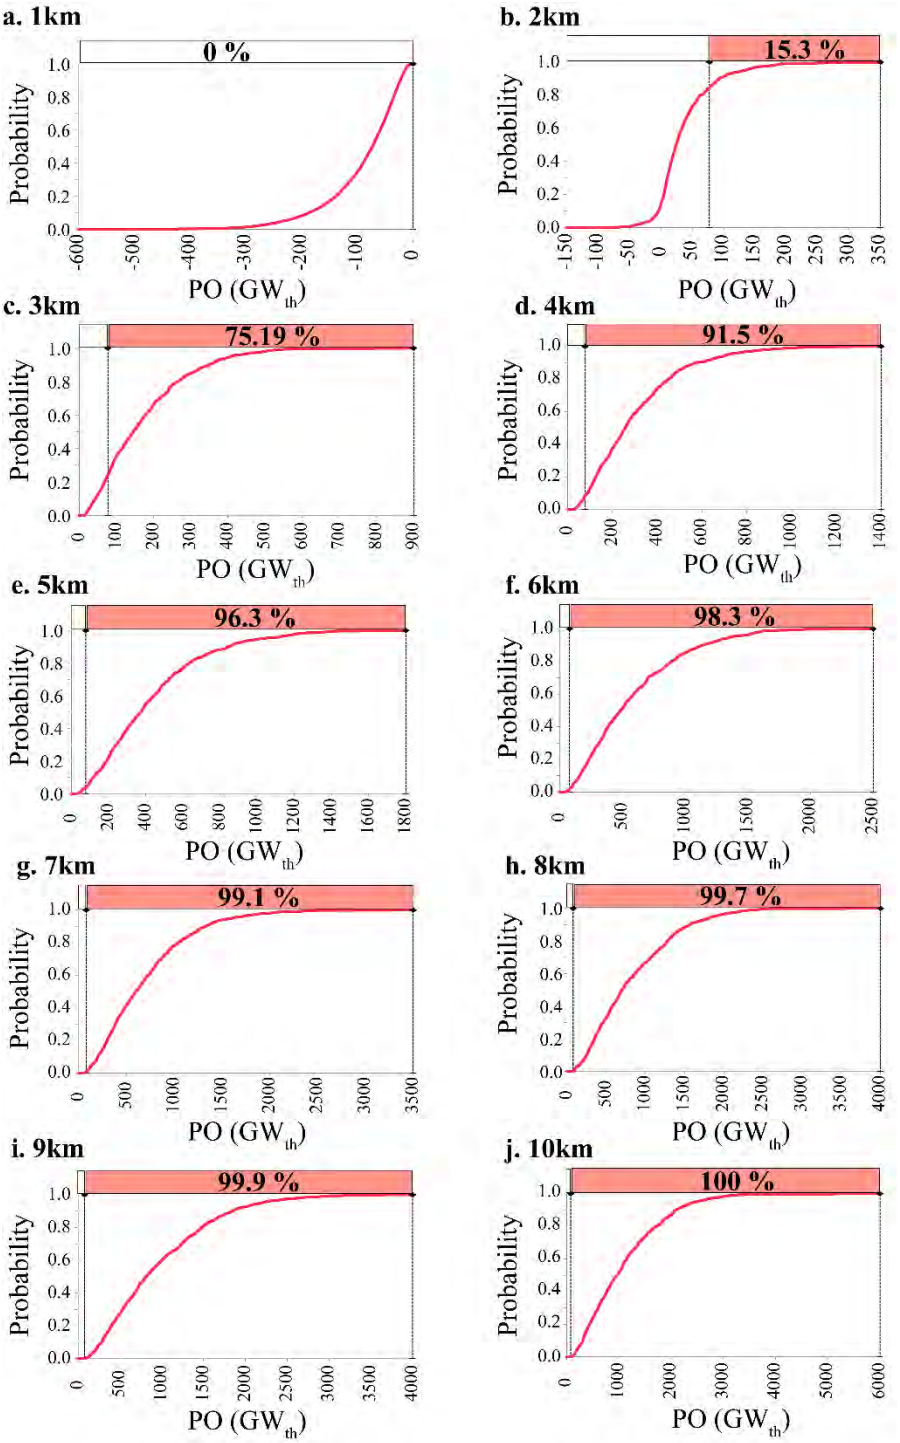

Figure 4.4: Probabilities of meeting the community's thermal energy demand, evaluated at 77 GWh, as a function of heat power in GWh between 1 and 10 km deep. The ten graphs feature an ascending curve, with the x-axis adjusted based on the increasing probability, ranging from 0 to 100%. As the depth increases, each graph illustrates how the probability of meeting the thermal energy demand evolves based on the available heat power at that specific depth. The probability of meeting the 77 GWh demand is indicated in the top right portion of each graph, expressed as a percentage. This approach visually analyzes the impact of depth on the probability of meeting the community's thermal energy demand, providing a detailed understanding of the potential variation in geothermal availability with depth.

4.5.2 Electricity Generation

The estimates for electricity generation are less promising. There is a 0% probability of meeting the community's estimated annual electricity needs (i.e., 14 GWh) up to 5km depth (Figure 4.5.a-c). At 5 km depth, the probability increases to 11% (Figure 4.5). As the depth continues to increase, the likelihood of achieving the energy target rises significantly. At 6 km depth, the probability is 61.5%, and at 7 km, it increases to 87.6% (Figure 4.5.d,e). At 8 km depth, the probability reaches 96.2% (Figure 4.5.f). Finally, at 9km depth and below, the probability of achieving 14 GWh is more than 99% (Figure 4.5.g,e).

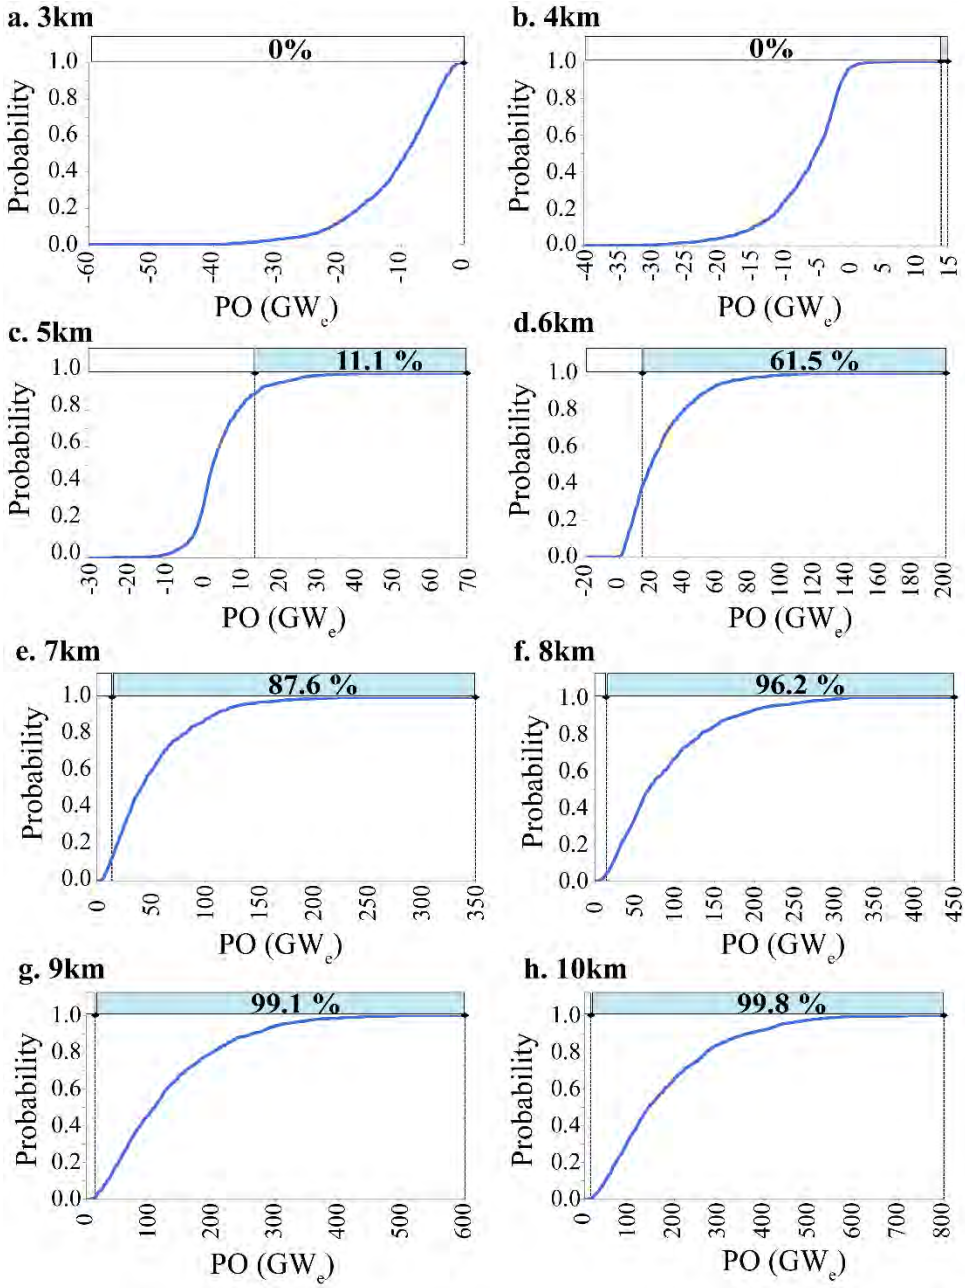

Figure 4.5: Probabilities of meeting the community's electric energy demand, evaluated at 14 GWh, as a function of heat power in GWh between 3 and 10 km deep; Depths under 3 km were excluded due to zero probability.

4.5.3 Cogeneration

In the context of improving the sustainability of a geothermal power plant, cogeneration of heat and power could be an option. Waste heat from the electricity generation process could be used for space heating instead of being released to the atmosphere. The results suggest probable depths between 6 and 10 km (Figure 4.6), although the residual heat production may not suffice to meet all heating needs (i.e., 77 GWh/year) but significantly contribute to addressing them (Figure 4.6).

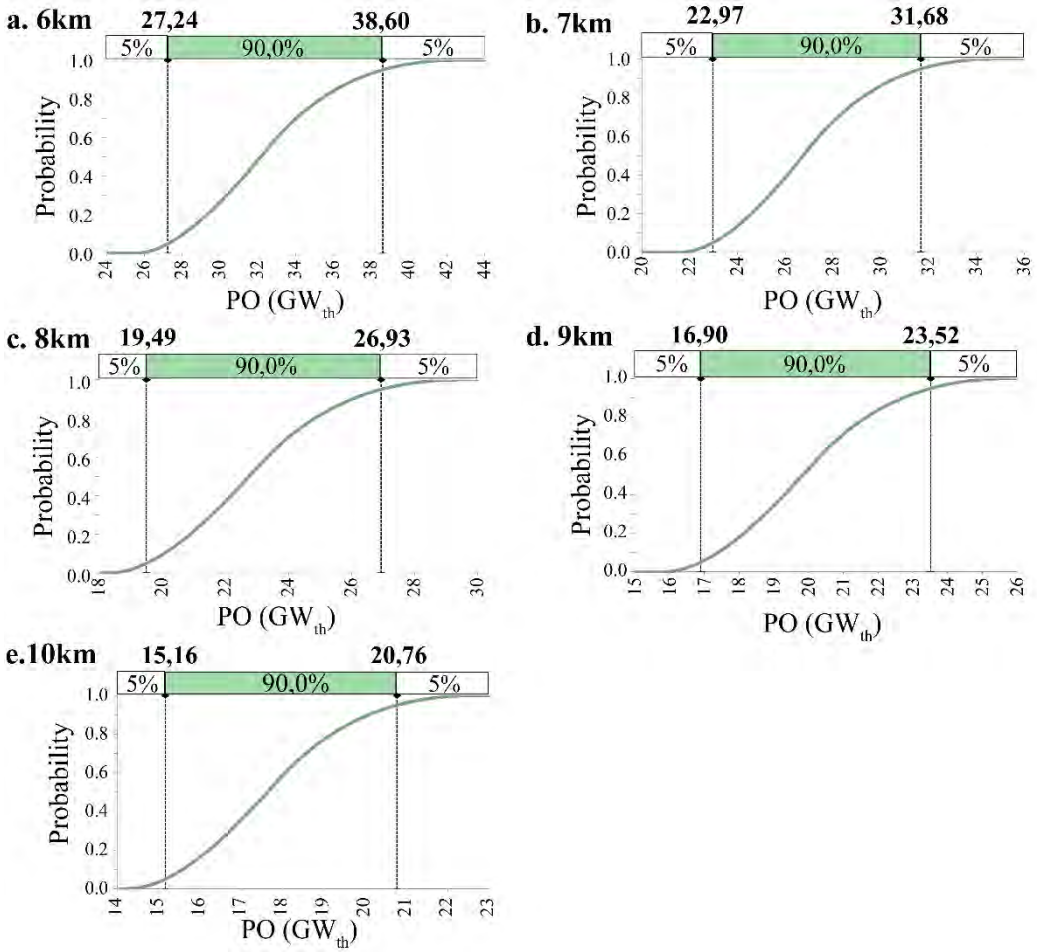

Figure 4.6: Probabilities of meeting the community's thermal energy demand, evaluated at 77 GWh, as a function of heat power in GWh between 6 and 10 km deep.

4.6 Sensitivity Analysis

The Monte Carlo-based sensitivity analysis carried out suggests that, for heat production, the recovery factor and the reservoir volume are the most important parameters, strongly influencing the quantity of thermal energy that can be provided to the end user (Figure 4.7) while project lifetime has a lower impact (Figure 4.7). The least influential parameters are the subsurface temperature distribution, the heat capacity of the reservoir host rocks, the reservoir abandonment temperature, and the availability of the surface facilities throughout the year (Figure 4.7). For electricity generation, on the other hand, the main influential parameters are subsurface temperature distribution and cycle efficiency up to 7 km depth (Figure 4.8.a,b). Below this depth, the recovery factor gains importance (Figure 4.8.c-f).

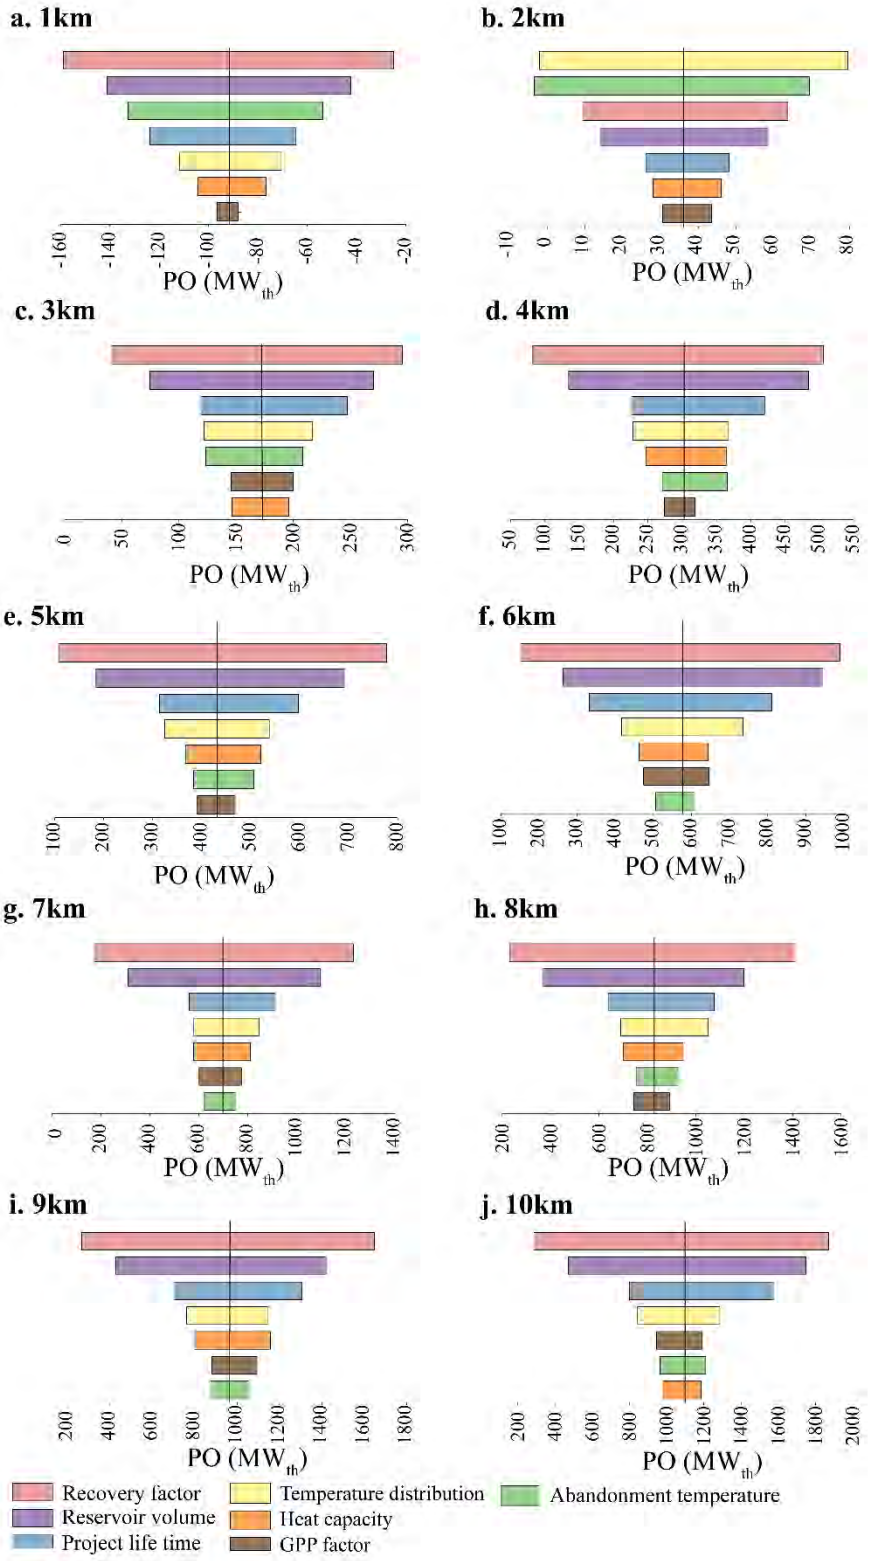

Figure 4.7: Potential impacts on heat output between 1 and 10 km deep. Longer bars indicate greater influence on heat production potential.

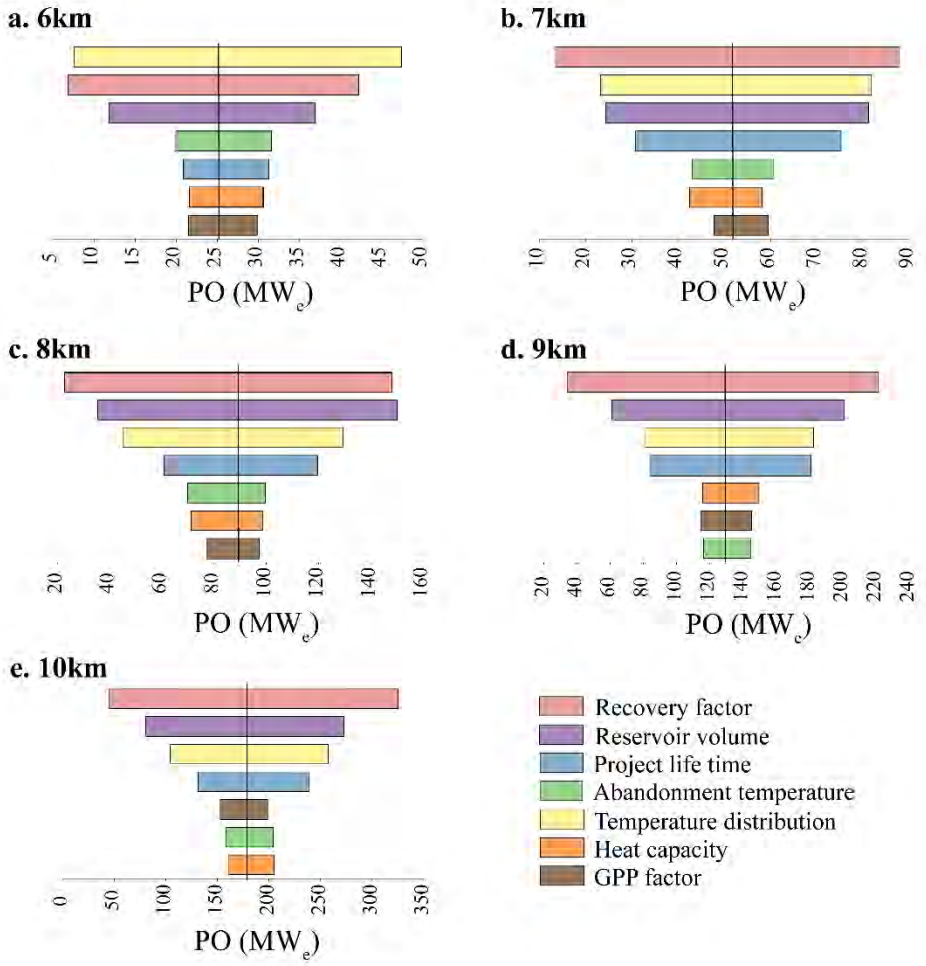

Figure 4.8: Potential impacts on heat output between 6 and 10km. Longer bars indicate greater influence on electric generation potential.

5. Discussion

The isolation from the national energy grid is a major challenge for Canada's northern communities. The search for an alternative solution to diesel is a crucial mission (Pinto and Gates, 2022), supported by QEC (QEC, 2018) and the community themselves. In fact, the desire to create an affordable, sustainable, reliable and environmentally responsible energy system has been expressed by Nunavut residents, and in 2007, the Government of Nunavut launched the Government of Nunavut Energy Strategy called Ikummatiit (Government of Nunavut, 2007). Although developing renewable energy sources is a key component of Ikummatiit, reducing dependence on diesel not only involves harnessing different forms of energy, but also making more efficient use of energy and strengthening energy system management. Another important aspect is energy literacy. Educating the public to promote energy conservation and inform the citizens about the different energy sources will help them make better, well-informed decisions about their energy use.

The key findings of the previous study made by Minnick et al. (2018) to estimate geothermal resources beneath Baker Lake revealed a low potential that would be suitable for heat or electricity generation using an EGS. However, extrapolation of data from scarce and sparse wells, on a regional scale, is a method associated with major uncertainties. Thus, Minnick et al. (2018) called for an in-depth study of the community's potential to be achieved via the drilling and evaluation of data from a 500 m-deep geothermal prospecting well. This study presents the findings of that evaluation based on a well that was drilled in December 2022.The following sections discuss the contributions of this work in terms of improving conventional resource assessment methods, and in terms of the potential use of geothermal energy to offset diesel consumption in Baker Lake via an EGS. Next steps to de-risk geothermal potential evaluation in this community are further discussed.

The heat flux calculation method used in this study, although it was based on the optimization method of Miranda et al. (2021), was modified to simplify the evaluation protocol. The new heat flux methodology uses an Excel solver instead of a numerical simulation software such as COMSOL multiphysics. This reduces complexity and calculation time, while maintaining a stochastic approach to quantify risk. The results obtained by Miranda et al. (2023) for Baker Lake following different analytical methods suggest heat flux varying between 68 and 75 mW m^{-2}. The optimization method used here results in a heat flux of 68 to 78 mW m^{-2} for cold to warm paleoclimate scenarios. These results show the importance of considering various paleoclimate scenarios in heat flow assessment.

In addition, compared to the subsurface temperature estimates of Miranda et al. (2023), the paleoclimatic correction term was added to the analytical solution of the 1D heat conduction equation to improve the accuracy of the vertical temperature profile. This term allows the influence of paleoclimatic conditions to be taken into account, the effect of which was to reduce the estimated temperatures at shallow depths. This avoids an overestimation of subsurface temperatures and energy potential in the first kilometers.

Regarding resource estimation, the methodology used in this study integrates the recovery factor in the calculation of available thermal energy, unlike the original Beardsmore et al. (2010) protocol. This adjustment was done to better reflect the nature of porous and/or fractured reservoirs, and the fraction of thermal energy that can realistically be extracted depending on the reservoir permeability. In addition, the calculation of potential production capacity included a surface facilities factor, $F_{GPP,}$ which represents the percentage of time during which the surface facilities can operate each year and accounts for periods when the facility is not operational due to issues such as maintenance. The Beardsmore protocol does not include this factor, which can lead to an underestimation of the production capacity by assuming continuous and uninterrupted operation. Finally, the reference temperature used in the calculation of energy potential is specific temperatures found in the literature, representing the minimum temperatures at which resource extraction stops. The Beardsmore protocol uses, generally, the ambient air surface temperature. In this work, we decided to use reservoir abandonment temperatures to make a more realistic assessment of the resource. The minimum reservoir abandonment temperature of 30°C and 50°C were set for space heating, and a minimum required temperature of 120°C to 140°C was set for electricity production with a binary geothermal plant. This approach ensures that the chosen temperatures are relevant in the geological and climatic framework, especially in Arctic conditions.

The preliminary study of Minnick et al. (2018) expected a heat flux of about 50 and 60 mW m^{-2}, with temperatures of 120°C reached at depths of 6 to 7.5 km. However, the present study, with reduced uncertainties, shows a heat flux ranging from 68 to 78 mW m^{-2}, and temperatures of 120°C reachable at depths starting at 5 km depth. In fact, the most likely value is 139°C at 5 km depth.

Similarly, Miranda's et al. (2021) study focused on assessing the deep geothermal potential of the Kujjuaq community in Nunavik without the use of deep borehole data. Miranda's et al. approach involved a numerical model to simulate the impact of paleoclimate events and infer heat flow by reproducing a temperature profile at 80 m depth. Due to the lack of deep well data, the uncertainties in their studies were higher. The uncertainty in heat flow in Miranda et al. (2021) was 40%, and the uncertainty in subsurface temperature distribution in Miranda et al. (2020) was greater than 75%. In contrast, our study used data from a 500 m-deep well, significantly reducing uncertainties in heat flow and subsurface temperature distribution. This access to deeper data allowed for a reduction in uncertainties in our final heat flux assessment. The uncertainties in heat flux and subsurface temperature in this study are 13% and less than 50%, respectively.

The Monte Carlo-based sensitivity analysis carried out allowed us to rate the parameters in terms of their uncertainties and their impact on the estimation of the geothermal energy potential. The recovery factor is the most decisive, and its uncertainty could be reduced by carrying out flow tests in deep wells. However, this is only done at later stages of geothermal projects, when the risk has been reduced. At early stages, characterizing the reservoir permeability through an analysis of the fracture network in the field is a valuable option. The information collected can be used to parameterize numerical models and simulate the geothermal reservoir behavior. This can help the project moving forward to justify the cost of exploration drilling. The reservoir volume is another important factor influencing heat production. The uncertainty associated with the reservoir volume can be reduced with large-scale hydraulic stimulation and microseismic monitoring. Again, this can only be done at the later stages of the project. At early stages, numerical models to optimize well locations considering the fracture network observed in the field can be a helpful option. Finally, the reservoir abandonment temperature also has a significant influence on the estimates, and its improvement will require innovations in the technology of EGS and the development of their use.

6. Conclusions

This study demonstrates the significant potential of geothermal energy as an alternative to meet the energy needs of the Baker Lake community. Analysis of a 500 m-deep well drilled in Baker Lake provided new data allowing the assessment of heat flow and temperature distribution at depth. The corrected geothermal gradient of 28 °C/km and a terrestrial heat flux of 73 mW/m^2 suggest that geothermal energy can be realistically exploited for space heating at a depth of 4 km and for electricity generation at a depth of 8 km. The feasibility of geothermal cogeneration, using waste heat from electricity generation, is a technology that can boost the efficiency of an EGS project. The estimates of this work suggest that although the waste heat is insufficient to meet all of the community's heating needs, it can partially meet them. Sensitivity analysis based on the Monte Carlo method showed that the recovery factor and reservoir volume have the most uncertainty and are the most impactful. Reducing their uncertainty at an early stage of the project would require detailed fieldwork focused on fracture and geostructure characterization, combined with numerical modeling.

This study provides a foundation for transitioning from diesel to renewable energy in Nunavut, highlighting geothermal energy as a viable and environmentally friendly alternative. This study supports the broader goal of energy independence for northern communities.

ACKNOWLEDGMENTS

This study was funded by a discovery grant from the Natural Sciences and Engineering Research Council (NSERC) and additional INRS revenues awarded to Jasmin Raymond. The authors express their gratitude to Philipe Girard, Félix-Antoine Comeau, Xavier Leveillee-Dallaire, and Maria Jose Oviedo Valencia for their invaluable support during the analyses of the thermophysical properties. We also thank the laboratory teams at INRS and RESPEC for assisting with sample analysis, and Qulliq Energy Corporation for providing access to the drilling cores.

Keywords

Greenfield, Exploration, Alaska, DoD

ABSTRACT

Motivated by a Department of Defense directive to reduce coal consumption and guided by the 2022 United States Army Climate Strategy, the Army Office of Energy Initiatives began pursuing geothermal energy opportunities for various locations throughout the United States, carried out through the Defense Innovation Unit (DIU). One of these projects was awarded to Teverra, to explore, quantify, and design a geothermal prototype energy utilization system for Fort Wainwright (FWA) in Fairbanks, Alaska. Fairbanks is within the Tanana Valley in interior Alaska. The Tanana Valley has no significant hydrocarbon or geothermal exploration but may have geothermal potential because of the regional tectonic setting and limited far field heat flow data. As such, the FWA geothermal initiative is a greenfield exploration project located within a favorable regional tectonic setting. To date, existing datasets have been collated and used to build a simplistic 3D geologic model, and new data were collected during Summer 2024, which are being incorporated into the existing model. Here, we present a review of the project goals, existing data, and new data that were collected that will be used for defining next steps in the exploration and development process.

1. Introduction

As part of the Department of Defense (DoD) directive to reduce coal consumption, Fort Wainwright (FWA) is the location of a new opportunity through the Defense Innovation Unit (DIU), a geothermal protype that is meant to provide geothermal energy directly to a DoD facility. FWA is located within the Tanana Basin of central interior Alaska. This area and the adjacent Nenana Basin are one of the most seismically active regions in North America, associated with the Denali Fault System. This area is also known to have significant Cenozoic coal-bearing formations which is of interest to energy and mining industries. Previous research in the basin that loosely encompasses Fort Wainwright includes geophysical studies and geological studies to define the tectonics and energy resource geology in the area (Dixit and Hanks, 2021).

The Alaska Department of Geological and Geophysical Surveys (DGGS), the US Army Corps of Engineers, Alaska Department of Natural Resources, and University of Alaska Fairbanks have all produced various reports, datasets, and maps that provide data and analysis to determine the basin structure. These data sources were collected and collated to use for further analysis in this geothermal feasibility study.

2. Existing Data

As part of this work, existing data were collected and combined into a single geologic model for the Tanana Valley – Fairbanks area. Data collected includes common greenfield geothermal exploration data as well as examination of public databases for any additional data within the general study area that may then help interpretation in the specific area of interest (AOI). Data examined are reported in Table 1. Because there are limited existing geothermal studies for the AOI, data needed to be collated to find all the necessary elements for a traditional geothermal system: heat, fluid, and fluid flow pathways. Data were mapped individually as well as collectively to examine total data coverage as well as data value for geothermal exploration. Below, the most abundant data sources are discussed.

Table 1. Summary of Data Collated for Fort Wainwright Geothermal Exploration.

Category	Data Available	Data Use	Sources
Geophysical	Low-quality magnetics maps Gravity data points Earthquake locations	Identify sedimentary thickness and potential subsurface structures	DGGS, USGS Dixit and Hanks, 2021
Structural	State Geologic Map Mapped Faults	Fluid pathways and structures that may alter the depth of thermal resource	DGGS, public database
Lithological	Regional Stratigraphic columns and cross sections	Stratigraphic column development for thermal mapping and identification of key rock formations	DGGS GMC 446 report Dixit and Hanks, 2021
Thermal	Shallow water well data Heat flow data points	Temperature characterization	Alaska Department of Natural Resources, SMU heat flow database
Geochemistry	Shallow water well data Rock samples		Alaska Department of Natural Resources DGGS
Hydrology	Reports	Permafrost and aquifer studies	DGGS Army Corps of Engineers report

2.1 Well Data

Within the Fairbanks area, there is no deep oil and gas or geothermal exploration. The nearest deep wells are at Eielson Air Force Base, oil and gas exploration wells in the Nenana Basin, and Chena Hot Springs geothermal wells. The Eielson deep well is approximately 30 km away, and both the Nenana Basin and Chena Hot Springs wells are approximately 75 km away from the AOI. These are too far away for local exploration relevance but do provide potential regional thermal regime context. These wells have surface heat flow values of approximately 90 – 100 mW/m² (Batir et al., 2016). These values, while sparse, suggest there is a regional elevated thermal regime.

The local water well database was examined through the Alaska Department of Natural Resources Mining, Land & Water Well Log Tracking System (WELTS). The database was searched for deep water wells which are opportunities to collect regionally relevant thermal data and water chemistry information (Figure 2). There are more than 3,000 water wells within the Fairbanks area, with a large number also on FWA; however, only 70 wells are greater than 500 ft (152 m) deep. Past research shows that climatic warming is visible in temperature logs in Alaska to a depth of approximately 80 m (Batir et al., 2017). Here, a minimum well depth of 150 m is used to provide the opportunity to collect temperature logs that may be deeper than the recent climatic warming signal, and as such, be at thermal equilibrium. These 70 wells are actively being examined for temperature logging opportunities. Water chemistry data is available for major components; however, many of the common geothermal constituents, such as those for the various geothermometry estimations, were not recorded.

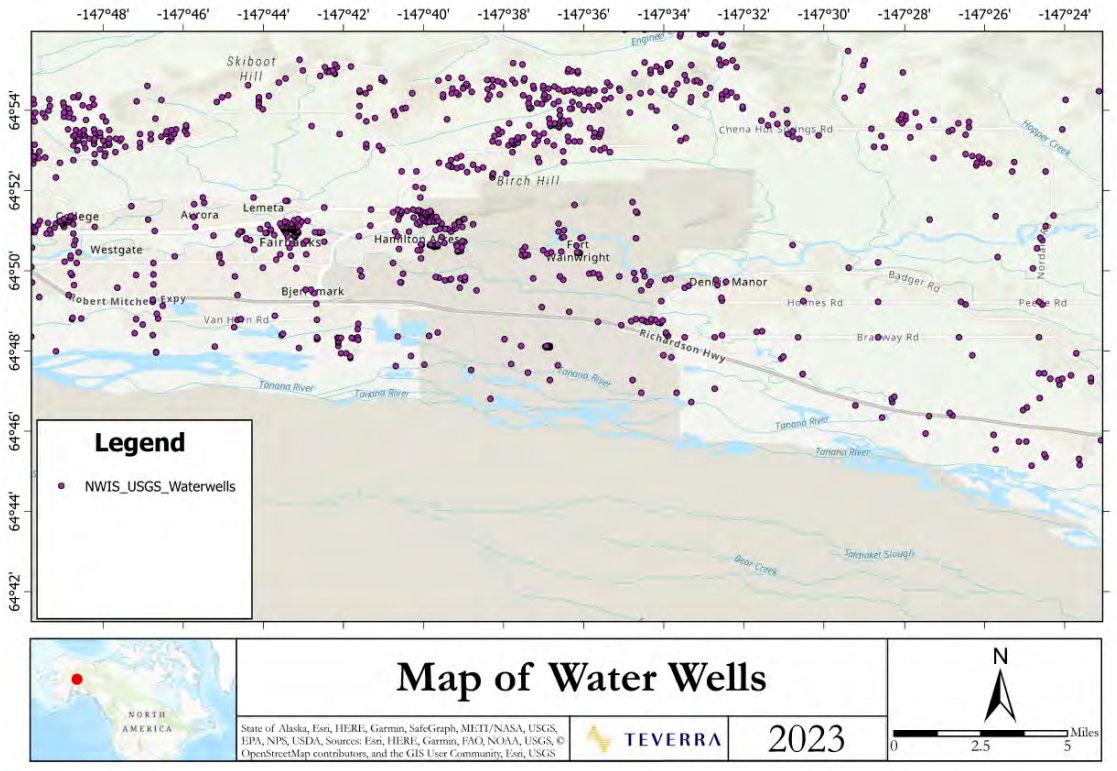

Figure 1. Water wells near the Fort Wainwright AOI, extracted from WELTS (Alaska DNR, 2023).

2.2 Geophysical Data

Previous work produced regional cross sections of the Nenana Basin and Tanana Valley utilizing only gravity and magnetic surveys for inversion modeling (Dixit and Hanks, 2021). As such, geophysical datasets were expected to be abundant and directly applicable to geothermal exploration. Processed gravity and magnetic data points (as opposed to gridded maps) were searched for, and where available, collated (Figure 3 and Figure 4, respectively). Because of the limited data from past studies directly crosscutting the AOI, it was determined that the individual data points, if available should be collated, combined with new data, and then used to perform gridding and inversion modeling. In addition to gravity and magnetic field data points, earthquakes were collected to infer potential for active faults on or near the AOI (Figure 5). To our dismay, data coverage for the AOI is subpar. Gravity stations for the AOI are low in number and not evenly distributed. There is a recent high resolution aeromagnetic survey, however, the survey only covers a portion of the AOI, and individual flight lines are still being converted to a usable format. Earthquake data is an exception to the poor data coverage in that there are sufficient earthquakes that can be used to infer seismically active areas.

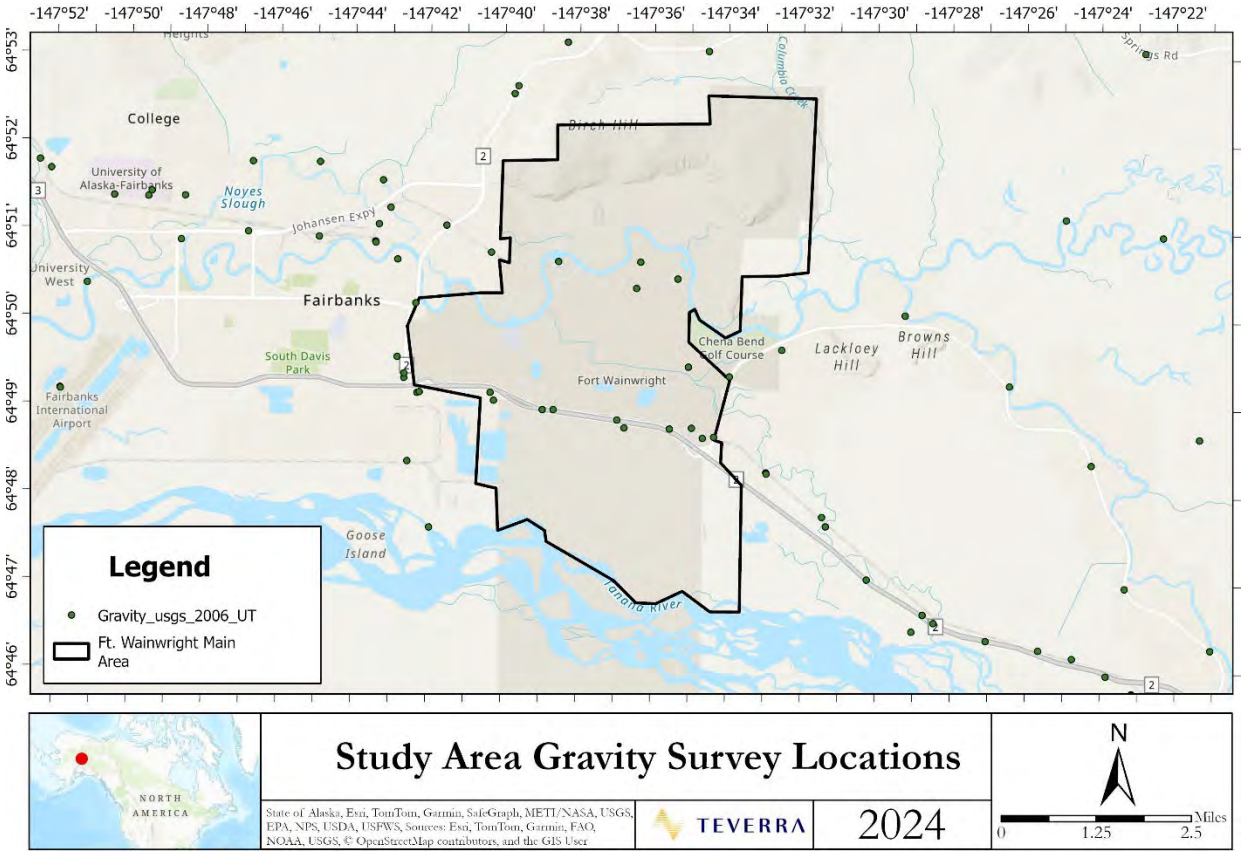

Figure 2. Location of gravity data points near the AOI (USGS, 2006).

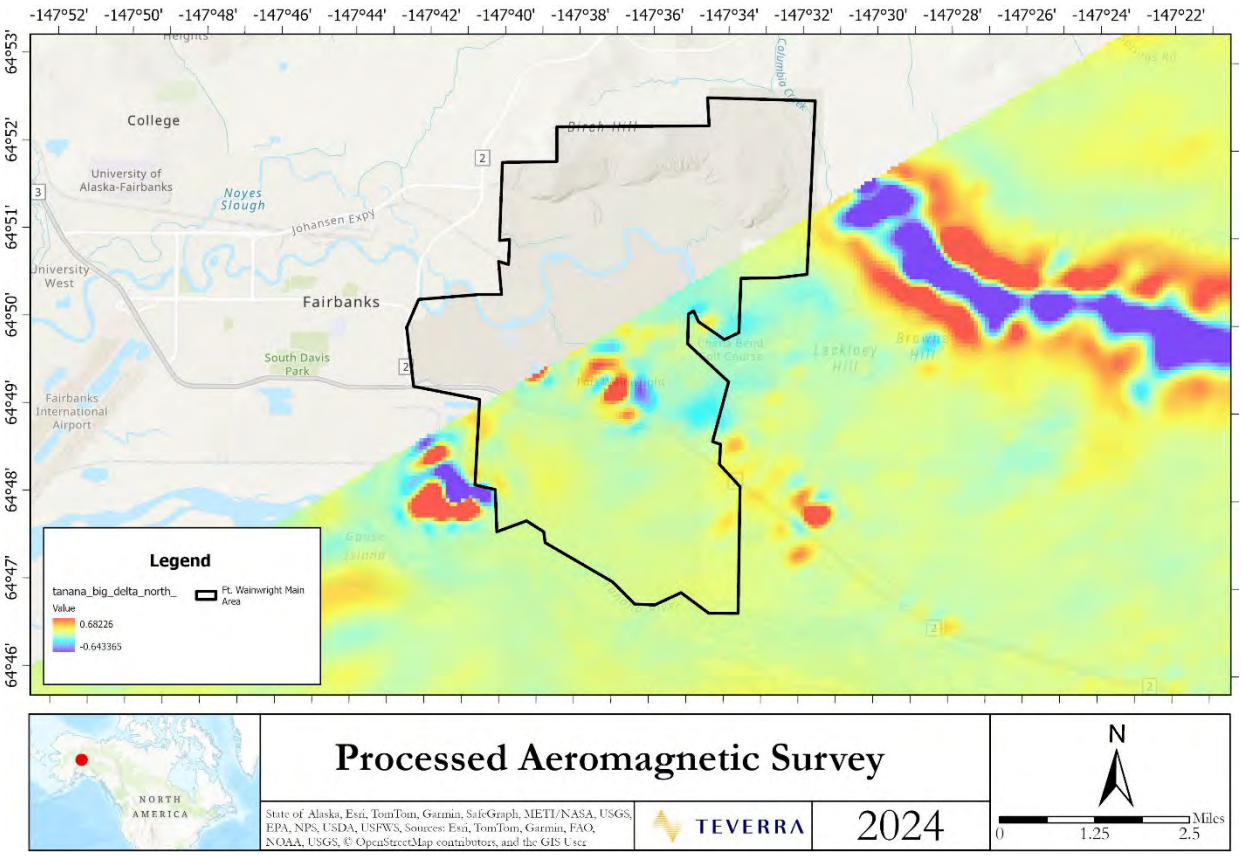

Figure 3. Regional magnetic anomaly map of AOI (Emond and MPX Geophysics LTD, 2022). Note that this is shown as a gridded map surface, but the raw data are available and were collected.

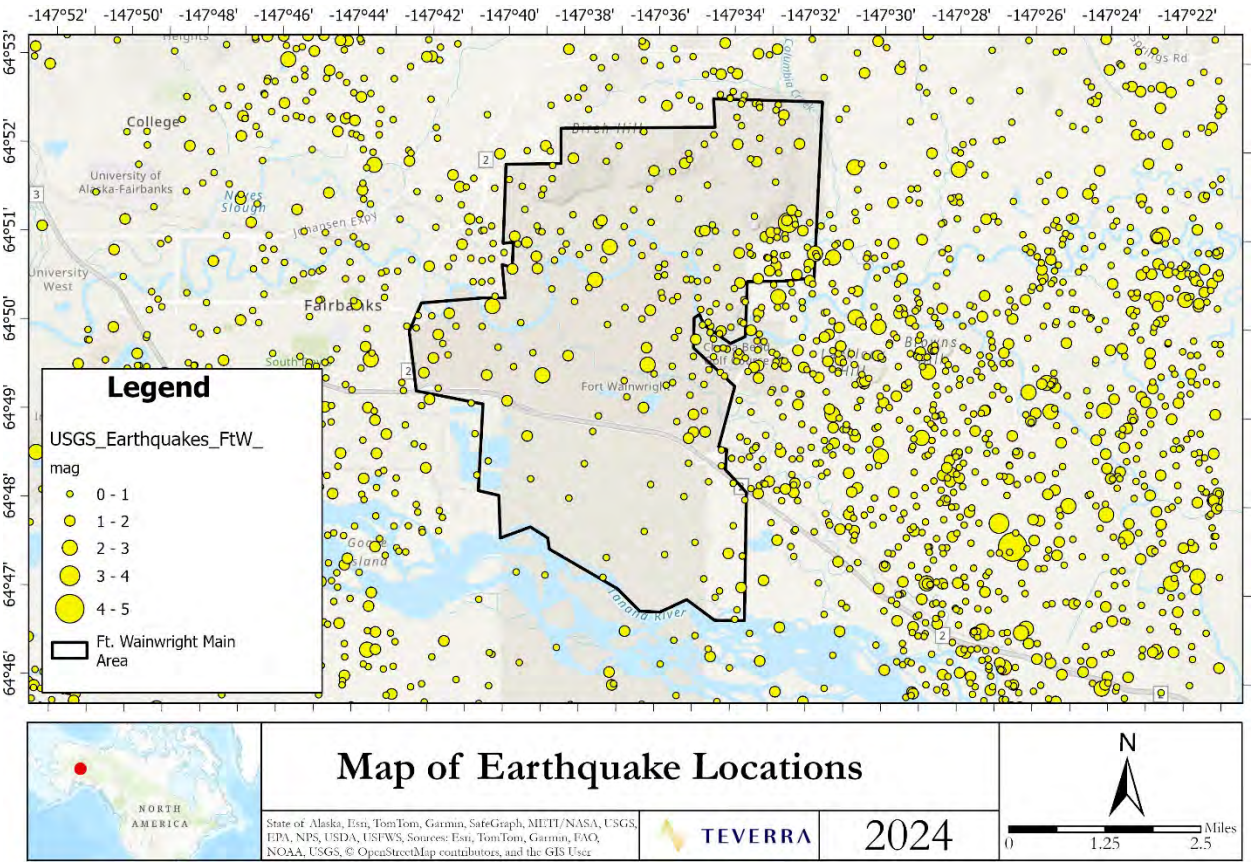

Figure 4. Location map of USGS earthquake catalog for the AOI, 1973 - 2023 (USGS, 2023).

2.3 Geologic Data

As stated previously, there are no regionally relevant deep wells within the AOI. As such, regional stratigraphy and structural trends are interpreted from regional surface mapping and limited, shallow water well drilling. In general, there is a package of Cenozoic sedimentary formations overlying Mississippian and older metamorphic rocks, which are labeled as basement. Depending on location, basement rocks outcrop at surface, including within the AOI (Figure 6). Additionally, surface mapping identified strike-slip faults within outcrops that are projected to crosscut the AOI. Previous models show there can be significant sedimentary sequences where there is vertical offset along faults, which could then be a target for geothermal exploration (Dixit and Hanks, 2021).

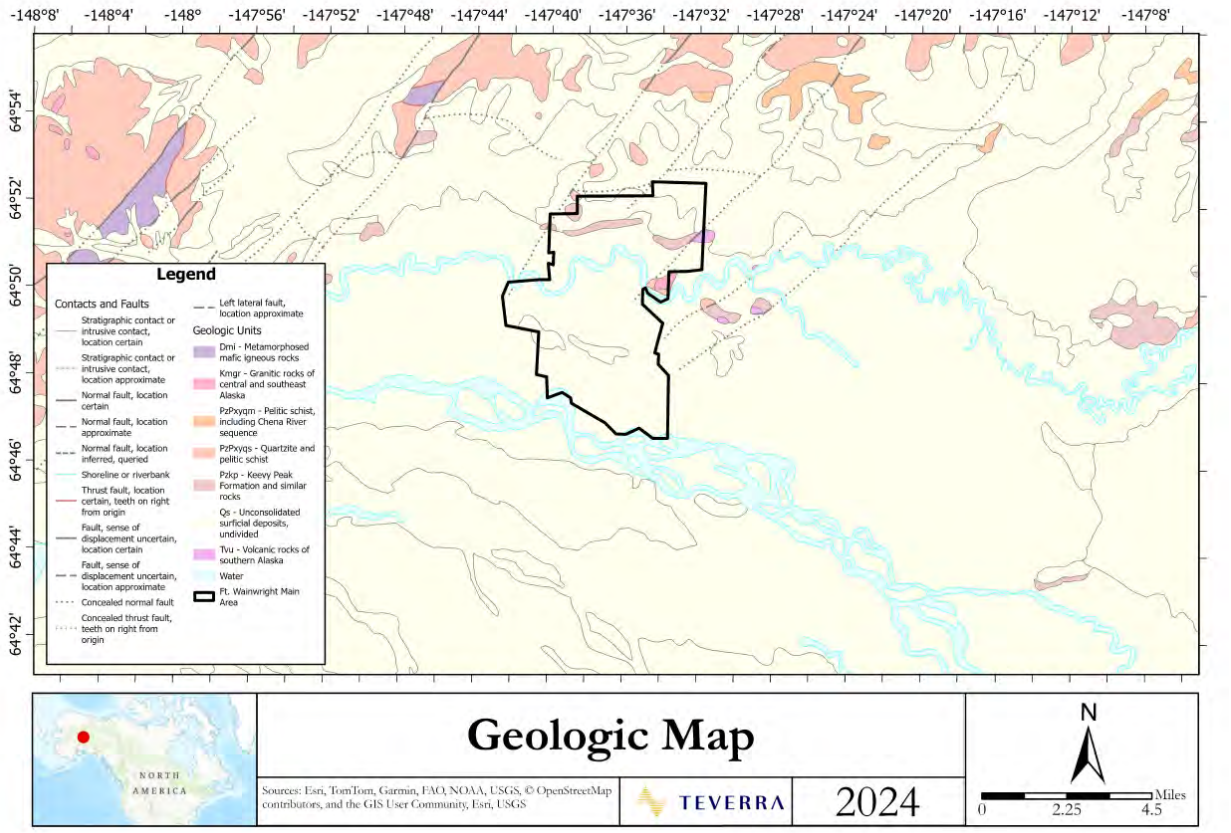

Figure 5. Geologic map of the Fort Wainwright region, with the AOI indicated as the thick black bordered polygon (Wilson et al., 2015). The map shows potential faults crosscutting the installation as well as several formation outcrops in the northern portion of the installation.

3. Interpretation

While there is limited data, there is sufficient data to begin interpretation and geothermal exploration.

One of the previous geophysical inversion model cross sections produced by Dixit and Hanks (2021) intersects the Tanana Valley west of the AOI, while all others are south and west. Still, the Dixit and Hanks (2021) cross sections are used to project subsurface formation thickness from the nearby cross section to the AOI. This projection shows that there is potential for the sedimentary package to be approximately 750 ±300 m (2500 ±1000 ft) thick, at which point the metamorphic rocks would begin. This thickness is heavily dependent on fault location and total fault offset, which were previously interpreted from the sparse and low-resolution gravity and magnetic field data.

Based on the existing far field heat flow data points, heat flow should be 75 ±20 mW/m² and hypothesized to be on the higher end based on the nearby data. Using this estimated heat flow, the subsurface should be approximately 45 ±5 °C (115 ±15 °F) at the base of the sediment 750 ±300 m (2500 ±1000 ft). This temperature may be further elevated if one of the extrapolated faults is acting as a fluid flow pathway that enables deep circulation of fluids and upflow of elevated

temperature water. While there is no surface indication of deep-seated fluid circulation, this is the primary target for this exploration.

3.1 Key Challenges

There are several identified challenges associated with the limited data available. First, the heat flow and estimated thermal regime is calculated from far field data. These data points are not directly relevant to the local AOI and as such may not be representative of the thermal regime within the AOI. Second, there are limited data points to build new inversion models for estimating basement depth. Both of these uncertainties are reflected in the large error estimations within the heat flow and basement depth.

4. New Data Collection

New data collection will have taken place during summer 2024, before the GRC 2024, but after the writing of this paper. New data collection is planned to fill in these two key uncertainties of sediment thickness and thermal regime. Sediment thickness will be estimated by collecting a ground-based gravity survey, an aeromagnetic survey, and a passive seismic survey. The gravity and passive seismic will be collected in a grid pattern similar to the example grid below (Figure 7). The goal of the grid style data collection will be to produce a complete gravity survey and passive seismic survey, centered on the AOI. Additionally, an aeromagnetic survey will be conducted, and data collected over approximately the same area to complete the magnetic anomaly map over the AOI. By combining these three geophysical datasets, we anticipate producing a higher resolution inversion model to estimate sediment thickness as well as potential regional variation in the sediment formations (i.e., structural features such as faulting or formation dip). A secondary goal of the multiple geophysics data collection will be imaging/interpretation of faults underlying the AOI. This goal will be more difficult to achieve because of the still limited resolution that will be able to be collected, but processing will be completed to attempt imaging of faults within the AOI.

Similar to the geophysical data collection, temperature logs will be attempted to be collected throughout the Fairbanks region. As stated previously, there are 70 wells that are deeper than 500 ft (152 m). These wells are the highest opportunity wells to measure the thermal regime of the Fairbanks region. While there is an abundance of wells, these may be a challenge to get final permission for logging.

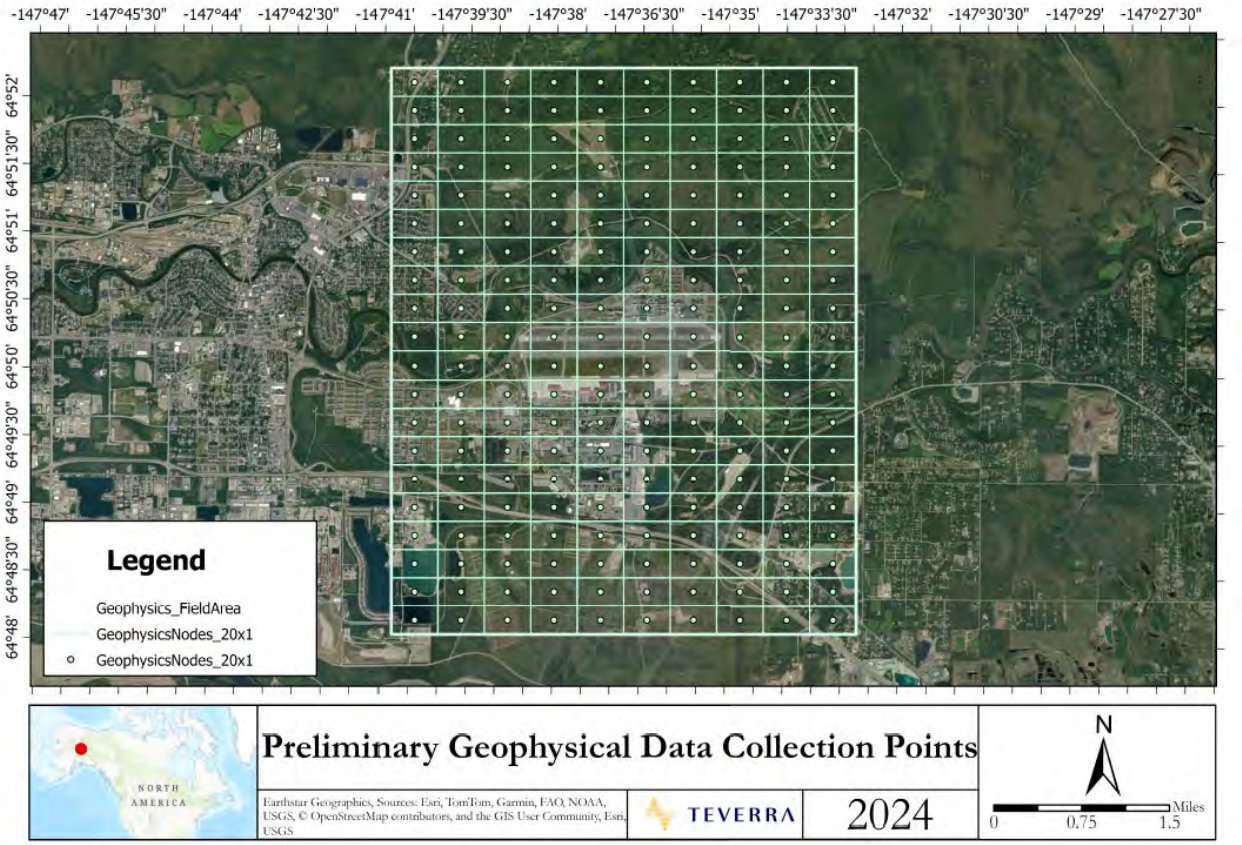

Figure 6. Preliminary data collection plan. Each point will be a location for a geophone and a gravity station. The aeromagnetic survey will cover nearly all of this area.

5. Conclusions

Fort Wainwright has a clear desire for more power and is pursuing options for lower carbon fuel sources, as evidenced by this project. While there is a clear demand, the understanding of the potential resource is lacking because of a lack of proper geothermal exploration data. Still, there is sufficient evidence to support further exploration, taking place Summer 2024. The Summer 2024 data collection campaign will consist of gravity stations, a passive seismic survey, an aeromagnetic survey, temperature logging, and rock sample collection. With successful collection of these data, we anticipate being able to provide better estimates of the local thermal regime and sediment thickness.

Canadian Expertise and Financing in Global Geothermal Exploration and Development

Catherine Hickson and Brian Fairbank

Alberta No. 1

Keywords

Canada, Geothermal Exploration, International, financing

ABSTRACT

Canadian companies and Canadian experts have made a mark in the global exploration and development of all types of mineral and hydrocarbon resources including geothermal energy. Most of the worlds exploration funds are raised on the Toronto Stock Exchange (TSX and TSX-V) that fuels the global search for mineral wealth. This is also true of the geothermal sector. But Canada's global ambitions came after focus on Canadian geothermal resources starting in 1975. The early 1970's worldwide oil crisis spurred increased interest in geothermal resources globally. The crises fostered an increased interest in both the USA and Canada, major oil producing nations, in geothermal resources. In 1973, a small group of energy professionals, scientists and academics came together in California to explore potential synergies and research projects that might help their countries combat the coming fuel shortages with another way to produce power. This was the nascent beginnings of the US-based Geothermal Resources Council (now Geothermal Rising). Several Canadians attended that meeting and upon returning to Canada, established the Canadian Geothermal Association as a not-for-profit technical association to bring together Canadians interested in geothermal energy both domestically and globally. The association is still active today, 50 years later, after rebranding as Geothermal Canada in 2018. During these 50 years Canadians have been active globally in all aspects of geothermal development from green-field exploration to brown-field development, to building and operating plants, to reservoir management. Canadian drilling expertise was also sought after based on the drilling of 1000's of wells since the early 1940s. Canadian drillers and engineers found themselves involved in geothermal exploration projects in Japan, USA and elsewhere. Research also included exploration technologies such as the development of electromagnetic geophysical methods. These methods were developed and first used in Canada at Mount Meager, supported by funding from Canada's Federal Government Natural Resources Canada (Geological Survey of Canada and the Earth Physics Branch).

1. Introduction

Canadians first became interested in geothermal energy resources in the early 1970's when a global oil crisis spurred increased interest in geothermal resources globally (Figure 1). The crises fostered an increased interest in both the USA and Canada (Hintz 2023). In 1973, a small group of energy professionals, scientists and academics came together in California to explore potential synergies and research projects that might help their countries combat the coming fuel shortages with another way to produce power. This was the nascent beginnings of the US-based Geothermal Resources Council, now known as Geothermal Rising.

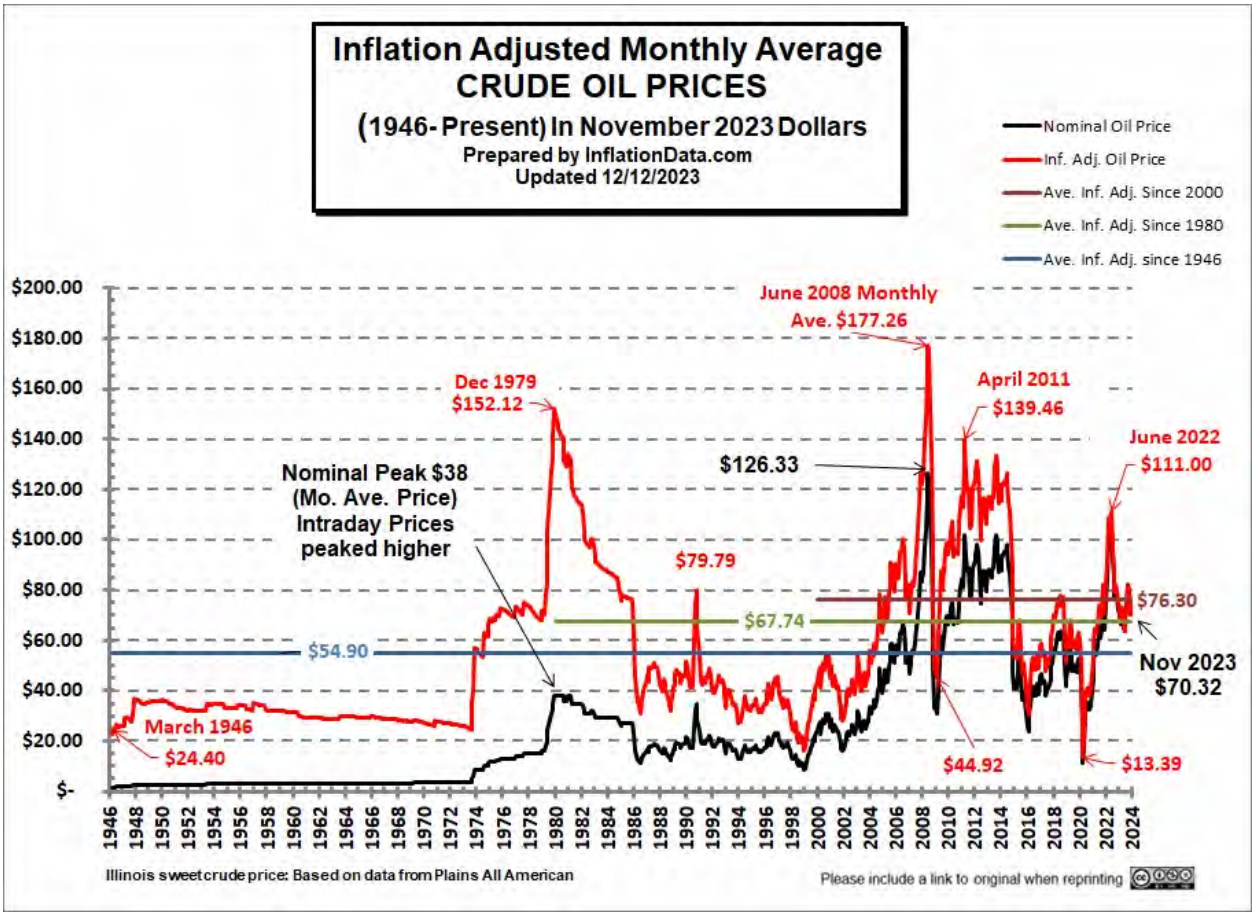

Figure 1: Inflation adjusted crude oil prices (https://inflationdata.com/articles/inflation-adjusted-prices/historical-oil-prices-chart/), showing the rise and fall of crude oil prices that fueled and cooled geothermal investments globally.

Three Canadians attended that meeting, Dr. Jack Souther, Geological Survey of Canada, Tim Sadlier Brown, and Andrew Nevin, both from Nevin-Sadlier Brown-Groodbrand and Associates. Upon returning to Canada, they established the Canadian Geothermal Association as a not-for-profit technical association to bring together Canadians interested in geothermal energy both domestically and globally. The association is still active today, 50 years later, after rebranding as Geothermal Canada in 2018. During these 50 years Canadians have been active globally in all aspects of geothermal development.

Canadians have been involved in everything from green-field exploration to brown-field development, to building and operating plants, to reservoir management. For more details on the efforts by Canadians in Canada see Jessop (2008) and Jessop et al. (2024). These papers chronical the significant investment made by the Canada Government between 1975 and 1985, to support geothermal research and development in Canada. In addition to the efforts at home in the 1980s and 1990's Canadian drilling expertise was sought after globally. Canadian drillers, well known from oil and gas exploration in the Western Canada Basin where 1000's of wells had been drilled since the early 1940s, found themselves involved in geothermal exploration projects in Japan, USA and elsewhere.

Canadian expertise in mineral exploration using geophysical methods was directed at the exploration for geothermal resources in the mid-1070's. Early R&D efforts by Greg Shore, Premier Geophysics, in the use of electromagnetic methods for exploration of high temperature systems, were first used in Canada at Mount Meager, supported by funding from Canada's Federal Government, Dept of Natural Resources (Shore 1978). These methods were soon being tested and deployed globally.

It was these early efforts and the training of a cadre of young geologists, geophysicists and engineers that led to expansion of the involvement of Canadian's in geothermal development efforts globally. Throughout the decades these investments have been largely financed by the Toronto Stock Exchange (TSX) and TSX Venture Exchange (TSX-V). These exchanges are home to 42% of the world's public mining companies. In 2021, 203 mining firms were listed on the TSX and 967 firms listed on the TSX-V. These firms had a combined market capitalization of $558 billion and raised $10 billion in equity capital in 2021.

2. Global Efforts

In the early 1980's Toronto based Polaris Renewable Energy became active in Nicaragua, developing an operating asset there (Tiffer et al. 1988). In Nevada, Vancouver based Nevada Geothermal explored and developed the Blue Mountain Geothermal field (Fairbank et al. 1999, Fairbank 2024). The mid-2000's saw several Canadian companies entering the scene, among these Western Geothermal, Siera Geothermal, and Magma Energy Corp. The capital investment in these companies was bolstered by the steady rise in crude oil prices noted from the early 2000s to the 2008 financial crises (Figure 1) (Helleiner 2011).

Western Geothermal focused on assets in Canada such as Meager Mountain, and Siera Geothermal was involved in exploration in Canada and the USA. In 2007 Magma Energy Corp was formed and commenced a global exploration program as well as purchasing operating assets in Nevada (Soda Lake) USA and Iceland (HS Orka Svartsengi and Reykjanes). Headquarters were in Vancouver, Canada in addition to offices in Lima, Peru; Reno, Nevada; Santiago, Chile; Sienna, Italy; and Keflavik, Iceland, they also established additional subsidiary companies in Chile (Hickson 2011), Italy, Nicaragua, and Peru. The company merged in 2011 with Plutonic Power Corp, becoming Alterra Power Corp. Eventually the company was bought by Innergex Renewable Energy, who continues developing renewable energy projects, but is no longer actively engaged in geothermal development, despite holding key geothermal assets in Italy and Chile.

The 2008 financial crises left many companies struggling to raise capital. Publicly traded Magma Energy Corp. was the first Canadian company of any type to go to the markets post-crises with an

"initial public offering." In June 2009, they raised just over $CDN120MM on the TSX. By 2013, many geothermal companies were again challenged to raise capital as crude oil prices fell (Figure 1) and the geothermal value proposition for electrical generation vs natural gas declined.

By the early 2020s, most of the financial and development emphasis for Canadians was on home grown projects (Huang et al 2023). With time the focus in Canada has shifted from low-cost Natural Gas and coal power generation to renewable energy projects, geothermal energy for power production is slowly gaining momentum in Canada (Huang and Hickson 2024). However, wind, solar and run-of-river hydro, still make up the bulk of renewable electricity projects in Canada.

Of note, is the 2023 achievement of Calgary based, Futera Energy Corp to produce the first geothermal electrons in their co-production facility in the Swan Hills of Alberta (https://www.globenewswire.com/news-release/2023/03/22/2632687/0/en/Canada-s-First-Co-Produced-Geothermal-Power-Project-is-Operational.html) , 40 years after the 250 kw generator produced power at Mount Meager, British Columbia in 1983. Additionally, Parex Resources Inc, based in Calgary, Alberta and operating in the Llanos Basin, Colombia, installed and operates two ORC units powered by a high temperature water cut from their hydrocarbon operations (Figure 2). Generation began in 2021, as the second only geothermal power plant operating in South America. Polaris continues to develop the geothermal resources of Nicaragua and has also expanded into solar and hydro projects in Latin America.

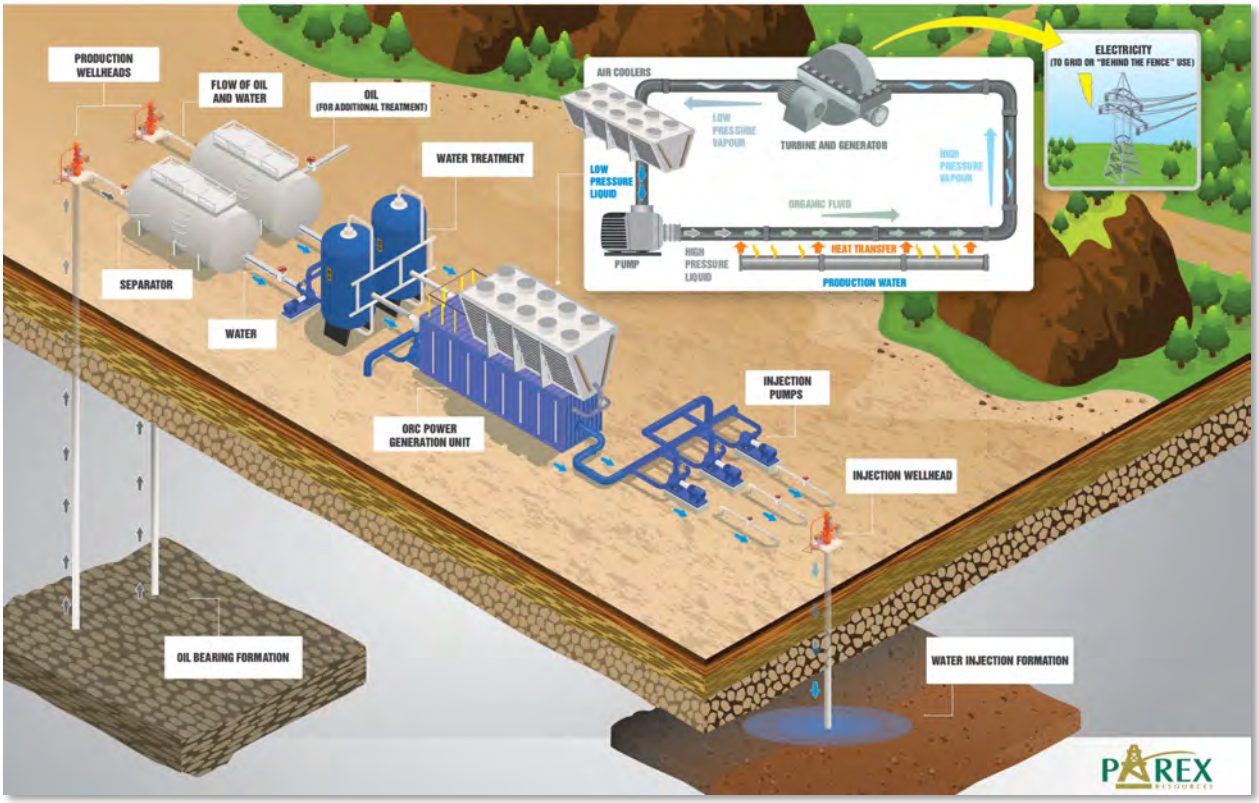

Figure 2: Parex Resources Ltd. operating ORC unit in the Llanos Basin, Colombia, utilizes a high temperature water cut to produce electricity then used in the field operations.

Acknowledgement

The Canadian pioneers who laid the groundwork for the current cohort of geothermal geoscientists and engineers are thanked for their perseverance and fortitude. Innovation and advances in the oil and gas sector have fueled new ways of looking at geothermal development, these pioneers are thanked for their contributions over the decades. The authors apologize for projects and developments where Canadian's have been instrumental and have been missed in this brief review. The mention of any specific project is not an endorsement of that project or the development team. We welcome updates and additions.

ABSTRACT

The increased demand for energy, commitment to develop more renewable energy, and need for baseload renewables has pushed geothermal energy development in Canada in recent years. The country's geological diversity, as well as population distribution and infrastructure, require a variety of geothermal systems. Conventional geothermal systems need heat, fluid, and permeability, however, only portions of Canada's orogen and platform provinces have all 3 parameters. Unconventional methods and shallow geothermal systems have been/are being developed to produce geothermal energy in areas that lack one or more of the conventional requirements. As well, new innovations allow for re-purposing existing end-of-life wells and creating heat storage and utilization for use in conjunction with intermittent renewables. This paper outlines seven classes of geothermal energy systems and suggests where each class is suitable for development in Canada. Geologically, Canada is made up of a number of geological "provinces", the most aerially extensive is the Canadian Shield. The Shield, which is comprised of crystalline Precambrian rock and characterized by lower temperatures and low permeability, cannot produce geothermal energy from conventional means; alternative technology is required. This region is potentially suitable for ground source heat pumps south of the permafrost zone (and possibly with heat augmentation within permafrost zones), shallow subsurface hydrological systems, Advanced Geothermal Systems (AGS), Enhanced/Engineered Geothermal Systems (EGS), and heat capture and storage. On the other hand, conventional geothermal development is possible in some sedimentary basins within the platform geological provinces, and there are already several projects being developed. In Canada's orogenic geological provinces, conventional geothermal projects are possible in fault-hosted systems, especially within the volcanic belts that have been shown to have high subsurface temperatures. In both the platform and orogen provinces, AGSs and EGSs are options in areas that lack permeability and/or subsurface fluid, and can also support the shallow systems, borehole heat exchangers, and heat capture and storage.

1. Introduction

The geothermal landscape in Canada continues to be shaped by both challenges and successes, emulating many similar setbacks that projects have faced over the past several decades, such as regulatory hurdles, limited funding, and geological challenges. Despite this, the geothermal industry in Canada is still growing as commercial projects in several provinces and territories continue to develop, while new projects are entering planning phases. Research in many fields of geothermal energy, such as direct heat use, co-production, Enhanced/Engineered Geothermal Systems (EGS), and more, is also very strong across universities and research groups. The continual increase in interest and drive to develop the industry shows strong promise as geological and energy conferences grow their focus on geothermal energy. This is a strong preparation for Calgary, Alberta to host the World Geothermal Congress in 2026.

Development of geothermal energy projects is especially critical since the announcement of the 2030 Emissions Reduction Plan which pledges to reduce emissions of 40% below levels from 2005 and reach net zero greenhouse gas emissions by the year 2050. This plan includes reducing emissions from oil and gas development, lowering energy costs for homes and buildings, and investing in renewable electricity. The Government of Canada plans to invest $600 million for renewable electricity support and grid modernization through the Smart Renewables and Electrification Pathways Program as well as $250 million to support predevelopment work of large-scale, clean electricity projects (Environment and Climate Change Canada, 2022).

The increasing need for renewable energy has in part driven companies and researchers to develop novel technologies, including geothermal energy systems that generate electricity and heat, collaborate with the oil and gas industry, and work with other existing renewables like solar and wind. As well, the variation in geology across the country, the population distribution, infrastructure, and climate lends itself to different requirements and needs. The country's 14 onshore geological provinces (plus 3 offshore) can be divided into orogens (which include mountain and volcanic belts), platforms (hosting sedimentary basins), and the Canadian Shield (Precambrian rock) (Figure 1). These provinces generally outline which technologies may be suitable for development.

This paper provides an overview of the geological provinces in Canada, outlines seven different geothermal classes, attributes which technologies are being used and could be used in each area, and provides examples of each class.

2. Regions and Provinces of Canada

Canada is comprised of 17 geological provinces based on their general rock type, age, and history (Geological Survey of Canada, 1981; Figure 2). The Canadian Shield, characterized by crystalline Precambrian rocks, includes seven geological provinces. Extending beyond the Canadian Shield are platforms where these Precambrian rocks are overlain by younger strata; these are known as the Interior, Arctic, Hudson, and St. Lawrence Platforms, and there are several sedimentary basins within them. At the western, northern, and eastern edges of Canada are the Cordilleran Orogen, Innuitian Orogen, and Appalachian Orogen, respectively. These geological provinces are comprised of mountains, volcanic belts, and other sequences that have undergone significant metamorphism, folding, faulting, and uplift. Finally, there are three continental shelves (not shown on Figure 1).

The use of varying classes of geothermal energy is dependent on many factors. Where favourable geology is present, population density plays a role. The population distribution map of Canada shows that the majority of the country's population lives within the Interior Platform, St. Lawrence Platform, Appalachian Orogen, and Cordilleran Orogen, which has led to progress of several conventional geothermal projects (applicable mostly in platforms or orogens) and ground source heat pumps (GSHPs) (Figure 2). Smaller populations within the Canadian Shield not only have geological challenges, but also limited infrastructure, requiring innovative solutions.

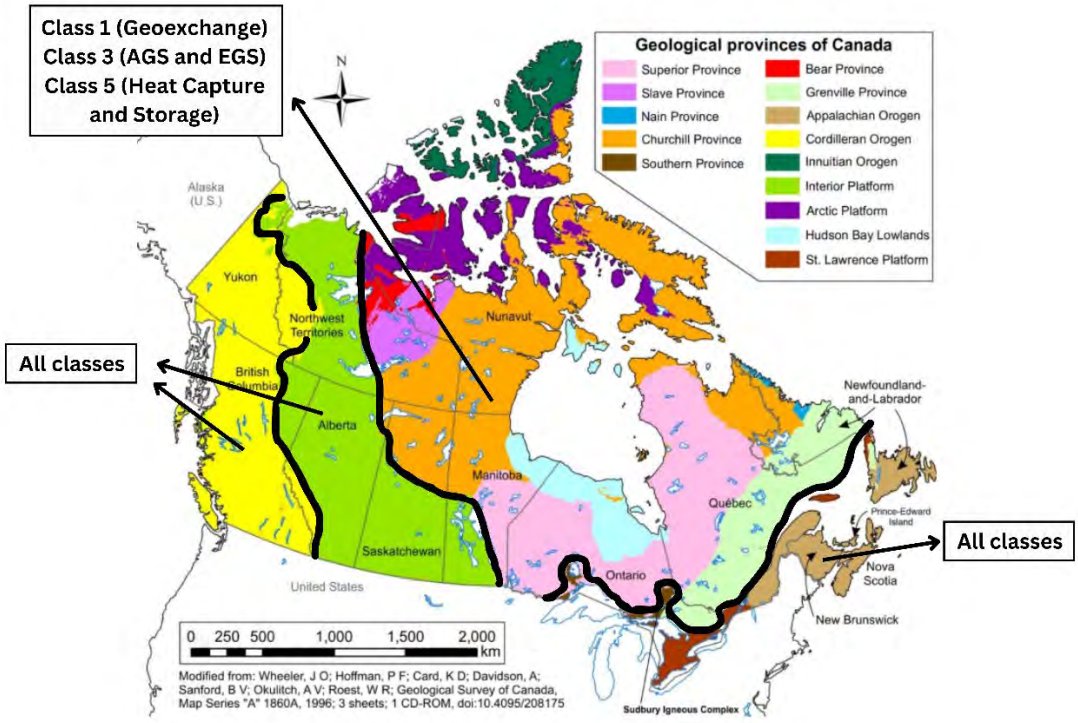

Figure 1: Geological provinces of Canada with suggestions of each geothermal class that could be developed in each (modified from Mercier-Langevin, 2017 and Wheeler et al., 1996).

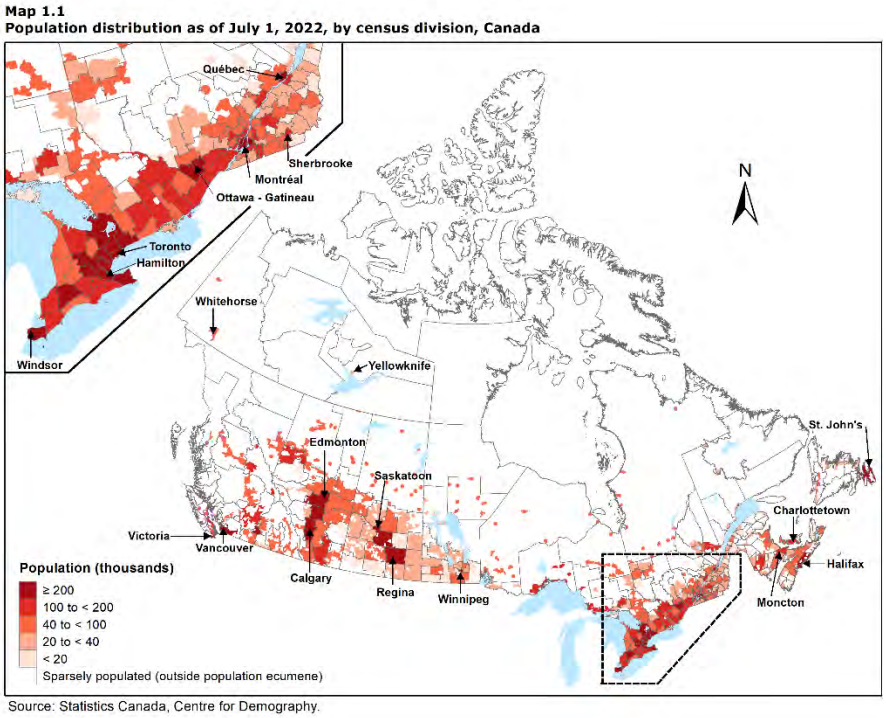

Figure 2: Population distribution map of Canada (Statistics Canada, 2022). The Canadian population reached 40 million in 2023.

3. Classes of Geothermal Systems

This paper divides the potential available geothermal systems into seven classes (Figure 3; Hickson and Smejkal, 2024). Class 1 utilizes the shallow ground/water as a battery for heating and cooling and is divided into 2 subclasses: Class 1 A: Ground Source Heat Pumps (GSHP) and Class 1 B: Shallow Subsurface Hydrological Systems. The most widely known system is Class 2: Conventional Geothermal, which uses a hydrothermal system. Class 3 encompasses 2 types of unconventional geothermal system technology. Unconventional systems are gaining traction in both research and utilization in many areas globally because they provide a solution to "geothermal anywhere". Class 3 systems are defined here as Advanced Geothermal System (AGS) and Enhanced Geothermal System (EGS). Both of these classes have also been referred to as Petrothermal Systems (Hickson et al., 2022) because they are well suited for reservoirs with insufficient permeability and/or fluid volumes for conventional geothermal. Class 4: Deep Borehole Heat Exchangers utilize similar technology to GSHP systems but are deployed down hole into deeper wells. Finally, Class 5 G: Heat Capture and Storage describes an emerging technology which use a subsurface reservoir for artificial heat storage much like those in Class 1, but is capable of storing excess heat at higher temperatures from other energy sources.

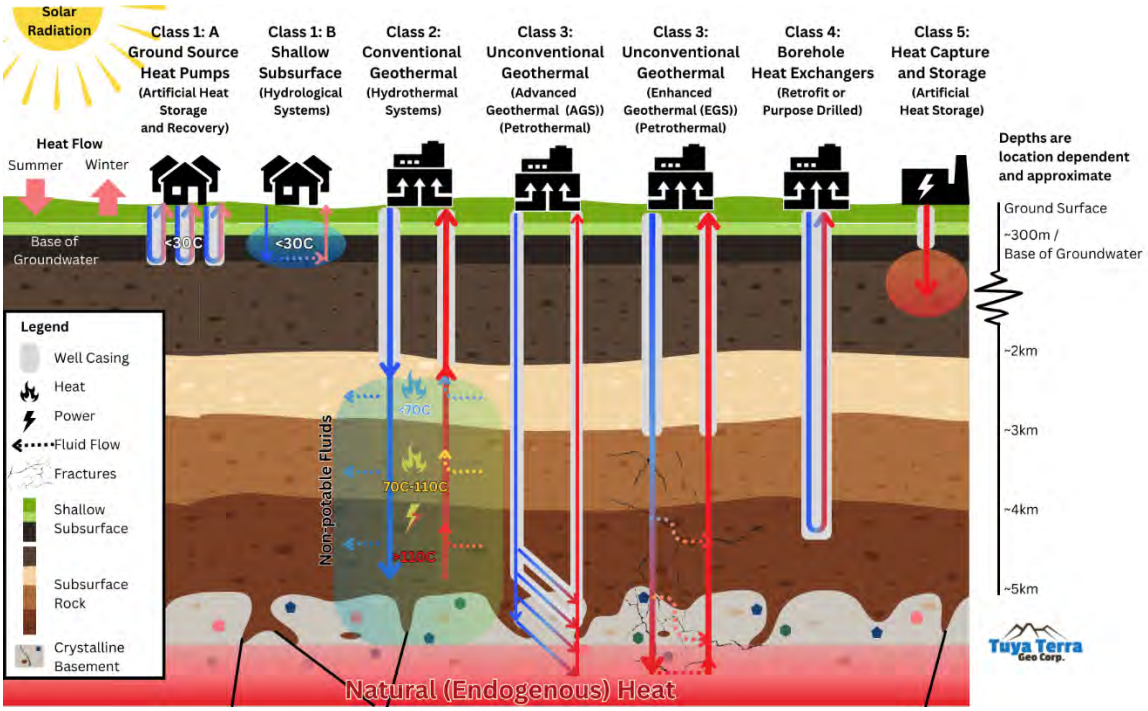

Figure 3: The 7 classes of geothermal systems that are described in this paper as possible solutions in various geological provinces and areas in Canada (Hickson and Smejkal, 2024).

3.1 Class 1: Ground Source Heat Pumps (Artificial Storage and Recovery)

3.1.1 Overview

Ground Source Heat Pumps (GSHP), also called GeoExchange®, are HVAC (heat, ventilation, and air conditioning) systems which use the ground temperature at shallow depths (generally above the base of groundwater) for heating and cooling. The technology extracts temperatures from the soil through closed-loop pipes, a borehole heat exchanger, and a ground source heat pump (Khodayar and Björnsson, 2024). These systems can also be used for artificial heat storage and recovery by storing heat in the shallow ground through heat pumps, then extracted at a later time (Khodayar and Björnsson, 2024).

3.1.2 Potential Areas in Canada

GSHPs can be used anywhere in Canada and have particular importance within the Canadian Shield where the geology limits use of other geothermal systems. However, permafrost zones in Canada's north create challenges for use of GSHPs due to permanently frozen ground and challenges balancing of the heat requirements in the winter months with the ability to store heat in the summer at shallow depths. In general, GSHPs can be easily utilized within the 'No Permafrost' zone (yellow-brown in Figure 4) and may be feasible within the permafrost zone by using heat augmentation and careful load balancing.

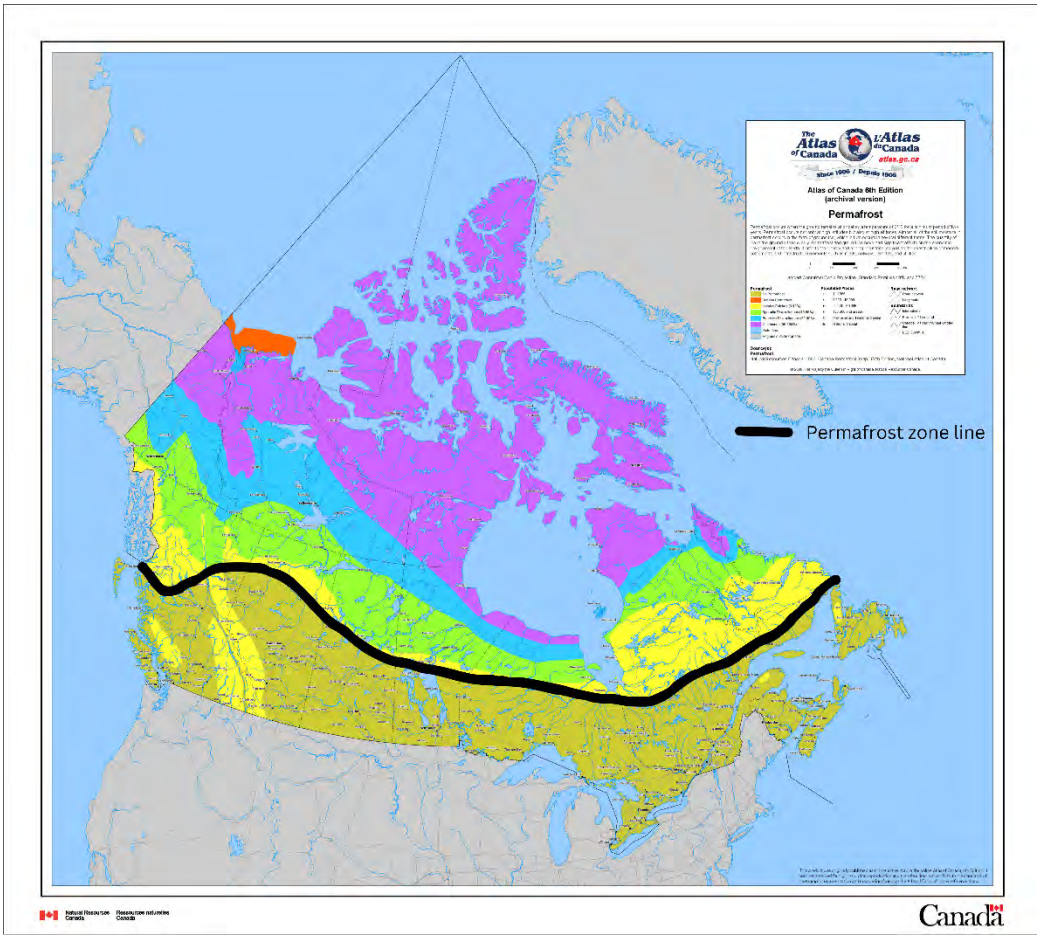

Figure 4: Canada's permafrost zones. The black line separates the zone of no permafrost (yellow-brown region) and zones of isolated patches, sporadic, and continuous permafrost zones to the north of the line. GSHPs can be used below this line but require heat augmentation for use to the north of the line (modified from Natural Resources Canada, 1993).

3.1.3 Examples

There are many GSHP operations in Canada. In Northern Quebec, within the Canadian Shield, the town of Kuujjuak has installed a 30-kW horizontal GSHP system for the community's swimming pool facility (Giordano and Raymond, 2020). A 240-m deep slim hole has also been drilled with the goal of installing a 145-m deep vertical closed-loop GSHP (Geothermal Solutions Inc, 2022). GSHP use is not limited to the Canadian Shield- in the St. Lawrence Platform, for example in Toronto and surrounding towns, GSHPs are becoming popular for district energy systems. The University of Toronto is constructing a large GeoExchange® system on its St. George campus for heating and cooling (University of Toronto, 2022). GeoExchange® systems are already constructed and utilized for select buildings at University of Toronto Mississauga and University of Toronto Scarborough campuses. Additionally, companies like Subterra Renewables partnered with Enercare Inc. plan to provide heating and cooling systems to homes in Canada through GeoExchange® systems.

3.2 Class 1:B Shallow Subsurface (Hydrogeological System)

3.2.1 Overview

Class 1 B systems are very similar to Class 1 A but instead of the ground being used to store heat captured by the GSHP, these systems utilize water sources at shallow depths such as aquifers, lakes, ponds, seas, or even flooded mines (Khodayar and Björnsson, 2024). Generally, these systems work more efficiently for cooling than heating, for example, Toronto's Deep Water Lake Cooling (DWLC) system, but are currently operational in Canada for both uses.

3.2.2 Potential Areas in Canada

In Canada, Class 1 B systems can be installed anywhere with shallow water sources with temperatures that remain relatively consistent throughout the year. They are not suitable for areas of permafrost, but there may be some limited energy gains using deep large lakes or ocean water. Deep mine shafts in areas of permafrost are also potential sources of energy (see below).

3.2.3 Examples

There are several operations in Canada which use shallow hydrogeological systems for heating and cooling. In Nova Scotia, which lies within the Appalachian Orogen, the abandoned coal mines of Springhill are flooded with approximately 4,000,000 m^3 of water. The system pumps this water to the surface (recovered at around 18°C) and through heat pumps where it is used for heating and cooling of many buildings in the nearby geothermal business park (Jessop, 1995; Saltwire, 2019).

Within the Canadian Shield, the City of Yellowknife, Northwest Territories is home to the Con Mine, an abandoned and flooded gold mine. A 2019-2021 study by the Northwest Territories Geological Survey concluded that the thermal energy within the water in the Con Mine contains thermal energy sufficient for heating and cooling buildings for several decades (Huang et al., 2024).

3.3 Class 2: Conventional Geothermal (Hydrothermal Systems)

3.3.1 Overview

Conventional geothermal (hydrothermal) systems utilize the heat and fluid from relatively deep in the earth to create electricity and/or for direct heat use. These systems require permeability and as such do not involve stimulation of the reservoir like EGSs (Khodayar and Björnsson, 2024). As well, conventional geothermal uses open loop technology, in contrast to Advanced Geothermal Systems (AGSs).

3.3.2 Potential Areas in Canada

Conventional geothermal energy production has potential in the sedimentary basins within Canada's platform provinces as well as in the Cordilleran Orogen through fault-hosted and volcanic settings. Several projects are being developed within the Interior Platform, while research is being conducted for potential within the St. Lawrence Platform. Potential for development within the Arctic Platform is also being assessed (Figure 1).

3.3.3 Examples

Conventional geothermal projects in the Interior Platform throughout British Columbia, Alberta, and Saskatchewan are pushing forward. Examples include the Deep Earth Energy Project (DEEP) in southern Saskatchewan that targets the Williston Basin. In the Western Canada Sedimentary Basin (WCSB), Alberta No. 1 near Grande Prairie, Alberta, and Tu Deh Kah outside Fort Nelson, British Columbia, are in various development stages. Near Swan Hills, Alberta, Futura Power has begun operations on their geothermal and natural gas co-production plant where geothermal energy powers approximately 30% of the 21 MWe power plant (Huang et al., 2024).

In the Arctic Platform, several studies have been conducted to assess the geothermal potential in Nunavut. In 2018, a feasibility assessment by the Qulliq Energy Corporation indicated that power could be produced within the sedimentary basins of the northern Arctic Islands (Minnick et al., 2018), but noted major data gaps that still must be addressed. In 2023, researchers from the University of Alberta assessed the potential for geothermal energy development in Resolute Bay and Cambridge Bay (both within the Arctic Platform) as data from oil wells drilled in the 50s and 60s suggest slightly higher than average temperatures; they also found that heat might be sufficient to generate electricity (The Weather Network, 2023). As all communities in Nunavut rely on diesel for power generation, geothermal energy could drastically change the territory's energy usage.

In the Cordilleran Orogen, Geoscience BC is studying the Kootenay Lake, British Columbia area for direct heat use potential within a deep-seated fault system. The 2023 summer and fall research phase found evidence of a geothermal reservoir of over 70 °C within the fractured rock (Geoscience BC, 2024). The Kitselas project is also assessing for potential for direct heat use near Lakelse Lake, British Columbia and has recently received funding. Within the Garibaldi Volcanic Belt of British Columbia, Mount Meager has seen multiple rounds of geothermal investigations, including drilling of several wells in the 1990s. These wells discovered high-temperature resources exceeding 250 °C but found that permeability was insufficient for economic geothermal energy production (Jessop, 2008; Witter, 2019; Grasby et al., 2022). The Garibaldi Volcanic Belt has recently been the focus of a geothermal study by GeoscienceBC, with Phase 1 focusing on developing methods to more accurately map high permeability zones in the reservoir (Grasby et al., 2022).

3.4 Class 3: Unconventional Geothermal (Advanced Geothermal (AGS), Petrothermal)

3.4.1 Overview

Unconventional geothermal describes systems that utilize technology to extract heat from the subsurface in geological settings that lack fluid and/or permeability. This paper describes two sub-classes of unconventional systems- Advanced Geothermal Systems (AGS), and Enhanced (or Engineered) Geothermal Systems (EGS). These systems have also been referred to as "petrothermal" (Hickson et al., 2022).

AGSs utilize long drilled wells that are connected and closed to the formation rocks into which they are drilled. Heat is extracted by proprietary fluids (working fluids) circulating through the radiator like system of connected wells. Heat is transferred by conductive heat transfer from the surrounding rocks into the working fluid (IRENA 2023). Because these systems rely on conductive heat transfer, long and/or many well bores are required which can increase drilling and total project

cost, however, they have the potential to successfully extract heat in almost any location globally, fulfilling the dream of “geothermal anywhere” (IRENA 2023).

3.4.2 Potential Areas in Canada

These systems are most efficient in areas of high rock conductivity, high heat flow and tight crystalline rocks that do not require casing or synthetic “rock pipe” to prevent escape of the working fluid. They can potentially be installed anywhere depending on how the technology develops and the investment limits. The deeper and cooler the system the more expensive the installation due to drilling costs. Within Canada, there is potential within the platforms and orogens where local permeability and fluid volumes are limited, and especially within the Canadian Shield where outcrop and subsurface is Precambrian granite.

3.4.3 Examples

Canada-based company, Eavor, has developed two AGSs- Eavor Loop 1 for sedimentary rocks and Eavor Loop 2 for igneous rocks. Eavor Loop 1 includes vertical production and injection wells drilled 50 – 100m apart to around 4.5 km depth. At this depth, the wellbores bend and 24 lateral wells are drilled to maximize surface area for conductive heat transfer (Khodayar and Björnsson, 2024). If the temperatures are high enough, water is circulated then heat is converted to power at the surface using an Organic Rankine Cycle (ORC); otherwise the system operates to provide thermal energy through a heat exchanger system. Eavor Loop 2 is very similar but the wellbores are drilled deeper to reach hotter temperatures. Their demonstration project for Eavor Loop 1 near Hinton, Alberta (in the Interior Platform) is operating at a thermal output of approximately 800 kWth (Huang et al., 2024; Toews et al., 2020).

3.5 Class 3: Unconventional Geothermal (Enhanced Geothermal (EGS), Petrothermal)

3.5.1 Overview

EGSs utilize stimulation, either by hydraulic, chemical, or thermal means, to increase the permeability of a geothermal reservoir (IRENA 2023). They are viable options in reservoirs with limited permeability and/or subsurface fluid. They generally require elevated temperatures but can be drilled very deep to access hot, deep rocks.

3.5.2 Potential Areas in Canada

Almost all areas in Canada are potentially viable for EGS development. There are reservoirs within the platform and orogenic provinces where subsurface temperatures are sufficient for conventional geothermal, but permeability in the target formations have been shown to be too low, such as in the Liard Basin of the Northwest Territories, which lies within the Interior Province (Huang et al., 2024). EGSs also have potential within the Canadian Shield if drilled deep enough. EGSs have advantages over AGSs in that they require significantly less drilling and thus have a much lower CAPEX compared to AGSs. However, the CAPEX for EGSs is still higher than conventional Class 2 systems. Currently there is significant research funding being directed towards these systems in jurisdictions such as the US as they are seen as the most likely solution to “geothermal anywhere”, notably, the Utah Frontier Observatory for Research in Geothermal Energy (FORGE) initiative.

3.5.3 Examples

U.S.-based company Fervo Energy has developed and tested an EGS technology which uses pairs of horizontal injection and production wells (Norbeck et al., 2023). In 2023, they announced the completion of “Project Red”, a 3.5 MW test plan in Nevada which now delivers power to the local grid (Fervo Energy, 2023). They have also begun development of a 400 MW power plant in Utah which plans to be operational by 2026 (Fervo Energy, 2024). In Canada, E2E Energy Solutions is planning to use a new technology called Enhanced Geothermal Reservoir Recovery System (EGRRS) to provide power and heat in the community of Rainbow Lake, Alberta, which lies within the Interior Platform. The EGRRS plans to combine conventional and EGS technologies by injecting the reservoir fluid into a deeper, stimulated reservoir to increase the temperature (E2E Energy Solutions, 2024). Utah FORGE, sponsored by the US Department of Energy, is an ‘underground field laboratory’ dedicated to developing and testing EGS technologies. The research and development initiatives are focused on basement fracture networks and how they can be initiated and sustained (Office of Energy Efficiency and Renewable Energy; Utah FORGE, 2024). The goal is to understand and develop EGS technologies and resources to make geothermal development possible anywhere.

3.6 Class 4: Borehole Heat Exchangers (Retrofit or Purpose Drilled)

3.6.1 Overview

Borehole heat exchangers are a part of GSHP systems, however, this class refers to installation of borehole heat exchangers in deep wells to extract the heat from circulating fluids. A borehole heat exchanger is comprised of a heat exchanger inside a borehole where fluids are heated up through conductive heat transfer from the rock and circulated. This is a closed-loop system that does not involve production of fluid to the surface (Toth, 2017). As well, they are drilled to shallower depths than conventional geothermal and generally only used for direct heat purposes. Two possibilities with this technology are to repurpose existing wellbores and/or to drill purposed-drilled new wells. The former option is attractive because it has the potential to utilize dry, unsuccessful or end-of-life wells, however, most existing oil and gas wellbores lack the diameter to allow for sufficient heat transfer.

3.6.2 Potential Areas in Canada

Deep borehole heat exchangers can be utilized almost anywhere with sufficient thermal conductivity and have high potential in areas with high heat flow. One example is in the Dehcho Region near Nahanni Butte, Northwest Territories in the Interior Platform, as the thin sedimentary cover overlaying the rocks of the Canadian Shield in the area make conventional geothermal development challenging, but its elevated heat flow suggests potential for deep borehole heat exchangers (Grasby et al. 2021; Smejkal et al., 2023).

3.6.3 Examples

One example of this developing technology is the GreenLoop Closed Loop Geothermal system, developed by Greenfire Energy, which consists of several closed-loop borehole pipes in a single well with various working fluids to produce either electricity or heat. Their 2019 field test in Coso, California indicated that their technology installed in an idle well could produce approximately 1.2 MWe (Scherer et al., 2023).

3.7 Class 5: Heat Capture and Storage (Artificial Heat Storage)

3.7.1 Overview

Class 5 describes a heat capture and storage system that creates an artificial reservoir to store excess heat from other energy sources for later use. In the cases of wind and solar power, the power would be stored as hot water or steam, then brought to the surface for electricity production when wind and solar are not producing (World Economic Forum, 2022). This emerging technology has potential to provide a storage solution for excess wind and solar energy as Canada looks to decarbonize its grid with intermittent renewable power sources.

3.7.2 Potential Areas in Canada

In Canada, heat capture and storage systems can be used anywhere that there is excess heat and/or power production. Based on results of pilot projects and new studies (described below), there is potential for storage in EGS reservoirs and depleted oil and gas reservoirs.

3.7.3 Examples

Vantaa Energy is planning the construction of an innovate heat storage system in Finland. The project plans to build underground caverns to store hot water. When renewable electricity production is cheap or production is in excess of load, it will power electric boilers to heat water which will then be stored in the underground caverns (pv magazine, 2024).

U.S.-based company Sage Geosystems has developed a system called EarthStore™ for heat capture and storage. The pilot project in Texas involved initially creating a large vertical reservoir (over 3 km deep) using fracturing technology then pumping and storing water in the 3,200-foot vertical reservoir deep underground using its novel fracturing technology. Demonstrating long-term and short-term storage capabilities, the pilot produced 200 kWe for over 18 hours and 1 MWe for 30 minutes (Sage Geosystems, 2023).

In 2023, the National Renewable Energy Laboratory (NREL) announced a new project to evaluate the potential of heat capture and storage systems. This will involve a case study to assess using depleted oil and gas reservoirs for solar thermal storage in California, and another case study for storage of excess wind power into water reservoirs in Texas to explore using legacy oil/gas reservoirs with solar thermal hybridization in California (NREL, 2023).

4. Conclusions

The increasing global demand for renewable energy has birthed innovations within geothermal energy systems, making geothermal energy production possible in reservoirs with limited permeability, low heat flow, and inadequate fluid volume. Geothermal energy is a viable solution to help meet Canada's emissions reductions goals, however, unconventional methods must be considered for energy production within many of the country's geological provinces. The seven different classes of geothermal systems described in this paper include two types of shallow, GeoExchange® systems (GSHPs and hydrological systems; Class 1), conventional geothermal (Class 2), two types of unconventional systems (AGS and EGS; Class 3), borehole heat exchangers (Class 4), and heat capture and storage (Class 5). While many areas within Canada's interior platform and orogenic provinces host reservoirs capable of producing conventional geothermal

energy (in both sedimentary basins and fault-hosted volcanic systems) at lower cost, the geology of the rest of the country lacks one or more of permeability, heat flow, and fluid volume. In the Canadian Shield, where Precambrian rock outcrops, geothermal energy production is possible through AGS, EGS, GeoExchange®, and heat capture and storage, although environmental implications in zones of permafrost must be considered for GeoExchange®.

ABSTRACT

Geothermal power generation started at Lardarello, Italy in 1904, resulting in the first commercial plant of 250 kW being installed in 1913. New Zealand came on-line in 1958 with a 1.2 MWe plant at Wairakei followed by Mexico in 1959 with a 3 MWe plant at Pathe. The first plant in the USA was at The Geysers in northern California at 11 MWe in 1960. All these plants were of the flash steam type. The first binary power plant was at Paratunka, in Kamchatka, Siberia, Russia (1967), followed by binary plants in Japan and Iceland in 1966, and China in 1970. Today (2023), 29 countries produce electricity from geothermal resources for a total estimate of 18,000 MWe generating 108,000 GWh of electricity. Geothermal direct use is one of the oldest, most versatile, and most common forms of utilizing geothermal energy. Direct use has been documented for over 2000 years throughout the world. Today (2023), it is estimated the installed capacity is 126,000 MWt and the annual energy use is 1,280,000 TJ (355,600 GWh) in over 88 countries. The average worldwide capacity factor over the past 25 years for direct use is 0.327, indicating 2,866 full-load equivalent capacity hours per year. Direct uses include bathing and swimming, space heating including district heating, greenhouse and aquaculture pond heating, industrial applications, and snow melting and cooling. Geothermal (ground-source) heat pumps using ground or ground-water temperatures between 5 and 30 degrees C for both heating and cooling are found throughout the world and are the largest direct use application. The leading countries for geothermal direct use are China, United States, Sweden, Germany, Turkey, France, Japan, Iceland, Finland, and Switzerland (>2000 MWt). In summary, lower temperature resources (<90 degrees C) are becoming more economical for greenhouses, aquaculture and drying aquacultural products such as fruit and

vegetables. Lower temperatures are now possible down to 90 degrees C for power generation with units less than 1 MWe becoming economical. Geothermal heat pumps are becoming more popular and economic with over 6.5 million units presently installed worldwide.

1. Introduction

This paper presents a review of world-wide applications and uses of geothermal energy for both electric power generation and direct utilization, including geothermal (ground-source) heat pumps, for the last 25 years (1995-2020). These data are summarized from world geothermal congresses (WGC) held every five years. These include chronologically, congresses held, in Italy, Japan, Turkey, Indonesia, Australia, and Iceland. The data included in this paper for 2020 are from 88 countries/regions; however additional areas most likely exist, but unfortunately have not been documented. We have estimated the data for 2023. See Table 1 for data from 1995 to 2023.

Table 1: Summary of geothermal capacity of production 1995-2023

Year	Installed Electric Capacity MWe	Produced Electric Energy GWh/yr	Installed Thermal Capacity MWt	Produced Thermal Energy TJ/yr
1995	6.832	38,035	8,664	112,441
2000	7,972	49,261	15,145	190,699
2005	8,933	55,709	28,269	273,372
2010	10,897	67,246	48,493	423,830
2015	12,635	73,549	76,885	592,638
2020	15,950	95,098	107,727	1,020,887
2023*	18,000	108,000	126,000	1,280,000

*Estimated

The resource temperature along with a sustainable flow rate and fluid chemistry will determine the best and most economical use of the resource. The following temperatures are general guidelines for the use of a geothermal resource. However, for these cases the temperature range can vary depending on the location.

- >175°C (350°F) – dry steam and flash steam electric power generation
- 100 to 175°C (212 to 350°F) - binary electric power generation
- 100 to 150°C (212 to 300°F) – industrial process heating/cooling
- 60 to 100°C (140 to 212°F) – space heating
- 30 to 60°C (90 to 140°F) – greenhouse and aquaculture pond heating
- 5 to 30°C (40 to 90°F) - geothermal (ground-source) heat pumps

2. Geothermal Electric Power Generation

The first geothermal power generation was from a reciprocating steam engine powered by geothermal steam at Larderello, Italy on 4 July 1904 under the supervision of Prince Piero Ginori Conti. It lit four light bulbs. By 1905 the power had been increased to 20 kWe and the first commercial power plant of 250 kWe was built there in 1913. By 1916 it distributed 2,750 kWe of electricity to the surrounding cities. Italy was the world's only industrial producer of geothermal electricity until 1958.

In 1958 New Zealand became the second country to produce geothermal electricity at Wairakei on North Island using wet steam to generate 11.2 MWe. This was followed by the first geothermal power plant in Mexico at Pathė, Acambay in 1959 at 3 MWe. In the USA, Pacific Gas and Electric began operation of the first geothermal power station in the country located at The Geysers in northern California in 1960 at 11 MWe.

The first binary cycle power plant was demonstrated in 1967 at Paratunka, in Kamchatka, Siberia, Russia at 750 kWe. Binary geothermal power was introduced in the USA in 1981 at Heber in southern California at 45 MWe. These were followed by geothermal binary plants in Japan and Iceland in 1966 and China in 1970. These plants use a secondary working fluid, a hydrocarbon, heated by low temperature geothermal fluid producing a vapor used to turn the generator for electricity (Figure 1).

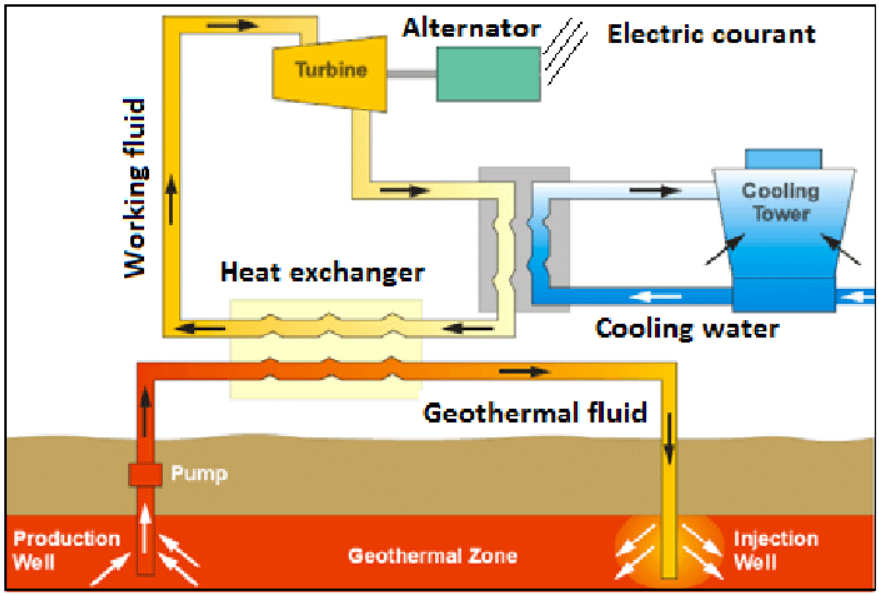

Figure 1: Binary power cycle diagram.

In 2020, 29 countries produced electricity 95,098 GWh/yr from geothermal resources, from an installed capacity of 15,950 MWe. From 2015 to 2020 geothermal electricity had the highest growth rate compared to other periods, amounting to 26.2% in MWe and 29.3% in GWh/yr. By 2023, it is estimated that geothermal power and generation has increased to 108,000 GWh/yr and 18,000 Mwe and 108,000 GWh/yr. See Table 2 for a summary of data from 2020 for countries producing greater than 100 MWe.

Table 2: Installed and generating capacity for geothermal worldwide >100 MWe in 2020

Country	MWe	GWh/yr
USA	3,700	18,366
Indonesia	2,289	15,315
Philippines	1,918	9,893
Turkey	1,549	8,168
Kenya	1,193	9,930
New Zealand	1,064	7,728
Mexico	1,006	5,375
Italy	916	6,100
Iceland	755	6,010
Japan	550	2,409
Costa Rica	262	1,559
El Salvador	204	1,442
Nicaragua	159	492
Total*	**15,950**	**95,098**

*29 countries

Electricity produced is a better measure of the geothermal contribution than installed capacity, since geothermal plants usually operate at a higher capacity factor, around 95%, than other types of power plants. Unfortunately, geothermal energy only contributes less than 0.4% of the world's electricity.

3. Geothermal Direct Utilization

Direct utilization (direct use) of geothermal energy is one of the oldest, most versatile, and most common form of utilizing this resource (Dickson and Fanelli, 2003/2013). The early history of geothermal direct use was reviewed from over 25 countries in: *Stories from a Heated Earth – Our Geothermal Heritage* (Cataldi et al., 1990). The information presented here is based on country update papers submitted to the various World Geothermal Congresses that are held every five years from 1995 to 2020. Data has been estimated to 2023 by the authors. The number of countries reporting direct use has increased from 28 in 1995 to 88 in 2020. The thermal capacity and produced thermal energy in these years have increased from 8,664 MWt and 112,441 TJ/yr to the present figure of 107,727 MWt and 1,020,887 TJ/yr (283,580 GWh/yr) with annual increases of 10.61% and 9.23% respectively. This is estimated to have increased by 2023 to 126,000 MWt and 1,280,000 TJ/yr. The average worldwide capacity factor over the past 25 years is 0.327, indicating 2,866 full-load equivalent capacity hours per year. More detailed information on geothermal direct use can be found in *Geothermics Volume 90* by Lund and Toth, 2021.

The authors have relied on country update reports from World Geothermal Congress (1995-2020), as well as from five *Geothermics* publications (Lund and Freeston, 2001; Lund et al., 2006; 2011; Lund and Boyd, 2016; Lund and Toth, 2021) along with reports from the European Geothermal Congresses in 2007, 2013, and 2019, together with information gained from personal communications.

The worldwide leaders in direct use of geothermal energy including geothermal heat pumps for 2020 are shown in Tables 3 and 4. Tables 5 and 6 show data by various categories and by regions.

Table 3: Leading countries in 2020 in terms of installed capacity including geothermal heat pumps (>2,000 MWt)

Country	MWt	Major uses
China	40,610	Bathing, district heating
United States	20,713	Heat pumps, bathing
Sweden	6,680	Heat pumps, district heatings
Germany	4,806	District heating, heat pumps
Turkey	3,488	District heating, bathing
France	2,597	Heat pumps, district heating
Japan	2,570	Bathing, heat pumps
Iceland	2,373	Bathing, district heating
Finland	2,300	Heat pumps
Switzerland	2,197	Heat pumps, space heating

Table 4: Leading countries in 2020 in terms of annual energy use including geothermal heat pumps (>12,000 TJ/yr)

Country	TJ/yr	Major uses
China	443,492	Bathing, district heating
United States	152,110	Heat pumps, bathing
Sweden	62,400	Heat pumps, district heatings
Turkey	54,584	District heating, bathing
Iceland	33,598	Bathing, district heating
Japan	30,723	Bathing, heat pumps
Germany	29,139	District heating, heat pumps
Finland	23,400	Heat pumps
France	23,280	Heat pumps, district heating
Canada	14,512	Heat pumps, bathing
Switzerland	13,292	Heat pumps, space heating
Norway	12,610	Heat pumps

Table 5: Summary of direct use by various categories for 2020

Utilization	Capacity MWt	Utilization TJ/yr	Capacity Factor
Geothermal heat pumps	77,547	599,981	0.245
Space heating/district heating	12,768	162,979	0.405
Bathing and swimming	12,253	184,070	0.472
Greenhouse heating	2,459	35,826	0.462

Total	**107,627**	**1,020,897**	**0.300**

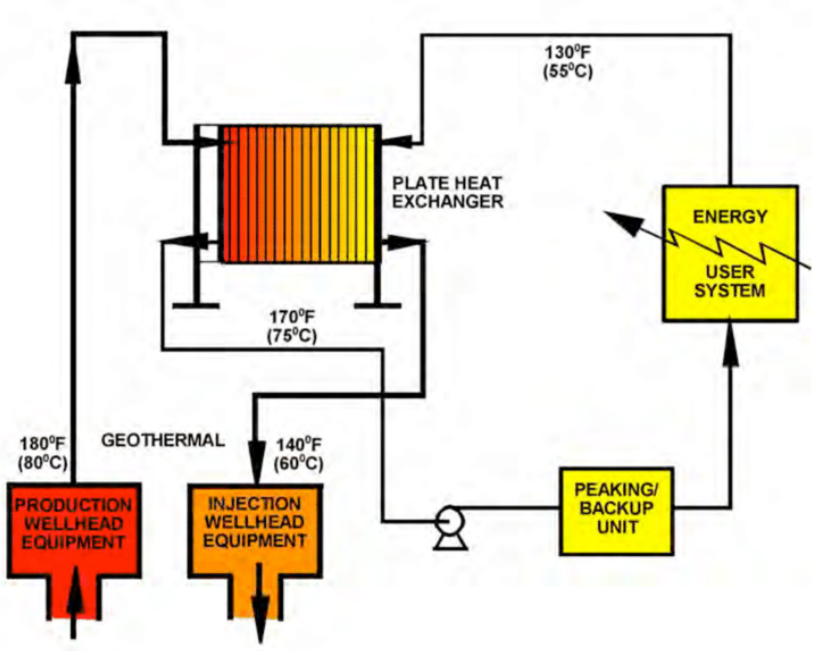

Figure 2. Geothermal direct use diagram.

Table 6: Summary of direct use data worldwide by region and continent for 2020 (Indicates number of countries)

Region/Continent	MWt	TJ/year	GWh/year	Capacity
Africa (11)	198	3,730	1,036	0.597
Americas (17)	23,330	180,414	50,115	0.245
Central America and	9	195	54	0.687
North America (4)	22,700	171,510	47,642	0.24
South America (8)	621	8,709	2,419	0.445
Asia (18)	49,079	545,019	151,394	0.352
Commonwealth of	2,121	15,907	4,419	0.238
Europe (34)	32,386	264,843	73,568	0.259
Central and Eastern Europe	3,439	28,098	7,805	0.259
Western and Northern	28,947	236,745	65,762	0.259
Oceania (3)	613	10,974	3,048	0.568
Total (88)	**107,727**	**1,020,887**	**283,580**	**0.300**

Based on data from the European Geothermal Congress (EGC) (Sanner et al, 2022), the geothermal power generation capacity of the 32 European countries, totaled about 3,496 MWe, while the geothermal heating from medium to low temperature sources exceeded 11,600 MWt. About half of that is used for district heating. Regarding shallow geothermal energy, including ground source heat pumps (GSHP) and Underground Thermal Storage (UTES), direct use capacity of at least 30,300 MWt was achieved by the end of 2021, distributed over about 2.1 million installations. In Europe, Turkey is a new leader, having very dynamic developments with 17 geothermal district heating systems in operation serving the equivalent of 116,000 residents. There are also six major greenhouse areas covering 4.3 million square meters, mainly growing tomatoes, most of which are sold internationally. In addition, twenty million local and 20,000 foreign visitors annually enjoy the balneological uses of Turkey's geothermal waters.

The former Soviet Union dominated countries in eastern Europe, comprising of Bulgaria, the Czech Republic, Hungary, Lithuania, Macedonia, Poland, Romania, Servia, Slovakia, Slovenia, and Ukraine, have never been energy independent. They have always had to import the energy they needed, mainly from Russia. Thus, these countries' overall energy consumption has dropped to levels not seen since the 1970s due to lack of funding and leadership. However, more recently, the shallow geothermal direct use sector has grown steadily, but very slowly in Eastern Europe with Poland in the lead. Hungary has shown some strong direct use development, especially in the district heating and agricultural sectors. A summary of the former Soviet Union countries in eastern Europe using ground source (geothermal) heat pumps is based on the Summery of EGC 2022 Country Update Reports on Geothermal Energy in Europe by Sanner et al, 2022. It is shown in Table 7.

Table 7: Ground Source Heat Pumps use in the leading former Soviet Union Countries in 2022 (Sanner et al, 2022)

Country	Number GSHP	Capacity MWt	Production GWh/yr
Poland	78,480	900	1,200
Czech Republic	22,740	320	472
Slovenia	14,818	237	329
Lithuania	10,647	140	314
Hungary	7,353	81	161
Slovakia	10	2	14

Serbia	2,850	53	117
Macedonia	1,000	3	21
Romania	600	40	100
Bulgaria	n/a	n/a	1,174

4. Summary and Conclusions

Although the number of countries now using geothermal energy to generate electricity is still small in comparison to the many countries that use geothermal resources for direct use such as for space and district heating, agricultural, aquaculture, and industrial processes, there are new nations producing geothermal electricity since 2015. These include Belgium, Chile, Honduras, and Hungary. By 2023 we may see small geothermal power on-line in Argentina, Australia, Canada, China, Dominica, Ecuador, Greece, Iran, Montserrat, Nevis, Saint Lucia, Saint Vincent, and Taiwan. In the East African Rift Zone, Malawi, Rwanda, Tanzania, and Uganda, are also trying to bring electric plants on-line. In the last five years, there has also been increased attention shown to the possibility of developing Engineered Geothermal Systems (EGS) to tap the vast thermal energy resources trapped in rocks of low natural permeability. This work is proceeding in the USA, Iceland, Great Britain, Germany, China, Portugal, Denmark, and The Netherlands.

Overall, it appears that the initial, high-risk phases of new and expanded uses of geothermal resources are being funded by federal government agencies, quasi-federal entities, and international multilateral lending banks rather than private industry. Turkey, the Philippines, and the USA appear to be the only exception to this trend. The early-stage involvement of public funds is a way to mitigate the risks perceived by private investors. Once suspected resources have been discovered, characterized and, their extent preliminarily delineated, projects can be transferred to the private sector for the necessary confirmation, development and production as the risk has been reduced.

The countries that stand out as major producers and consumers of geothermal fluids for direct use are listed in Table 3. In most countries, however, development has been slow as fossil fuels are a major competitor. Another obstacle is the high initial investment costs for geothermal projects. Countries where geothermal direct use provides a significant contribution to their energy needs are summarized in Table 8. The distribution of geothermal use by continent is shown in Table 9, indicating that Asia and Europe are the leaders, with 57 of the 88 countries reporting that they provide 77.5 % of the world's installed capacity (MWt) and 80.8% of the direct uses (TJ/yr).

Table 8: Significant contributions of direct use geothermal energy to a country's economy

Iceland	90% of buildings space heated
Japan	2,000 onsens, 5,000 public baths, 1,500 hotels serving 15 million guest/year
Sweden	40% of buildings heated using geothermal heat pumps
Switzerland	110,000 geothermal heat pumps installed (~3.7 units/sq. km)
Tunisia	244 ha of heated greenhouses
Turkey	116,000 apartments/residences heated in 17 cities
USA	Approximately 1.685 million geothermal heat pumps (4.0% growth/year)

Table 9: Distribution of direct use geothermal energy utilization by continent

Continent	Countries	%MWt	%TJ/year
Africa	11	0.2	0.4
Americas	17	21.7	17.7
Asia	19	45.6	53.4
Europe*	38	31.9	27.4
Oceania	3	0.6	1.1

* Includes CIS Countries (Georgia, Russia and Ukraine)

With the increased interest in geothermal deep drilling for direct use and ground-source heat pumps, it is now evident that geothermal energy can be developed anywhere for both heating and cooling. Heat pumps now make up 72.0% of the installed capacity (MWt) and 58.5% of the annual energy use (TJ/yr). This use has increased since 2015 by 54% of installed units reported. Low-to-moderate temperature geothermal resource are also being used in combined heat and power plants (CHP), where hot water, often with temperatures below 100^{o}C, is first run through a binary (organic Rankine cycle) power plant, then cascaded for direct uses, before being injected back into the aquifer. GHP projects can maximize resource use, while improving the return on investment. This has been shown in Iceland, Austria, Germany, as well as on the Oregon Institute of Technology Campus in the USA.

Approximately US$ 22.262 billion was reported as invested in geothermal energy by 53 countries during the period 2015-2019 for both electric power (64%) and direct use (36%). The average was US$ 420 million per country, with countries investing over US$ 500 million being Indonesia, Turkey, China, Taiwan, Kenya, Republic of Korea, Mexico, Chile, and Italy (in descending order). Investments were 27.9% for electric power utilization in 16 countries, 15.4% for direct use in 30 countries, 32.4% for field development including production drilling and surface equipment in 33 countries, and 24.3% for R&D including surface exploration and exploratory drilling in 47 countries. The following are the percentages of the worldwide geothermal investments and funding by continents (total US$22.262 billion). The world summary by country of ground source (geothermal) heat pumps ≥ 15.000 units are shown in

Table 10. A total of 54 countries/regions report using geothermal heat pumps, with a average unit size of 12 kW.

- 6.3% in Africa by 7 countries (US$1.412 billion)
- 10.2% in the Americas by 11 countries (US$2.275 billion)
- 74.2% in Asia by 11 countries (US$16.506 billion)
- 8,7% in Europe by 22 countries (US$1.926 billion)
- 0.6% in Oceania by 2 countries (US$0.143)

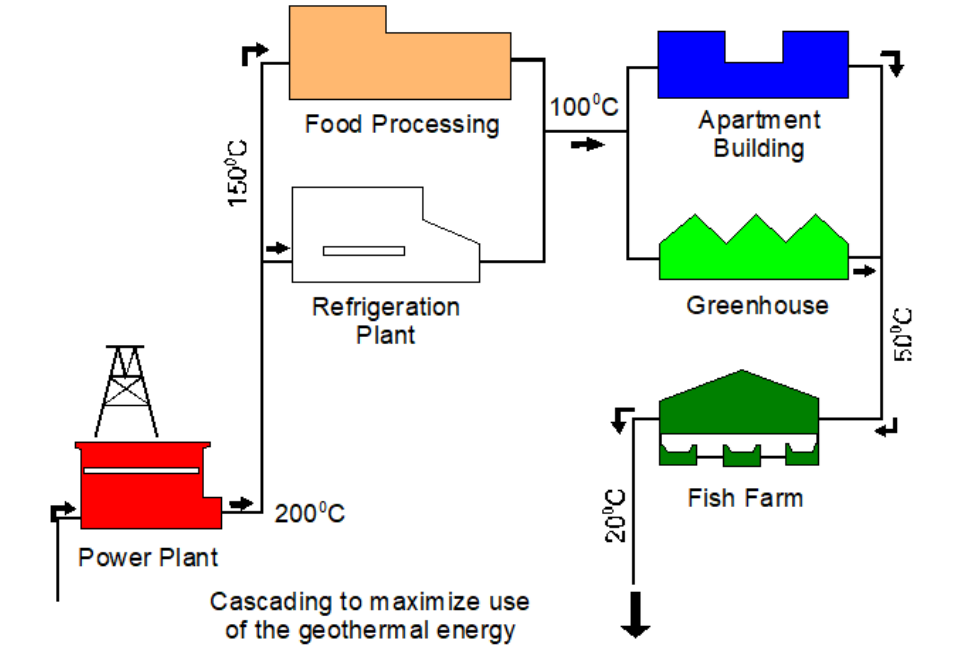

Figure 3. Cascading of geothermal power and direct use.

Table 10: Worldwide leaders in geothermal (ground-source) heat pumps in 2020 (≥15,000 units)

Country	Units	MWt	TJ/yr	GWh/yr	L.F.
United States	1,686,000	20,230	145,460	40,406	0.23
China	1,000,000	26,450	246,212	68,392	0.30

Austria	15.000	1,000	6,309	1,752	0.20
Worldwide total	**4,608,261**	**70,557**	**570,872**	**158,574**	**0.23**

As oil and gas supplies dwindle and increase in price, geothermal energy becomes a more economically viable alternative energy source. Even though the initial cost of developing a geothermal resource is high (exploring, drilling well, constructing pipelines and plants), the long-term cost is low. Compared to 2015, geothermal direct use has doubled its contribution to the world's annual energy mix from about 0.13 to 0.27%. As geothermal energy becomes more competitive with fossil fuels, especially if carbon penalties are applied to the price, and the environmental benefits are better understood and accepted, development of this natural "heat from the earth" should accelerate. An important task for all of us in the geothermal community is to spread the word about geothermal energy, its various applications, and the many environmental benefits that can accrue from its use.

5. The Future of Geothermal Energy.

Geothermal energy use is trending as follows (Lund et al., 2006, 2021).

- Lower temperature down to 90°C is now possible for economic power generation
- Electrical units less than 1 MWe becoming economical.
- Lower temperature resources can be made economical such combined uses as:
  - power generation and space heating
  - power generation and industrial applications
- Lower temperature resources <90°C, are becoming more economical for green-houses, aquaculture, and drying agricultural products such as fruit and vegetables.
- Geothermal ground-source heat pumps are becoming more popular and economic with over 6.5 million units presently installed worldwide. These units provide both heating and cooling and only need a 5° to 30°C temperature resource, which are typical ground temperatures in most of the world.

country update Türkiye

ABSTRACT

This paper provides a comprehensive overview of the geothermal energy landscape in Türkiye on the occasion of the 100th anniversary of the Turkish Republic. The study examines the country's progress and internationally recognized applications in geothermal energy, highlighting key milestones and the impact of the founding vision that underscores the central role of geosciences in economic development. The use of legislation and feed-in tariff mechanisms to promote the use of indigenous energy resources is discussed in the context of cause-and-effect relationships, highlighting the dynamics of geothermal development.

MTA (The Institute of Mineral Research and Exploration) started geothermal exploration in Türkiyein the 1960s. From the drilling of the first geothermal well in 1963 to the centenary celebration in 2023, Türkiye has made its name in the global rankings and secured a pioneering position in the field. There are currently over 2000 thermal springs and wells, with drilling depths of up to 5 km, and direct use applications have resulted in 6300 MWt. This includes district heating (1422 MWt), greenhouse heating (2417 MWt), heating for thermal facilities, hotels, etc. (680 MWt), balneological use (1763 MWt), agricultural drying (9.5 MWt), cooling (0.35 MWt) and geothermal heat pump applications (8.5 MWt). The total installed capacity has reached 1710 MWe and the carbondioxide that is produced is used in the production of 400,000 tonnes of dry ice per year.

In 1982, the first Turkish-Italian seminar on geothermal energy was held. The first geothermal electricity was produced in 1984. In 1999, the Izmir-Balçova geothermal heating system was

selected as a best practice by the European Geothermal Energy Council (EGEC). The World Geothermal Congress (IGA-TGA) was held in 2005 and the European Geothermal PhD Days were held in Türkiye for the first time in February 2020. In April 2023, with the inauguration of the first geothermal-solar hybrid power plant, Türkiye has reached another significant milestone, demonstrating its commitment to innovative and sustainable energy solutions as it looks to the future.

1. **Introduction**

Geothermal is a domestic, renewable, environmentally friendly, base-load resource with multiple integrated uses such as electricity generation, district heating, greenhouse heating, spa and thermal tourism, liquid CO_2 and dry ice production, fruit and vegetable drying, production of various minerals, and aqua fishing. It is technically and economically attractive. If appropriate technology is used and reinjection is carried out, there is no discharge of uncondensed gas.

In Türkiye geothermal areas are mainly located along the main grabens in Western Anatolia, along the North Anatolian Fault Zone, and in volcanic regions in Central and Eastern Anatolia (Figure 1).

The utilization of geothermal potential in Türkiye extends far beyond the foundation of the Republic. For example, the ancient city of Hierapolis, recognized as a UNESCO World Heritage Site, was spa town and the use of geothermal resources here dates to the Roman Empire. In these lands, geothermal resources were used by Hittites, Romans, Seljuks, Ottomans and Turks for health and cooking purposes in BC and AD, and some of them were built spas, some of which are still in use. This study focuses on the utilization of geothermal resources in the first hundred years of Turkish Republic starting from 1923 to 2023.

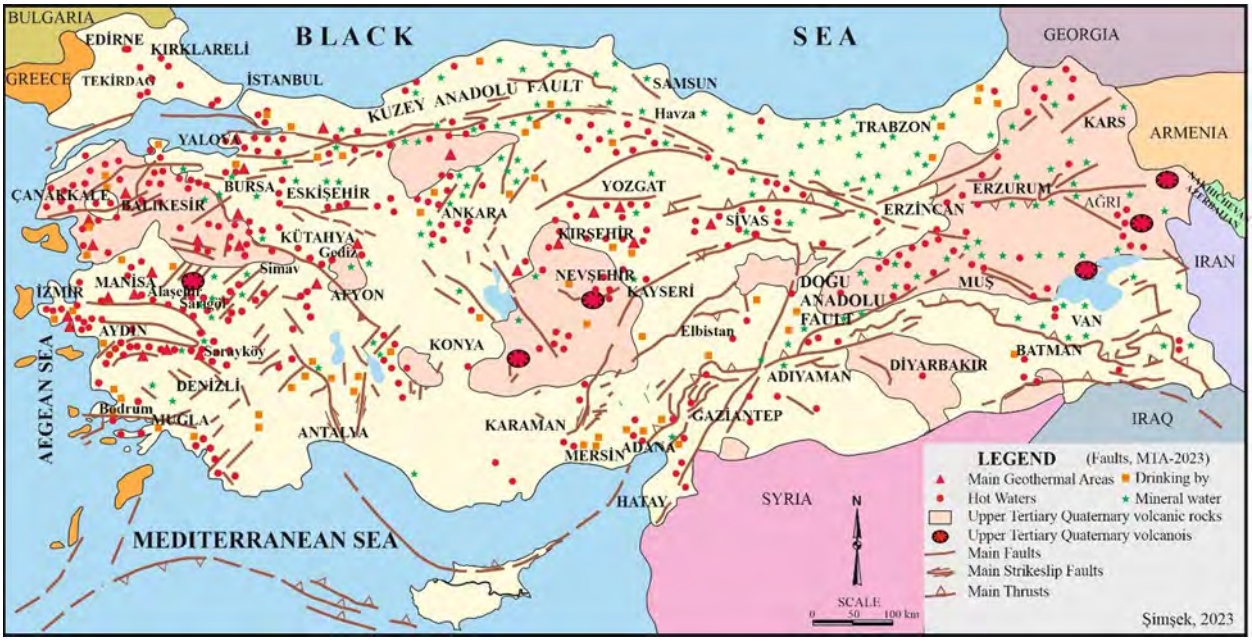

Figure: Türkiye map showing the main geothermal sites with main neotectonic lines, hot spring distribution, and volcanic areas (Şimşek, 2023).

2. Past

In the early years of the Republic, geothermal hot springs were used for spa, treatment and health purposes. The first law on the exploitation of hot springs was passed in 1926, just three years after the foundation of the Turkish Republic, reflecting the founder's vision of the vital role of earth sciences. This foresight led to the establishment of the Institute of Mineral Research and Exploration (MTA) in 1935, when the Republic was only 12 years old. The vision also included sending the country's youth abroad for higher education and training cadres with a strong belief in science (Law No. 1416). The MTA, as one of the institutions employing these cadres, carried out surveys and inventory studies throughout the country.

In some regions, natural springs continued to be used in traditional spas, and in the 1970s they were also used for simple greenhouse heating. The first geothermal borehole was drilled by MTA in 1963 in Izmir-Balcova. The well-bottom temperature of the 40-meter deep well was measured at 124°C. The well was in production for a few days but was closed due to scaling and then abandoned as it was considered unviable.

In 1968, with the financial and technical support of the United Nations, drilling was started in the Denizli Sarayköy-Kızıldere geothermal field as part of the geothermal exploration for electricity generation under the United Nations - UNDP project of MTA. A 200ºC reservoir was discovered and 2-decare geothermal greenhouse was heated as a pilot application. A 0.5 MWe pilot geothermal power plant was designed, built and commissioned using MTA facilities. Fundamental information and experience on geothermal scaling, corrosion, non-condensable gases (NCG), etc. were gained from this power plant. This power plant provided free electricity to the villages of Kızıldere, Karatas and Savcılı for 7 years. The work carried out at these stages are all exploration investments and geothermal services of MTA.

In the following years, exploration and drilling continued and in the light of these developments, the first commercial power plant with a gross capacity of 20 MWe was established by the Turkish Electricity Authority (TEK in Turkish initials) in 1986. Subsequently, an integrated liquid carbon dioxide-dry ice (CO_2) factory was established by the private sector. This factory cleaned and liquefied the carbon dioxide released into the air by the geothermal power plant and distributed it all over Türkiye. In those years, this factory was a first in the world. Today, its total capacity is 400.000 tonnes/year.

Subsequently, MTA carried out geothermal survey and exploration drillings in hundreds of places such as Afyonkarahisar, Gönen, Simav. In 1983, the downhole heat exchanger was applied in Izmir-Balcova and the heating of Dokuz Eylül University hospitals, campus and thermal facilities was provided. It paved the way for the heating of Afyonkarahisar city centre by conducting heat exchanger tests. In 1974, a 1000m deep well was drilled in Afyonkarahisar. Under the conditions of the time, 1000m was an important depth for geothermal energy.

In addition to electricity generation, district heating, central heating, CO_2 production, the use in spas and thermal facilities has gained momentum and the first 5-star thermal touristic facility of the private sector was established in Afyonkarahisar. Gönen became the first town geothermally heated in 1986 and it was followed by Simav, Kırsehir, Balcova, Narlıdere, Edremit, Kızılcahamam, Kozaklı, Sarayköy, Sandıklı and Bigadic. District heating has been achieved using 55-60°C geothermal fluids and this has had a global effect. In 1999, İzmir-Balcova geothermal

heating system was selected as the best practice by the European Geothermal Energy Council (EGEC). District heating has been an investment that has made great contributions to the benefit of the people, the environment and raising the standard of living. However, it has slowed down after the 2000s.

The Turkish Geothermal Association (TGA), which was established in 1992, has organized congress and conference trips to various countries of the world such as Germany, France, Italy, Japan, Japan, USA, Iceland for the promotion of geothermal, ensured the participation of ministers, members of parliament, governors, mayors, bureaucrats and engineers in these countries, organized technical trips and carried out promotional activities. All these expenses were covered by TGA and its sponsors.

MTA continued exploration, discovered geothermal fields by taking risks and started the preparation of geothermal law through the commissions established. However, the biggest development came after the World Geothermal Congress (WGC2005), organized by the International Geothermal Association (IGA) and the Turkish Geothermal Association (TGA) in Antalya in 2005. 2000 people from Türkiye and the world attended this congress. In addition, the participation of ministers, member of parliaments, scientists and bureaucrats was ensured and the importance of geothermal was understood. Thereupon, the Law No. 5686 on Geothermal Resources and Natural Mineral Waters was enacted as a stimulus law. In addition, the model of leasing the geothermal sites, explored and discovered by MTA, to the private sector for 30 (+10) years with 1 or 2 wells drilled was accepted and appreciated by the Turkish private sector. As a result, MTA has leased the fields for very large amounts (up to $109 million). Additionally, MTA has conducted hundreds of tenders and leased low temperature fields to the private sector.

The Turkish private sector has acted swiftly, drilled additional production and reinjection wells, prepared feasibility studies and projects, started investment, and constructed and commissioned a power plant in record time. Congratulations and thanks are due to the State and Government of the Republic of Türkiye, the Ministry of Energy and Natural Resources, the universities, the private sector and, of course, MTA.

The milestones in Turkey's geothermal history are presented in chronological order in Table 1.

3. Present

After the Law No. 5686 on "Geothermal Resources and Natural Mineral Waters" entered into force in 2007, significant developments have been achieved and investments have started as mentioned in the previous chapter. Power plants have started to be established rapidly and the adventure that started with 0.5 MWe pilot power plant and 20 MWe commercial power plant has reached 1710 MWe of installed capacity today, ranking 1st in Europe and 4th in the world. 3-4% of country's electricity production is met from geothermal resources. Table 2 presents the full list of geothermal power plats active in Türkiye.

Geothermally heated greenhouses have gained momentum and importance in the last 10 years due to the importance of food security, economic use of geothermal heat, export and employment. Today it has exceeded 10400 acres and ranks 1st in the world.

Table 1: Year-based development in Turkish geothermal sector.

Year	Development
1926	A law was enacted regarding hot springs.
1935	The General Directorate of Mineral Research and Exploration (MTA) was established.
1947	'Türkiye Mineral Waters' book was prepared (Çağlar, 1947).
1948	'Tectonics of Aegean Region, Hot Springs, Mineral Water Sources' was published (Pınar,1948).
1960s	MTA General Director Dr. Sadrettin Alpan emphasized geothermal research.
1962	The first geological surveys were conducted in Balçova.
1963	The first geothermal drilling was carried out in Balçova.
1966	Several studies including thermal mineral resources were published (Erentöz and Ternek, 1966).
1967	The Western Anatolia and Kızıldere geothermal exploration project was initiated by MTA-UNDP.
1968	The first high-T reservoir was discovered at 198°C at a depth of 540 meters in Kızıldere.
1974	The first geothermal power test plant with a capacity of 0.5 MWe was established in Kızıldere.
1975	The book 'Türkiye Mineral Waters' was published by Istanbul University Faculty of Medicine.
1979	The first draft geothermal law was prepared by MTA.
1982	The Germencik (232°C) and Tuzla (174°C) fields were discovered through drilling.
1982	The first Turkish-Italian seminar on geothermal energy took place.
1982	The first geothermal regulation was included in the Mining Law.
1983	The first geothermal heating system with an in-well heat exchanger was established in Balçova.
1984	The first GEPP with single flash steam technology was commissioned in Kızıldere (15 MWe) by TEK.
1986	The first CO_2 factory was established in Kızıldere.
1987	The first centralized geothermal district heating system was initiated in Gönen.
1990	The scaling problem was resolved, leading to increased investments in heating applications.
1990s	Heating became widespread, started in Afyon, Kırşehir, Balçova, Narlıdere, Edremit, Bigadiç, Salihli.
1999	Balçova geothermal heating system was selected as a best practice by EGEC.
2000	After earthquakes in 1999, TÜBİTAK, universities, MTA monitored field (Simsek&Yildirim, 2000).
2002	The first reinjection studies were carried out in the Kızıldere.
2003	The Bank of Provinces (İller Bankası) began research and credit support for geothermal projects.
2005	The World Geothermal Congress (WGC-2005) was held in Antalya. MTA inventory was published.
2006	The first private sector plant (Mege) and binary system power plant were established in Salavatlı.
2007	The Geothermal Resources and Natural Mineral Waters Law was published, and the related regulation
2008	Kızıldere was privatized.
2009	The first double flash steam power plant was established in Germencik (47.4 MWe).
2011	MTA auctioned off the fields it had discovered to allow private sector exploration and operation.
2013	A new 80 MWe power plant was commissioned in the Kızıldere.
2014	The total installed capacity of geothermal power plants reached 400 MWe by the end of 2014.
2015	The installed capacity in Ömerbeyli reached 162 MWe.
2016	Türkiye's heat flow data were added to IRENA Atlas.
2017	Türkiye joined 1 GW country club. OrmaTürk started domestic manufacturing.
2020	11th European Geothermal PhD Days was hosted for the first time in Türkiye.
2022	awarding of WING Türkiye with the WING Global Operations role.
2023	inauguration of the first geothermal-solar hybrid power plant by Zorlu Energy

Approximately 40000 houses in İzmir-Balcova, 30000 houses in Afyonkarahisar, hotels, greenhouses and university campuses have started to be heated with geothermal energy. The total residential heating capacity has increased to 158000 housing equivalents.

According to the type of evaluation of geothermal resources in direct applications (non-electricity), it is in the 2nd - 4th position in the world. This success of Türkiye has been the subject of all conferences, aroused curiosity and appreciation.

Türkiye started to be a part of international projects such as GEOCOND, GECO, GEOENVİ, GEORISK, GEOSMART, REFLECT Horizon 2020 projects. For Horizon Europe projects, Türkiye signed an agreement to participate with same conditions as EU members (Directorate for EU Affairs, 2021).

Therefore, the biggest driving forces in the development of geothermal in the country can be listed as the organization of the World Geothermal Congress in 2005, followed by the introduction of a geothermal law and incentive system, scientific and technical monitoring of geothermal developments in the world by scientists in Türkiye, and organizing seminars, summer schools, national symposia and training courses. In addition, the fact that MTA took the risk of exploring and discovering the fields and opening them up to the Turkish private sector through competitive bidding has ensured progress and development.

The economic activity contribution of geothermal to the Turkish National Economy through electricity generation, geothermal district heating, greenhouse heating, carbon dioxide production, thermal tourism and others has been calculated as approximately 172 billion TL per year by 2023 (October 2023 in US$). Total (direct/indirect) employment in the sector is 240.000 people.

In addition, according to the separate calculation of all existing geothermal assessments according to the electricity tariff and state-supported heating tariff, it is approximately 78 billion TL natural gas equivalent (October 2023). In addition, if all existing assessments are made with natural gas, it will be approximately 5 billion m^3/year natural gas equivalent. (Note: October 2023 average US dollar value is taken as 28 TL.)

In Türkiye, as of 2023, a depth of 5000m has been reached. The number of thermal resource outputs and wells has exceeded 2000. As a result, as of 2023, 100th anniversary of Turkish Republic, Türkiye has reached an important position in the world with the studies carried out by the government, technical staff, engineers, employees and investors for the development of geothermal resources in the country. However, due to the size of the geothermal potential, it is of great importance to accelerate and support continuous exploration and development activities in order to meet the energy needs of the country and to benefit from these domestic resources socially and economically.

Here is the Türkiye's geothermal technical potential according to various estimations:

- The geothermal technical heat potential is 107000 MWt. This potential is equivalent to approximately 13 million house heating or 400 thousand acres of greenhouse heating or approximately 90 billion m^3/year natural gas equivalent.
- Technical economic electricity potential is 9000 MWe.

- EGS/HDR (Enhanced Geothermal System/Hot Dry Rock) technical economic potential is 40000 MWe.

Now, a new geothermal law regulating exploration, operations and increasing non-electricity geothermal incentives has been initiated by MENR (ETKB in Turkish initials) and is expected to be finalized.

Table 2: Full list of geothermal power plants active in Türkiye and their characteristics.

Region	Plant - Company	Start Year	Number of Units	Unit Type	Total Installed Capacity (MWe)
Denizli	Kızıldere (Zorlu)	1984/2003	2	1F, 2F+B	80 + 15
Aydın	Salavatlı Dora 1,2,3 (MeGe)	2006/2013	3	B	50.86
Aydın	Germencik (Gürmat)	2009	1	2F	47.4
Çanakkale	Tuzla (Enda)	2010	1	B	7.5
Aydın	Hıdırbeyli (Maren)	2011/2013	3	B	92
Aydın	Pamukören (Çelikler)	2013	1	B	45
Denizli	Kızıldere (Bereket)	2007	1	B	6.85

4. Future

Table 3 represents the 2030 projections in the country.

Table 3: Türkiye's 2030 projection for geothermal applications and the additional investment required to reach this target

Geothermal Application	Estimated Targets for 2030	Additional Investment Required (USD) (2024 to 2030)
Electricity Production	3000 MWe (24 billion kWh)	5.4 billion
Heating (residential, hotel, etc.)	5000 MWt (Equivalent to 500000 Households)	1.2 billion
Greenhouse Heating	5600 MWt (Equivalent to 24,000 Acres)	2.5 billion
Drying, etc.	80 MWt (Equivalent to 300000 tons/year)	30 million
Thermal Tourism (Renovation and Development)	2000 MWt (520 Facilities including Thermal Springs, Health Tourism Facilities)	1.0 billion
Cooling	350 MWt (Equivalent to 20000 Households)	140 million
Fishing and Other Uses (Mineral Extraction, etc.)	400 MWt	100 million
Total Investment		10.37 billion

Natural Gas Equivalent of All Geothermal Uses (additional): 6.8 billion USD/Year

Economic Impact of Geothermal Electricity Production, Heating (residential, thermal facilities, etc.), Thermal Tourism (thermal springs), Greenhouses, Drying, Fishing, and Other Applications by 2030: 420 billion TL/Year (as of October 2023)

Direct and Indirect Employment Created by 2030: 420000 People

Further suggestions to pursue the development in the country can be listed as follows:

- Strengthen Public-Private Partnerships: Encouraging collaboration between government agencies, private companies, and research institutions can drive innovation and increase investment in geothermal projects. Public incentives and subsidies can be used to attract private sector participation.
- Invest in Research and Development: Supporting R&D initiatives focused on improving geothermal technologies, such as enhanced geothermal systems (EGS) and resource assessment methods, can help unlock new resources and increase efficiency.
- Expand Workforce Training: Developing specialized training programs and educational initiatives to build a skilled workforce will ensure that the sector has the expertise needed for advanced geothermal projects.

- Promote International Collaboration: Engaging in international partnerships and knowledge exchange with countries. Türkiye can be an international hub for geothermal energy as it enables in-situ learning, observation of different geological settings and different utilization ways and holds a geopolitical position between Europe and the rest of the world.
- Explore Hybrid Energy Solutions: Integrating geothermal with other renewable energy sources, such as solar or wind, can create more resilient and efficient energy systems, maximizing the potential of available resources.
- Establish a 'National Data Repository and Processing Center for Geothermal Resources' in Türkiye (Turan, 2019) while making subsurface data older than 10 years open to public (i.e. Germany).

5. Conclusion

The Turkish geothermal sector has evolved significantly from its early exploration phases in the 1970s to becoming a global leader in geothermal energy production by the 2020s. This growth has been driven by strategic regulatory changes, increased investment, and a strong emphasis on sustainable practices. Moving forward, Turkey's focus on innovation and efficiency will likely further enhance its position in the global geothermal market.

ABSTRACT

Fort Providence, Kakisa, Hay River, and Enterprise are four South Slave communities located in the Northwest Territories (Canada). These communities rely on fossil fuels for space and water heating, and could benefit from geothermal systems. The South Slave Region is estimated to have the highest heat flow (>100 mW m^{-2}) in the Western Canadian Sedimentary Basin (WCSB), therefore is a target for geothermal exploration. However, an analysis of the deep geothermal resources has not been undertaken in this region. This research project objective is to fill this knowledge gap by providing a Precambrian basement temperature assessment below the sedimentary basin, around the four communities.

The Devonian sedimentary rock sequence on which the communities lie is thin (500 to 750 m) and has relatively low permeability (on average $<10^{-14}$ m^2). The lack of information on the Precambrian basement below Devonian sedimentary rocks limits the development of deep geothermal energy resources due to high uncertainty and risk. Deep borehole heat exchangers (DBHE) could be an appealing technology for direct use of heat in this geological context. However, a comprehensive assessment requires a detailed understanding of the thermal properties of the rocks. This information is mandatory to model such systems and provide accurate temperature estimates at depth.

A rock sampling campaign focusing on the Precambrian basement rocks was made in summer 2023, during which 91 outcrops and drilling cores were sampled to analyze their thermal properties. A range of thermal conductivity expected in the Precambrian basement was determined for the location of each community. Then, the results were used to extrapolate the subsurface temperature in the Precambrian basement until 10 km depth. The newly available information confirmed the presence of a significant geothermal potential in these communities.

In the more likely scenario (the normal one), the temperature at the top of the Precambrian basement ranges from 30.5 to 36.5 °C, with a basement surface heat flow of 99 mW m^{-2} to 157.7 mW m^{-2}. At 3 km depth, the temperature ranges from 100.4 to 156 °C; at 10 km depth, the temperature ranges from 303.6 to 511.6 °C for each community. Hay River has the highest values and most promising geothermal potential for deep closed-loop systems.

1. Introduction

Energy costs in northern Canada, populated by several indigenous communities, are higher than in the rest of the country. For example, electricity rates in the Northwest Territories (NWT) are more than twice the national average (Canada Energy Regulator & Government of Canada, 2023). The NWT, like many other northern regions, mainly relies on carbon-intensive fossil fuels such as oil to meet its electricity, space heating, and water heating needs. The Government of the NWT aims to ensure a balance between energy security, affordability, and reduction of greenhouse gas emissions in its 2030 Energy Strategy (Government of Northwest Territories, 2018). Key initiatives include replacing diesel with renewable energy solutions by exploring the potential of technologies such as deep geothermal resources in areas that have been identified as having high geothermal potential (EBA Engineering Consultants Ltd., 2010). These areas have yet to be defined and characterized.

This research project focuses on the geothermal potential of four communities in the southern part of the NWT with the intent of characterizing its deep geothermal resources. The communities (Figure 1) are located within the South Slave administrative region, part of the Dehcho First Nations: Hay River (Xátł'odehchee, K'atlodeeche First Nation and Ts'ueh Nda, West Point First Nation), Fort Providence (Zhahti Kų́ę́, Deh Gáh Got'îê First Nation), Enterprise, and Kakisa (K'ágee, Ka'a'gee Tu First Nation). Due to their close vicinity, Hay River Town and Hay River Dene (Katlodeeche First Nation Reserve) are referred to as "Hay River" in the study.

These four communities are situated within the largest high heat flow anomaly in Canada, known as the Northern Plains Heat Flow Anomaly (NPHFA) or Northern Anomaly (Majorowicz, 1996; Majorowicz & Weides, 2014). This anomaly is approximately 300 km wide and stretches 500 km from north to south. The geothermal gradient and heat flow in the research areas are significantly higher compared to other Precambrian platform locations worldwide (Majorowicz & Jessop, 1981). Several hypotheses have been proposed to explain the thermal anomalies in this region. Bachu (1993) suggested that the unusually high temperatures measured could be related to hydrogeological effects which can disturb heat flow patterns. Majorowicz (1996) suggested the presence of an increased mantle upflow beneath the region which aligns with other heat flow anomalies along the western margin of the North American Craton. Despite these hypotheses, Majorowicz (2018) concluded that the exact cause of the heat flow anomaly remains speculative.

Rajaobelison et al. (In press) measured thermophysical properties on the NWT South Slave's sedimentary rocks. Then, Rajaobelison et al. (2024) created 1D temperature models based on temperature data from vintage oil and gas wells to evaluate the geothermal potential in the sedimentary sequence of NWT South Slave's communities.

Due to the generally low permeability and porosity inferred for the matrix of the sedimentary rocks analyzed in these studies and the shallow depth of the basement (525 to 729 m), the potential technologies that can be envisioned to produce geothermal energy are closed-loop DBHE relying on conduction to extract heat from rock formations and/or enhanced geothermal systems (EGS) requiring stimulation of potential reservoir formation to extract heat by forced convection.

A temperature model for the Precambrian basement, which lies below the sedimentary sequence, could not be made in previous studies due to a lack of information on the basement thermal properties. Very little information and data exist about the basement below the communities, representing a limitation when it comes to understanding and assessing the geothermal resources of the region. To reach higher temperatures below the sedimentary cover (>37 °C, Rajaobelison et al., 2024), Precambrian basement depth must be considered.

Therefore, this study objective is to assess the temperature at depths within the basement rock beneath the communities. To achieve this goal, we intend to determine a range of thermal properties for each tectonic domain (i.e., the Precambrian bedrock underlying each community). Additionally, we wish to extend previous work on sedimentary sequences (Rajaobelison et al., 2024) by incorporating new data from previously unsampled formations. This will help reduce uncertainties related to the rock thermal properties and temperature calculation at depth.

2. Geological Settings

The four NWT communities are located on the eastern edge of the WCSB. It is positioned between the Cordilleran Orogen to the west and the Canadian Shield to the east (Figure 2). Significant oil and gas exploration activities have taken place since the 1950s, with over 400 exploration wells drilled, most of which are now abandoned (OROGO, 2024) but has contributed to the identification of the high geothermal potential in the area (Figure 1).

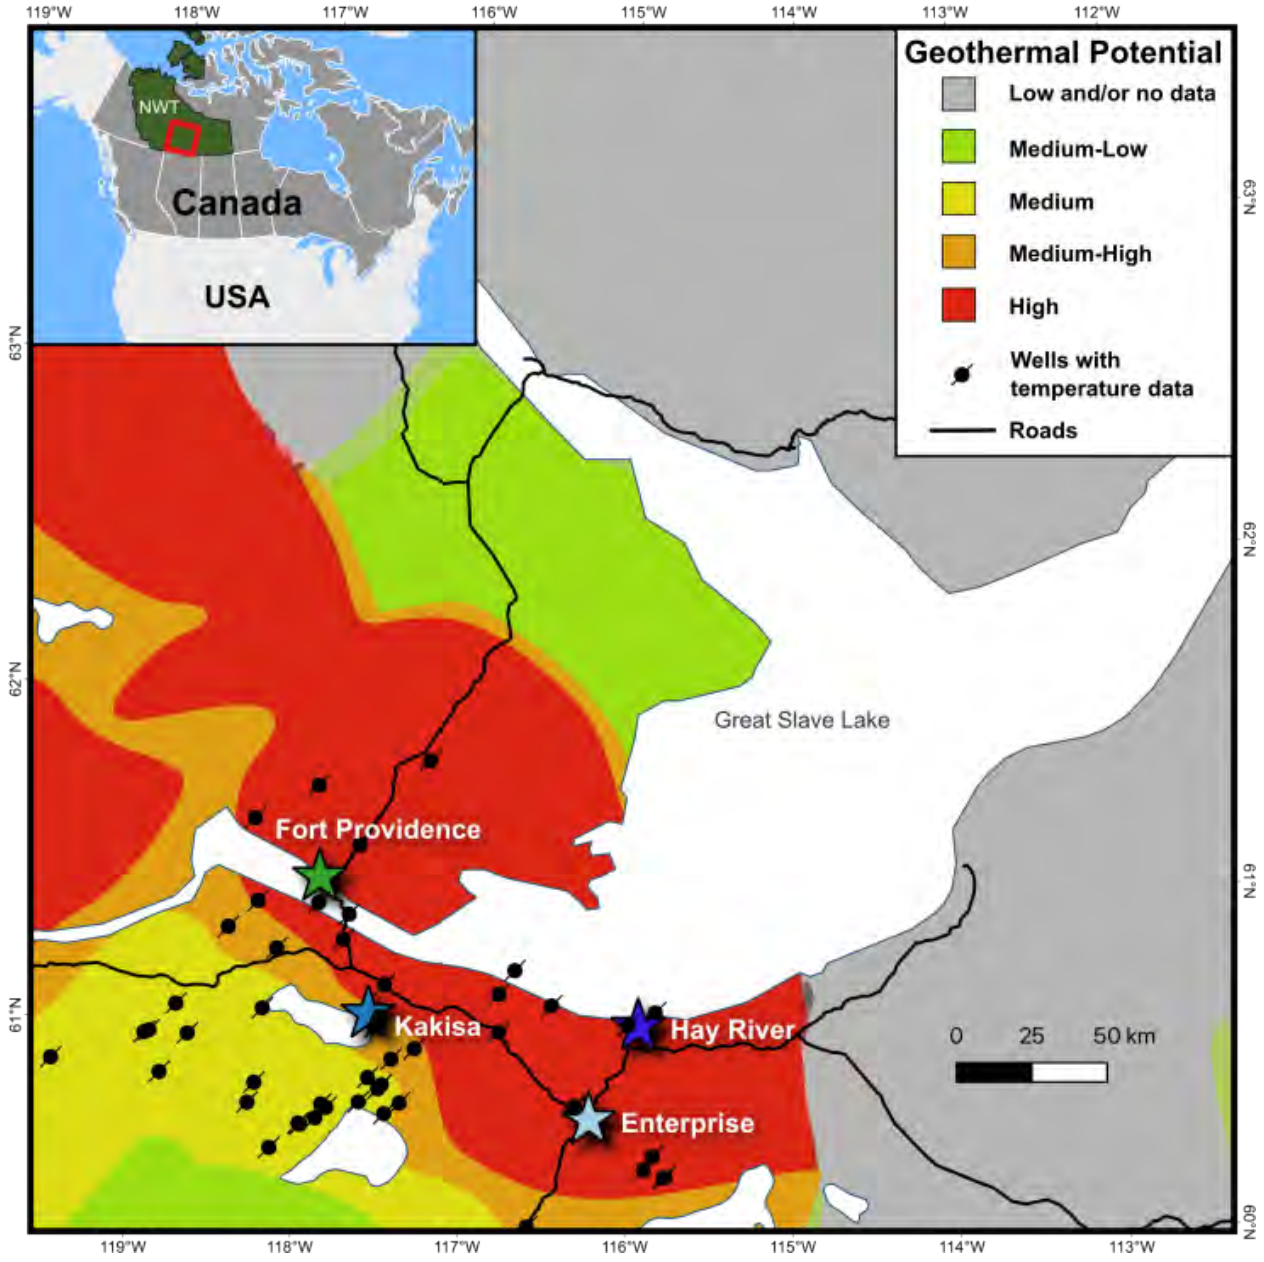

Figure 1: Geothermal potential map based on temperature (adapted from EBA Engineering Consultants Ltd., 2010) showing wells (abandoned) with temperature data and community locations.

The Quaternary glacial sediment, often called soil or alluvium, is between 4 m and 20 m thick at the community's location. It was deposited unconformably over the Paleozoic-Cenozoic sedimentary rock formations.

The sedimentary rocks lie on the top of a Precambrian crystalline basement that is part of the Canadian Shield. The sedimentary strata gradually thicken from east-northeast to west-southwest, ranging from about 500 m to 715 m in thickness at the community's locations. Furthermore, the geological formations in the region exhibit low porosity and permeability, implying a limited

potential for hot sedimentary aquifers, as noted by Rajaobelison et al. (In press). The anticipated permeability is expected to be mostly influenced by fault and fracture networks rather than the intrinsic porosity of the formations. Conduction is the dominant mechanism for geothermal heat flow in the region (Bachu, 1993; Gray et al., 2012; Majorowicz et al., 1999; 2012), which is the focus of the present study.

The Precambrian basement underlying the sedimentary cover consists of a poorly known mix of igneous and metamorphic rocks. It is characterized and subdivided by tectonic domains (Figure 2). The domains in the study area, listed from east to west and in chronological order of age are; Slave Craton, Great Bear Magmatic Zone, and Hottah Terrane that is part of Wopmay Orogen accreted terranes (Ootes et al., 2015). All tectonic domains of the Precambrian basement have various compositions, ages and tectonic histories, as well as different thermal properties that are critical for geothermal assessment. Thus, we employ tectonic domain terminology in this study to address basement classification. Hay River and Enterprise are part of the Slave Craton tectonic domain. Fort Providence and Kakisa, on the other hand, are located in Hottah Terrane.

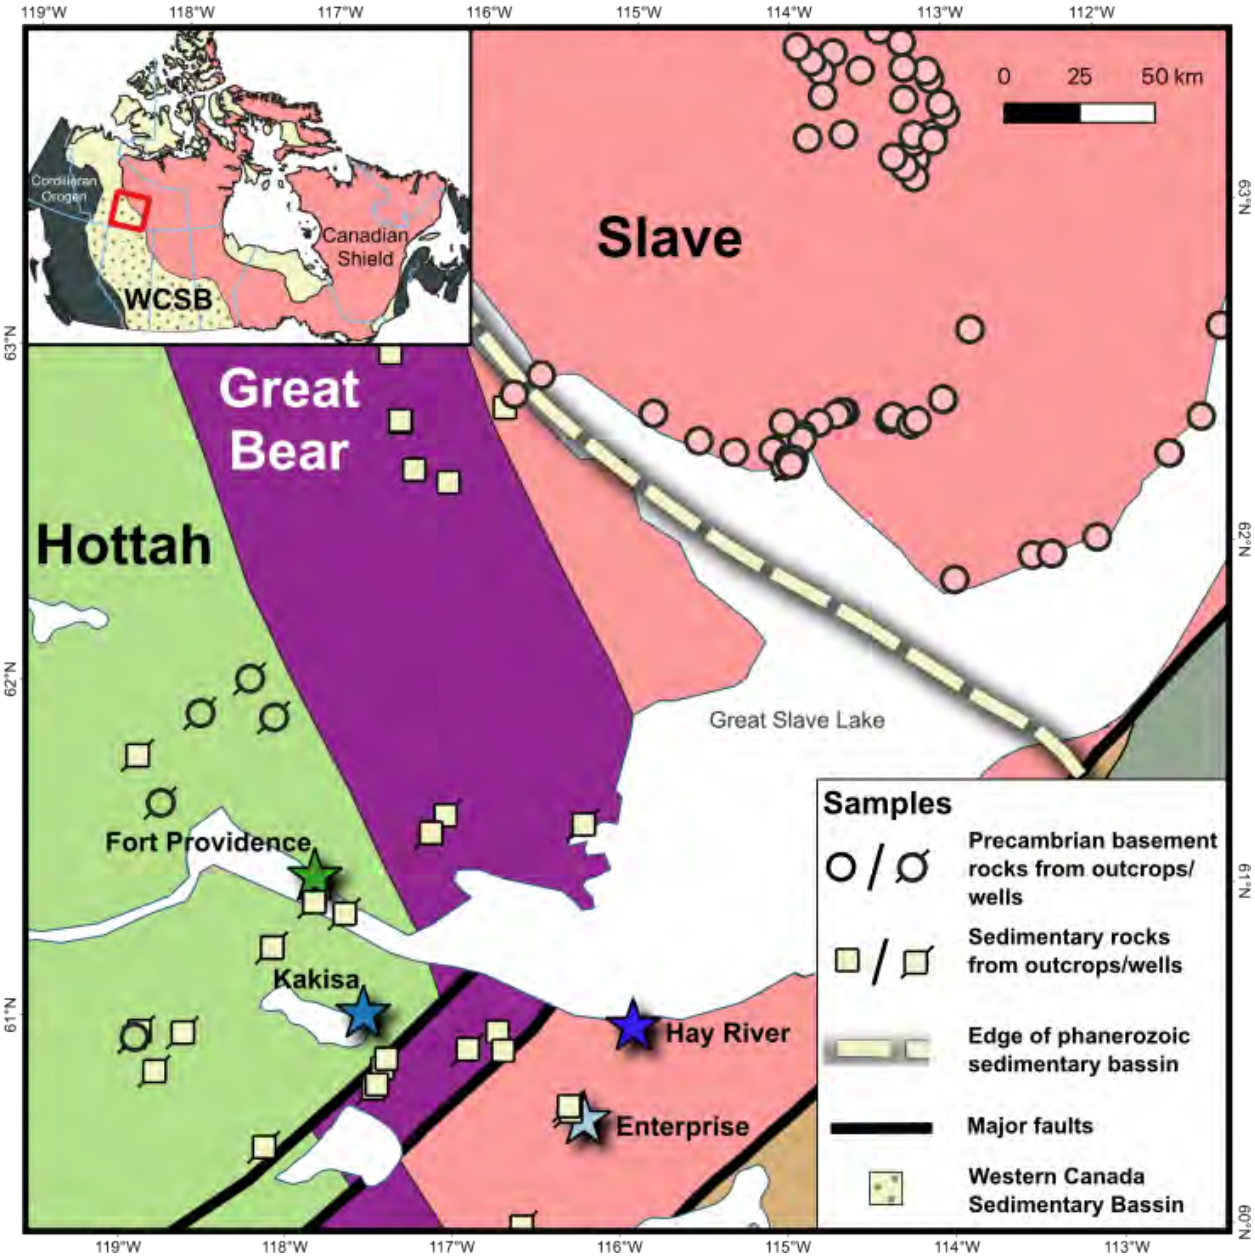

Figure 2: Tectonic domain map (based on Ootes et al. (2015) domain division), with samples and community locations.

3. Material, Methods and Input Data

To accurately predict temperature at different depths, it was essential to use representative input data that accurately reflected the geological characteristics of the location. Due to the lack of information on thermal properties for geological materials in this area, we conducted extensive sampling and laboratory measurements. Collected data was used as input and is the foundation of subsequent analyses and thermal assessment. We therefore present below an updated

thermostratigraphic assessment, providing a new comprehensive dataset for the Precambrian bedrock and enhancing the previous sedimentary rocks sequence data.

This section gives an overview of the sampling process, thermal property analysis, undisturbed ground temperature assessment, input data and scenario examination, and a comprehensive thermostratigraphic assessment. All this information was used to create temperature profiles until the basement's top, 3 km and 10 km depths, which are the main results of this research.

3.1 Sampling overview

In 2022, we sampled 84 split core samples from 43 vintage oil and gas exploration wells of the South Slave region. Related descriptions and laboratory results are presented in Rajaobelison et al. (In press). Some sedimentary formations under the communities remained unsampled and thermal conductivity values from literature were assigned based on their lithologic content.

A rock sampling campaign in 2023 allowed the collection of 91 Precambrian basement rock samples, for which we think to have recovered a variety of geological units of each tectonic domain related to each community that could give us a good approximation of the material that can be encountered under these communities (Table 1). Sedimentary rocks sampling was partial and had to be interrupted due to forest fires and an evacuation order in the area (Figure 3).

Table 1: Sampling overview.

Geological material			Number of samples		
Alluvium					3
Sedimentary Rocks					112
Precambrian Basement Rocks	Igneous	Plutonic	54	66	91
		Volcanic	12		
	Metamorphic	Sedimentary	16	25	
		Plutonic	5		
		Volcanic	4		

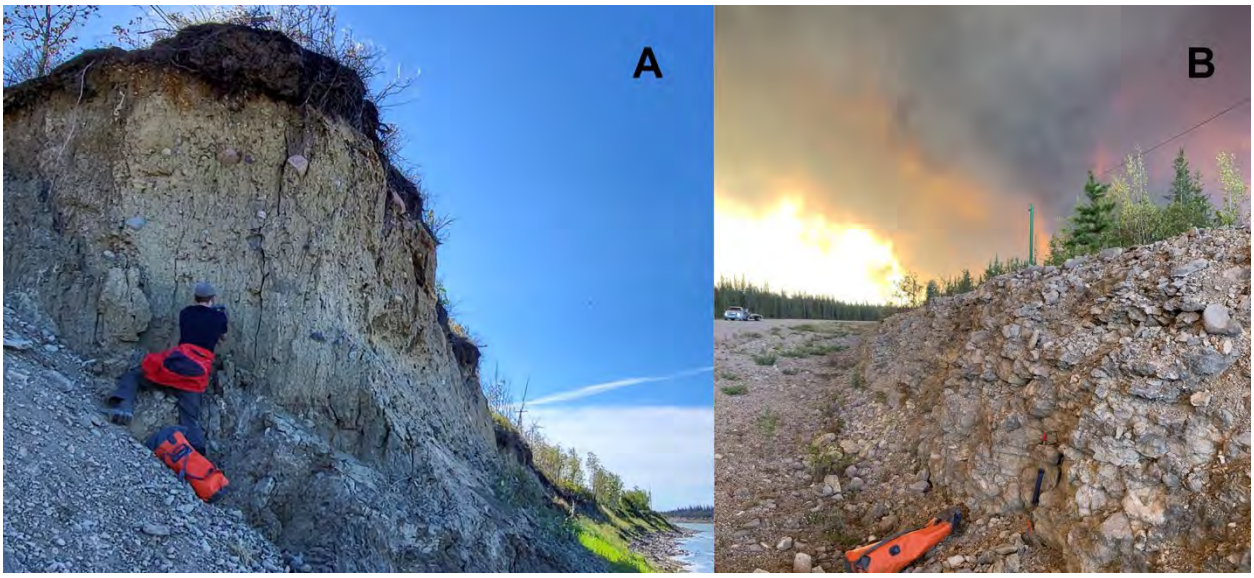

Figure 3: A) Soil sampling in Fort Providence on a glacial till cliff along the DehCho Dr road. B) Sedimentary rock outcrop sampling on the roadside of Highway 1 between Kakisa and Enterprise, one of the last samples before the evacuation order.

3.2 Thermal Properties

3.2.1 Thermal Conductivity

All sedimentary and basement rock samples collected (Table 1) were analyzed for thermal conductivity. The methodology follows that of Rajaobelison et al. (In press). Transient measurements were made using an optical scanning instrument developed by Popov et al. (2023) under dry conditions (Figure 4).

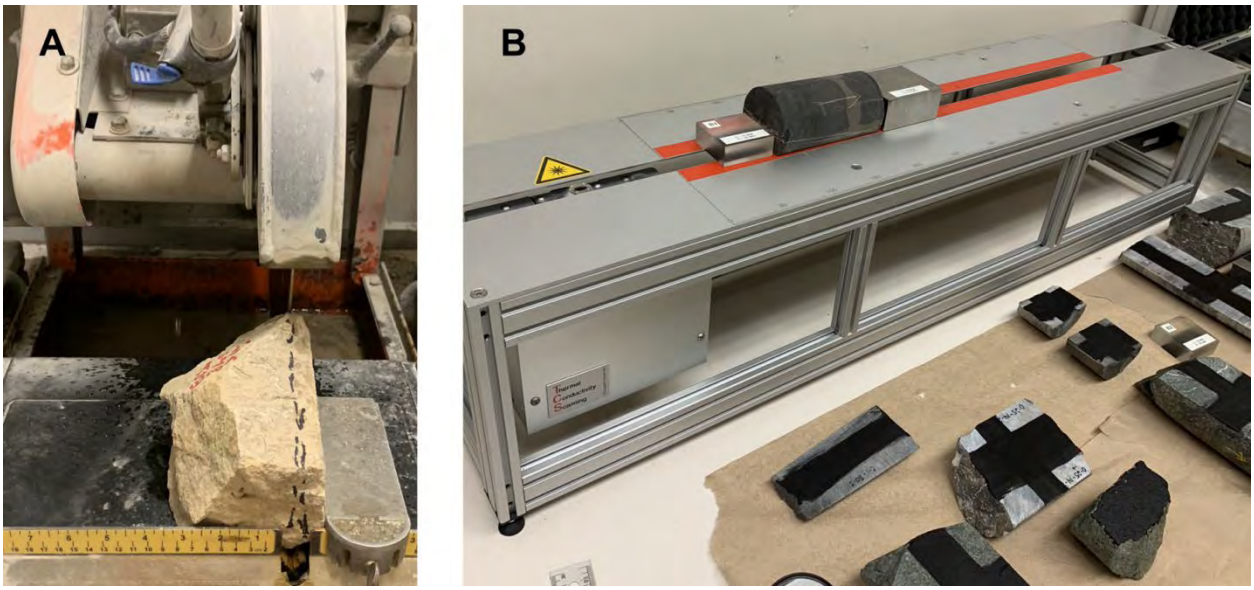

Figure 4: Sample preparation and analyses. A) Rock sample saw cutting. B) Thermal property measurement on the optical scanning instrument developed by Popov et al. (2023).

The average thermal conductivity values for all the measured samples, presented by types of material are shown in Figure 5. The classification of rocks according to their insulating to conductive potential indicated on Figure 5 and 6 is based on Rajaobelison et al. (In press), Sass & Götz (2012) and Sass et al. (1992).

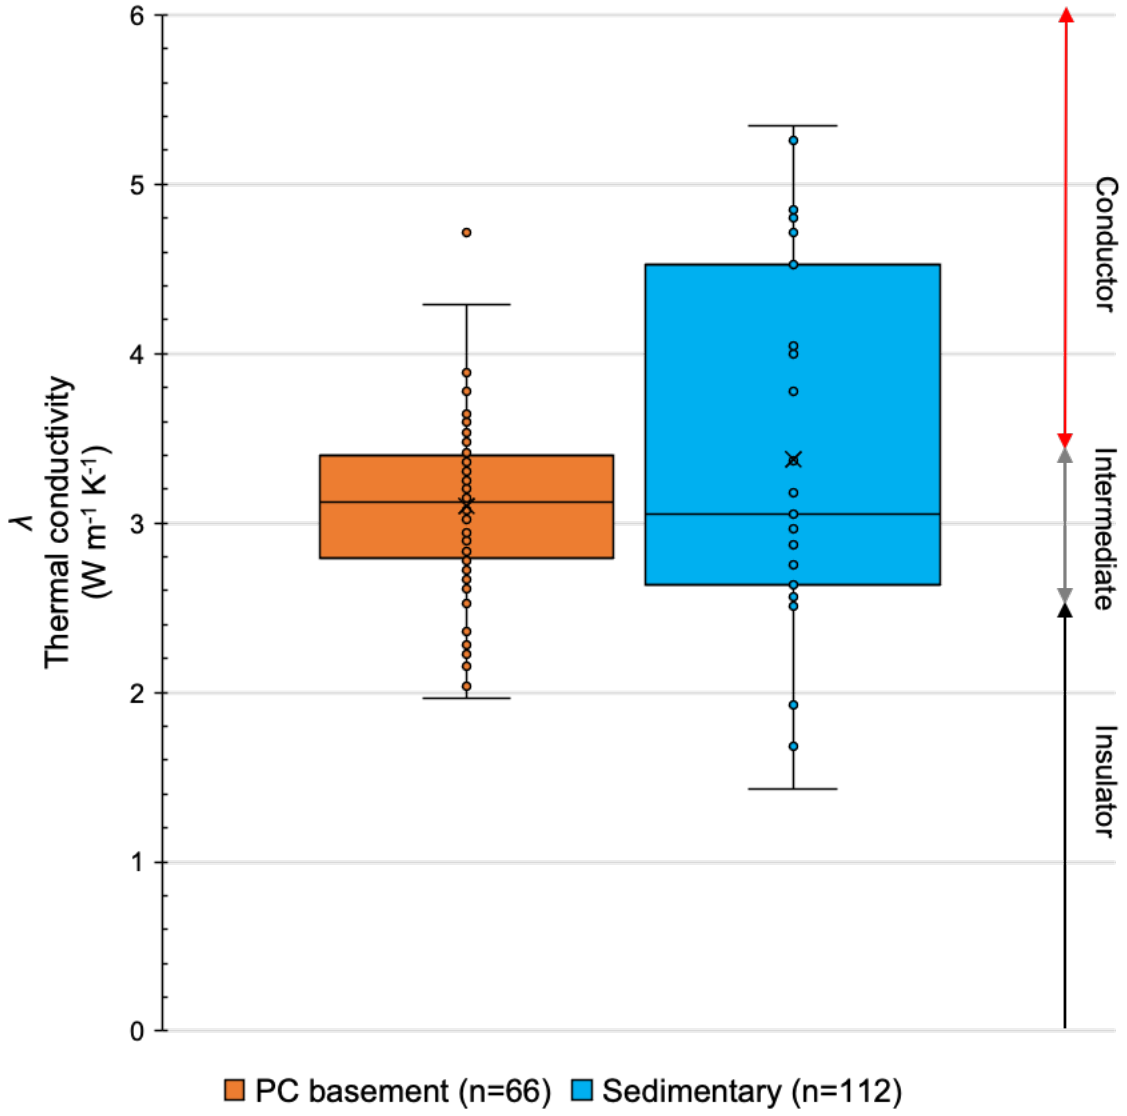

Figure 5: Thermal conductivity for the overall sampled Precambrian (PC) basement and sedimentary rocks.

In this study, we treat each tectonic domain (Figure 2) as a uniform thermal unit. Sixty-six samples from the outcropping Slave Province were analyzed for the Slave Craton tectonic domain, which is associated with the Hay River and the Enterprise Precambrian basement. For the Hottah Terrane tectonic domain (Fort Providence and Kakisa), we sampled eleven core cuttings and surface rocks. We added ten additional previously measured core cuttings from other locations in our data set, which came from Majorowicz et al. (2014). Figure 6 shows the corresponding thermal conductivity ranges.

The values attributed to the Slave Craton account for a wide range of lithologies that represent practically all geological units visible at the surface of the Slave Province, from which these Precambrian structures extend beneath the sedimentary layer (Ootes et al., 2015). The Hottah Terrane has slightly higher thermal conductivity values, a broader spread, and fewer samples.

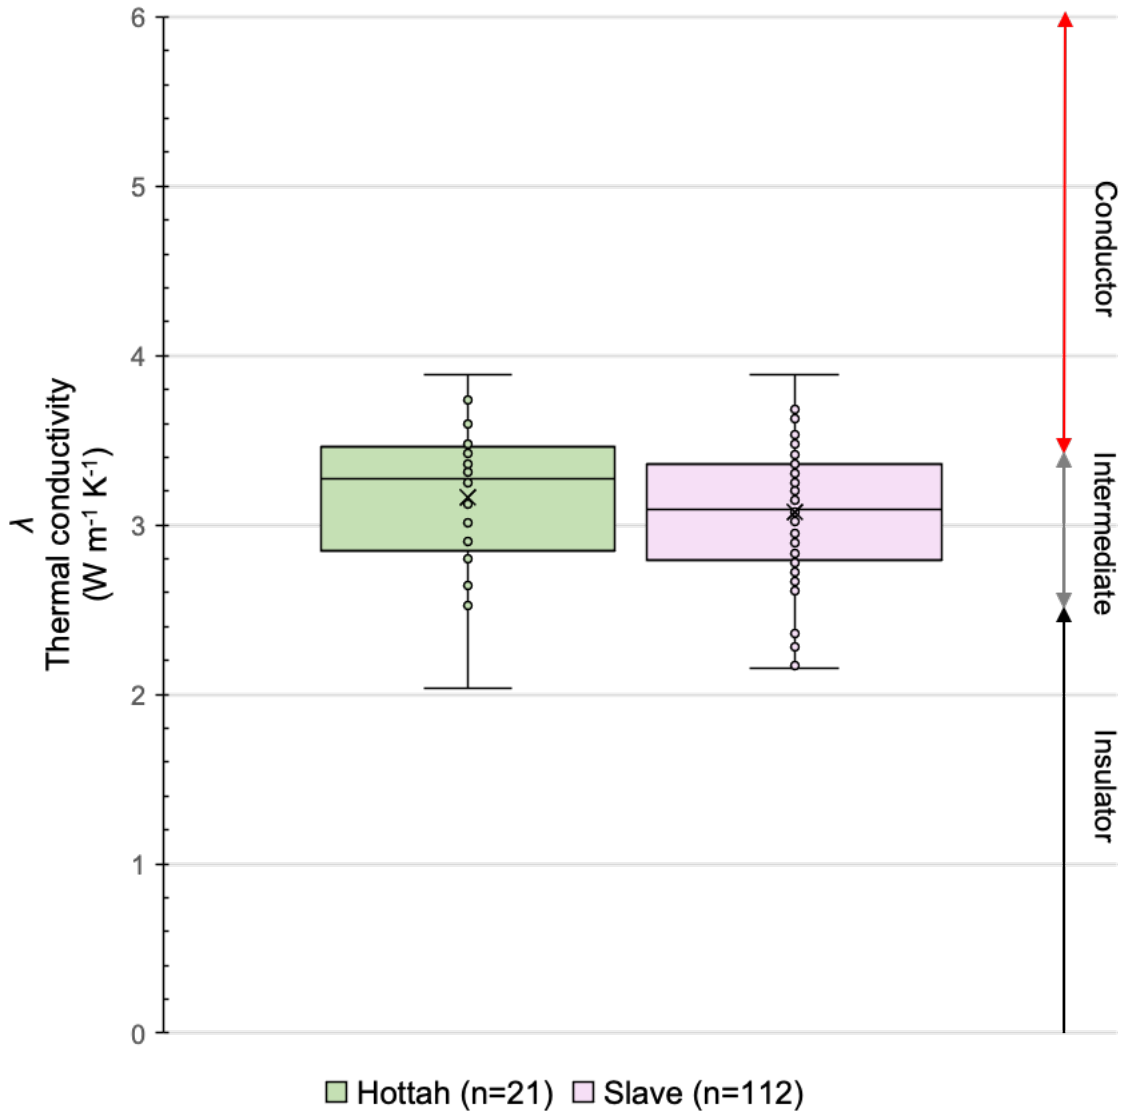

Figure 6: Thermal conductivity for basement domain related to each community.

3.2.2 Heat Generation Rate

Table 3 shows the heat generation rate expected for sedimentary units and basement domain. The sedimentary formations values were obtained from Rajaobelison et al. (2024). The basement heat generation rate was determined according to literature values specific to each tectonic domain, including Jessop (1992) for the Hottah Terrane and Perry et al. (2010) for the Slave Craton.

3.3 Undisturbed Ground Temperature

The undisturbed ground temperature T_s (K) was estimated using the equation proposed by Ouzzane et al. (2015):

$$T_s = 17.898 + 0.951 T_{amb} \quad (1)$$

where T_{amb} (K) is the ambient air temperature, which is considered to be -2.5 °C based on the mean annual air temperature from the Hay River-A weather station (Government of Canada & Environment and Natural Resources, 2024). T_s is thus estimated to be 2.1 °C in the South Slave region.

3.4 Input Data and Scenarios

In this study, various scenarios were proposed based on the probabilistic distribution of thermal properties. This provides for a normal, pessimistic, or optimistic outlook. These are presented in Table 2 as input for thermal properties and in Table 3 as results.

The normal scenario employs the 50th percentile (P_{50}) values of basement thermal conductivity, heat generation rate, as well as the heat flow and geothermal gradient acquired from the corrected well temperature measurements, resulting in a neutral approach. The pessimist scenario uses the 25th percentile (P_{25}) value of heat flow and temperature gradient, the minimum heat generation rate value and the 75th percentile (P_{75}) percentile values for the thermal conductivity, embodying a cautious approach. In contrast, the optimist scenario utilizes P_{75} values for heat flow and temperature gradient, the maximum heat generation rate, and P_{25} values for the thermal conductivity, providing insight into best-case scenarios. These diverse perspectives allowed for a comprehensive analysis of potential outcomes across different scenarios.

Table 2. Thermal properties (thermal conductivity and heat generation rate) values assigned to each scenario (normal (N), pessimist (P) and optimist (O)) for each community in the sedimentary sequence and the Precambrian (PC) basement (Hottah Terrane and Slave Craton tectonics domain). The number of samples is denoted by *n*.

			λ Thermal Conductivity ($W\ m^{-1}\ K^{-1}$)				***A*** Heat Generation Rate ($\mu W\ m^3$)

		Enterprise								

3.5 Thermostratigraphic Assessment

Temperature was calculated at the base of each sedimentary rock units and at each 500 m intervals in the basement. To be consistent with previous work, we used for each community the same well temperature data listed in the assessment of Rajaobelison et al. (2024), where well temperature measurements from drill-stem tests (DST) and borehole temperature (BHT) were corrected for drilling disturbance and paleoclimate effects. This temperature assessment of the sedimentary basin served as inputs for the present temperature assessment in the Precambrian basement.

3.5.1 Paleoclimate corrections

Past glaciations in Canada lowered subsurface temperatures at shallow depths, due to both the cooling effects of lower surface temperatures and crustal compression induced by the weight of ice sheets that covered the land. These paleoclimate effects persist today to consideradable depth, necessitating paleoclimate corrections in temperature assessments for accurate deep geothermal estimations out of shallow wells temperature measurements (Jessop, 1992). The effects of past glaciations in Canada can be significant to the depth of two kilometres or more (Bédard et al., 2016; J. Majorowicz, Chan, et al., 2014; J. Majorowicz et al., 2012). While this influence diminishes with depth, it's essential to account for paleoclimate corrections, particularly for this area where temperature measurements from old oil and gas exploration wells are mainly less than a thousand metres deep. Beyond a certain depth, temperatures tend to reach equilibrium, reflecting the long-term geothermal gradient of the region. In this study we consider a depth of 3 km, from which climatic variations no longer have a significant impact on temperature and that we consider as equilibrium temperature. The 3 km cut-off value for the South Slave region seems reasonable, considering that northern Alberta estimates are 2200 m based on the first heat flow measurement in a well that reached the basement under the WCSB below the depth of the paleoclimatic influence (Majorowicz, Chan, et al., 2014; Majorowicz et al., 2012). In areas where paleoclimates have a deeper influence, such as the St. Lawrence Lowlands sedimentary basin in Quebec (Bédard et al., 2016; Chapelet, 2022), the influence on temperatures and heat flow are minimal below 3 km depth. The equilibrium temperature at depth $T_{z\,(\mathrm{eq})}$ is calculated with the following paleoclimate correction equation (Jessop, 1990; Rajaobelison et al., 2024):

$$T_{z(\mathrm{eq})} = T_{\mathrm{m}} + \sum_{\mathrm{i}}(T_{\mathrm{i}}) \left[erf\left(\frac{z}{2\sqrt{\alpha\, t_1}}\right) - erf\left(\frac{z}{2\sqrt{\alpha\, t_2}}\right)\right] \quad (2)$$

where T_{m} (°C) represents the temperature measured at a certain depth z (m), corrected from drilling disturbance and T_{i} (°C) is the temperature step between glaciations. The error function is represented by *erf*, α ($\mathrm{m^2\ s^{-1}}$) is the mean thermal diffusivity of the rocks, t_1 (s) represents the end of the ice age, while t_2 (s) represents the beginning of the ice age. Specific information regarding the values employed can be found in the laboratory and thermostratigraphic studies conducted by Rajaobelison et al. (2024).

Thus, to estimate the actual subsurface temperature at a depth of less than 3 km, the paleoclimatic correction (equation 2) was removed such that temperature is characteristic of the value that can be measured (i.e., affected by glaciation). However, the paleoclimate correction was applied to calculate temperature until 10 km depth since glaciations are expected to have a low impact at great depth.

3.5.2 Geothermal Gradient

The geothermal gradient g (°C m^{-1}) refers to the rate at which temperature increases with depth below the Earth's surface. It can be stated by the following:

$$g = \frac{\Delta T}{\Delta z} = \frac{T_z - T_s}{z} \quad (3)$$

where ΔT (°C) is the difference between the temperature at the depth being assessed T_z (corrected measured temperature are from Rajaobelison et al., 2024) and the undisturbed ground temperature (T_s = 2.14 °C), and z (m) is the depth of the corrected temperature assessed.

3.5.3 Surface Heat Flow

Heat flow in the context of geothermal energy refers to the movement of thermal energy from the Earth's interior toward the surface, often used to assess the potential for geothermal energy extraction. Surface heat flow Q_0 (W m^{-2}) quantifies the rate at which this heat energy is transferred per unit area over the Earth's surface. The following equation (Bédard et al., 2016; Jessop, 1990; Rajaobelison et al., 2024) is used to compute surface heat flow in a sedimentary basin:

$$Q_0 = \lambda_{sed} g + A_{sed} \frac{z}{2} \quad (4)$$

λ_{sed} (W m^{-1} K^{-1}) denotes the effective thermal conductivity of the sedimentary sequence, determined by calculating the weighted harmonic mean of the λ for the different lithologic units that make up the sedimentary rock cover at each location, g (°C km^{-1}) refers to the geothermal gradient determined from temperature measurements as described previously, A_{sed} (W m^{-3}) is the effective heat generation obtained from the weighted arithmetic average in the sedimentary rock sequence and z (m) is the rock sequence thickness between the measured temperature depth and the ground surface.

3.5.4 Basement Heat Flow

The basement top heat flow Q_{PC} (W m^{-2}) is defined here as the heat flow at the boundary between the sedimentary layers and the underlying Precambrian basement rocks. It is calculated by removing the heat generation effects A_{sed} within the sedimentary rocks from the surface heat flow through the sedimentary sequence, according to the following equation (Bachu, 1993; Bédard et al., 2016; Majorowicz, Nieuwenhuis, et al., 2014; Majorowicz & Grasby, 2010b):

$$Q_{PC} = Q_0 - A_{sed} \frac{z_{sed}}{2} \quad (5)$$

where z_{sed} is the thickness of the sedimentary rocks sequence, which is the depth between the top of the Precambrian basement and the ground surface.

3.5.5 Temperature at Depth in the Sedimentary Rocks Sequence

Each sedimentary rock formation has a distinct effective thermal conductivity λ, hence the temperature at depth $T_{z(sed)}$ (°C) was calculated at their boundaries. It was computed analytically under steady-state condition, taking into account conductive heat transfer using a one-dimensional approach (Rajaobelison et al., 2024; Stein, 1995):

$$T_{z(sed)} = T_s + \frac{Q_0 z}{\lambda} - A \frac{z^2}{2\lambda} \quad (6)$$

where *T*s (°C) is the temperature at the base of the sedimentary formation, *z* (m) the formation thickness and λ (W m^{-1} K^{-1}) the formation effective thermal conductivity.

3.5.6 Temperature at Depth in the Precambrian Basement

The temperature at any depth in the Precambrian basement $T_{z(\mathrm{PC})}$ was calculated at each 500 m intervals, using the same relationship mentioned above for $T_{z(\mathrm{sed})}$:

$$T_{z(\mathrm{PC})} = T_{PC} + \frac{Q_{\mathrm{PC}}\, z_{\mathrm{PC}}}{\lambda_{\mathrm{PC}}} - A_{PC}\, \frac{{z_{PC}}^2}{2\lambda_{\mathrm{PC}}} \quad (7)$$

where T_{PC} (°C) is the temperature at the top of the basement, Q_{PC} (W m^{-2}) is the basement heat flow, z_{PC} (m) is the depth from the top of the basement, λ_{PC} (W m^{-1} K^{-1}) the thermal conductivity of the basement and A_{PC} (W m^{-3}) is the heat generation of the basement rocks.

4. Results

4.1 Input data

Table 3 presents the calculated geothermal gradient and surface heat flow for the sedimentary sequence, which were used in the temperature calculations.

Table 3: Geothermal gradient and heat flow assigned to each scenario (normal (N), pessimist (P) and optimist (O)) for each community (Fort Providence (FP), Kakisa (K), Hay River (HR) and Enterprise (E)) in the sedimentary sequence.

		g Geothermal Gradient (°C km^{-1})			***g*$_{eq}$** Equilibrium (°C km^{-1})			***Q*$_0$** Surface Heat Flow (W m^{-2})			***Q*$_{0(eq)}$** Equilibirum (W m^{-2})

4.2 Temperature in the Sedimentary Rocks Sequence

Each temperature point used for calculations in the sedimentary rock sequence corresponds to the top of each sedimentary formation (fm.; Figure 7). The calculated temperature is based on heat flow assessed in wells near the communities. The profiles represent an estimate of the current temperature found in the sedimentary rocks, thus affected by glaciations and uncorrected for paleoclimates.

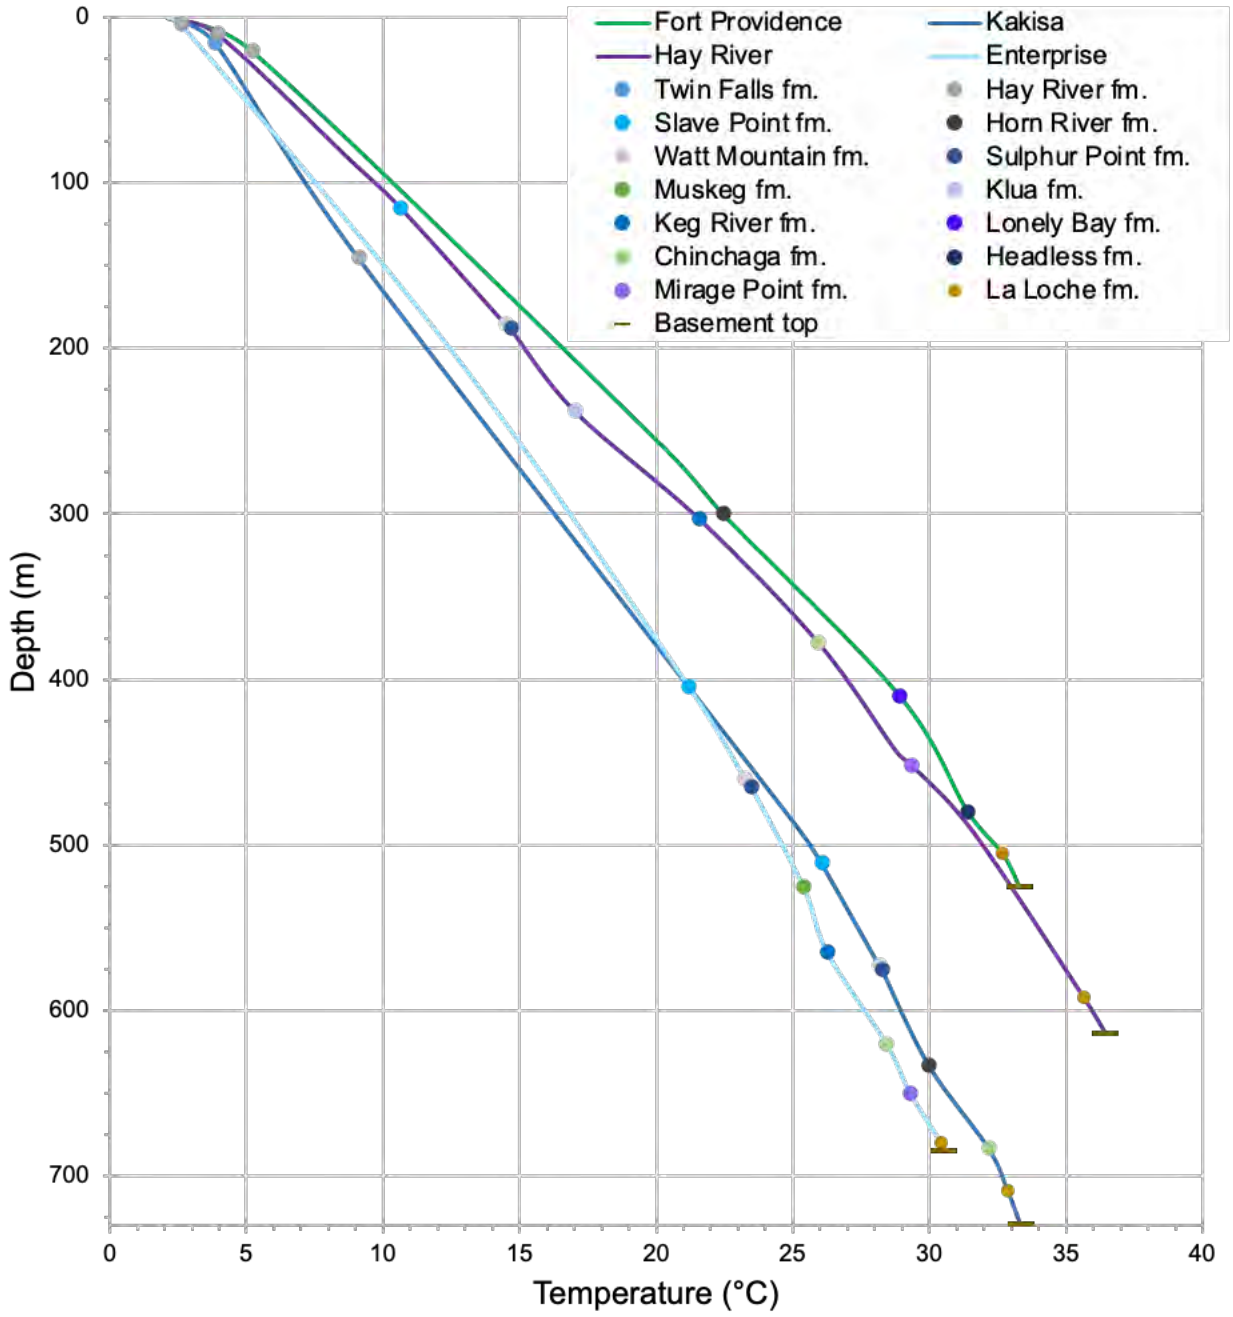

Figure 7: Temperature at depth in the sedimentary sequence, with normal scenarios, considering heat flow uncorrected for paleoclimates. Each community is represented by a distinct coloured line, and each geological formation (fm.) top is represented by a specific coloured circle.

4.3 Temperature in the Basement until 3 km depth

The temperature calculated until 3 km depth (Figure 8, 9, 10, 11, 12) incorporates uncertainty scenarios. The calculated temperatures represent an estimate of expected and current temperatures found in the basement, thus affected by glaciations and uncorrected for paleoclimates.

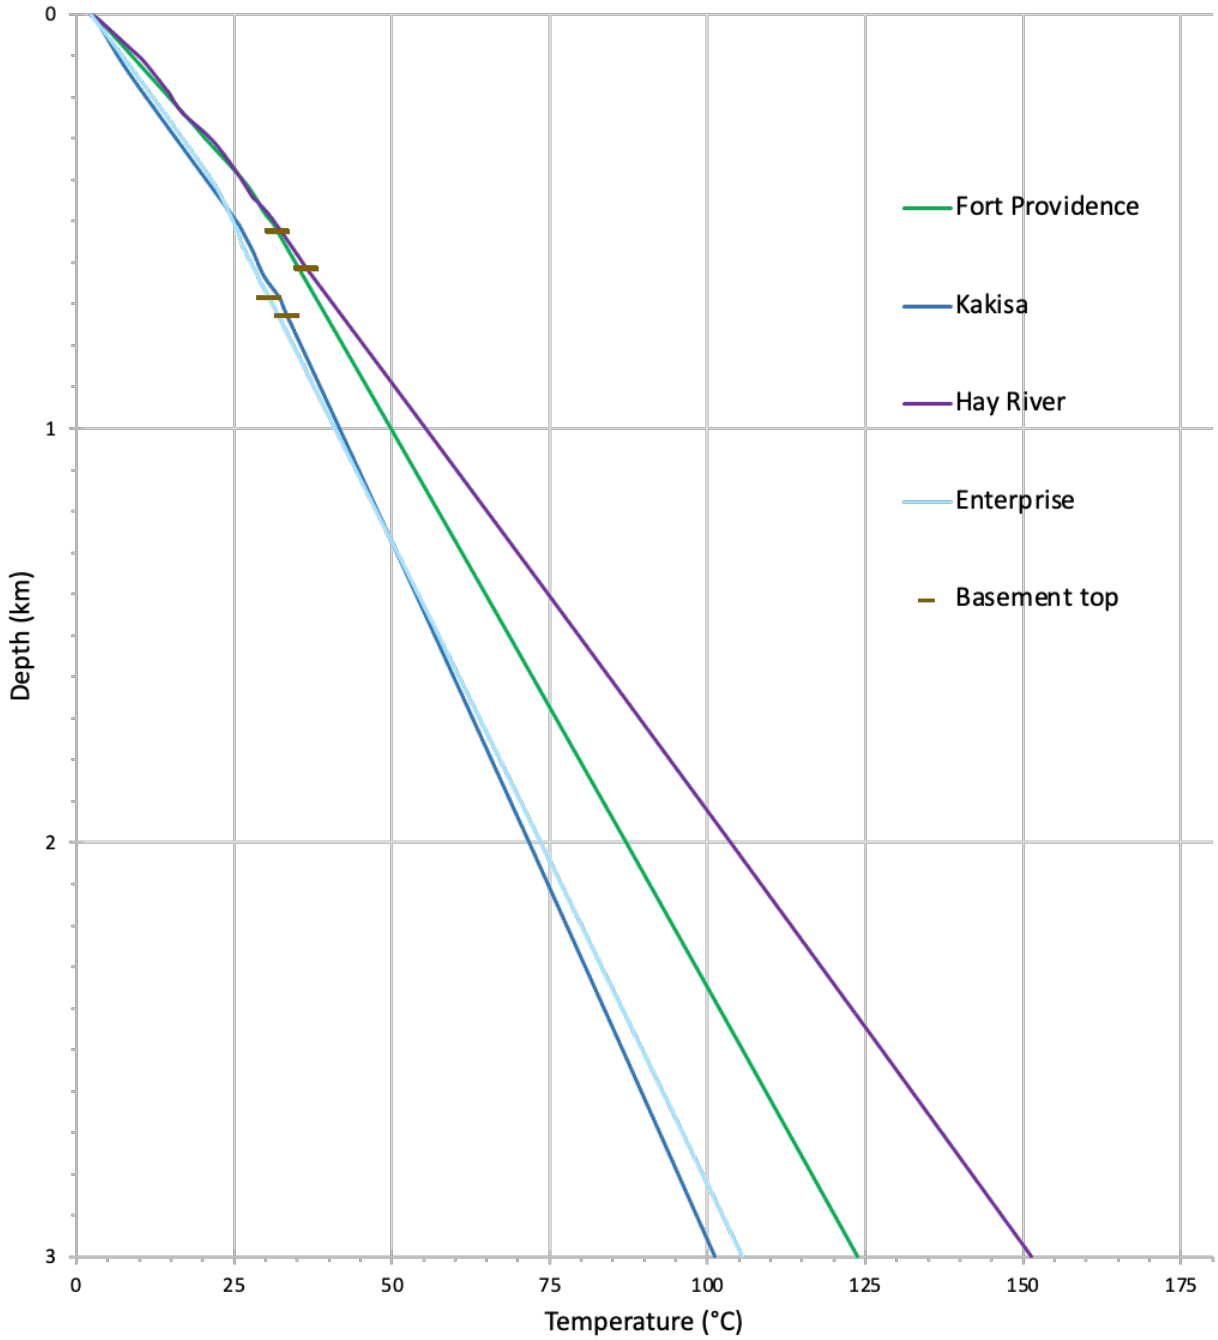

Figure 8: Temperature until 3 km depth, with normal scenarios, considering heat flow uncorrected for paleoclimates. Each community is represented by a distinct coloured line.

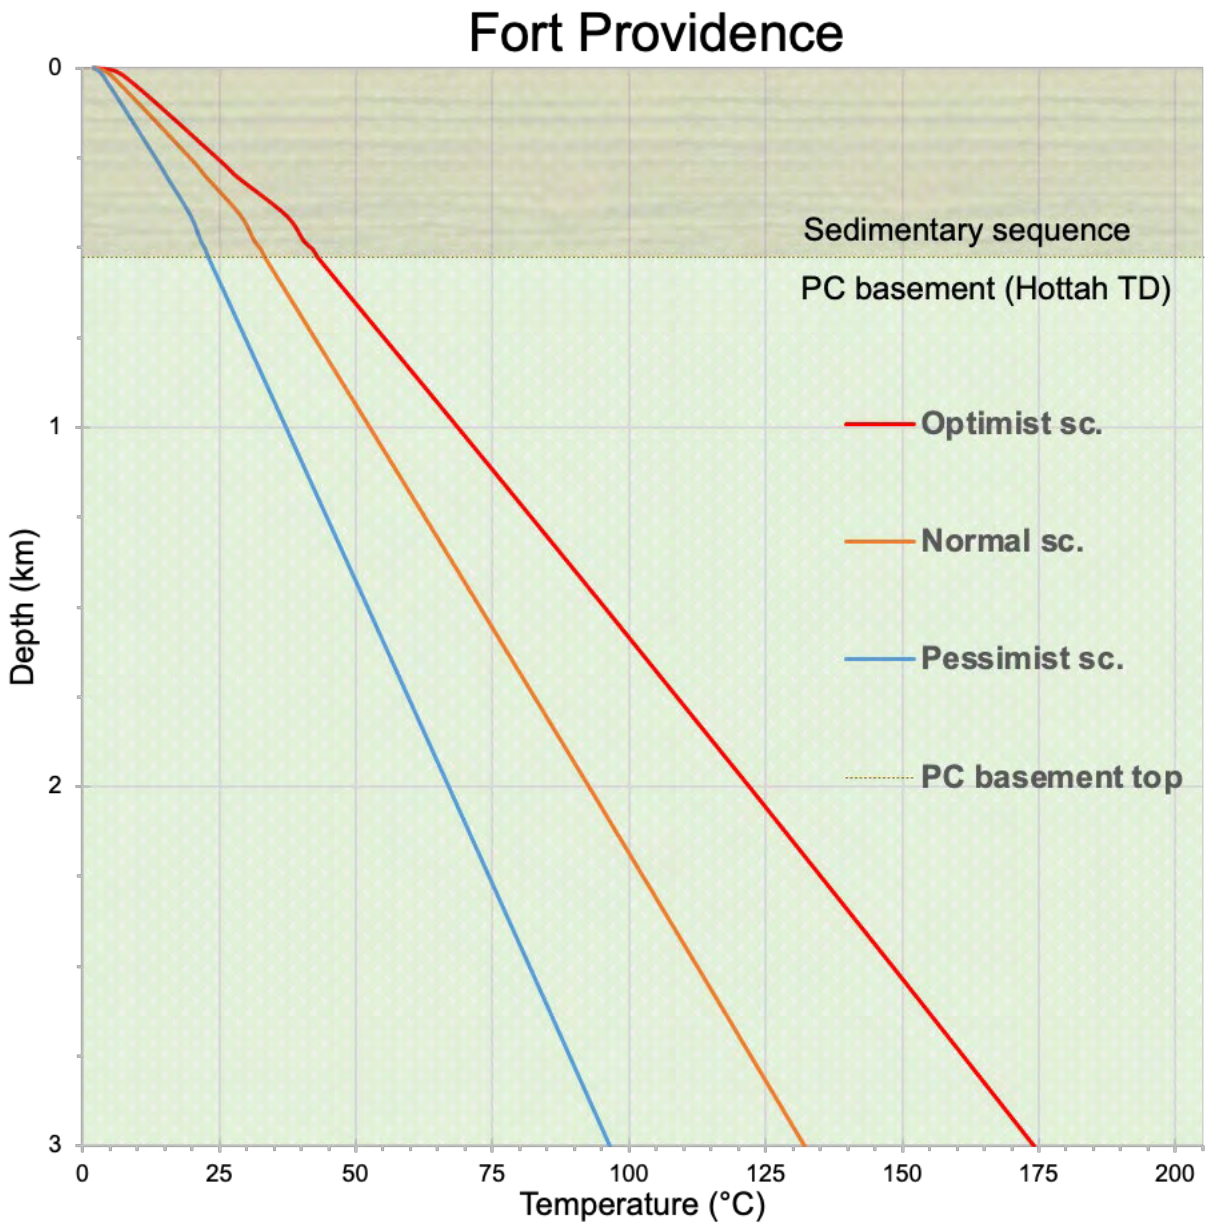

Figure 9: Temperature until 3 km depth for Fort Providence, with optimist, normal and pessimist scenarios, considering heat flow uncorrected for paleoclimates.

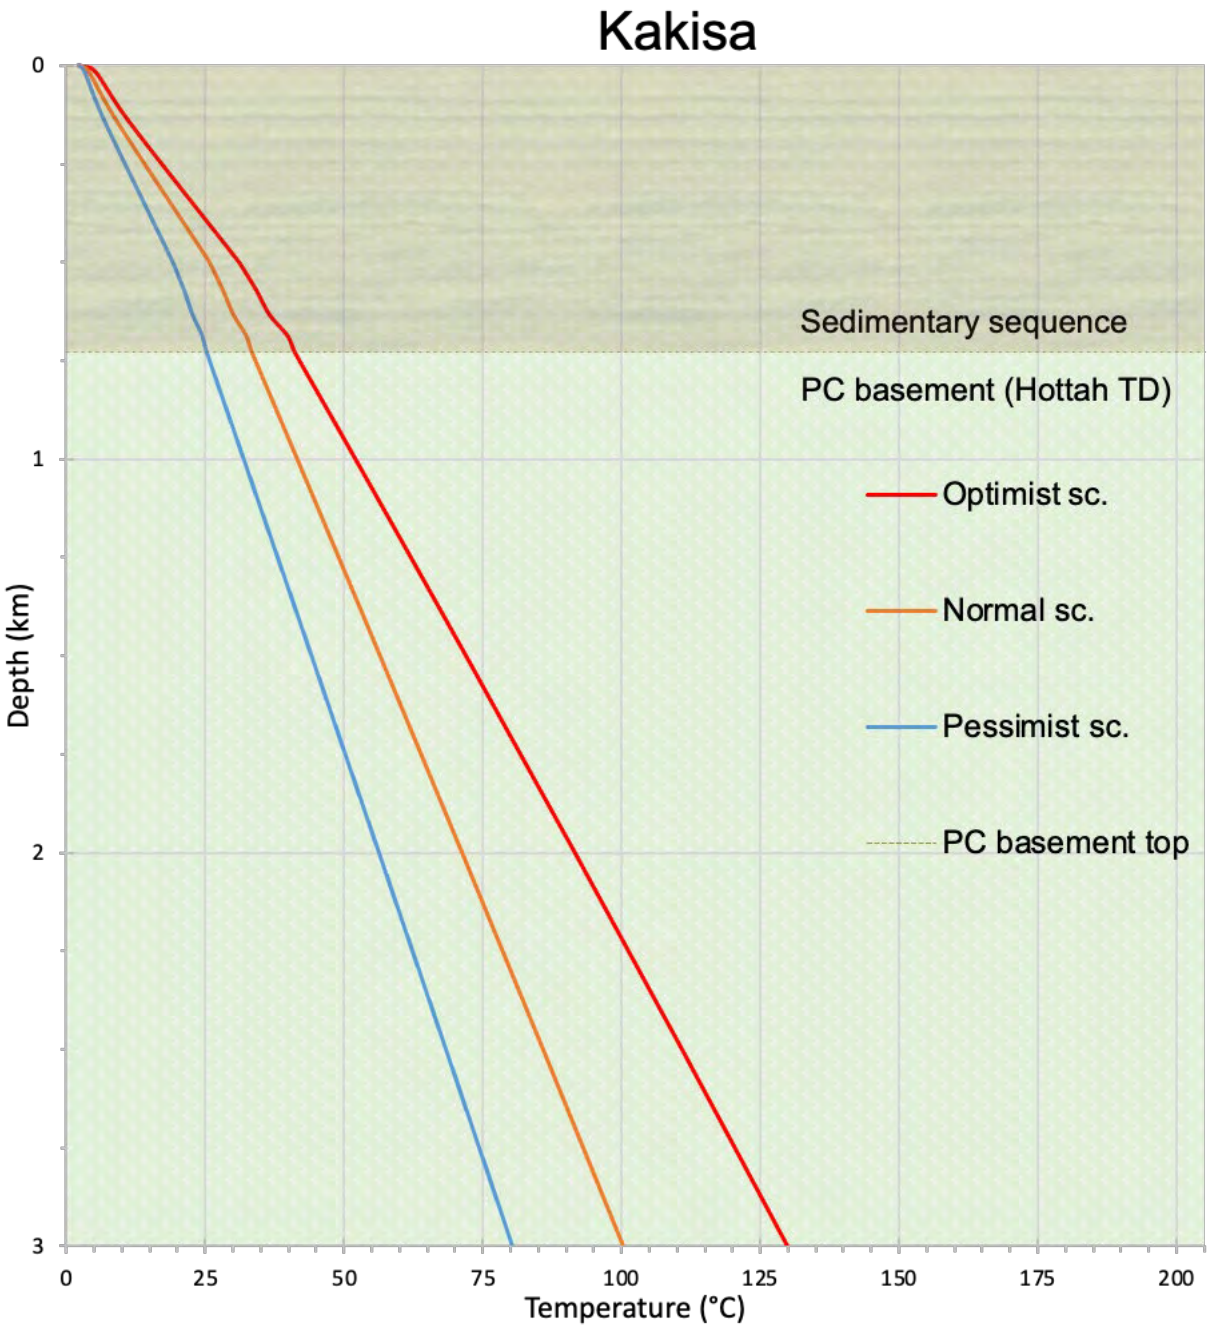

Figure 10: Temperatures at depth until 3 km depth for Kakisa, with optimist, normal and pessimist scenarios, considering heat flow uncorredted for paleoclitates.

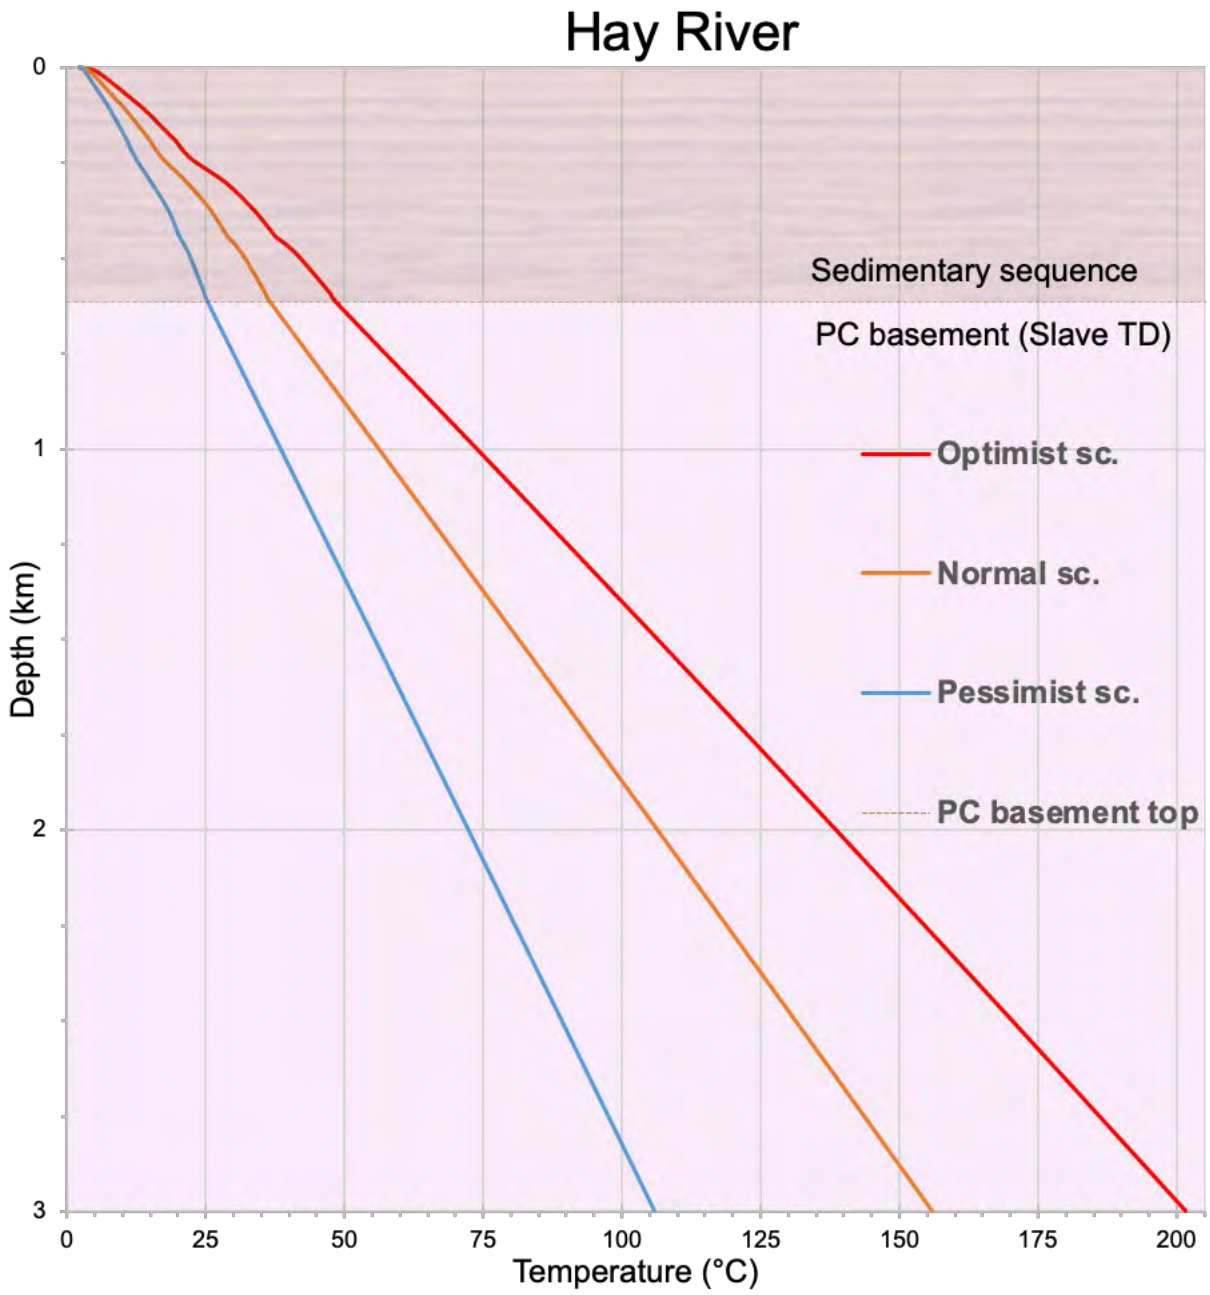

Figure 11: Temperatures at depth until 3 km depth for Hay River, with optimist, normal and pessimist scenarios, considering heat flow uncorrected for paleoclimates.

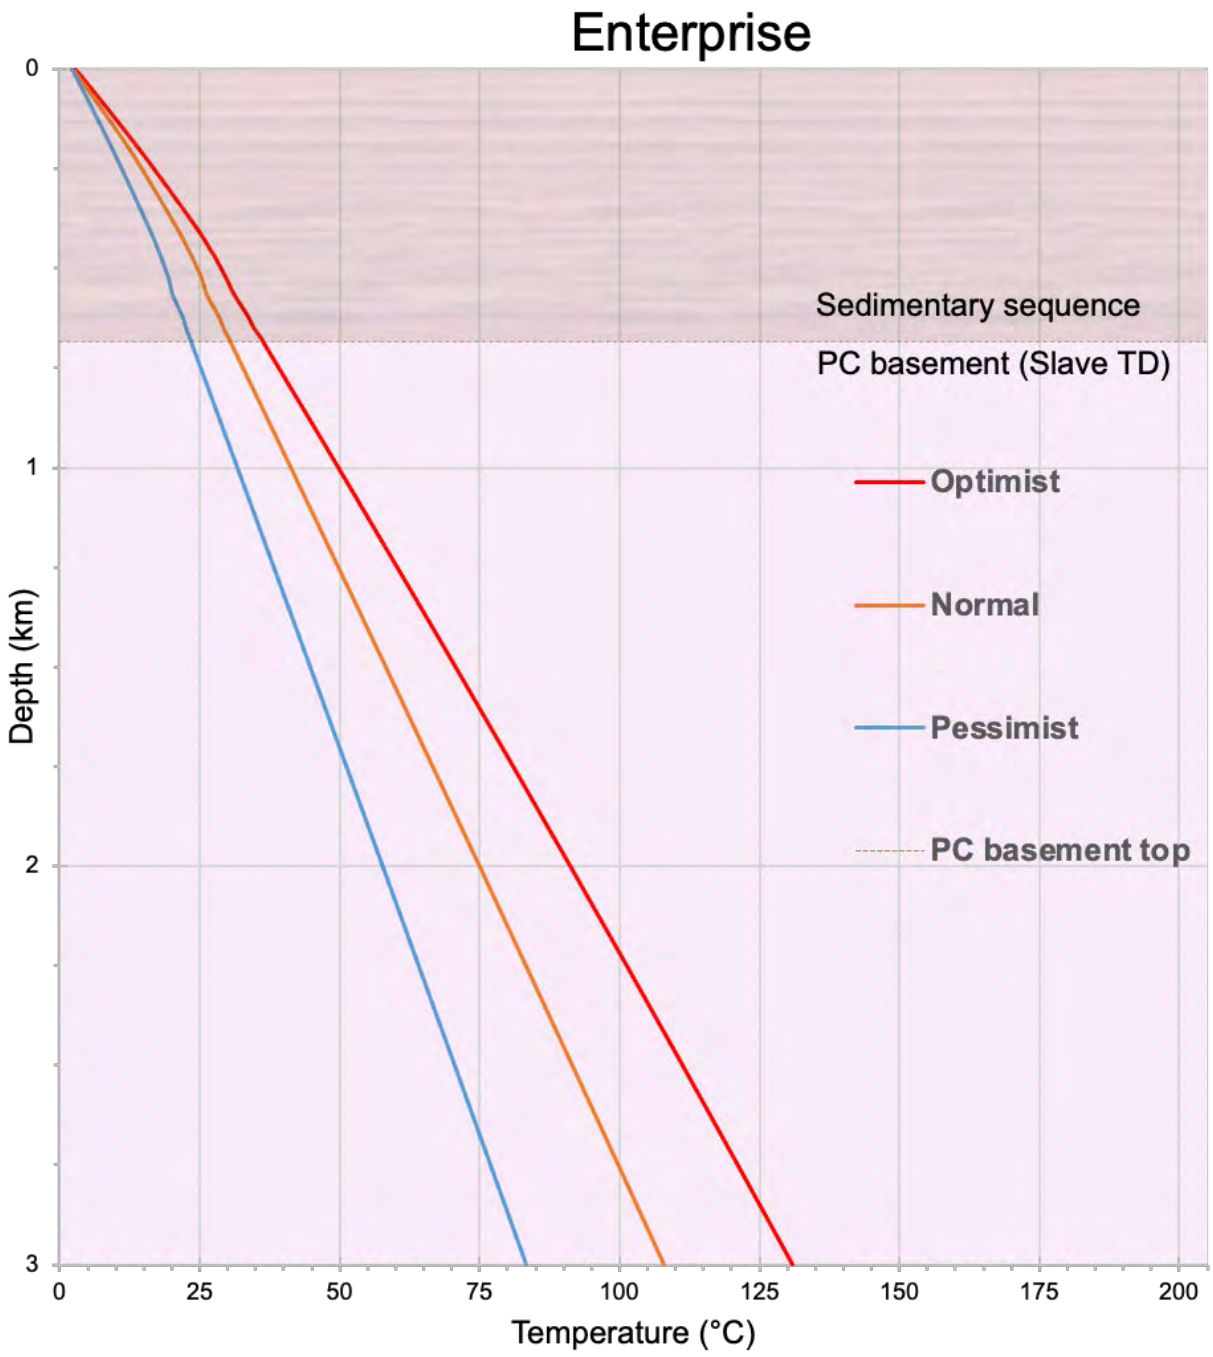

Figure 12: Temperatures at depth until 3 km depth for Enterprise, with optimist, normal and pessimist scenarios, considering heat flow uncorrected for paleoclimates.

4.4 Temperature in the Basement until 10 km depth

For the sake of clarity, only the normal scenario is considered for the temperature calculated until 10 km depth below each community (Figure 13). The calculated temperatures represent an estimate of the equilibrium temperature, considering heat flow corrected for paleoclimates.

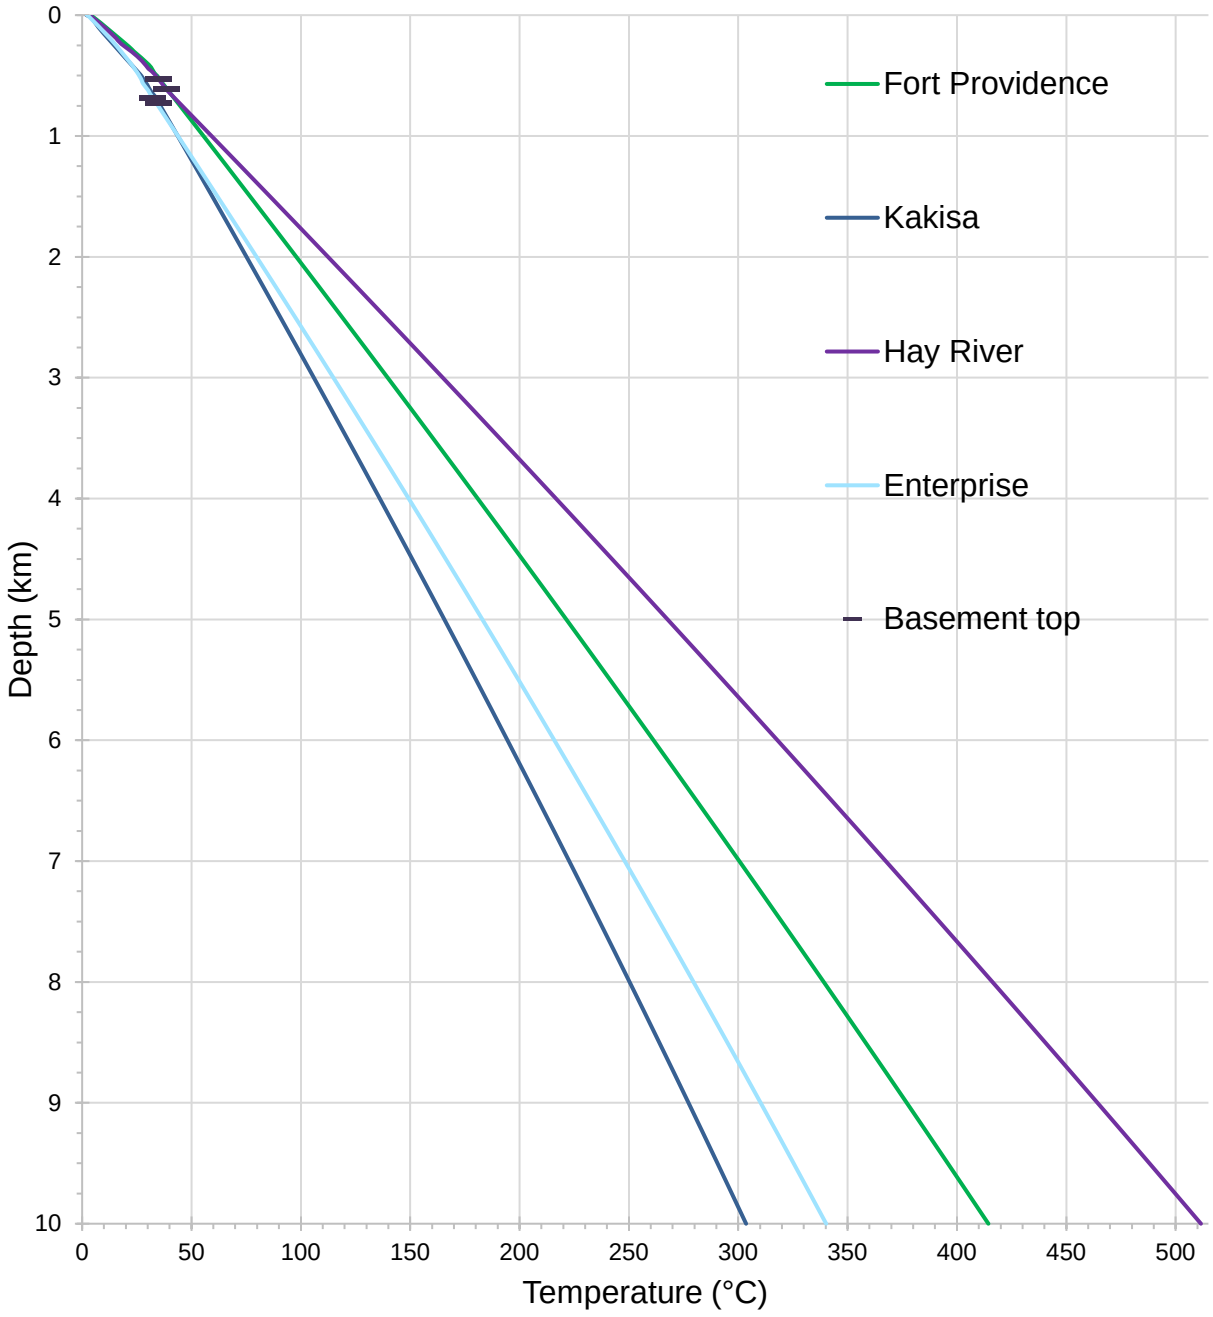

Figure 13: Temperature until 10 km depth, with the normal scenario, considering equilibrium heat flow, corrected from paleoclimate effects. Each community is represented by a distinct coloured line.

5. Discussion

This basement thermal property assessment allowed to predict temperature at depth below the sedimentary rock cover for the NWT communities of Hay River, Fort Providence, Enterprise, and Kakisa. The new thermal properties data present in this study will be publicly available and can be used for additional subsurface studies in other regions of the WCSB and the Slave Province.

This research builds upon previous studies that focused on the shallow sedimentary sequence (<730 m) (Rajaobelison et al., 2024, In press) by extending the assessment to the deeper Precambrian basement, further demonstrating how oil and gas exploration data can be used for early stage deep geothermal resource assessment.

Thermal conductivity values significantly influence the geothermal gradient. Precambrian basement rocks exhibit higher thermal conductivity than sedimentary rocks, resulting in a slower temperature increase within the basement. In contrast, the sedimentary sequence, with its lower effective thermal conductivity, act as a 'thermal blanket', trapping heat and causing a higher temperature increase with depth.

Our findings indicate that the highest geothermal gradient is expected below Hay River, with temperature increasing more rapidly than in other communities. Conversely, Kakisa has the lowest geothermal gradient, followed closely by Enterprise. The variation in subsurface temperature among these communities, despite their proximity within a 120 km radius, highlights the importance of localized resource assessments rather than relying on extrapolated values from a regional scale assessment.

Temperature at depth for Hay River and Fort Providence reveal a similar profile within the sedimentary sequence, but is significantly different in the Precambrian basement. This disparity can be explained by a lower thermal conductivity and a higher heat flux inside the Slave Craton for Hay River. These factors contribute to a faster increase in temperatures at depth. Similar observations can be made for Enterprise and Kakisa.

Although we would have expected similar temperature due to their proximity, Hay River and Enterprise (approximately 30 km apart and part of the same tectonic domain) show a notable temperature difference at depth. This discrepancy is primarily due to the different heat flow values used in calculations and originating from well temperature measurements that can enclose a high uncertainty (Rajaobelison et al., 2024).

Upon comparing our findings with those of other studies (Grasby et al., 2011; Majorowicz & Grasby, 2010b, 2010a), notable disparities in temperature estimations emerge, particularly in Hay River. Majorowicz & Grasby (2010b) estimate a temperature of approximately 85 °C at 3 km and around 250 °C at 10 km for Hay River. On the other hand, we estimate temperatures slightly above 150 °C at 3 km and 500 °C at 10 km. Moreover, Grasby et al. (2011) report a depth of 3.5 km to reach 150 °C in that region. Also, Majorowicz & Grasby (2010a) estimate a temperature slightly below 350 °C at 10 km for the community locations. However, the temperatures we calculated at depth in Hay River and Fort Providence are much higher than those reported in previous studies. Enterprise and Kakisa values are also higher albeit slightly lower than the other two communities. This is mostly attributed to the utilization of a larger heat flow estimate in our calculations. For example, when using a lower heat flow value, similar to these studies, 95 ± 5 mW m^{-2}, our results align more closely with those of previous studies.

Input temperature is the most influential factor in the estimation of the geothermal gradient and heat flow; therefore, its variability directly affects the results. Noisy or poor-quality data can significantly bias geothermal gradient assessments. The reliability and accuracy of temperature measurements can be influenced by factors such as the method of measurement, quality, depth, season, and the age of the data, as discussed by Majorowicz et al. (1999, 2014b). In this region, the availability of high-quality thermal data is limited, with most drilling reports dating from the 1960s to the 1980s. Also, wells are limited in depth, with only four boreholes exceeding 1000 m and situated at a reasonable distance (<50 km) from the communities. Reconsidering the input values, particularly for unusually high heat flows such as those observed in Hay River and Fort Providence, which may have been overestimated, could lead to more consistent results between communities and with literature values.

Another limitation of the study is that the 1D analytical temperature models do not account for expected decreases in thermal conductivity with increasing temperature and pressure at depth (Clauser, 2011; J. Majorowicz, Nieuwenhuis, et al., 2014). These factors could influence the values obtained by increasing our temperature values at greater depths, especially those predicted to 10 km. Additionally, our results are theoretical predictions that should be interpreted with caution. They heavily depend on the inputs used in calculations, and the uncertainty increases with depth, as highlighted by the optimistic and pessimistic scenarios and in comparison to the literature.

This study is not intended as a regional or large-scale analysis and does not evaluate three-dimensional resource distribution. It does not focus on potential aquifers or consider structural geology impacts, such as faults and fractured patterns on localized resources.

However, one of the strengths of our study is the use of representative thermal properties for the geological formations under the communities. These were obtained from laboratory measurements on the same geological formation rocks that we expect to be found below the communities, rather than from broad literature values, as was done in previous studies. Furthermore, our localized approach ensures relevance to community end users, making our findings directly applicable and reliable for the community's geothermal resource assessment.

Geothermal resources within the sedimentary sequence (<37 °C) could be used for heating applications, most likely requiring the use of a heat pump system. However, for applications requiring temperatures above 40 °C, which can support a wide range of geothermal energy uses, drilling into the Precambrian basement would be necessary to reach such temperature. Specific applications, such as electricity production, necessitate temperatures above 80°C, below which it becomes uneconomical. However, a high temperature above 150°C is more commonly employed for power generation (Ahmadi et al., 2020). Based on our 1D models, such temperature is expected at depths about 1500 m and 3000 m for the community of Hay River and around 2250 m and 4500 m for Kakisa. Low permeability crystalline rocks are expected at such depth, which would either require EGS or DBHE.

While our results indicate a great geothermal potential for the South Slave communities, with high temperature at depth, these are theoretical estimates. This potential can only be validated through exploration drilling to confirm the geothermal potential.

6. Conclusions

This study provides critical insights into the thermal properties of the Precambrian basement rocks beneath the sedimentary basin in the South Slave communities of the NWT. It was combined with previous temperature assessment in the sedimentary rock cover.

The calculated temperature profiles highlight the importance of local resource assessments for the community's end user, from which geothermal development could potentially contribute to energy independence, reduce greenhouse gas emissions, and promote regional economic development.

The temperature profiles presented in this work can be used as input for future work, focusing on numerical simulations aimed at evaluating the efficiency of heat extraction for each community considering DBHE. Such systems, when coupled with heat pumps, present a promising technology for heating applications in the South Slave Region. Numerical modelling will further assist in defining the thermal output of these systems in locations without deep aquifers. These efforts will provide important information for future decision-making about energy supply in that region as well as any further geoscience study in the area.

Acknowledgement

We would like to thank the Office of the Regulator of Oil and Gas Operations and the Geological Survey of Canada Core Repository in Calgary for providing access to the drilling cores and assistance with sampling, Northwest Territories Geological Survey (NTGS) staff to provide access and assistance with archive samples and Dr. Jacek Majorowicz and Rod Smith for constructive discussions. This research was funded by a scholarship from the Natural Sciences and Engineering Research Council of Canada to the first author as well as research grants given to INRS under the Northern Scientific Training Program, GEM-GeoNorth program of Natural Resources Canada and the NTGS. The Centre d'études nordiques is also acknowledged for help with logistics.

Geothermal Resource and Transmission Planning in the Western United States:

A Review of Recent Results and a Roadmap for Continued Expansion

Paul Thomsen and Kayla Dowty

Ormat Technologies

Keywords

Geothermal, electric power, resource planning, transmission planning, decarbonization, planning assumptions and models, regional coordination, Western U.S. states

ABSTRACT

Long-term electric power resource planning is a primary mechanism for driving geothermal procurement in the western United States. At the same time, transmission expansion is required to further unlock the region's abundant geothermal resources. In a prior paper, Thomsen (2021) described the regulatory processes and analyzed geothermal selection across various resource plans and other resource procurement decisions issued from 2019 to mid-2021. A key finding was that geothermal selection was highly variable from year to year, and, among other things, the paper recommended several revisions in resource modeling and proposed enhanced regional coordination. Since the paper's publication, the geothermal sector has received significant boosts from 2021 and 2023 procurement decisions by the California Public Utilities Commission (CPUC), which have resulted in new projects and contracts, and California planning scenarios which include large capacities of geothermal over the next 10-20 years. With a few exceptions, the rest of the West has been less proactive in supporting the geothermal industry, but there are new developments which reflect increased federal and state support (as well as a new interest in corporate procurement). This paper updates the prior findings, evaluates whether the recommendations have been addressed, and provides suggestions for further resource and transmission planning improvements. In addition, the paper proposes development of a planning roadmap to support high geothermal scenarios across the region.

1. Introduction

Resource planning is a primary input into clean energy procurement decisions by load-serving entities (LSEs) in Western U.S. states and transmission planning to support rapidly changing resource portfolios. Almost all the larger LSEs in the region conduct integrated resource planning (IRP), and in some cases, state agencies and regional entities also conduct such planning. These resource plans guide subsequent resource procurements and transmission expansion options. This

paper elaborates on two earlier papers,[1] which are starting points for an updated survey of how geothermal is evaluated in resource planning and extended to include some developments in transmission planning.

Geothermal energy has received significant commercial interest in the past 2-3 years due in large part to the California Public Utilities Commission's (CPUC) 2021 and 2023 Mid-Term Reliability (MTR) decisions requiring buyers to procure geothermal or other clean firm energy resources (CPUC 2023a, 2021). These decisions actually reversed the CPUC's lack of consistent support for geothermal in its prior planning processes, and led to new geothermal contracting by almost all LSEs in California and interest in more significant geothermal development. There has also been an increase in procurement associated with industry innovation and federal and state government support elsewhere in the region.[2] Overall, this new direction for geothermal energy reflects many of the recommendations that were made in the earlier papers and by the geothermal industry.

Additionally, commercial and industrial customers have a strong interest in geothermal energy seeking clean, firm baseload energy. A common application is for data centers, which typically have relatively firm loads but also some capability to shift load during operations to reduce costs or emissions. Load growth due to these uses is being reflected in utility resource planning. Some corporate customers are also entering directly into clean energy contracts with developers.

Transmission development is required to facilitate any significant growth in regional geothermal development. Since geothermal resources must be located at particular sites, transmission availability can limit geothermal development—several utility resource plans reviewed in this paper note that further geothermal procurement will require transmission availability. In the western U.S., a number of new transmission lines are being energized over the next few years and others are in advanced planning for operations in the early 2030s. For geothermal development to meet demand, it is necessary to identify specific transmission upgrades and be ready to utilize the new transmission capability before it is contracted for other resources. The geothermal industry needs to create its preferred long-term transmission plan for the West; otherwise, geothermal access to transmission could be an afterthought of the planning for other resources.

2. Regulatory Framework and Methods for Resource Planning

IRP is conducted by almost all LSEs in the western U.S., with different types of regulatory oversight. Since the last rounds of IRPs in the western states reviewed in the prior paper (Thomsen 2021), most of the planning entities have continued to conduct resource planning using variants of the same methodologies. As discussed below, California seems to be the state in the region with the most changes in the past few years, both in terms of state policies and planning methods as they pertain to geothermal energy.

[1] These include Thomsen's (2021) survey of geothermal in Western resource planning, which provided a framework for analysis of trends and identified the need for certain planning improvements, while in an earlier paper, Thomsen (2018) demonstrated how a resource planning model used by the California Public Utilities Commission (CPUC) could be tested for geothermal selection.

[2] See, e.g., the Department of Energy's (DOE), Pathways to Commercial Liftoff: Next-Generation Geothermal Power (DOE 2024) and the Western Governors' Association (WGA), The Heat Beneath Our Feet (WGA 2023).

No standard method or set of analytical tools is used in resource planning, making comparative analysis of trends in geothermal selection more difficult (Thomsen 2021, Warren *et al*., 2021). Additionally, the ongoing changes in state clean energy policies and programs, and in utility strategic objectives, have required almost continuous adaptation of both methods and tools. This has resulted historically in variations in geothermal selection in the planning studies reviewed in the prior surveys and, to some degree, this continues to the present day.

In our observation, the challenge is not so much in how geothermal is represented operationally in planning models since it is typically analyzed relatively simply as a flat (or firm) block of power, possibly with some shaping throughout the year and by the time of day. Usually, geothermal is assigned a capacity factor[3] of 80-90% and a capacity value[4] in that same range; actual assumptions used by different planners are discussed below. Whether these models select geothermal as a desirable resource has to do with various factors specific to geothermal, including the estimated regional resource potential for geothermal and geothermal cost assumptions and operational attributes, but as importantly, how the costs, profiles and operations of the competing resources, wind (onshore and offshore) and solar, and more recently batteries (stand-alone or hybrid), are captured, as well as their assumed capacity value. Most resource planners have not yet modeled geothermal power as a dispatchable generator (Warren *et al*., 2021). However, operational flexibility was examined in some studies discussed below, and has been incorporated into some recent geothermal contracts.

The following sections turn to specific results from each region's resource and transmission planning processes, which help illustrate some of the findings on models and methods.

3. California

Over the past few years, California has been the leading state for geothermal procurement, building on the MTR orders by the CPUC to support reliability in response to the 2020 blackouts and subsequent scarcity events during peak net load hours. These orders have re-set the resource planning process, setting a floor but not a ceiling for geothermal procurement. At the same time, subsequent long-term resource planning simulations for the state suggest that geothermal selection could dramatically increase over the coming decade if the geothermal industry can deliver at forecasted costs.

[3] Capacity factor is the percentage (%) of total possible output based on nameplate capacity (MW), typically calculated annually or monthly. Hence, a 100 MW generator which operates at an average of 90 MW production for a year has a capacity factor of 90%.

[4] Capacity value refers to the capacity (MW) or the percentage of capacity (%) which is available during the subset of peak load or net peak load hours being evaluated for resource adequacy. Hence, if a 100 MW generator is expected to operate at 75 MW during those hours (as identified by the planning entity), its capacity value is 75 MW or 75%. Capacity value thus typically focuses on a subset of hours, and may take into account hourly variability during those hours and expected forced outage rates, whereas capacity factor is an average of production in all hours.

California has the most resource plans running in parallel of all the states in the region, and geothermal is present in all of them.[5] Table 1 lists California's critical resource planning processes and indicates their timing and relationship.

Table 1 – California primary resource planning processes

Resource planning process	Recently Completed	Forthcoming
CPUC Integrated Resource Planning proceeding (CPUC and jurisdictional LSEs)	2018-19, 2020-21, 2022-23	2024-25
CPUC Mid-Term Reliability (MTR) procurements	2021, 2023	
Joint state energy agencies - SB 100 decarbonization scenarios	2021	Ongoing process
CPUC resource portfolios for CAISO Transmission Planning Process (TPP)	Annual	Annual
State agency resource portfolios for CAISO 20-Year Transmission Outlook	2022, 2024	2026
Los Angeles Department of Water and Power (LADWP)	2017, 2022, 2023	2025
Other publicly owned utility (POU) integrated resource plans (CEC oversight)	2018-2019, 2023-2024	2028-2029 (every 5 years)

3.1 CPUC Procurements to Address Mid-Term Reliability in the 2020s

Even though the CPUC IRP proceeding pre-dates the CPUC's Mid-Term Reliability (MTR) decisions (CPUC 2021, 2023a), for this survey, we begin with the MTR decisions since these are so influential to geothermal planning and procurement. The MTR decisions corrected the CPUC IRP proceeding's early failures (over the first two planning cycles in 2018 and 2020) to properly value geothermal in resource planning, which caused several years of stagnation in geothermal procurement.[6]

The first MTR procurement decision in 2021 (CPUC 2021), established a target for jurisdictional LSEs to procure 1 GW of geothermal power by 2026-2028.[7] This target was then incorporated and increased in the CPUC's subsequent IRP decision, determining a final 2020 Preferred System Plan (PSP) (also issued in 2021). These decisions were motivated by the heatwaves and blackouts in September 2020 and the strong reliability contribution of geothermal energy, which was not reflected in the prior IRP results. This procurement process has been underway and is reflected in the results shown in the figures and tables below. The CPUC's Supplemental Mid-Term Reliability

[5] In some years, when planning cycles for the CPUC-jurisdictional LSEs and the publicly owned utilities (POUs) roughly coincide (such as 2022-2023) this results in over 100 different studies for individual LSEs and regional entities, such as CAISO. This includes about 70 integrated resource plans for CPUC jurisdictional LSEs and about 20 plans for publicly owned utilities.

[6] Thomsen (2018, 2021) provide many details about why the CPUC IRP proceeding did not select geothermal consistently.

[7] The CPUC 2021 MTR defined the procurement to require 1 GW of “firm resources with zero on-site emissions” with a capacity factor of at least 80% (and hence not subject to use limitations or weather dependence) by 2026 or at latest 2028. The CPUC 2020 IRP final decision explicitly named geothermal.

procurement decision (2023a) then identified a resource planning need for up to 1,863 MW of new geothermal by 2033. Figure 1 below summarizes the results of these two CPUC decisions. The response to the MTR decisions by jurisdictional LSEs was to commit to new geothermal procurement, reversing years of inactivity in the geothermal market.

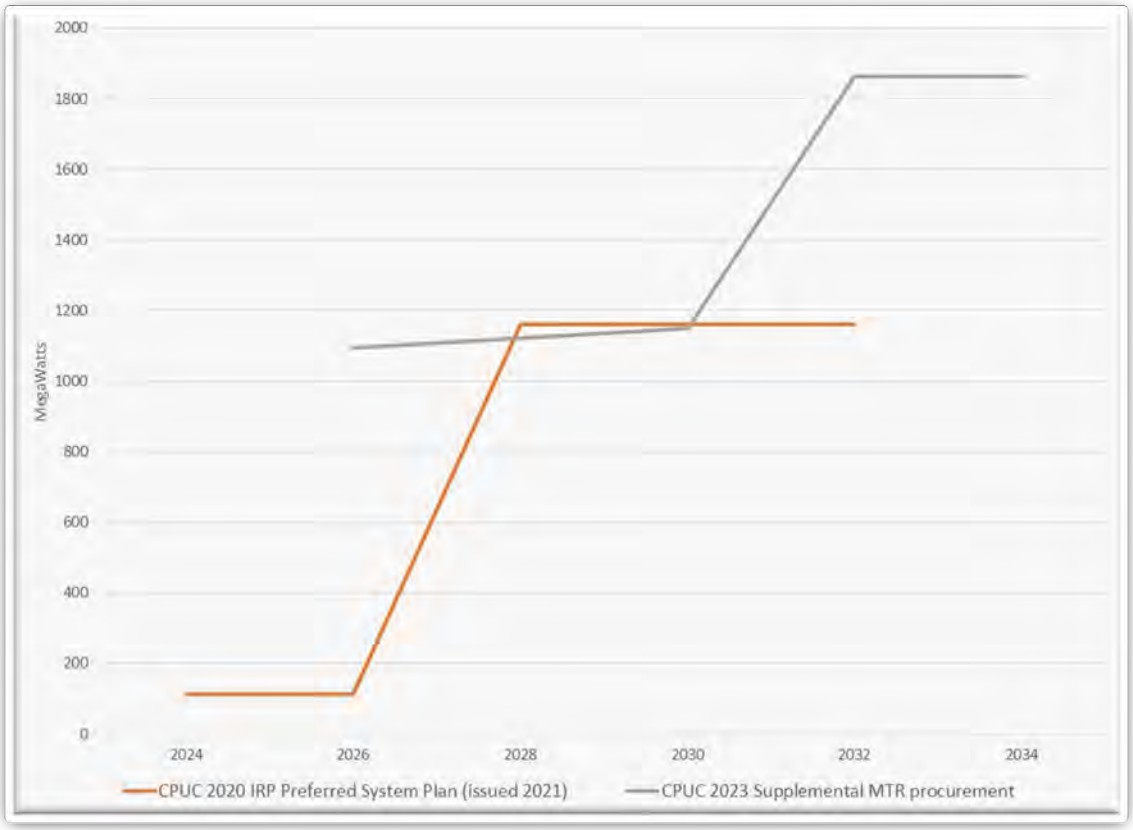

Figure 1: CPUC resource planning and procurement recommendations on geothermal, 2021 and 2023

3.2 CPUC 2022 IRP Results and Trends

The MTR procurement decisions became the baseline for the subsequent IRP cycles. The 2022 IRP PSP (CPUC 2024) increased the geothermal selected in the 2023 MTR and includes 2 GW of new geothermal by 2035 in the core scenario (which targets 25 million metric tons of carbon emissions). This is shown in Figure 2, below.

Although not the preferred case, the 2022 IRP includes a High Gas Retirement Sensitivity Case, which will retire about 16 GW of natural gas plants (including combined heat and power) by 2040. As also shown in Figure 2, in response to the progression of gas retirements, the model builds 4.6 GW of new geothermal by 2035 and up to 5.1 GW by 2045. None of this geothermal is

characterized as EGS, due to the high assumed cost.[8] The CAISO will study the high gas retirement case in its 2024-25 Transmission Planning Process (TPP).

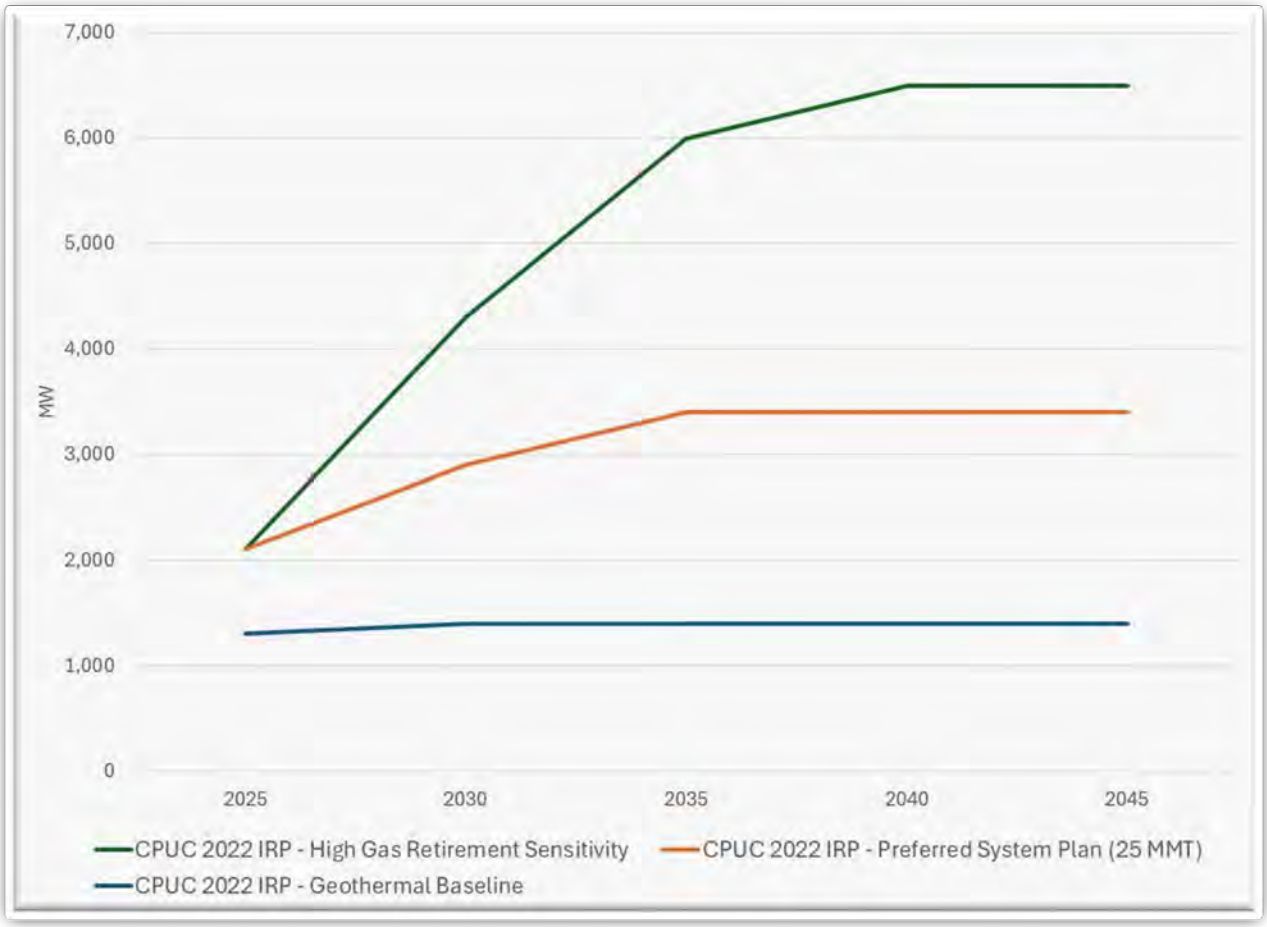

Figure 2: CPUC 2022 IRP selection of geothermal

While the CPUC 2022 IRP portfolios establish the benchmark for associated LSE resource planning and procurement, each LSE can determine an equivalent resource portfolio that suits their needs. Moreover, the LSE can open a procurement to meet CPUC requirements but determine that offers are not cost-effective. Hence, the LSE planning and procurement decisions can be tracked to assess the accuracy of the CPUC planning forecasts.

Table 2 provides data on geothermal selection by some of the larger CPUC-jurisdictional LSEs in their 2020 and 2022 IRPs; we have not tracked all actual procurements. The planning results show that in almost all cases, LSEs selected more geothermal in their 2022 IRPs than in their 2020 IRPs (but in a few cases, lower selection in 2022 reflected procurement concluded since 2020). In

[8] The CPUC is contemplating specific procurement targets for EGS, which will not be finalized prior to publication of this paper.

addition, some LSEs have begun additional planning initiatives to support geothermal development.

Table 2 – Geothermal selection by selected CPUC-jurisdictional LSEs, 2020-2022 IRPs

LSE	Type of LSE	Aggregate geothermal in preferred scenarios (MW)	
		2020 IRP	2022 IRP
Southern California Edison (SCE)	IOU	180	379
Pacific Gas & Electric (PG&E)	IOU	None, existing contracts to expire	Not specified
San Diego Gas & Electric (SDG&E)	IOU	None	42
Clean Power Alliance (CPA)	CCA	175	228
Clean Power SF	CCA	50	49.3
East Bay Community Energy (EBCE)	CCA	78	40
San Diego Community Power (SDCP)	CCA	100	100
Pomona Choice Energy	CCA	0	5.73
San Jose Clean Energy	CCA	0	59
Sonoma Clean Power Authority (SCPA)	CCA	31	85.52

3.3 Geothermal in Resource Planning by the POUs

The California Publicly Owned Utilities (POUs) in southern and northern California include several utilities with long experience with geothermal resources, both through ownership and contracts. They comprise about 20 percent of California load. Each POU conducts an IRP, with oversight by the California Energy Commission (CEC).[9]

3.3.1 Los Angeles Department of Water and Power (LADWP)

LADWP has been a leading buyer of geothermal in the western U.S., and its resource plans in recent years have examined scenarios for significant geothermal expansion. At the same time, similar to some other planning entities, LADWP has issued different results over time, reflecting revised modeling and the availability of new geothermal resources to procure.

Until 2017, LADWP issued an annual IRP, which is now called the *Power Strategic Long-Term Resource Plan*. The annual planning process was suspended for 2-3 years while a very detailed, scenario-based planning study called LA100 was conducted jointly with the National Renewable Energy Laboratory (NREL) and issued in 2021 (Cochran and Denholm, eds., 2021). In 2022, the utility issued a new IRP (LADWP 2022), which took some of the LA100 results into account and then submitted a version of the results to the CEC as its 2023 IRP (LADWP 2023).

[9] The recent IRPs cited in this section can all be found in one location on the CEC website and are not listed in the paper references.

As summarized in Table 3, LADWP planners have typically forecasted the need for around 500 MW of geothermal over the next 10-15 years.[10] As of 2022-23, LADWP has contracts for 223 MW with nine geothermal plants, which is around 10% of annual energy (LADWP 2023). At the same time, the 2022 and 2023 resource plans have reduced the forecast for potential new geothermal compared to the prior studies.[11] Although the discussion isn't clear, the 2023 IRP supply tables suggest that 52 MW of additional geothermal are under consideration as "Planned Utility-Scale Geothermal."

Table 3 – LADWP geothermal portfolios in recent IRPs

IRP year	Existing geothermal capacity in starting year (MW)	Total geothermal capacity in final planning year (MW)
2022, 2023	223 operational + 52 planned	52
2021 (LA100)	230	500 - 1,600
2017	106	445
2016	108	498
2015	69	293

* For 2015-2017, 20 years, for 2022-23, 2045; Sources: Cochran and Denholm, 2021; LADWP 2023, 2022, 2017, 2016, 2015

3.3.2 Other POUs

Table 4 summarizes geothermal results in the other recent POU IRPs, and incorporates the results from their prior IRPs for easy comparison. Similarly to other western resource plans, these POUs have increased the selection and procurement of geothermal energy, typically through the collective procurement under the Southern California Public Power Authority (SCPPA), and similar to other planners, their resource forecasts for geothermal energy are higher in more rapid decarbonization scenarios. It is worth noting that while the POUs are not CPUC-jurisdictional, they are influenced by the CPUC's current emphasis on firm resources to support resource adequacy.[12]

A few results stand out:

- since the 2018-19 IRPs, several POUs have already procured more geothermal than they envisioned over the next 20 years in those prior IRPs (e.g., Pasadena Power and Light, SVP);
- similarly to other LSEs reviewed in this paper, the POUs would have to dramatically increase their resource capacity to achieve clean energy goals;

[10] In its 5 scenarios, the LA 100 study adopted a baseline target for geothermal of around 500 MW, which reflected internal LADWP judgement rather than independent modeling. In addition, the study examined sensitivity cases which accelerated decarbonization and added some constraints on other technologies. Those sensitivity cases resulted in 1,500-1,600 MW of geothermal in the solution, amounting to around 10% of LADWP's peak load.

[11] Unfortunately, the data presentation in these recent IRPs isn't clear. In several figures, geothermal is bundled with biofuels in a category which is called "long-duration renewable capacity."

[12] For example, City of Anaheim's 2023 IRP (pg. 88) observes that "Firm resources refer to geothermal, biomass, biogas, nuclear, gas and coal generation, and are considered preferable under the CPUC reliability evaluations. While APU is not a CPUC-jurisdictional entity, CPUC considerations are considered for potential future impacts to the CAISO Resource Adequacy accounting rules."

- geothermal is selected more often than in the prior submissions, and is almost always selected for full decarbonization scenarios;
- In some cases where geothermal is not selected, planning assumptions may play a role. For example:
    - SVP's 2023 IRP, the quantity of available geothermal is limited to 350 MW by assumptions about the available resource potential;[13]
    - City of Redding's 2024 IRP, very little geothermal is selected, but this may be because the model uses a geothermal price of $109.38/MWh in 2031

In 2021, SMUD issued a 2030 decarbonization plan which was subsequently adopted as a 2022 update to its prior IRP. This plan aims to develop portfolios which could achieve decarbonization on an accelerated time-frame, by 2030. This plan selects 100-220 MW of geothermal, out of a total 6,400 MW in the 2030 clean energy portfolio.

City of Anaheim's 2023 IRP Update only selects new geothermal in its Zero Emissions Portfolio (with procurement beginning in 2025), where it ultimately comprises 26% of total capacity, but does not select geothermal in its other higher carbon portfolios.

Table 4 – Geothermal selection in selected California publicly-owned utilities (POUs) resource plans, 2018-2024

POU IRP	Planning scenarios for geothermal
City of Anaheim	**2023 IRP** – Twenty year forecast. Zero Emission Portfolio – 100 MW geothermal (775 MW new resources), Reliability Portfolio – no geothermal (575 MW new resources); RNG Portfolio – no geothermal (475 MW new resources) (currently 39 MW of geothermal)
	2018 IRP – Small adjustments to existing geothermal contracts
City of Redding	**2024 IRP** – Three major scenarios - Low "Base Case" (current portfolio, does not meet mandates), Mid "Net-Zero Carbon 2045" (meets mandates and targets), High "100% Zero Carbon 2045" (exceeds mandates and targets). Geothermal was only selected in a sensitivity case of the Net-Zero scenario, requiring resource diversity, under which 25 MW were selected in the late 2030s. Model uses a very high cost of geothermal, beginning at $109.38/MWh in 2031. Final Preferred Plan maintains gas generation and adds 315 MW of solar and 55 MW of 8-hour batteries.
	2019 IRP – Geothermal not specifically evaluated
Pasadena Power and Light	**2024 IRP** – Scenario 1: 100% Carbon-Free by 2030 (No Limit on Internal Resources) – 46 MW of geothermal by 2040 under existing contracts beginning in 2027, no "new" geothermal; Scenario 2: 100% Carbon-Free by 2030 – Maximum Limit on Internal Resources – 10-20 MW of new geothermal in 2030s; Scenario 3: 100% Carbon-Free by 2030 (Maximum Limit on Internal Resources and Doubled Distributed Resources) – 10-20 MW of new geothermal in 2030s; plan assumes that geothermal prices in 2027 will be in the range of $70.00/MWh – $110.00/MWh. Current resource portfolio is around 700 MW, clean energy scenarios need up to 1,500 MW by 2040.

[13] SVP observes that "… the CPUC Mid-Term Reliability order requires CPUC-jurisdictional LSEs to procure approximately 1,000 MW long lead-time clean firm resources by 2028, and geothermal is one of the best available candidates to meet that order. An assumption of this IRP is that SVP may not be able to procure that 1,000 MW tranche. SVP would then be limited to a maximum of about 350 MW, which is approximately 15% of the remaining potential. The three scenarios in this IRP build to, or slightly below that limit."

Table 4 – Geothermal selection in selected California publicly-owned utilities (POUs) resource plans, 2018-2024

POU IRP	Planning scenarios for geothermal
	2018 IRP – Multiple scenarios; existing geothermal contracts to expire in most scenarios, but considers 15 MW of additional geothermal in some scenarios for purposes of diversification, with online dates in 2023, 2033 and 2038
Sacramento Public Utilities District (SMUD)	**2030 Zero Carbon Plan (2021)** – To achieve a zero carbon power system by 2030, SMUD would accelerate procurement of geothermal to achieve 100 to 200 MW (currently 52 MW)
	2019 Resource Planning Report - Resource plan estimates 650 MW of geothermal resource potential in WECC. New geothermal in addition to 51 MW of existing geothermal capacity under contract is currently not anticipated until after 2030, but may be reconsidered if baseload power needs change.
Silicon Valley Power (SVP)	**2023 IRP** – Available new geothermal to SVP is capped at 347 MW in 2028. By 2035, "Scenario 1: Base SB 100" – 290 MW of geothermal, out of ~2.5 GW total capacity; "Scenario 2: Accelerated SB 100" – 330 MW of geothermal out of ~2.7 GW; Scenario 3: Zero Emissions with Emerging Technology – 350 MW of geothermal out of ~2.5 GW; Additional sensitivity case on "Geothermal Limitations and Hydrogen Challenges" which limits new geothermal to 50 MW in 2028. (SVP is currently contracted for 58.4 MW of geothermal in operations; 70 MW planned to be available in 2025-2027, increased to 100 MW by 2036)
	2019 IRP – Decline forecast in geothermal production by about 20% from 2020 to 2030 (from 350 GWh to 282 GWh)

3.4 California SB 100 Modeling

California Senate Bill (SB) 100 (2018) committed the state to achieve electricity decarbonization by 2045. In addition, the legislation required statewide planning studies, the first of which was released in 2021 (CEC, CPUC, CARB 2021), and introduced the concept of geothermal as one type of "zero-carbon firm resources."[14] The second phase of this modeling is currently underway (CEC 2023). In addition, the study results are being used to inform other planning processes, such as the CAISO's 20-Year Transmission Outlook discussed below, which requires the geothermal industry to remain involved in scenario development.

3.5 Geothermal in CAISO Transmission Planning

CAISO conducts regional transmission planning to support the CPUC-jurisdictional LSEs and the POUs located in its footprint. Each year since 2021, the CPUC selects a resource portfolio from its IRP proceeding to recommend to the CAISO for its annual Transmission Planning Process (TPP), a 10-year plan. Over the past few years, the geothermal selection has fluctuated, reflecting some of the evolution of the IRP modeling noted above. For the CAISO 2023-2024 TPP, the CPUC

[14] Thomsen (2021) provided a review of the results of the first SB 100 study mentioned above, which will not be extensively repeated here. The study included the analysis of "zero-carbon firm resources," for which geothermal was one eligible technology, priced at $60/MWh, which was selected at 15-20 GW in sensitivity cases. In addition, while the model didn't select much geothermal priced at $85/MWh for its core scenarios, it did select up to 2.3 GW of geothermal at this price in accelerated decarbonization scenarios.

recommended two 2035 scenarios: a Base Portfolio, which included 2,037 MW of geothermal, and an Offshore Wind sensitivity case, which included 1,149 MW of geothermal.

The CAISO 20-Year Transmission Outlook was started in 2021 to complement the state's SB 100 resource planning discussed above. The first report was released in 2022 (CAISO 2022) and the second version in 2024 (CAISO 2024). For the first report, the core "Starting Point scenario" includes 2.3 GW of geothermal, which the agencies adopted from the first SB 100 report (CEC, CPUC, CARB 2021), most located in the Imperial transmission zone and some in southern Nevada.[15] The subsequent 20-Year Transmission Outlook study, developed over 2023-2024, used the same geothermal assumptions but increased the planning horizon to 2045 and also included a 5 GW allocation for "generic clean firm/long-duration energy storage," a category for which geothermal would be eligible. The key observation about the CAISO's latest 20-Year Outlook is that there is no explicit transmission planning for geothermal outside the identified zones, but some of the other new inter-regional transmission lines could facilitate geothermal development.[16] The geothermal industry needs to continue to inform this long-term transmission planning process based on a collective expectation about the transmission needed to meet and exceed the 2.3 GW of new geothermal which the California state agencies are planning towards.

3.6 Conclusions About California

Over the last few years, California has set the pace for geothermal selection in resource planning and procurement. This was due primarily to policy decisions to authorize the 2021 and 2023 MTR geothermal procurements. This approach has had the benefit of stabilizing the geothermal market and stimulating geothermal contracting. It also provided the geothermal industry with a development path to much higher potential geothermal procurement, which is forecast for California's scenarios with more rapid decarbonization. The state agencies have converged on a forecast of at least 2.3 GW of geothermal by the 2030s, and possibly up to 5-6 GW in some recent 2045 scenarios (CPUC 2024).[17]

4. Other Western States

Since the prior paper (Thomsen 2021), there has been little advancement in geothermal resources planning and procurement in the other western states, with the exception of Nevada. Most buyers in the region will consider geothermal energy through their procurement processes, but they mostly screen it out or limit it otherwise in resource planning models. However, there are planning scenarios with high geothermal development in some states and utilities. These need support from the geothermal industry and to be considered within a western regional planning vision and roadmap. This section provides a brief review organized by subregion, with additional data from

[15] This scenario had 2,332 MW of geothermal, essentially the full geothermal resource potential in California and southern Nevada which the CPUC has used since the start of its IRP, of which 2,012 MW was assigned to the Imperial transmission zone and 320 MW to southern Nevada. The study noted that geothermal assumptions should be updated with stakeholder input.

[16] In stakeholder comments, Fervo Energy observed that CAISO needed to account for EGS resources which may be located in other regions which can supply California buyers, such as Fervo's Cape Station plant in Utah (see discussion below), and which is planned to become operational before 2030.

[17] We note that the modeling in Thomsen (2018) was able to calculate modeled results for geothermal in California of 5-6 GW when CPUC model constraints on geothermal expansion were relaxed.

the resource plans provided in Table 5, below. In the conclusions, we also turn to some potential lessons learned for these states from the California experience.

4.1 Southwestern States

After California, the southwestern states of Nevada, Arizona, New Mexico, and Colorado appear to present the most significant opportunity for geothermal commercial activity in the West in the coming decade.

Nevada has a large existing geothermal resource portfolio serving customers within the state as well as in California. With sufficient transmission availability, further resource development could serve additional buyers across the southwest and the northwest. NV Energy has the largest geothermal portfolio outside California, but geothermal typically is not selected through the utility's integrated resource plans (NV Energy 2020, 2023) but rather negotiated through bilateral contracts, which includes some recent portfolio procurements and contracts with individual new projects (PUCN 2023). NV Energy has also facilitated significant corporate geothermal contacts in recent years (NV Energy 2023, PUCN 2023).

Arizona has growing electricity demand and advanced clean energy goals. The state is not considered to have significant conventional geothermal resource potential. In general, the major utility IRPs consider geothermal as a marginal addition and dependent on transmission availability to access imports (APS 2023, TEP 2023, SRP 2023). Salt River Project (SRP) has the most existing geothermal capacity, with around 167 MW contracted with the plants in the Salton Sea area, but there is only limited expectation of additional procurement. SRP allowed for up to 1 GW of new geothermal power in its 2023 Integrated System Plan (SRP 2023), but only 50 MW was selected by 2035. Arizona could soon be served by new transmission lines interconnecting to New Mexico (such as Sunzia and several others in advanced development) and between the other neighboring states, potentially allowing increased transfers to and from Nevada and the Pacific Northwest. Additional transmission upgrades could improve transmission transfer capability to California and geothermal development in the Salton Sea region. For Arizona utilities, transmission is the key to further geothermal procurement.

New Mexico has a history with geothermal research, and since 2023, state legislation and workshops have sought to advance geothermal development.[18] There is only one small commercially operating geothermal plant in the state, contracted with Public Service Company of New Mexico (PNM). PNM has not selected additional geothermal resources through its 2023 IRP but will accept offers in its all-source RFPs. El Paso Electric Company evaluated geothermal in its 2021 IRP but did not select any through the modeling. A successful geothermal expansion in New Mexico could serve both the LSEs in the state and even export to the other states in the region. The new transmission projects under construction or planned to connect New Mexico to its western neighbors were developed mostly to export wind generation. These lines could also present an opportunity for any new geothermal projects in the state to have export opportunities.

Finally, Colorado does not yet have any operating geothermal projects. Still, the state has undertaken ambitious recent initiatives to advance geothermal energy through legislation to support research and financial incentives, which were implemented through the Colorado Energy

Office (CEO). As such, there are new projects in the planning stage. Xcel's most recent IRPs for Colorado (Xcel 2022, 2024) did not select any geothermal through the planning scenarios, but subsequent RFOs have received some offers for geothermal projects.

In 2024, the CEO released a simulation study of decarbonization in the state by 2040, which included new geothermal in several scenarios (CEO 2024). The "Optimized 100" scenario is intended to be the least cost pathway, and selects 800 MW of geothermal by 2040. A sensitivity case on Accelerated Geothermal Adoption selects 2 GW of geothermal by 2040, which represents 10% of annual electric energy.

4.2. Pacific Northwest States

The Pacific Northwest has consistently been estimated to have significant potential for geothermal development (Northwest Council 2020), and will have increased access in the future to expanded transmission connections across the region and in the southward direction, which could either facilitate geothermal exports from the region or geothermal imports, including from Nevada. As of early 2024, there are only about 50 MW of operational geothermal resources in the region (28.5 MW in Oregon), but several new hydrothermal and EGS projects underway. Among the drivers of a potential geothermal expansion will be state clean energy policies and resource adequacy requirements. However, most resource planners in the region have not included significant geothermal in their recent planning scenarios, in part due to a lack of geothermal offers in renewable energy procurements.

Among the few utilities that has recently selected new geothermal through planning, Idaho Power (Idaho) evaluated up to 150 MW of new geothermal resources in its 2023 IRP, assuming a price of $78/MWh and with 2030 as the first available year. The preferred portfolio selected 30 MW of geothermal in 2030. More geothermal was selected in sensitivity cases.[19]

Interest in geothermal is currently more tentative elsewhere in the region, given the limited resource development and policy support. PacifiCorp (Utah, Oregon, Washington, Wyoming, Idaho, and California) has significant potential as a buyer of new geothermal generation due to its large footprint and access to other regional resources and transmission. The utility is also engaged in significant transmission expansion, which will facilitate renewable development across the region. However, its recent IRPs have evaluated, but not selected new geothermal, while allowing geothermal offers in its (recently suspended) clean energy procurement processes (PacifiCorp 2023, 2024).

Most other utilities in the region are following this approach. The most recent IRPs by Portland General Electric (Oregon), Puget Sound Energy (Washington), Avista (Washington, Idaho), and Northwest Energy (Montana) do not select any geothermal (see Table 5). Despite these results, several of these utilities have indicated interest in new offers by geothermal through their RFOs.

There is also continued interest from out-of-state buyers. Notably, the CPUC remains potentially interested in geothermal from these states. The CPUC's estimate of geothermal resource potential in the Pacific Northwest for its resource planning has been reduced from 850 MW in the previous

two IRP cycles (2018, 2020) to 520 MW in the 2022-2023 cycle (CPUC 2023). This reduction was due to several factors, including a review of transmission availability by CPUC staff during the planning period. As in prior planning cycles, the CPUC modeling did not select any Pacific Northwest geothermal in its preferred portfolio, despite authorizing an increasing amount of out-of-state wind from the region. Despite these planning results, new contracts have been signed between geothermal companies with projects in the region and California buyers. If these new resources can be developed, new transmission projects linking California and Nevada to the Northwest region such as SWIP-North, may also facilitate additional geothermal contracting.

Table 5 – Assumptions and attributes of geothermal resources in recent selected western planning studies

Planning Entity	Resource Plan	Existing geothermal resources	Geothermal as candidate resource	Assumed geothermal costs, as presented	Other selected financial assumptions	Other attributes mentioned	Selection in IRP preferred portfolio and/or other scenarios	Other geothermal procurements
A. California								
CPUC	Integrated Resource Planning proceeding, 2022-2023	1,397 MW by 2027	Yes	NREL ATB		Capacity value of 80-90%, depending on location	See Figure 2 above	See LSE IRP and procurement results above
LADWP	2022 Power Strategic Long-Term Resource Plan	223 MW	Yes	NREL ATB 2021			52 MW	
B. Southwestern states								
NV Energy	2024 IRP and PUCN (2023)	448.1 MW operational, ~534 MW including existing contracts	Yes	As reported in PUCN (2023): Avg. contract price of portfolio: $75/MWh; Eavor Valmy project contract price: $70/MWh; Fervo contract price with corporate customer: $107/MWh		Geothermal ELCC of 41%; geothermal candidate hourly production profile	No, but IRP references geothermal procured through bilateral contracts; see PUCN (2023)	Bilateral contract for 105-135 MW through portfolio contract; new 20 MW contract; add'l 115 MW contracted for corporate client (PUCN, 2023)
	2021 IRP	385 MW (15 projects), 150 MW	Yes				No, but 500 MW of add'l geothermal evaluated in one	140 MW procured through bilateral contracts

Table 5 – Assumptions and attributes of geothermal resources in recent selected western planning studies

Planning Entity	Resource Plan	Existing geothermal resources	Geothermal as candidate resource	Assumed geothermal costs, as presented	Other selected financial assumptions	Other attributes mentioned	Selection in IRP preferred portfolio and/or other scenarios	Other geothermal procurements
		add'l under contract					scenario (Net-Zero with GEO ("Geo") Plan) from 2030	
Arizona Public Service (APS)	2023 IRP	10 MW (Salton Sea, contract ends 2030)	Yes	Capital cost $6,226/kW (note increase from 2020)	Book life - 30 yr; Tax life - 5 yr	Capacity factor – 80%	No	
	2020 IRP	10 MW	Yes	Capital cost $3,034/kW	Book life - 30 yr; Tax life - 5 yr		Not specified	
Tucson Electric Power (TEP)	2023 IRP	No	Yes	$91/MWh, 2024 LCOE (Lazard)			No	
Salt River Project (SRP)	2023 Integrated System Plan	Yes	Yes, up to 1 GW	NREL ATB 2022		90% capacity factor	No	Eligible for 2024 all-source RFPs
	2017-18 IRP, 2019-2021 updates	105 MW existing and recently contracted	Yes				Selected in most scenarios	No
Public Service of New Mexico (PNM)	2023 IRP	11 MW	No	Not specified		47% or 77% capacity value, depending on table	No	No
C. Pacific Northwestern states								
Northwest Power and Conservation Council (NPCC)	Seventh Northwest Conservation and Electric Power Plan (2016), Interim	Yes, in region	Yes, significant regional potential identified; opportunities for enhanced	PPA cost $85/MWh (2016); Geothermal reference plant (2021): Capital Cost,	Geothermal reference plant (2016, 2020): Economic life – 30 yr;	80% - 90% capacity factor, depending on technology	Identifies up to 475 MW of resource potential (2016, 2020)	

Table 5 – Assumptions and attributes of geothermal resources in recent selected western planning studies

Planning Entity	Resource Plan	Existing geothermal resources	Geothermal as candidate resource	Assumed geothermal costs, as presented	Other selected financial assumptions	Other attributes mentioned	Selection in IRP preferred portfolio and/or other scenarios	Other geothermal procurements
	Assessment (2019), Eighth Plan in development (2021)		geothermal systems	$5,400/kW; fixed O&M, $150/kW-yr, var. O&M Cost, $5/MWh (see also Geothermal reference plant, 2016 version)				
Avista	2023 IRP	No	Yes	PPA $54.03/ MWh in 2023			None in preferred portfolio; 20 MW selected in several scenarios.	
	2021 IRP	No	Yes	PPA $81/MWh in 2022			None in preferred portfolio; 20 MW selected in several scenarios.	
Northwestern Energy	2019 IRP, 2020 Supplement	No	Yes	Geothermal Flash Steam, 20 MW, $2,800/kW, $123.98/kW-yr fixed O&M, $9.88/MWh var. O&M	Project life – 30 yr	95% capacity factor	No	
PacifiCorp	2023 IRP (suspended), 2019 IRP	34 MW owned and operated; 3.65 MW under contract	Yes	Greenfield Binary: $5,973/kW, $103.85/kW-yr fixed O&M, $1.16/MWh var. O&M; generic	Greenfield plant – 40 yr PPA – 20 yr	90% capacity factor	No	Eligible for renewable procurements

Table 5 – Assumptions and attributes of geothermal resources in recent selected western planning studies

Planning Entity	Resource Plan	Existing geothermal resources	Geothermal as candidate resource	Assumed geothermal costs, as presented	Other selected financial assumptions	Other attributes mentioned	Selection in IRP preferred portfolio and/or other scenarios	Other geothermal procurements
				geothermal PPA: $77.34/MWh				
Portland General Electric	2023 IRP	Yes	Yes, hydrothermal flash and EGS	NREL 2021 ATB	10% cost reduction, 2026-2040	80-90% capacity factor	No	
	2019 IRP	Yes	Yes	Flash steam plant $6,216/kW, 30 MW, $120/kW-yr fixed O&M, $2.39/MWh var. O&M		92.2% capacity factor	No	

5. Conclusions and recommendations

As in previous years, the geothermal sector must continuously be proactive in analyzing resource and transmission planning methods and models to ensure that geothermal resources are appropriately valued.

5.1 General findings and recommendations

5.1.1 Targeted policy support for geothermal

The CPUC MTR decisions in 2021 and 2023 provided a needed planning target for geothermal in California, creating a floor for subsequent CPUC planning scenarios and stimulating the geothermal market. While the California market now has sufficiently high geothermal planning forecasts to maintain commercial momentum, some other states and regions in the West feel similar to California before 2021, with fluctuating interest by LSEs and a lack of consistency across the state or region in how they treat geothermal in resource planning. Even a modest policy target of a few hundred MW could help to organize the geothermal markets in the other states in the region. In addition, such targets could help encourage transmission planners and developers to consider geothermal appropriately as a major Western clean and reliable energy resource.

5.1.2 Geothermal in higher renewable energy and more rapid decarbonization scenarios

The opportunity for geothermal expansion since 2020, is due to several factors. Still, two stand out: (1) shorter-term power system reliability needs arising in the 2020s as conventional generation is replaced by variable energy resources, combined with higher summer temperatures, and (2) the high value for clean firm energy in longer-term decarbonization scenarios which address the 2030s and after. This updated survey finds that, at least in some resource plans, the opportunities for high geothermal selection on scales of several GW is correlated with higher decarbonization objectives. We find this particularly in the California resource plans and elsewhere in the Western region (most recently, in Colorado).

5.1.3 Advanced geothermal technologies

Compared to 3-4 years ago, there is more mention of advanced geothermal technologies, such as EGS, in resource plans. Still, resource planning models will typically not select these technologies at current known prices. Hence, while EGS contracts are being signed (DOE 2024), for these next few years, these technologies will continue to seek procurement primarily through bilateral negotiations rather than through modeled resource planning portfolios. We noted above that even the CPUC's most aggressive recent geothermal scenario to support gas plant retirement does not select any EGS among the almost 8 GW of new geothermal (CPUC 2024). The geothermal sector thus needs to coordinate efforts to establish how these technologies are considered in regional resource planning.

5.2 Recommendations on IRP and capacity expansion models

Resource planners use a wide diversity of methods and tools and a range of inputs and assumptions about geothermal resources. In the past few years, there have been efforts by government and national laboratories to advise on these processes (e.g., Warren *et al*., 2021, DOE 2024). The WGA (2023) recommends further that "DOE should develop guidance on how to incorporate the full

value of geothermal projects into resource planning." As discussed below, there does seem to be some convergence among planners on certain inputs, such as using the NREL ATB geothermal costs. The geothermal industry must continue to evaluate these planning processes and provide advice where possible to ensure that the results for geothermal are not simply artifacts of model inputs, assumptions, and structures.

5.2.1 Geothermal costs

Many resource planners have adopted the NREL ATB costs for geothermal, which helps with coordination and transparency. At the same time, actual geothermal contract prices are a function of specific project costs and market conditions. Further, because of the variation in locations and technologies and the companies involved, there has been a wide range of contract prices in recent years, ranging from $67/MWh to $107/MWh, as noted above from public sources (e.g., some utility IRPs, NREL ATB survey and DOE 2024). As such, resource planners should continue to test a wider range of geothermal cost assumptions in their planning models so that the industry can understand how sensitive geothermal selection is to cost (see, e.g., Thomsen 2018).

5.2.2 Geothermal attributes

Similarly to what was found in Thomsen (2021), resource planners mostly assume capacity factors of 80%-90% for new geothermal resources and similar ranges for capacity value (for resource adequacy). As reviewed in Table 5 above, there are still a few exceptions where utilities with existing geothermal plants have assigned lower capacity factors or capacity values, which reflect older plants sometimes operating well below their original rated installed capacities. As such, the geothermal sector needs to provide clear guidance on calculating capacity factors and capacity value, distinguishing between plant vintages and individual plant and fleet averages. Geothermal plants can also offer operational flexibility (e.g., Nordquist *et al*., 2013, Warren *et al*., 2021, DOE 2024), and there have been some recent examples of contracts which allow for system operator dispatch control. However, flexible geothermal is typically not evaluated explicitly in resource planning.

5.2.3 Geothermal development timelines

The CPUC MTR procurement decisions have smoothed the development pathway for geothermal projects that can sell into California and instigated growth in exploration. There is still substantial work to be done between the geothermal industry and resource planners to conceptualize how the geothermal expansion will continue and what reasonable milestones are for resource development, including possibilities for significant expansion in the 2030s to meet decarbonization needs. Similar issues would arise in other states that determine to pursue higher geothermal scenarios.

5.3 Geothermal in the context of zero carbon firm and flexible resources

The concept of a generic category of "zero carbon firm/flexible resources" was introduced most notably in California's SB 100 decarbonization analysis (CEC, CPUC, CARB, 2021), which showed that at sufficiently low costs, such a resource could become a significant component in the state's resource portfolio; it remains a component in the state's procurement and planning processes (CPUC 2024). Given the limitations that most planners place on geothermal resource potential, this category remains a useful placeholder while geothermal development continues and newer

geothermal technologies such as EGS demonstrate whether they can expand the number of viable geothermal sites.

5.4 A regional vision and roadmap for geothermal expansion

Building on the progress achieved over the last 3-4 years, policymakers, planners and the geothermal industry need to develop a conceptual plan for the region that could tie together resource and transmission planning to 2045. As done in this paper, a preliminary step is reviewing the current set of resource plans and scenarios. But this must be followed by the analytical work to create a roadmap to geothermal power providing as much as 5-10% of the western region's power at the end of this planning period. This pathway needs to identify the geothermal resource costs that are needed to justify this buildout, as well as the attributes of the expanded geothermal fleet.

Of the transmission plans we have reviewed, the CAISO's 20-Year Outlook (2022) offers the most analysis of a transmission buildout to address increased geothermal needs, although still limited in regional scope. The CPUC's 2024 sensitivity case using an over 5 GW increase in geothermal by 2045 to support natural gas plant retirement (CPUC 2024) could go further in driving additional transmission upgrades and should be reviewed carefully by the geothermal industry. However, for most of the new regional transmission projects in advanced development, geothermal energy is very much a secondary consideration after wind and solar energy. To address these shortcomings, a western regional plan for transmission development to support geothermal expansion should aim to study two topics. First, the existing and advanced planned transmission network needs to be analyzed with respect how it would facilitate geothermal development and contracting, with appropriate upgrades identified. Second, conceptual transmission planning is needed to identify additional transmission needs for high geothermal scenarios.

How Can the EU's Post-Communist Countries Use Geothermal to Achieve Energy Independence?

Aniko N. Toth[1], David K. Fenerty[2], Orsolya L.Sztermen[1]

Keywords

EU, geothermal funding, legislation, projects, climate neutral, obstacles

ABSTRACT

At the forefront of the effort to resist climate change, the European Union (EU) is one of the first major regions to have proposed binding greenhouse-gas (GHG) emission reduction targets. In particular, the EU has set its sights on cutting GHG by at least 55% by 2030, as so to become the first climate-neutral continent by 2050. To meet these ambitious targets, the EU has instituted a number of public funding instruments. These are designed to support proposed investments in renewables and energy efficiency projects, to include but not limited to geothermal projects. Envisaged are a wide range of projects are, from some which are innovative to other more mature, well-established technologies, and ranging from small-scale Research, Development and Innovation (RD&I) to large-scale plants. This article tries to take a closer look at a representative sample of the post-communist EU members – Lithuania, Poland, Slovakia, Croatia, Slovenia, Hungary and Bulgaria – so as to assess how well they are equipped to take advantage of these new geothermal-development opportunities from a legislative, administrative and legal point of view. The analysis therefore necessarily applies to Renewable-energy (RE) law, a particular subset of energy law. RE relates primarily to transactional legal and policy issues involved in the development, implementation, and commercialization of such renewable-energy sources as solar, wind, geothermal and tidal.

1. Introduction

In the EU, a group of 27 European countries, the Covid pandemic and the war in Ukraine resulted in price volatility and supply disruptions of fossil fuels. This prompted the EU to intensify its focus on geothermal and other renewable energy systems. The Renewable Energy Directive, introduced in 2009, provides the legal framework for developing clean energy across all sectors of the EU

economy, supporting cooperation between EU countries towards this goal. In 2022, the highest penetration of renewables occurred in the power sector, with renewable energy accounting for 40.7% of all electricity generated in the EU. Next came the heating and cooling sector, with a Renewable Energy Source (RES) share of 23.2%. The RES share in transport was 9.6 % (data from the European Environment Agency EEA, 2023).

Renewable energy made up 24.8 % of total energy use for heating and cooling in the EU, up from 11.7 % in 2004. Developments in the industrial sector, services and households contributed to this growth. Also playing a role was the ambient energy captured by heat pumps used in heating and cooling.

Geothermal energy accounted for 9.6% of the total renewable energy supplied, and investment in heat pump installations was up by 12% in 2020 (data from the International Energy Agency IEA, 2023).

According to the European Environment Agency (EEA), the share of renewable energy sources in EU energy consumption has gone from 12.5% in 2010 to 22.5% in 2022, a share which is expected to continue growing. To meet the EU's new target of 42.5% for 2030, however, the entire European energy network will have to undergo a much more profound transformation.

2. Renewable energy legislation in The EU

EU decision-makers have the right to legislate on different issues affecting the geothermal energy sector, however deep beneath the surface the resource's location, or whether the resource is adapted to heating/cooling, electricity or combined heat and power (CHP). The EU has passed specific legislation aiming to increase renewable energy use by, among other efforts, incentivizing the use of geothermal energy technologies. In the EU as elsewhere, environmental-protection measures may restrict a new geothermal project's placement, which could affect the procedures required and perhaps increase implementation costs.

EU legislation on energy was long based on various provisions scattered throughout the EC Treaty, relating to the EU's authority over its internal market and environment. After the inclusion of a dedicated chapter in the 2009 Lisbon Treaty, energy officially become a subject of shared competence between the EU institutions and its member states. The Treaty on the Functioning of the European Union (TFEU) included energy policy among the shared competences.

The energy market regulation in its current form was developed step by step in the EU's legislative process over the last few decades. The rules created for each energy source vary significantly, and are still evolving in response to technological developments and global challenges. In its 2000 Green Paper, the European Commission stated that growing energy demand meant that new supplies and routes must be found and also that the use of renewable resources must be increased.

It was recognized at the time that energy security depended on diversifying Europe's energy sources. To that end, the 2006 Green Paper highlighted three objectives: sustainability, competitiveness, and security of supply. The Commission prioritised certain topics to support these three objectives. These topics included energy efficiency, energy saving, and the development of new renewable energy sources. The European Commission presented "Clean Energy for All Europeans" in 2016, a package of measures to address the EU's energy policy

The package was designed to meet the EU's 2030 climate and energy policy objectives. by emphasizing 3 main objectives: prioritizing energy efficiency, ensuring fair treatment of consumers, and making the EU a global leader in renewable energy. Considering the specificities of renewable energy production and electricity consumption, i.e., that much renewable energy production is weather-dependent, not consumed when or where it is produced, and difficult or expensive to store, it is understandable that the EU would also try to reward systems that have flexible capacity.

In 2014, the Council set itself an ambitious target, and decided that the share of renewable energy in terms of gross final consumption within the EU should reach 27%. EU member states are encouraged to contribute to this EU-wide binding target. One difference between the 2020 and the 2030 goals is that the 2020 target (based on the 2009 Renewable Energy Directive) was broken down into binding targets for Member States, whereas the 2030 target is not binding – it was only posited as a contribution to the EU target.

High levels of electricity transmission require an optimum uptake of renewable energy, with an extensive distribution grid structure and good interconnectivity between the EU's national and regional grids. To this last point, the 2014 Council Decision provides for a legislative package to help achieve the 15% interconnection target. One of the packages's main features is the Governance Regulation for the Energy Union. This seeks to harmonize member states' diverse planning and reporting bodies by consolidating and standardizing both climate and energy policy reporting into 1-year and 2-year reports. To that end, member States are required to submit Integrated Energy and Climate Plans based on the Table of Contents in the Annex to the Regulation.

Renewable energy legislation varies significantly from country to country and even within regions. In their current form, EU laws and regulations are designed to promote the development, integration, and utilization of renewable energy sources. These laws' key components frequently include targets for renewable energy deployment, financial incentives, grid access, and environmental standards. It is crucial to note that renewable energy legislation is dynamic and subject to change. EU governments occasionally update or revise policies based on technological advancements, economic considerations, and environmental goals.

2.1 How Geothermal Fits into Community Energy (CE) Development in Post-Socialist Europe

The EU plays a leading role in financing thousands of ongoing projects of small to medium size, but those projects are unevenly distributed over the continent. The majority of such CE projects are in northwest and central Europe. In the formerly communist nations of Eastern Europe, projects like those are much more rare. This paper gives an overview of the geothermal CE situation in a representative sample of post-socialist countries (PSECs): Bulgaria, Croatia, Hungary, Poland, Slovakia and Slovenia. Croatia stands out in this groupd as a positive example. The other countries are farther behind, although Hungary actually has far superior geothermal resources, since it enjoys the geographic advantage of being located mostly in the Pannonian Basin, a region blessed with abundant low-enthalpy and medium high enthalpy geothermal reservoirs. One generally valid explanation for this lack of development, true especially for Hungary and for other countries to differing degrees, is the widespread distrust of 'community projects' -- of which there have been few positive examples since the communist-system collapse over 30 years ago. Compared with the rural communities which could most benefit from CE projects, politically well-connected elites

in the PSECs usually have more access to investment capital or the expertise needed to prepare an EU-funded CE proposal. Those groups, however, are often less interested in geothermal CE projects, which do not entail any rapid profit for investors. This can pose a real problem, since a geothermal project's upfront exploration and drilling costs greatly exceed what a typical small village can scrape together.

2.2 Renewable in the Post-Socialist European Countries

Renewable energy usage conditions are critical in effecting an ambitious local energy transition in the post-socialist renewable energy policy environment that constrains local initiatives. Nonetheless, outliers can also be observed, e.g., the island of Krk in Croatia, a unique case of a shared vision of 100 % renewable energy. In spite of political commitments, RES potential, advanced technologies, and decreasing production costs, ongoing energy transition remains a challenge. The following representative survey of PSECs is presented in alphabetical order, and looks at the general energy situation and the renewable and/or geothermal CE situation.

2.1.1 Bulgaria

The main local energy source in Bulgaria is still lignite coal. Another local energy source is nuclear energy, which significantly contributes to energy independence. Bulgaria has a high solar-energy potential, especially in the south. From a total of 100 MW of solar power installed capacity in 2011, Bulgaria has raised that figure to more than 2,400 MW as of 2023, with 600 MW added in 2022 alone. The Energy from Renewable Sources Act regulates the establishment of citizen energy communities. They are becoming market participants, able to sell any surplus electricity they produce and legally entitled to sign bilateral contracts with suppliers.

There are more than 170 geothermal fields in the Republic of Bulgaria. They represent the main sources of geothermal energy in the country. These are spread all over the country. The temperature of the thermal water varies between 25-100 ^{o}C, and about 72 % of thermal water sources have low enthalpy, with water temperature below 50 ^{o}C. Geothermal water as a source of geothermal energy is used in local heating systems and greenhouses. This usage represents only 1.8 % of the total thermal water use. Regulatory change is one of the planned steps forward, which will result in better utilization and management of the geothermal resources (Deneva et al, 2022).

2.1.2 Croatia

Croatia has promising natural potential for the exploitation of RES, especially in the northern (Pannonian) part. As part of the Euro-integration process, the whole concept of the energy sector reforms through the legal and institutional frame- work was accepted, and conforms to EU requirements. Such official national documents as the National Action Plan, along with with the 2013/18/EU Directives, stipulate that the 19.6% gross share of RES will be used for direct heating and cooling consumption by year 2020.

The Croatian part of the Pannonian basin area has long been known as a high potential geothermal area. Deep geothermal energy is covered by the Mining Act if it is used for energy purposes, or by the Water Act. The commissioning of the first geothermal power plant, Velika 1, with a capacity of 10 MW at the Velika Ciglena site in 2018, triggered new developments in the geothermal sector.

Croatian investors with their partners started to develop Croatia's second geothermal power plant in 2022. The exploration work of Bukotermal indicates a geothermal resource of about 142 C at a depth of 2.4 kilometers .The proposed project site in the northern Varazdin County in Croatia can support a 16-MW geothermal power plant. Aew incentive for additional geothermal exploration has also recently come from Croatia's recovery and resilience plan, which funds the Croatian Hydrocarbons Agency with almost €30 million intended for confirmation of geothermal potential. This includes geophysical surveys and the drilling of two exploration wells for geothermal energy to be used in district heating.

Furthermore, Norway Grant's Energy and Climate Change Programme funds four calls for geothermal developments in Croatia that are currently being implemented. (Note: Norway has been a generous contributor of funds in PSECs, but recently suspended all such activities in Hungary after it decided that the grants it made there where not properly used.) All these funding opportunities triggered increased interest in geothermal exploration from private investors and local communities, resulting in more exploration licenses being issued. Consequently, 14 exploration and 7 exploitation licenses for geothermal waters are now active, promising new developments in the following years. Even though private investors are mostly interested in electricity generation projects, local communities and agricultural entrepreneurs have expressed their interest in geothermal heat production to reduce dependency on fossil fuels and to increase the security of supply. There is also a financial component of the heat projects, where users can save up to 30% on energy bills (Zivković et al, 2022).

2.1.3 Hungary

Hungary published its renewed Energy Strategy and National Energy and Climate Plan (NECP) in 2020. These documents highlight the role of geothermal energy especially in the heating/cooling sector, in agriculture and in making district heating more environmentally friendly.. Although the foreseen growth of geothermal in the heating-cooling sector is 58% (84.6 ktoe by2020, 116.6 ktoe by 2030), this would barely increase the overall share of geothermal within the total RES, which will stay around 5 %. The Hungarian NECP foresees 59 MWe installed capacity in geothermal power production, but only after 2040.

To foster geothermal project development, the Ministry of Innovation and Technology announced a Call for bids, promising to support geothermal heating by assuming the geological risks for the first wells. This Call supports only projects with reinjection, i.e., drilling doublets, or drilling only reinjection wells to complete already existing systems. The target depth is 1000-2500 m. The total budget is 6 billion Hungarian forints (approx. €16.6 million). The Call was open until December 31, 2023. The reimbursement rate is 30 % in case of success, 40 % in case of partial success and 60 % in case of unsuccessful projects. Due to institutional reorganizations at the end of 2021, the former program operator (Mining and Geological Survey of Hungary) has been replaced by the Western Balkan Green Center, which caused a temporary suspension of the application and evaluation procedures (Nador et al, 2022).

The Hungarian Ministry of Innovation and Technology National Energy Strategy 2030, looking ahead to 2040, has set very ambitious targets for the expansion of domestic renewable, mainly as regards photovoltaic capacity. The strategy thus seeks to contribute to meeting Hungary's EU commitments, promoting sustainable consumption, and providing financial market players with a stable portfolio. Taking into account the renewable energy currently being installed in Hungary

and the 2030, 2040- and 2040- targets for the EU, the EU is in a position to provide a more sustainable energy source. Given the ambition of its targets, and the investment costs of the renewable technology, Hungary will find it a challenge to achieve these goals in the current domestic regulatory and financing environment.

2.2.4 Lithuania

Lithuania depends on energy imports, as domestic production in 2022 covered only one-quarter of total energy supply (TES). Two-thirds of TES comes from oil and natural gas and a quarter from renewable such as wind, biomass and hydro. The Law of the Republic of Lithuania on Renewable Energy (the 2021 consolidated version) defines RECs as non-profit-making legal entities who own and develop renewable energy production facilities and have the right to produce, consume, store and/or sell energy in installations.

Lithuania has rich low-enthalpy geothermal resources. The first geothermal investigations was initiated in the periods of 1987-1989. From 1992 to1994 the government of Denmark financed the Baltic Geothermal Energy Project, covering Lithuania and Latvia. Based on this and other projects, Klaipeda Geothermal Demonstration Plant was engineered (prospective capacity 49MW, production of heat 598 TJ/year). The plant aimed to meet about 25% of yearly Klaipeda City heat demands. The main legal basis for geothermal energy growth is the new act “National Energy Independence Strategy of the Republic of Lithuania”, approved in 2018. The Baltic Geothermal Energy Project begun in 1992 was finally completed in 2000, when the geothermal plant in Klaipeda started producing heat. Various technical problems occurred, but by 2002 KGDP was producing 189000MWh of heat. The Klaipeda plant has also had to solve problems related to reaching the market and obtaining a profitable fixed minimum heat fee (Zinevicius, 2022).

2.2.5 Poland

Dependence on domestic coal has locked Poland into the carbon trap. Coal constitutes around 80% of the country's energy production and around 50% of the total primary energy supply. This makes Poland the EU-27 country with the highest emission intensity relative to its energy production Capellán-Pérez (2020). This context translates into very challenging conditions for RES deployment in general and for cooperatives and community initiatives in particular. Nevertheless, there are still some fragile projects to be found. The co-operative Spółdzielnia Nasza Energia in the district of Zamość, initiated in 2014 by a local company and several municipalities, has a democratic one-member-one-vote structure and operates a network of biogas stations. According to the Central Statistical Office (data source: GUS, 2021; 2) in 2020 the RES share in total primary energy acquisition was estimated at 16.3 % (499’338 TJ), then given by Eurostat as 16.1 % 3. The contributions of particular RES were as follows: solid biofuels 71.61 %, wind 10.85 %, liquid biofuels 7.79%, biogas 2.58%, heat pumps 2.38%, solar 1.99 %, municipal wastes 1.15 %, geothermal 0.20 % Kepinska and Hajto (2022).

Poland’s geothermal roadmap was published in May 2022. This is a comprehensive approach targeting geothermal in key sectors such as residential buildings and across its vast array of fossil-powered district heating systems. Heat reservoirs with temperatures between 30-90°C can be found across 40-55% of Poland’s land mass. The roadmap identified 491 localities with heating plants greater than 1 MW and 78 localities with 5 MW situated within the heat reservoir range. Around 114 geothermal plants have been identified by the plan. The next steps are to construct 78 test

holes to construct 78 geothermal installations with a combined capacity of 290 MW and 9,949.6 TJ generated by 2040.

2.2.6 Slovenia

Slovenia generated 68.8% of its electricity with zero carbon or carbon neutral sources in 2019, dominated by nuclear power and hydroelectricity. Indigenous energy sources – in the form of domestic coal, nuclear power, hydropower, and renewables —satisfy slightly more than half of Slovenia's energy needs. For 2030 the target is 27 %, to be reached mainly through solar and hydro power, and through the use of wood biomass Tsagarakis et al (2020).

Geothermal energy is considered to be a natural resource, owned by the Republic of Slovenia. Research and exploitation of SGE are regulated by two basic laws: the Mining Act and the Water Act. The Mining Act regulates the research and exploitation of geothermal energy without ground water, whereas the Water Act applies when thermal water extraction occurs. The Water Act regulates the management of surface and groundwater, which are a natural resource owned by the Republic of Slovenia. If there is a water temperature above 20 C (thermal water), a grant must be obtained by the Ministry of Agriculture and Environment. For boreholes deeper than 300 m, a revised mining project needs to be obtained and treated as a system that is not shallow (Tsagarakis et al, 2020). So far only direct use of geothermal energy is effective in the country with emphasis on exploitation of low temperature resources for district and individual space heating, for greenhouses and thermal spas. During the last 20 years direct use showed only slight and changing increase and more recently has remained stagnant. The reasons depend on the locality. Overexploitation of geothermal resources in some localities of the north-eastern part of the country is one of the problems, but there have also been some occasional technical difficulties, and weak incentives for efficient use of the resources. Total installed capacity and annual energy use (both deep and shallow geothermal) in 2021 are 298.45MWth, respectively. Installed capacity and energy use at all 31 users of thermal water from deep sources amounted to 60.70MWth, Rajver et al, (2022).

2.2.6 Slovakia

Slovakia’s is still an economy oriented towards fossil fuels, where RES contribute with roughly 29 % on heat production, whilst geothermal energy yields only a 2 % share. In power production, fossil fuels account for a 21 % share, renewables (including small to large hydro) are over 25 %, and nuclear power has the largest share. The Slovak National Energy and Climate Plan was approved by the Slovak Government in 2019. The planned total share of RES for 2030 is 19,2%, which is lower than the EU 2030 goal of 32%. Share of RES in transport is projected to be 14% by 2030.

Geothermal resources contribute exclusively as direct use in Slovakia. A total of 31 geothermal water bodies have been defined to date, responding to The Water Framework Directive No. 2000/60/EC of the EU Parliament and the European Council. Geothermal resources have already been proven with 282 wells, drilled in 30 out of the 31 geothermal water bodies (GWBs), yielding a proven 436 MWth of reserves Fričovský et al, (2022).

3. Renewable enery Share in EU

In 2022, renewable energy represented 23.0 % of energy consumed in the EU, up from 21.9% in 2021. The share of energy from renewable sources used in transport in the EU reached 9.6 % in 2022, up from 9.1% in 2021 (EUROSTAT, 2023).

Figure 1. shows the renewable energy production by percent of gross final energy consumption in 2004 and in 2022. The former socialist countries were close to each other in terms of renewable energy sources at the start. Initially, the use of renewables was not a priority in any of the countries, thanks to cheap Soviet energy sources, and EU quotas were not initially in place with regard to the energy use of the states. But there were clearly differences due to geography. In terms of renewable energy use, the Baltic states of Latvia, Estonia and Lithuania lead the pack. Serbia and Slovenia approached the EU average. The rest -- Bulgaria, Czechia, Slovakia, Poland, and Hungary -- fall below the EU average. For the EU as a whole, the share of renewable electricity increased from 38 % to 39 % between 2021 and 2022, whilst fossil fuels still represented 38 % of the EU's electricity production. In 2021, fossils produced 36% of the EU's electricity EGEC, (2023).

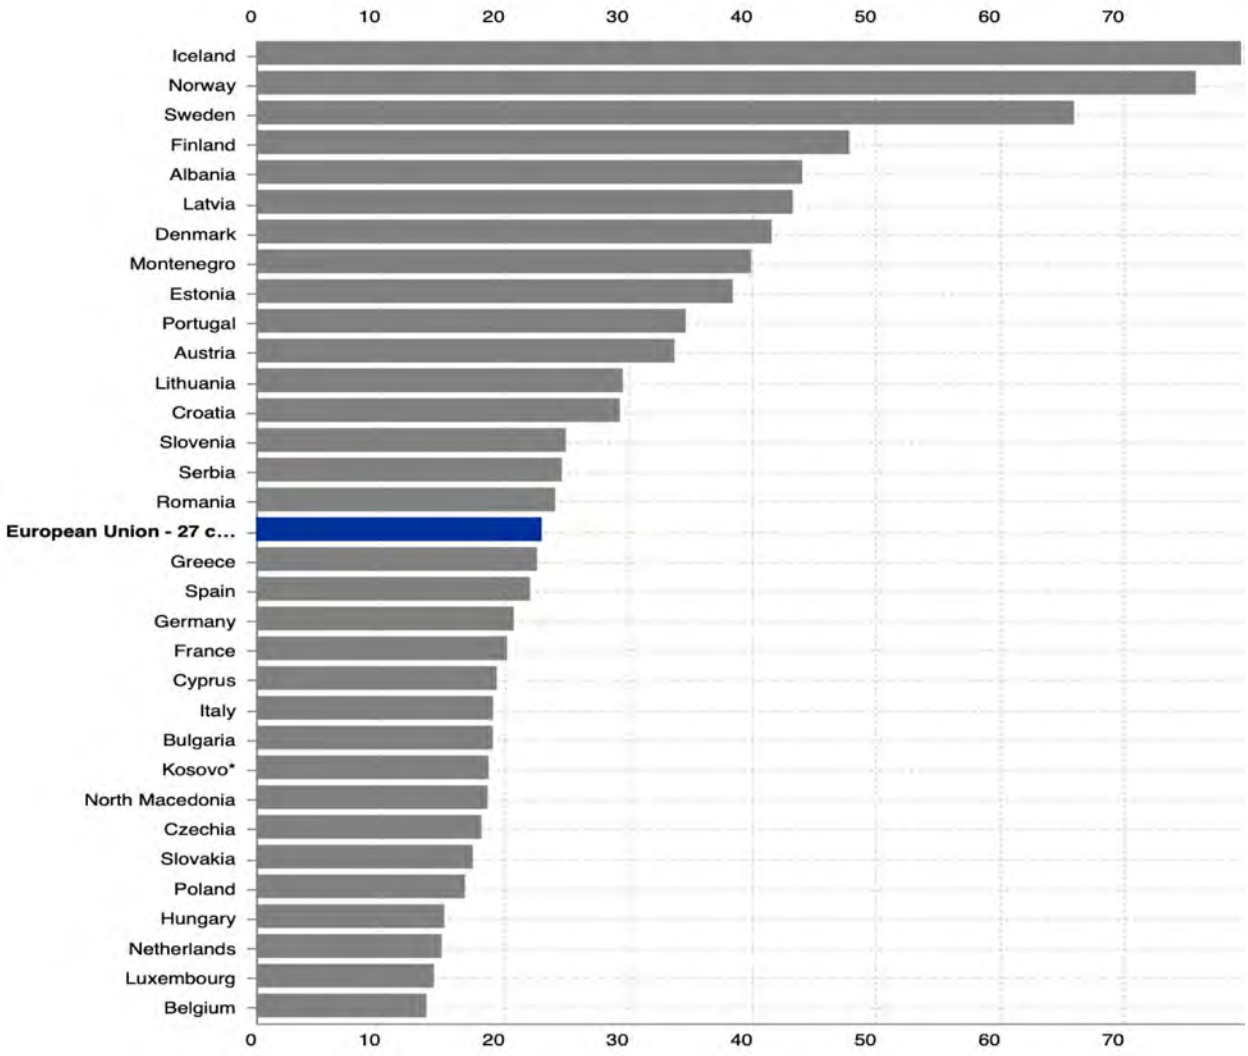

Figure 1: Renewable energy's share of gross final energy consumption

On Jan. 18, 2024, the European Parliament approved a resolution, led by Prof. Krasnodebski of the European Conservatives & Reformist Group (ECR), to support a common European geothermal energy strategy.

3.1 A Brief History of Geothermal in Europe

The geothermal energy situation varies from country to country according to the geological background and the geothermal technology that best suits the available natural resource. Figure 2 shows the geothermal heat-flow in Europe. The spectrum varies, led by power generation derived from high enthalpy resources in Iceland, Italy, Greece and Turkey – and in Italy, where the first geothermal electricity plant started its operation in Larderello, in 1913, and is still operating. It was composed of an alternator Ganz 250 kW, three-phase 50 Hz, and a voltage of 4500 volts coupled with a Tosi Parsons turbine of 350 horsepower.

A handful of geothermal power plants were installed in Europe in the 1970s, in Turkey, Italy, Iceland and French Guadalupe (which is European legally if not geographically). They were all high temperature plants using flash/dry steam turbine technology. The development of new turbine technologies, such as the binary cycle (i.e., Kalina and Organic Rankine Cycle-ORC), was a game changer as it allowed low and medium temperature geothermal power plants to be commissioned. Countries such as Austria, Germany, Portugal, Croatia, and Hungary have installed geothermal power plants over the last 20 years using these technologies. Figure 2 shows the significant difference between the high enthalpy and low enthalpy resources. In 2022, 142 geothermal power plants were in operation with an installed capacity of about 3,5 GWe and generating more than 22 TWh. The average capacity factor last year was 79% Sanner et al, (2022).

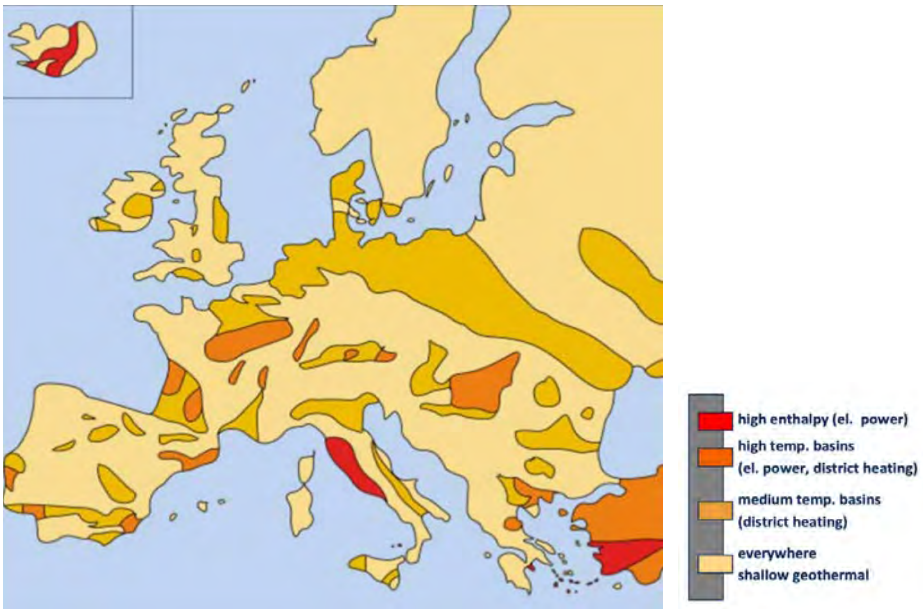

Figure 2: Heat-flow map of Europe

3.2 Geothermal Electricity Market in Europe

Demand in Europe has stagnated. This is an important issue when considering power decarbonization and possible demand for new geothermal power plants!

- 1923-2023: 100 years of geothermal power
- Oldest continually operating geothermal power plant has run since 1987.
- 4 plants operational since the 80's, 17 from the 90's, 32 from the 2000's.
- 21 power plants are more than 25 years old, 53 more the 15 years old.
- The geothermal electricity market is now entering a new development phase, with many plants to about to begin operating in the next 5-7 years.
- In total, 43 projects are currently being developed, and 140 are being considered.

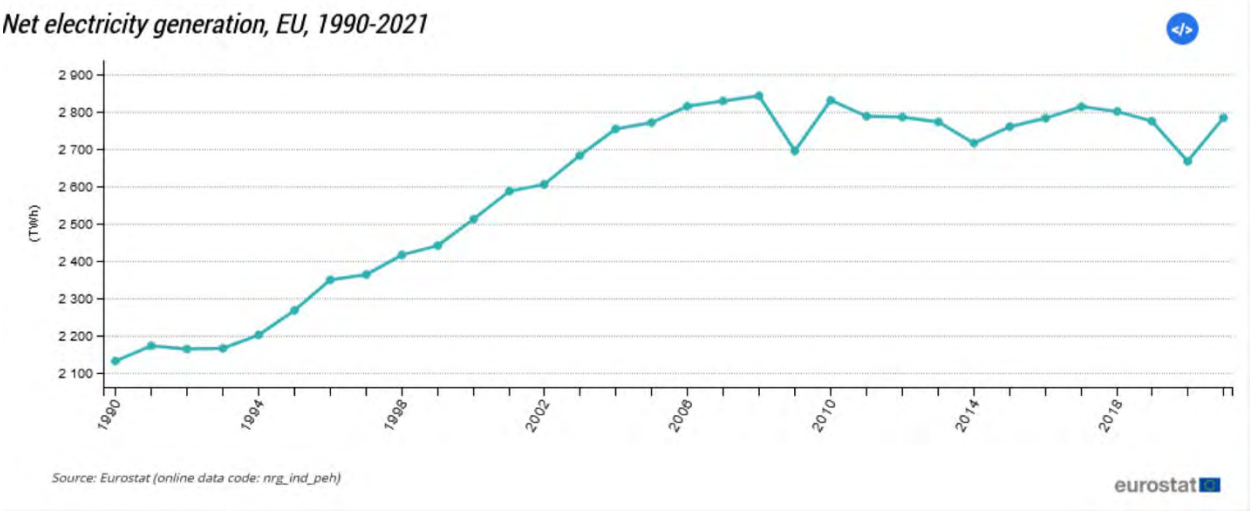

Figure 3: Electricity Demand in Europe (EGEC, 2023)

In 2022, the wholesale average electricity price in Europe was €230/MWh. This was 121% higher than in 2021. Italy had the highest wholesale electricity price at €304/MWh. From 2021 to 2022, renewable electricity's share increased from 38% to 39%. Fossil fuel's share of EU electricity production increased from 36% in 2021 to 38% in 2022.

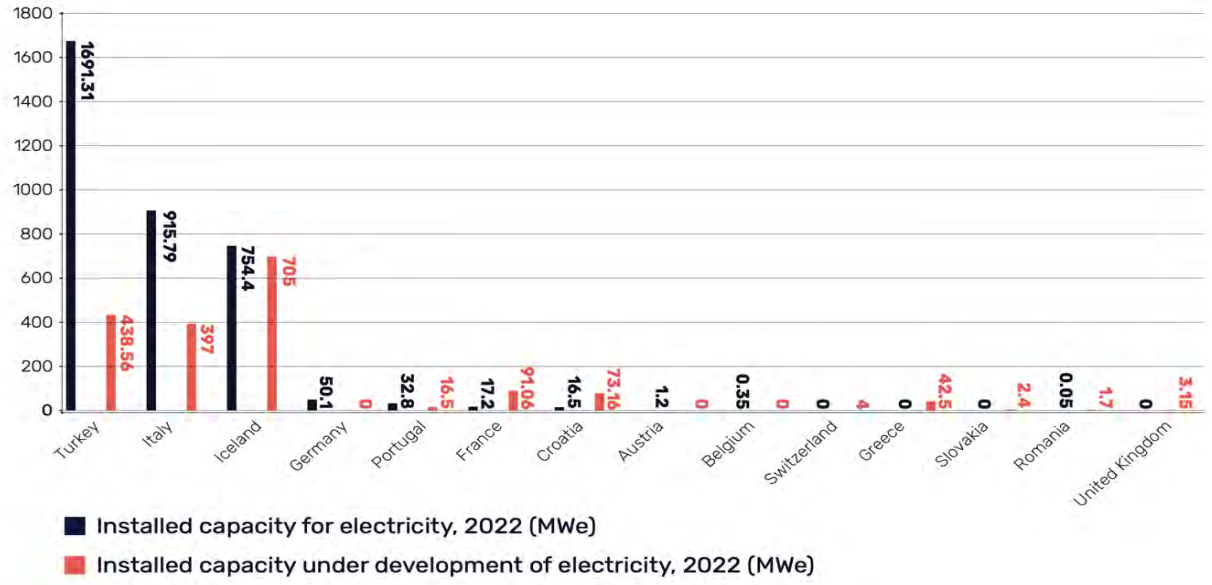

Figure 4: Installed capacityfor electricity (EGEC, 2023)

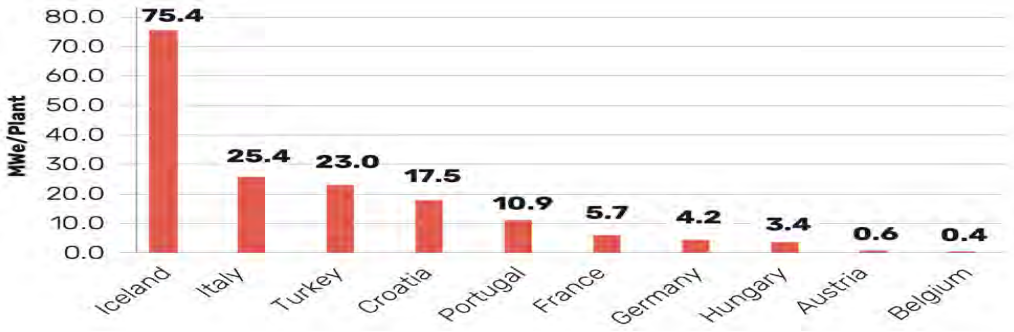

Figure 5: Average size of geothermal power plant (EGEC, 2023)

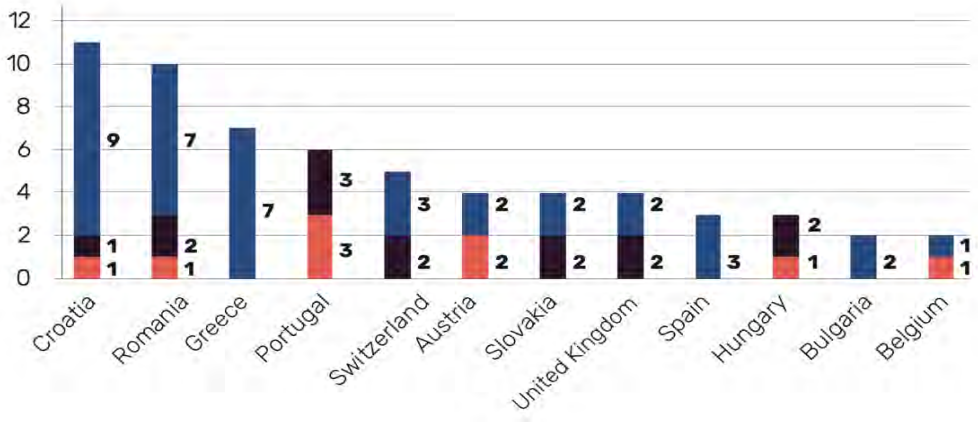

Figure 6: Number of geothermal power plants installed, planned, or being considered (EGEC, 2023)

For direct use of hydrothermal resources in sedimentary basins such as in France, Germany, Poland, Italy, Hungary, and Romania. Heat supply from geothermal energy in Europe is primarily achieved by using hot water from deep aquifers for district heating. Figure 7 shows geothermal direct uses in the EU countries. Figure 8 shows main geothermal reservoirs with existing DH systems In Europe.

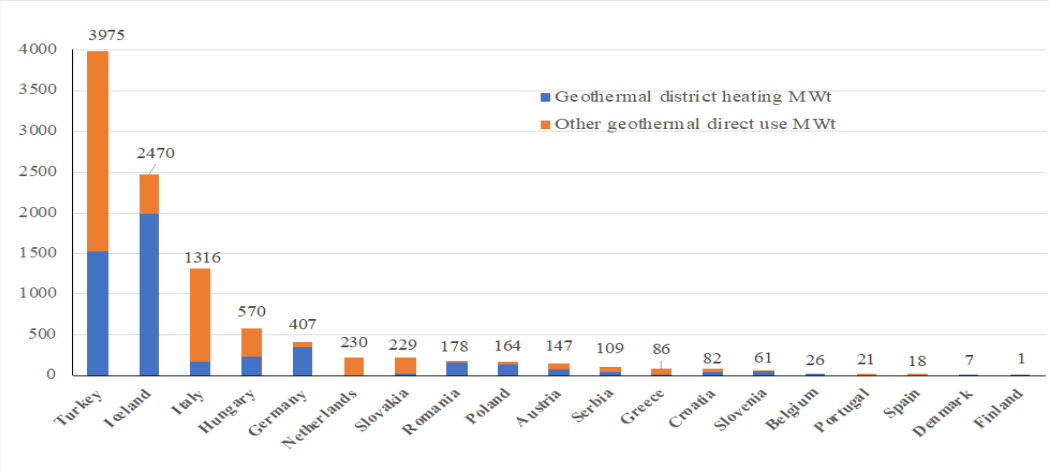

Figure 7:Geothermal direct uses (Sanner et al, 2022)

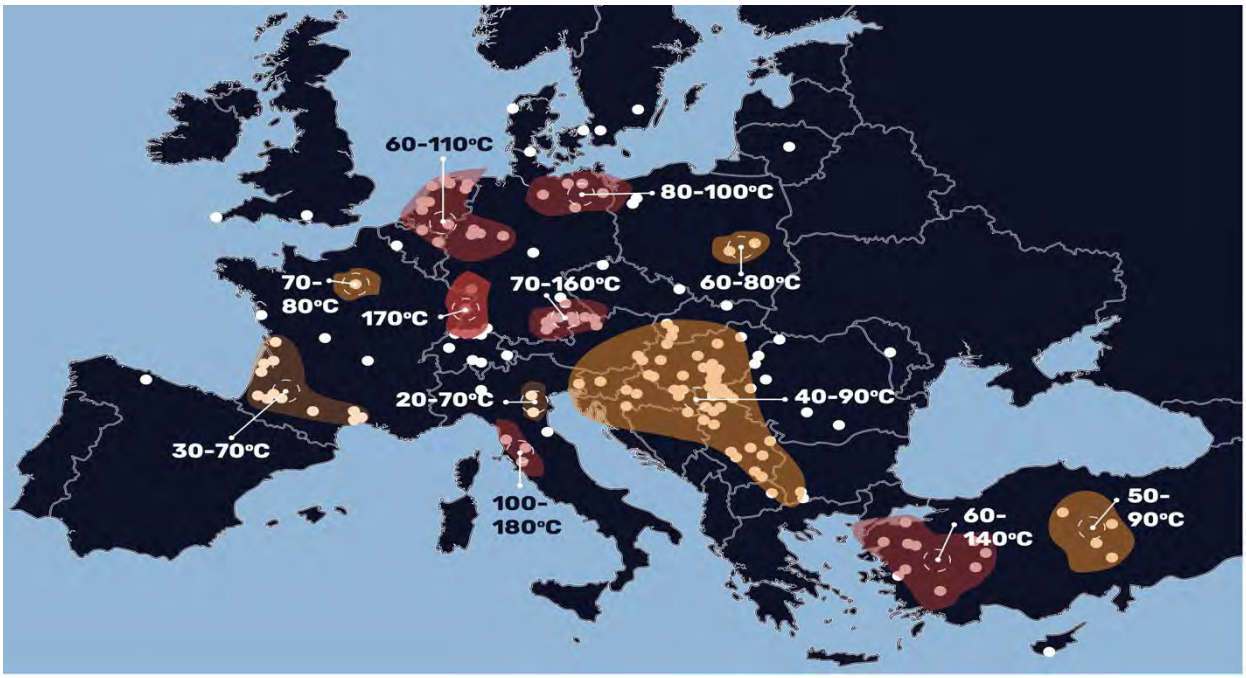

Figure 8: Mapping of main geothermal reservoirs with existing DH systems (EGEC, 2023)

Geothermal heat pumps represent by far the largest sector of geothermal energy use in Europe in terms of the number of facilities, installed capacity and produced energy. The shallow geothermal share accounts for more than 66% of the installed energy. The total number of geothermal heat pumps installed in Europe is more than 2.1 Mio units. The leader by far is Sweden; Germany, with a population more than eight times larger, comes in second. France is still in the 3rd rank, but due

to a relatively low annual number of new installations might lose that rank soon to Finland. Figure 9. shows the numbers of installed heat pumps per country for countries with at least 1000 existing units reported, compared to annual sales. In this regard, the post-socialist European countries lag far behind the European average.

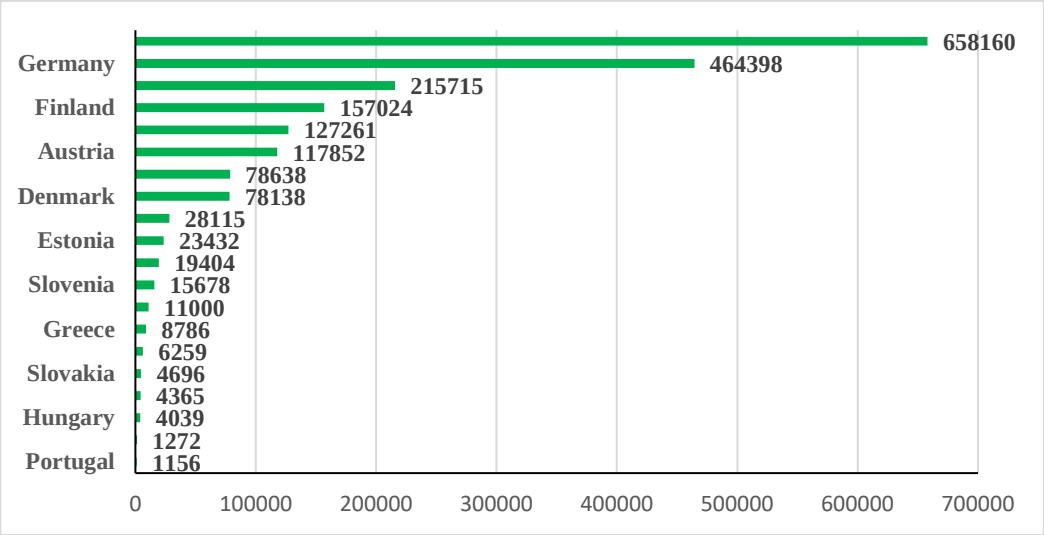

Figure 9: Number of geothermal heat pumps (Sanner et al, 2022 and Zinevicius, 2022)

4. How the EU Funds Geothermal opportunities

The EU supports research and development in geothermal technologies, funding projects for both direct use of heat and the use of extracted heat to generate electricity. EU support also focuses on reducing costs in exploration and drilling, because geothermal installations have high capital costs.

4.1 European Energy Efficiency Fund (eeef)

In the era of climate change and fossil fuel depletion, renewable energy sources (RES) also offer a key transformative potential from a social point of view due to their modularity and capacity to generate energy at a local level, allowing for the development of local, democratic and participative bottom-up initiatives.

EEEF aims to support the climate goals of the European Union (EU 2030 framework for climate and energy, and the climate-neutral objectives of the European Green Deal) to promote a sustainable energy environment and to foster climate protection by enabling projects in European cities, regions and communities so as to build resilient infrastructure. The final beneficiaries of eeef are municipal, local and regional authorities as well as public and private entities acting on behalf of those authorities such as utilities, public transportation providers, social housing associations, energy service companies etc. Investments can be made in Euros, or local currencies, although the latter is restricted to a certain percentage.

4.2 Horizon

Horizon Europe is the largest transnational program ever, supporting research and innovation, and will be implemented by the EU. The new EU research and innovation program will have a budget

of around €95.5 billion for 2021-2027 (current prices). This includes €5.4 billion (current prices) from Next Generation EU to boost Europe's recovery and make the EU more resilient for the future, as well as an additional reinforcement of €4.5 billion (current prices).

As of January 17, 2024, there are 17 ongoing funding and tender opportunities for the Innovative applications/integration of geothermal heating and cooling in industry (HORIZON-CL5-2024-D3-01-06), where the topic is high integration of geothermal heating and/or cooling in different industry sectors, with operation flexibility taking into account start-up time and ramp-up rate, and maximum cascaded use of thermal energy. Activities related to geothermal heat for industry and agriculture, underground thermal energy storage (UTES) including high-temperature storage, innovative and multiple uses for geothermal energy and side-products, balneological systems, and design and operation of geothermal doublets can be considered. Activities are expected to achieve TRL 5 by the end of the project.

4.3 European Climate Infrastructure and Environment Executive Agency (CINEA)

CINEA manages the Horizon Europe work program, which includes Energy Use, Energy Supply, Transport and Mobility and Climate Action areas. In total, it is expected that CINEA just for Horizon Europe will manage a budget of up to €15 billion for Horizon Europe under the 2021-2027 Financial Framework.

4.4 Life

The LIFE program began in 1992 and has co-financed thousands of projects in the field of environmental protection. It is the EU's funding instrument for environment and climate action. The budget of the LIFE Programme increased to €5.4 billion between 2021 and 2027. The LIFE Clean Energy Transition sub-program has a budget of nearly €1 billion over the period of 2021-2027 and aims at facilitating the transition towards an energy-efficient, renewable energy-based, climate-neutral and -resilient economy by funding coordination and support actions (Other Action Grants) across Europe.

4.5 NER 300 program

Renewable energy technologies are the focus of NER 300. It is a funding program pooling together about €2 billion for innovative low-carbon technology, focusing on the demonstration of environmentally safe Carbon Capture and Storage (CCS) and innovative renewable energy technologies on a commercial scale within the EU. The NER 300 program involving all EU Member States, was set up to support the demonstration of a wide range of renewable energy technologies, namely bioenergy, concentrated solar power, photovoltaics, geothermal, wind, ocean, hydropower, and smart grids.

4.6 European structural and investment funds (ESIF)

Over the period 2014-2020 more than half of EU funding was channeled through the 5 European structural and investment funds (ESIF). They were jointly managed by the European Commission and the EU countries. The Cohesion fund (CF) is of particular importance for Eastern European countries, because it funds transport and environment projects in countries where the gross national income (GNI) per inhabitant is less than 90% of the EU average. For the 2021-2027 period, the Cohesion Fund is providing support for 15 Member States: Bulgaria, Croatia, Cyprus, Czechia,

Estonia, Greece, Hungary, Latvia, Lithuania, Malta, Poland, Portugal, Romania, Slovakia and Slovenia. Over the period of 2021-2027, EU funds allocated to Cohesion Policy will have amounted to €392 billion.

5. Conclusion

Clearly, the EU as a whole has the expertise and political will to achieve the ambitious renewable- and geothermal-energy goals it has announced for itself. Even before the war in Ukraine made independence from Russian hydrocarbons an obvious priority, EU leadership had committed itself to a renewable energy as a way to protect against global warming and make each EU member more energy-independent. The problem comes when community-energy projects fail to take root in post-communist countries where the political and administrative disadvantages outweigh the projects' apparent advantages. In these cases, it might be helpful for the EU to 'twin' each project, by making sure there is a more experienced western European manager/advisor to guide the local managers and keep the project on track. Examples of this are the HORIZON-WIDERA 2023 Twinning Green Deal Calls. It would also help if, when evaluating bids for EU geothermal research project bids, the EU evaluators provided more detailed justifications to show why they accepted or rejected specific bids.

Keywords

Geothermal power, geothermal heating and cooling, modeling and analysis

ABSTRACT

Geothermal energy technologies have sometimes been excluded from large-scale renewable energy analysis efforts because of deficient geothermal representation in energy analysis models. Beginning in 2022, National Renewable Energy Laboratory (NREL) launched a 3-year effort supported by the Geothermal Technologies Office in the Department of Energy (DOE) to address this problem. The first phase consists of enabling geothermal representation in flagship NREL analysis tools and models with the same fidelity as solar and wind technologies. These tools and models are key in future-grid scenario studies that identify pathways to meeting U.S. goals for widescale electrification and decarbonization.

This paper summarizes Phase 1 progress, addressing expanded functionality of eight existing NREL modeling tools and data collection. This includes: (1) Updating the Regional Energy Deployment System (ReEDS) capacity expansion model and examining future scenarios to understand how the value and competitiveness of geothermal power is represented (e.g., grid decarbonization, emergent technologies, resource availability). (2) Updating the Geothermal Electricity Technology Evaluation Model (GETEM) with geothermal energy system costs and learning curves. (3) Enabling the Renewable Energy Potential (reV) geospatial platform to interface with GETEM for the entire continental United States, providing geothermal supply curves that account for conventional and emerging technologies. (4) Integrating ambient temperature loops in the Distributed Geothermal Market Demand Model (dGeo) and coupling dGeo with the GEOPHIRES tool. (5) Developing a template for binary geothermal power plants via the GEOPHIRES techno-economic model to derive cost-capacity relationships for Engage, a flexible web-based energy planning model for district energy to national scales. (6) Updating the ground source geothermal heat pump (GHP) model in ResStock and ComStock, which are a probabilistic representation of the U.S. national building stock. (7) Expanding the GHP module of

the Renewable Energy Integration and Optimization (REopt®) platform for energy system integration and optimization by including more technology diversity and techno-economic optimization of GHP systems. (8) Updating and integrating the Urban Renewable Building and Neighborhood optimization (URBANopt™) model (campus- to building-scale energy model) with robust, validated, and extensible open-source software that enables the computational analysis for designing community-scale district GHP systems.

In addition to these model updates, large data collection efforts include analysis of heating and cooling demand in the United States for residential, commercial, industrial, and data center sectors; and inventorying, classifying, and analyzing low-temperature datasets in Alaska, Hawai'i, and the contiguous United States.

1. Introduction

Execution of the GeoVision study (Hamm et al., 2019) revealed a few shortcomings of National Renewable Energy Laboratory (NREL) modeling tools in accurately representing geothermal technologies. These shortcomings are related to three main areas: (1) insufficient resource supply data for geothermal energy relative to other renewable energy resources; (2) lack of, or incomplete, representation of geothermal technologies in tools used for capacity expansion modeling; and (3) lack of, or incomplete, representation of geothermal technologies in building heating and cooling models. To address these gaps, NREL kicked off a 3-year portfolio of data, modeling, and analysis projects in 2022 aiming to improve baseline geothermal resource supply data for use in models, update geothermal tools with current technology and resource information, and improve representation of geothermal technologies in a variety of NREL software tools. This paper presents results to-date from the first half of this 3-year effort.

Many of the models referred to in this paper have interdependencies. In parallel with the improvements described above, efforts were also made to align baseline datasets, inputs, and assumptions across models when possible and to streamline the outputs and inputs for better model coupling.

2. Geothermal Electricity Generation: Modeling Tool Updates

This section of models only considers geothermal power. The upgrades described here allow for more robust and spatially finer supply curves of geothermally powered electricity compared to the estimates utilized in GeoVision.

2.1 ReEDS: Regional Energy Deployment System

Capacity expansion models forecast how the future electrical grid can evolve by representing climate policies and balancing the investment costs and values of different power sources. The common result from capacity expansion models includes the total capacity and the amount of power produced, but sometimes it is not apparent why the model selected certain electricity generation sources to invest in. The Regional Energy Deployment System (ReEDS) is an NREL capacity expansion model.

Since 2009, ReEDS has been the primary analytical tool in several studies, including the Hydropower Vision (DOE, 2016), Wind Vision (DOE, 2015), SunShot Vision (DOE, 2012), Geothermal Vision (Hamm et al., 2019), and Renewable Electricity Futures (NREL, 2012). The annual *Standard Scenarios* report, which provides a U.S. electric sector outlook under a wide range of possible futures, utilizes ReEDS (Cole et al., 2020). ReEDS has also been used to examine the impacts of a range of existing and proposed energy policies (Gagnon et al., 2017; Lantz et al., 2014; Mai et al., 2012). The ReEDS website (https://www.nrel.gov/analysis/reeds/) includes an up-to-date list of publications that use ReEDS.

As part of this effort, ReEDS researchers aligned how geothermal is represented in ReEDS with other renewable energy resources. Geothermal resource classes are now binned using a 10-class resource definition with the geothermal resource directly related to the reservoir temperature (Table 1). This is consistent with the approach used for wind, photovoltaics, and concentrated solar resources.

Table 1: Technical Resource Potential (GW)

Resource Class	Reservoir Temperature (°C)	Hydrothermal	Near-Field EGS	Deep EGS
Class 1	> 325		0.2	
Class 2	300–325	1.8	0.2	
Class 3	275–300	9.3	0.1	1.2
Class 4	250–275	0.7	0.1	8.2
Class 5	225–250	1.1	0.1	74
Class 6	200–225	2.4	0.2	320
Class 7	175–200	0.2	0.3	709
Class 8	150–175	2.6	0.3	995
Class 9	125–150	1.1	0.03	1270
Class 10	< 125	4.7	-	-
Total		23.9	1.4	3,375

EGS = enhanced geothermal system

With these improvements, ReEDS was used to evaluate value streams and competitiveness of geothermal electricity generation. Value streams include revenue obtained from all grid services, including energy, operating reserves, planning reserves, and reserved planning services. These value streams represent a more comprehensive picture compared to the more standard levelized cost of energy (LCOE) metric, which only considers the energy value of a plant and does not consider the interactions during operations between technologies. Competitiveness is a measure of

how much additional revenue or how much costs would need to be reduced to develop a specific resource.

Three types of future uncertainty were explored to understand how the value and competitiveness of geothermal power evolve in ReEDS: 1) Grid decarbonization, 2) Uncertain availability of emergent technologies, and 3) Limited resource availability for land-intensive renewables. Results suggest that while all the future uncertainties could improve the value proposition for geothermal power, the size and exact effects varied significantly. In the event of all three occurring simultaneously, the value of geothermal improves by 33%, and there is an order of magnitude greater geothermal capacity.

With decarbonization policies alone, the ReEDS model predicted no strong impact to the total geothermal electrical generation revenue, although the capacity value represented a higher fraction of revenues. Reduced cost metrics had more impact: a substantial divergence between a 95% and 100% decarbonization was observed, especially after $1,500/kW. Reduced resource availability showed small increases in geothermal revenue in scenarios such as drought and limited land access, with the reduced cost cases also showing small impacts. The most substantial change was observed in the technology availability grouping, where a restricting carbon capture and storage scenario increased value stream revenue by 7% and a restricting of carbon capture and storage, H_2, and nuclear small modular reactor increased revenue by 33% (Figure 1).

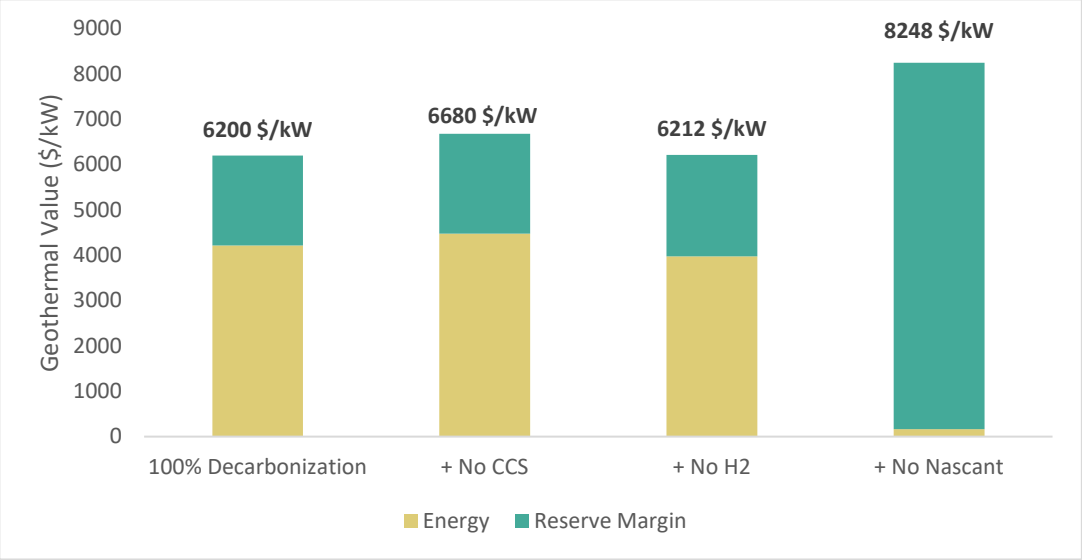

Figure 1 Value composition for geothermal power under select scenarios in 2050.

We found that the interactions in the assumptions of an uncertain future had substantial value implications for how the model predicted geothermal electricity generation to deploy with respect to other technologies. The change in value metrics within geothermal and among technologies in ReEDS provided useful insight into model behavior and useful context for consumers of capacity expansion model results to help them interpret the results by indicating the exact services provided by an invested grid technology and the economic value of those services, which are not well captured by metrics such as LCOE. Reduced cost metrics show how close undeveloped geothermal technologies are to deployment. These metrics allow decision makers to consider economic

viability of geothermal alongside other values and planning priorities not considered in a capacity expansion model.

2.2 reV: Renewable Energy Potential model

The Renewable Energy Potential (reV) model is a geospatial platform for estimating technical potential and developing renewable energy supply curves, initially developed for wind and solar technologies. The model evaluates deployment constraints, considering land use, environmental, and cultural factors, and estimates the distance to existing grid features to connect future plants (Maclaurin et al., 2021). Until last year, representation of geothermal electricity generation technologies was a pressing deficiency in the reV model.

In FY23, the reV Geothermal project brought representation of geothermal electricity generation closer to parity with wind and solar technologies in reV, and thus in downstream bulk power system models for the contiguous United States. The new geothermal module in reV relies on the U.S. Department of Energy's (DOE's) Geothermal Electricity Technology Evaluation Model (GETEM) implemented in the System Advisor Model (Blair et al., 2018). Both hydrothermal and enhanced geothermal systems (EGS) with binary and flash power plants are implemented. We developed the module to be flexible and extensible such that geothermal supply curves can rely on different geothermal resource datasets, support a wide range of deployment assumptions, and accommodate future improvements to data and modeling approaches.

This novel geothermal generation module in reV allows for representation and analysis at the same level of detail as other renewable technologies. We released the geothermal module as part of the open-source reV model to enable public access and encourage external collaboration. The process for evaluating data sources for the modeling and the initial reV geothermal results using two resource data sets were presented at the Geothermal Rising Conference (Pinchuk et al., 2023). Several sensitivity runs were presented. The results are encouraging, showing competitive LCOE values utilizing 2023 annual technology baseline (ATB) hydrothermal and EGS drilling costs.

The supply curves and LCOE results, which are posted on the DOE Geothermal Data Repository and NREL Geospatial Data Science pages for easy access, should be considered preliminary because of the uncertainty in geothermal resource potential data. We present median LCOE values for the contiguous United States for three scenarios: one hydrothermal (3.5 km depth) and two EGS (4.5 km—see Figure 2—and 6.5 km depth). The capital and operating costs for each respective technology are modeled. The reV supply curves are compatible with the ReEDS model. Understanding the relative technical potential for geothermal will better inform policy and planning for a high penetration of renewable energy. This first year of the project established the modeling foundation for additional functionality and further innovation in modeling geothermal electricity generation for the bulk power system. We have already seen industry interest in these data and look forward to further engaging with the private sector and external collaborators.

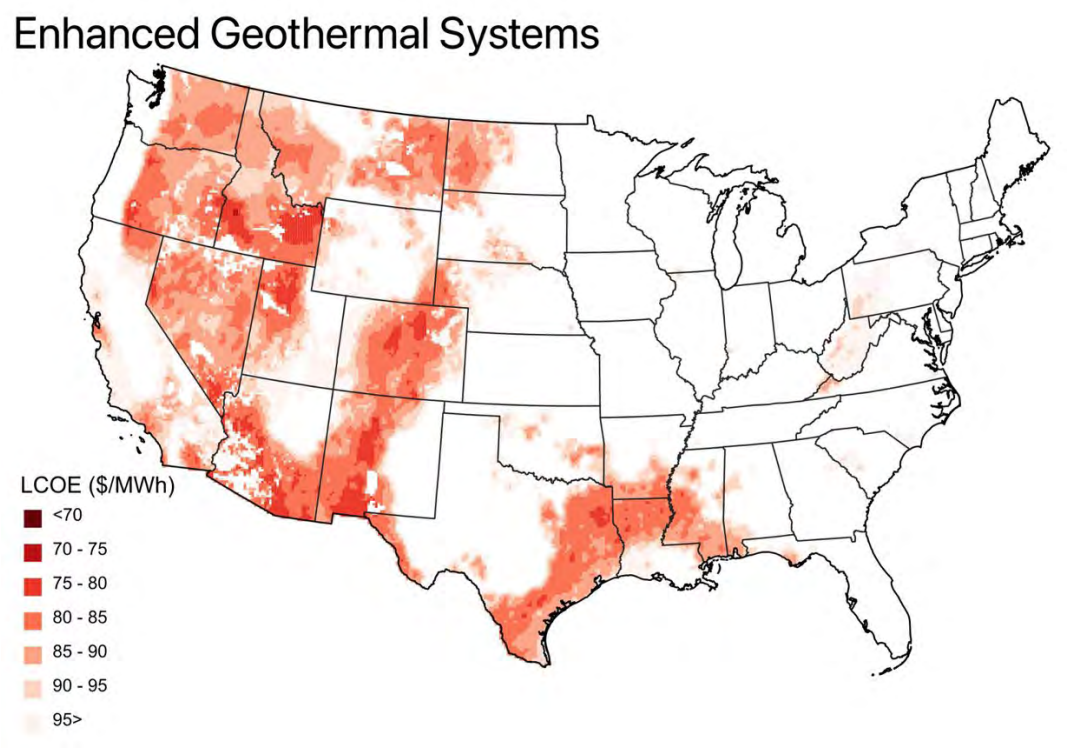

Figure 2: Projected LCOE using 2030 ATB Geothermal EGS Costs for 4.5 km depth

2.3 GETEM: Geothermal Electricity Technology Evaluation Model

The Geothermal Electricity Technology Evaluation Model (GETEM) is the prime techno-economic calculator for geothermal electricity for DOE. GETEM underwent several improvements to ensure accurate analysis of geothermal energy system costs, including a modification of the existing learning curve methodology used in the ATB projections. These costs were used for the geothermal inputs for NREL's ATB for 2023. Lastly, improvements to GETEM's functionality and user interface in the System Advisor Model were made.

Using data from industry and the Frontier Observatory for Research in Geothermal Energy (FORGE), EGS technology performance in the ATB is represented with reduction in exploration well requirements, increased exploration drilling success, and higher stimulation success rates resulting in a base year (2021 dollar) cost reduction from 41.3 c/kWh (in 2022) to 32.0 c/kWh (in 2023) for near-field EGS. NREL developed a new learning curve methodology to estimate future cost declines with respect to anticipated geothermal capacity deployments. The learning curve methodology, applied to the Moderate and Advanced ATB cases, is a single-factor model that accommodates historical "learning-by-doing" rates and learning rates experienced by the unconventional oil and gas industry (particularly for EGS). The learning-by-doing rate accounts for improvements in the cost of hydrothermal field development and plant construction that have driven historical capacity additions. For hydrothermal technologies, learning rates of 13% and 30% were defined for the Moderate and Advanced cases, respectively. For EGS technologies, the learning rates were 18% and 30%, respectively. This resulted in a better representation of cost reduction scenarios, especially for the Moderate ATB case.

NREL, the Geothermal Technologies Office, and industry stakeholders collaborated to ensure that the GETEM model assumptions for the 2023 ATB were aligned with current industry trends. Specific updates were made to delineate near-field EGS from deep EGS by treating the former as a brownfield that adjoins a producing hydrothermal resource. This resulted in a substantial reduction in the exploration costs for near-field EGS relative to deep EGS. Other significant changes to the GETEM input spreadsheets are listed in Table 2 and relate to those that characterize reservoir performance, drilling success, and plant contingency. We also aligned reservoir performance for hydrothermal resources with those encountered in real systems based on well flow and productivity data compiled by (Snyder et al., 2017).

Table 2: Updated GETEM input assumptions for EGS technologies

GETEM Input		**Near-Field EGS**			**Deep EGS**		
		Conservative	**Moderate**	**Advanced**	**Conservative**	**Moderate**	**Advanced**
ECONOMIC	Contingency	10%	10%	10%	10%	10%	10%
EXPLORATION	Successful Full-Size Wells	5	3	2	5	3	2
DRILLING AND COMPLETION	Success Rate (Exploration)	76%	76%	90%	52%	52%	90%
	Success Rate (Development)	76%	76%	90%	76%	76%	90%
	Success Rate (Stimulation)	75%	81%	90%	75%	81%	90%
RESERVOIR PERFORMANCE	Well Flow Rate	40 kg/s	80 kg/s (Binary) 60 kg/s (Flash)	110 kg/s (Binary) 80 kg/s (Flash)	40 kg/s	80 kg/s (Binary) 60 kg/s (Flash)	110 kg/s (Binary) 80 kg/s (Flash)
	Well Productivity	250 lb/hr-psi	1,365 lb/hr-psi	6,370 lb/hr-psi	250 lb/hr-psi	1,365 lb/hr-psi	6,370 lb/hr-psi
	Well Injectivity	300 lb/hr-psi	1,650 lb/hr-psi	7,645 lb/hr-psi	300 lb/hr-psi	1,650 lb/hr-psi	7,645 lb/hr-psi

2.4 GEOPHIRES tool

GEOPHIRES is a techno-economic simulation tool for analyzing geothermal technologies. GEOPHIRES stands for GEOthermal energy for Production of Heat and electricity IR Economically Simulated; “IR” represents electric current and resistance and refers to the electricity mode. GEOPHIRES is distinct from GETEM in that it can analyze both geothermal electricity generation as well as geothermal heating and cooling technologies (Beckers & McCabe, 2019). In FY23, GEOPHIRES, like GETEM, updated both the costs for the surface power plant and drilling

costs. Additionally, GEOPHIRES was used as the foundational code for two other modeling tool improvements: Engage (described next) and the Distributed Geothermal Market Demand Model (dGeo) (described in Section 3.2).

2.5 Engage

Engage is a flexible web-based energy planning model for scenario exploration from district energy to national scales. In FY23, the Engage team focused on allowing modelers to easily represent complex technologies such as geothermal bulk electricity generation technologies via Engage Technology Templates and invoking physics-based and techno-economic models for parameterized runs to derive cost-capacity relationships. The team implemented the new capabilities into Engage by building general purpose facilities in the database, user interface, and computational infrastructure (to invoke other physics-based models such as GEOPHIRES) along with new programmatic data exchange and translation capabilities to translate the physics-based model outputs to inputs appropriate to the Engage model.

The Engage model paradigm relies on archetype technologies that can be composed and configured to simulate real-world technologies such as solar photovoltaic, wind turbines, thermal power plants, etc. The compositions of these archetype technologies required to represent real-world technologies can be complex and require externally derived data to characterize their cost and performance characteristics. Engage Technology Templates allow for templating archetype technology compositions of any level of complexity and the automated translation of simulation and cost data into appropriate constraints in the Engage model via user-driven workflows.

Having developed the template and workflow capability, the Engage team developed a template for a Binary Cycle Subcritical Organic Rankine Cycle geothermal power plant relying on the GEOPHIRES techno-economic model to derive linearized cost-capacity relationships for Engage based on modeler input to the Engage template input forms. After the Engage inputs are derived from GEOPHIRES runs, the modeler can then instantiate the technology into the Engage model at the click of a button in the user interface. The new capability also implements application logic to allow the modeler to manage various components of the instantiated technology in ways that prevent inadvertent deletion of instantiated template technology components but facilitates reopening the template to edit and re-instantiate the technology.

The development of the template's capability was tightly integrated with other Engage development efforts including new carriers functionality allowing association of appropriate units of measure with each carrier in the model. Carriers in an Engage model refer to flows of energy or commodities. Engage models can now represent energy flows in, for example, kWh or MMBTU as desired and, for example, water flows in gallons or cubic meters with the capability to convert among compatible units of measure throughout the application seamlessly. This unit of measure functionality is fully integrated with Engage templates to facilitate unit of measure flexibility in template definitions, allowing modelers to think in familiar ways about the flows they are modeling and inherently document their models in terms of units of measure associated with their data sources, minimizing unit of measure errors. These combined features were tested and deployed to the live NREL-hosted Engage web application and are now accessible and usable by the general public and NREL modelers alike (https://engage.nrel.gov/en/login/?next=/en/).

3. Geothermal Heating and Cooling Model Updates

3.1 Geothermal Heating and Cooling (GHC) Geospatial Datasets and Analysis

Prior to evaluating the potential role of geothermal heating and cooling (GHC) in decarbonization strategies at different scales, better and more accessible baseline data and characterization for low- and medium-temperature geothermal resources is required. GHC is defined as "the utilization of geothermal energy underground or naturally arising at the surface of the ground for any purpose other than electricity generation" (International Geothermal Association, 2022). Some of the technologies associated with GHC are geothermal heat pumps (GHPs), geothermal direct use, and combined heat and power. The two aims of the "GHC geospatial datasets and analysis" project were: (1) establish baseline geospatial datasets for low-temperature resources (<150°C) relevant for evaluating GHC potential; and (2) establish a methodology for better geospatial analysis of low-temperature geothermal resources.

In the first phase of this project, we placed particular focus on the states of Alaska and Hawai'i because these states were excluded from prior geothermal potential evaluations because of a lack of data (e.g., GeoVision). We compiled baseline geospatial datasets for low-temperature geothermal resources including new data from oil and gas wells. Several low-temperature data inventories were submitted to the Geothermal Data Repository including Alaska, Hawai'i, and the contiguous United States (https://gdr.openei.org/submissions/1553 and https://gdr.openei.org/submissions/1518). Based on these compiled datasets, NREL's GeoRePORT Resource Size Assessment Tool was implemented to estimate the low-temperature resource base in Alaska (Figure 3).

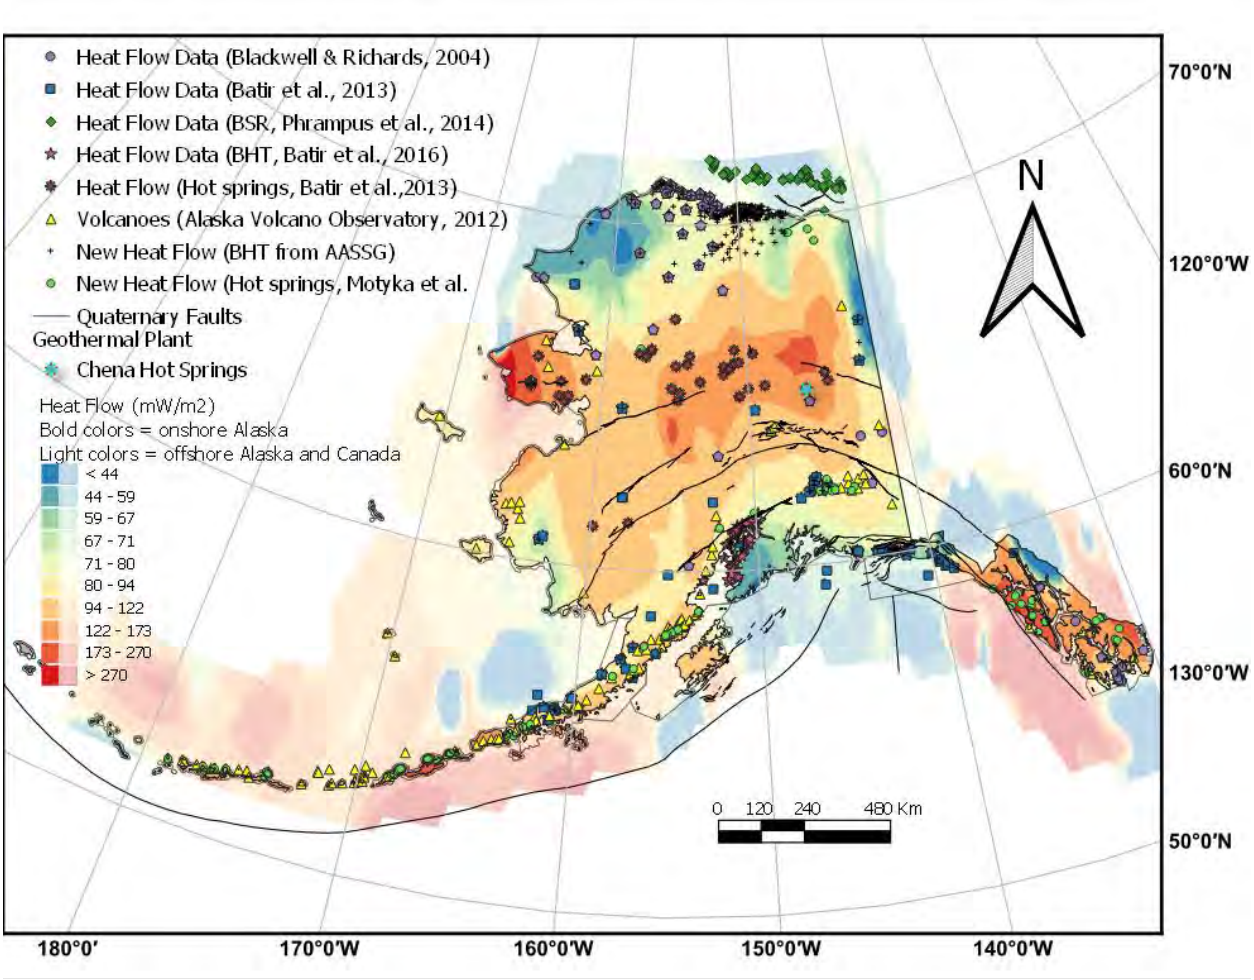

Figure 3: Updated heat flow map of Alaska modified from Batir et al. (2016). New heat flow values from 311 bottom-hole temperature data points by Association of American State Geologists and 72 hot springs by Motyka et al. (1983) were added to this version.

To establish a methodology for better geospatial analysis of low-temperature geothermal resources for GHC applications, a workflow based on prior work in geothermal Play Fairway Analysis was developed. A classification and characterization of low-temperature geothermal play types (sedimentary basins, orogenic belts, and radiogenic play types) and the identification of relevant data for exploration most suited to prospecting for these types of resources were presented at Geothermal Rising 2023 (Davalos-Elizondo et al., 2023).

Ongoing work includes compiling relevant data and Play Fairway Analysis workflows to the assessment of sedimentary basins for combined heat and power and direct uses, using the Denver Basin as an example. The goal of this project is to facilitate GHC analysis at multiple scales (e.g., national deployment analysis as well as community-scale planning). Additionally, a python code, geoPFA, was generated to create favorability maps, and it will be updated during the evolution of this and other projects at NREL. T The geoPFA Python library is expected to be released as an open-source tool in the future to enable others to use this code for their own PFA studies.

3.2 dGeo: Distributed Geothermal Market Demand Model

The Distributed Geothermal Market Demand Model (dGeo) was developed by NREL in 2016–2017 for use in the Geothermal Technologies Office-funded Geothermal Vision Study, with a primary objective of simulating the techno-economics of geothermal district heating systems and the adoption of GHPs. The tool is consistent with others in the family of Distributed Generation Market Demand models (Das et al., 2020), including the Distributed Solar Market Demand and Distributed Wind Market Demand models that explore the potential role of distributed energy resources in meeting energy demands in the United States. dGeo simulates the potential for deploying geothermal distributed energy resources in the residential and commercial sectors of the United States. Originally, GHPs and geothermal direct use for district heating could be simulated. Recently, an ambient temperature loop module was integrated in dGeo. To quantify the opportunity space for these technologies, dGeo leverages a highly resolved geospatial database and robust bottom-up, agent-based modeling framework. It can simulate the technical potential, economic potential, market potential, and technology deployment of geothermal technologies through the year 2050 under a variety of user-defined input scenarios. Through these capabilities, dGeo can provide substantial analytical value to various stakeholders interested in exploring the effects of various techno-economic, macroeconomic, financial, and policy factors related to the opportunity for GHP, geothermal direct use, and ambient temperature loop in the United States (McCabe et al., 2017).

The original model used simplified calculations to model the various aspects of a district heating system and, importantly, did not consider any physics-based representation to model the subsurface conditions. In this effort, dGeo was upgraded by integrating the updated GEOPHIRES v3 tool as the techno-economic engine that calculates surface plant considerations, subsurface conditions, and project economics. Coupling the more detailed modeling aspects of GEOPHIRES with the established, agent-based framework of dGeo enables more reliable, robust results for district heating system viability. In addition, GEOPHIRES has a built-in absorption chiller module and can be used to assess geothermal cooling. Further, the updated thermal demand maps for heating and cooling have been made available to use as input in dGeo.

To facilitate the coupling of the two models, we first updated the original source code for dGeo from Python 2 to Python 3. This enables the new model to use the latest capabilities from Python and to have longevity for future analyses. The new model also retains the original dGeo capability of simulating district heating systems for a comprehensive set of regions across the United States. The user can, for example, run dGeo for all counties of a single state for a more detailed analysis or can configure a scenario analysis for the entire United States, all while utilizing GEOPHIRES as the detailed techno-economic engine. Data input and output considerations are still handled based on the legacy GEOPHIRES setup—that is, dGeo will create a text file for the case considered, pass the file to GEOPHIRES for simulation, and then output results into dGeo for postprocessing needs (e.g., plotting, mapping).

We recently implemented several additional upgrades to dGeo including:

- Expanding the tool to Alaska and Hawai’i

- Upgrading the GHP module by leveraging ResStock and ComStock load profiles and the GHEDesigner tool for sizing the borehole field (Mitchell et al., 2023; Spitler, West, & Liu, 2022)
- Implementing a new module to simulate ambient temperature loops
- Updating the incentives database including accounting for the Inflation Reduction Act
- Incorporating the latest releases of the EIA thermal demand, building growth, and energy cost data.

An example dGeo simulation result for ambient temperature loops is shown in Figure 4.

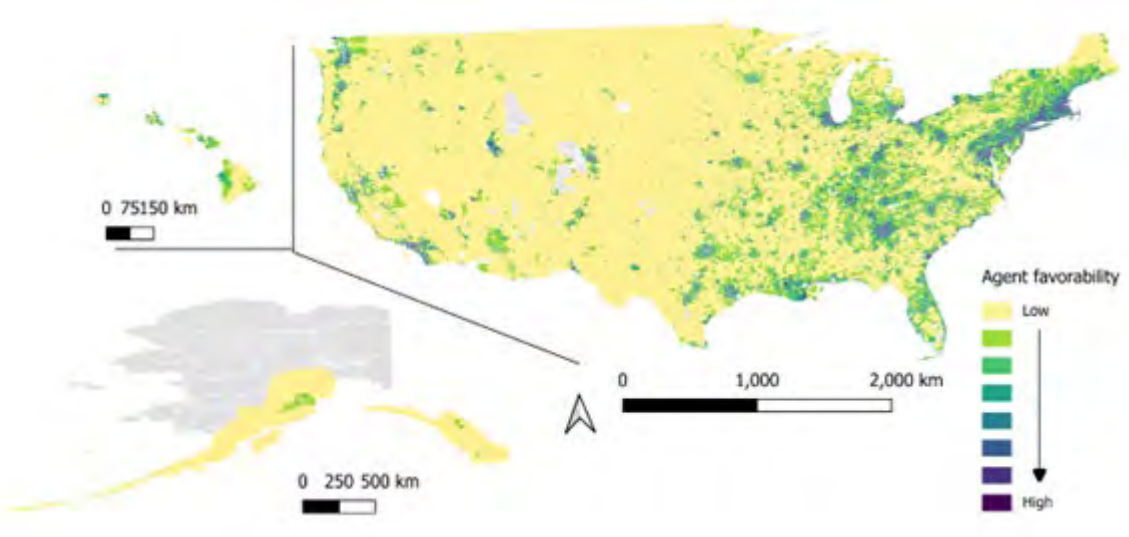

Figure 4: Example dGeo nationwide simulation run for ambient temperature loop, a new module recently integrated into dGeo (Simpson et al. 2024).

3.3 ComStock and ResStock: Commercial and Residential Building Stock

The ComStock and ResStock analysis tools developed and maintained by NREL help states, municipalities, utilities, and manufacturers identify which building stock improvements save the most energy and money. ComStock is a DOE model of the commercial building stock.

ComStock is a highly granular, bottom-up model that uses multiple data sources, statistical sampling methods, and advanced building energy simulations to estimate the annual subhourly energy consumption of the commercial building stock across the United States. ComStock asks and answers two questions: **(1) How is energy used in the U.S. building stock?** and **(2) What are the impacts of energy-saving technologies?**

ResStock leverages DOE's open-source building energy modeling ecosystem of OpenStudio® and EnergyPlus™. The model is a versatile tool that takes a new approach to large-scale residential energy analysis by combining large public and private data sources, statistical sampling, detailed subhourly building simulations, and high-performance computing to

accurately model the diversity of the housing stock and the distributional impacts of building technologies in different communities.

As part of this 3-year effort, the NREL ComStock and ResStock teams established a technical advisory group (TAG) of 15 academics, national laboratory researchers, and industry-leading companies, associations, and advocate groups. The TAG convened three meetings to solicit feedback and approval of the modeling methodologies and implementation. The TAG also conducted five focused interviews with specific technical advisory group members. TAG inputs, insights, and data were crucial to developing GHP functionality in the ComStock and ResStock tools, as well as others (e.g., Urban Renewable Building and Neighborhood optimization (URBANopt^{TM})).

3.3.1. Commercial GHP Modeling

During FY23, the ComStock team conducted research on the state of commercial-scale GHP systems through literature reviews, focus meetings with subject matter experts, and input from TAG members. Ultimately, the team selected three GHP configurations for modeling: central hydronic water-to-water, packaged water-to-air, and console water-to-air. The team developed extensive documentation explaining the applicability criteria, modeling methodology, and technical assumptions for each of these three systems. Three measures were developed in OpenStudio, which replace the existing system with the most compatible GHP configuration. The measures leverage an in-the-loop call to the GHEDesigner python package, which designs ground heat exchanger systems based on the time series of annual building loads and other borefield assumptions. The key output of GHEDesigner is the g-function, which are commonly used to simulate ground heat exchangers used with ground-source heat pump systems. The g-function is then imported back into the model and used in the final building simulation. Several output variables were added to the simulation that will inform the stock modeling results and analysis, including number of boreholes, borehole depth, ground heat exchanger flow, and GHP capacities. The team acquired real performance data representing the GHPs from Trane and Carrier and will integrate that data in the modeling in FY24 pending required OpenStudio capability upgrades.

3.3.2. Residential GHP Modeling

The major accomplishment of the residential GHP modeling in FY23 was updating the more than 10-year-old model of GHPs in OpenStudio-HPXML. To achieve this accomplishment, the team reviewed residential GHPs in the U.S. residential building stock. The team quantified the number of residential GHP systems and where they were located, identified correlations to various housing characteristics using U.S. Energy Information Administration's 2020 Residential Energy Consumption Survey (RECS), investigated installed mechanical equipment types and efficiencies, and reviewed the prevalence of geothermal loop configurations in the residential building stock. The team made numerous updates to the OpenStudio-HPXML GHP models including:

- Integrating a more complete and up-to-date published library of g-functions (Spitler et al., 2021; Spitler, West, Liu, et al., 2022) that support additional borefield configurations
- Updating ground thermal conductivity and undisturbed ground temperatures

- Expanding the input schema for HPXML
- Improving the borefield sizing methodology
- Providing fan and pump assumptions consistent with ISO 13256-1
- Updating GHP performance curves based on a newer GHP system.

3.4 REopt: Renewable Energy Integration and Optimization

REopt® (Renewable Energy Integration and Optimization) is NREL's techno-economic decision support model that evaluates the economic viability of grid-connected distributed energy resources at commercial and small industrial sites. A mixed-integer linear program, REopt optimizes distributed energy resource sizes and dispatch by minimizing system costs (and/or other energy goals such as resilience or emission reductions) over the analysis period, subject to system- and unit-level constraints. The GHP module of REopt has been expanded to increase its flexibility in configuring GHP, including hybrid vs. non-hybrid geothermal heat exchange system (Figure 5 and Figure 6) and central plant water-to-water GHP vs. distributed water-to-air GHP. The REopt help manual has been updated with details of these new capabilities, which are available in both the REopt Julia Package (REopt.jl) and web tool. Both the REopt Julia Package and web tool are open-source and can be accessed at https://github.com/NREL/REopt.jl and https://reopt.nrel.gov/tool, respectively.

In the web tool, when choosing GHP as one of the technology options, users now have access to four new inputs:

1) "Heat pump configuration" with the option to select "Central plant water-to-water heat pumps (WWHP)" in addition to the already available "Distributed water-to-air heat pumps (WAHP)"

2) "GHX configuration" with the option to select "hybrid" or "non-hybrid"

3) "GHX useful life (years)" with a default value of 50 years, which is used to calculate a residual value of the GHX if its useful life is longer than the analysis period

4) "Avoided HVAC upgrades ($)" with a default value of $0, which users can adjust if there are possible needed upgrades to their existing HVAC equipment, e.g., a chiller replacement, that could be avoided if a GHP retrofit is undertaken.

These new GHP configurations aim to improve the versatility of the REopt GHP module and the accuracy of its life cycle cost analysis.

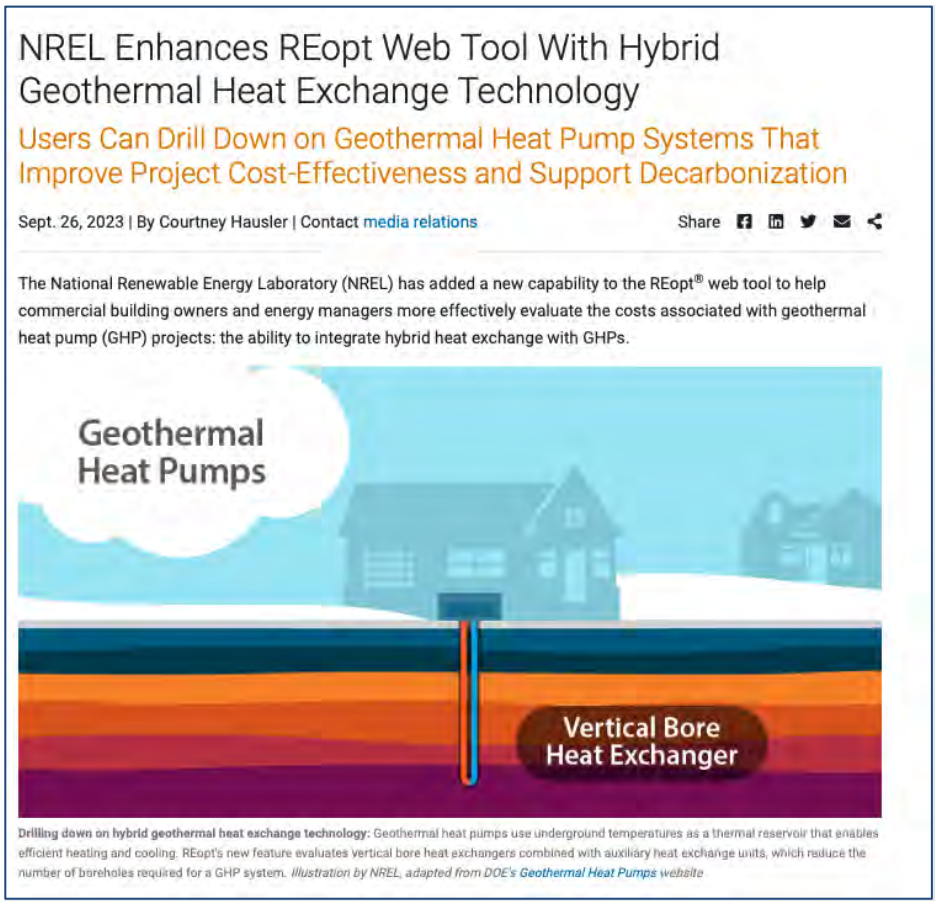

Figure 5: NREL news release of GHP inclusion to REopt web tool

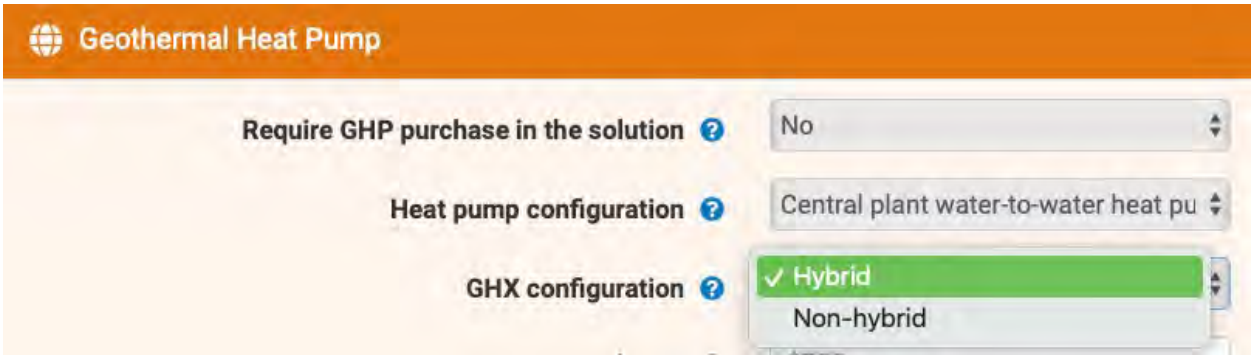

Figure 6: New GHP/GHX configurations in the REopt web tool

3.5 URBANopt™: Urban Renewable Building and Neighborhood optimization

Urban Renewable Building and Neighborhood optimization (URBANopt™) is an advanced analytics platform for high-performance buildings and energy systems within one geographically cohesive area in a city (e.g., a city block or district). URBANopt was developed by NREL to investigate:

- Detailed energy tradeoffs between building locations and geometry
- Building energy efficiency features

- Building and district energy storage strategies and technologies
- Aggregated grid services such as dynamic and responsive loads
- District energy system locations
- District energy system performance characteristics to identify best approaches for reaching site-wide energy goals.

URBANopt modeling capabilities leverage the DOE's open-source building energy modeling ecosystem of OpenStudio and EnergyPlus. The underlying URBANopt workflows and measures are open-source such that the broader urban energy modeling community can leverage them. Active partnerships to apply URBANopt for specific districts or neighborhoods, utility distribution feeders, and technology solutions are currently underway.

Updates for adding district-connected GHP systems were implemented to allow the tool to automatically calculate the size of GHEs (geothermal heat exchangers) given the campus thermal demand. In addition, URBANopt was updated to dynamically generate network models that represent the thermal pipe network and district energy systems with GHPs. The platform uses geometric and nongeometric user inputs related to the buildings, borefield, and district energy loop to generate these models that users can then apply to study the geothermal district GHP system. A case study was published to demonstrate the workflow and simulation result plausibility of the proposed platform (Wang et al., 2024).

4. Conclusions and Future Work

The DOE Geothermal Technologies Office is supporting a broad effort to demonstrate the multi-faceted value of integrating geothermal power and GHC technologies into national decarbonization plans and community energy plans. This paper presents a progress report on work performed by NREL to-date in updating flagship modeling tools and baseline data sets to better represent the state of the art in geothermal resource data, technologies, costs, and other key information. Model development is expected to continue, and future work will leverage these updated modeling tools to perform robust analyses of the role of geothermal power and heating and cooling technologies in decarbonization strategies across multiple scales.

Kamojang, Dry Steam Reservoir, Reservoir Process, Conceptual Model, Upflow Dynamics, Reservoir Engineering, Geoscience

ABSTRACT

A geothermal conceptual model reflects our understanding of reservoir processes and is continuously refined and updated as the reservoir evolves over time. Since the commencement of its commercial production in 1982, Kamojang geothermal field has been gathering numerous static and dynamic data from new well drilling and continuous monitoring of the reservoir's responses to various development scenarios. Changes to the interpreted reservoir boundaries, structures, and reservoir interconnectivity are examples of what have been made to Kamojang conceptual model over the course of its exploration and development phases.

Reservoir pressure is one of the most important dynamic data to have to interpret the fluid flows and permeability in a geothermal reservoir. Furthermore, in dry steam reservoirs such as Kamojang with currectly low observable superheat, reservoir pressure is directly related to enthalpy and potential for steam production. This paper presents the effort of data processing and analysis of Kamojang reservoir pressure distribution that was mapped from 66 wells distributed throughout Kamojang geothermal field over the time span of about 42 years. The observed reservoir pressure behavior shows multiple pressure regions exists in Kamojang and each differs in pressure magnitude that is increasing from the West to the East part of Kamojang with all the regions sharing similar reservoir pressure decline. This pressure behavior implies effective lateral permeability between each pressure region and fluid flows from the East toward the West of the reservoir.

As the East side of Kamojang is characterized with high reservoir and shut in pressure suggesting that the area is connected to the upflow, interpreting the location of the upflow in a dry steam reservoir requires multidisciplinary analysis. Therefore this analysis is still needed to be integrated with other disciplines to validate this finding and further refine the Kamojang conceptual model.

1. Introduction

The development of a geothermal resource conceptual model is an information organizing principle that depicts those aspects of the geothermal reservoir that are most relevant to high value economic decisions like well targeting and capacity assessment and provides a scientific hypothesis that a well will confirm or refute [Cumming, 2016]. A geothermal conceptual model reflects our understanding of reservoir processes and, to build it properly, several main components have to be placed, namely; heat source, fluid phase, isotherm, hydrology, thermal manifestation, reservoir boundaries, structures and permeability distribution.

Interpreting the hydrology of a geothermal reservoir plays a vital role in determining the flow of hot fluids from the bottom of reservoir to the the upper part of the reservoir that is accessible for further utilization. An upflow zone in a geothermal reservoir is a near vertical flow zone of which occurs the major flow coming from the heat source to the commercial reservoir zone. For dry steam reservoirs the upflow can represent most of the mass entry and a significant fraction of heat entry into the reservoir. Generally the temperature in an upflow zone is the highest and it increases with depth along the upflow path. As the flow reaches the reservoir cap rock, the upflow zone transition to the outflow zone where the flow become horizontal and the temperature declines with distance and depth. For most geothermal reservoirs a recharge zone, as the name suggest is the zone where cold water enter the reservoir and recharges the reservoir fluid. Most recharge zones in a geothermal reservoir comes in permeable pathways crossing into the reservoir. This cold water can enter the reservoir from the side boundary due to pressure difference or it may also enter from the overlying aquifer at higher elevation than the water level in the geothermal reservoir. Again for dry steam reservoirs these are usually very small leaks that can increase steam condensation where they occur.

These fluid flows in the reservoir along with the mass and heat transfer in a geothermal reservoir can be interpreted from multidisciplinary analysis. This paper will focus on the reservoir engineering role to the extent of available surface and downhole pressure trend data in unravelling the upflow dynamic in Kamojang, a dry steam geothermal reservoir located about 42 km Southeast of Bandung, West Java, Indonesia. An upflow in a volcano hosted geothermal reservoir is likely to be associated with recent magmatic activity or deep fluid circulation that enables the flow upward from the heat source. Certain geologic settings needs to exist that creates vertical permeability on an otherwise impermeable rock deposition and act as a conduit to the commercial reservoir zone. In a dry steam reservoir, the reservoir cap rock is completely sealed from the surrounding aquifers keeping the reservoir fluid in the steam phase. Steam from the upflow will be redirected laterally once it hits the cap rock and flow beneath the cap toward the lower pressure part of the reservoir.

2. Geoscience

2.1 Background

Kamojang field lies in a Quaternary Volcanic complex of Mounts Guntur-Rakutak in the Southern West Java volcanic chain. Several volcanic edifices and caldera structures are recognized within the prospects. Geothermal features are also manifested within the volcanic complex and marks its resource area.

Mt. Rakutak-Guntur is a volcanic chain that trends West-Southwest to the East-Northeast where the volcanic activity was believed to take place since the Pleistocene along the axis. The volcanic activity moved away from Mt. Rakutak (1.02 ± 0.02 mA) towards East-Northeast where Mt. Sanggar-Gandapura and Mt. Sigit-Guntur erupted in 0.425 ± 0.015 mA and (0.025 ± 0.1 mA) respectively. Another prominent volcanic feature in this area is the Pangkalan caldera where it erupted prior to the Mt. Masigit-Guntur eruption. Major geothermal activity is located within the Pangkalan caldera and Masigit-Guntur areas. The magmatic composition of this volcanic chain is predominantly Andesitic to Basaltic Andesite. Although there is also an indication of a compositional evolution to be more basaltic towards the eastern volcanoes such as Mt. Guntur.

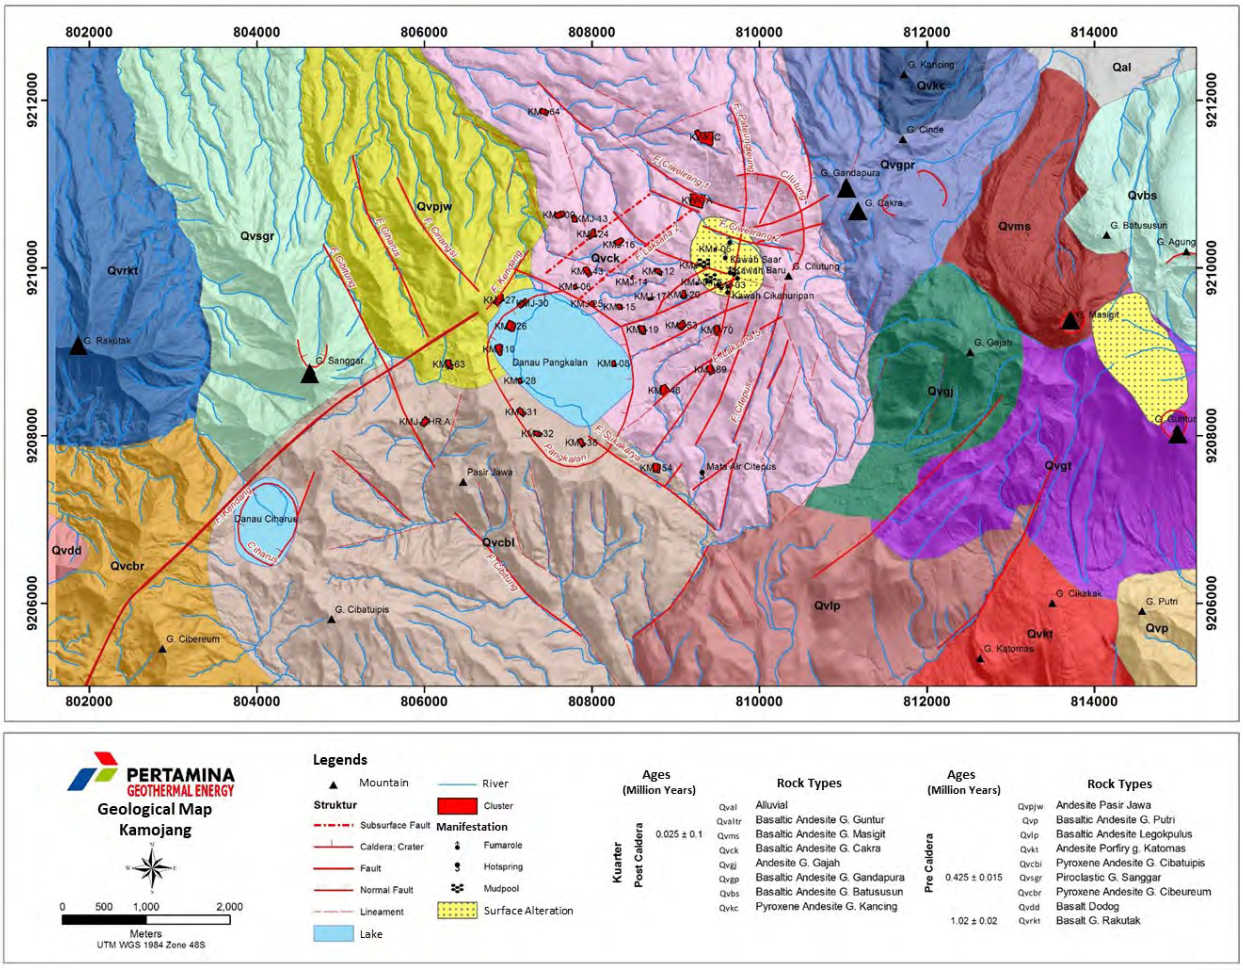

Figure 1: Geological Map of Kamojang

The main structural trends in the area are Northeast-Southwest and Northwest-Southeast where the most notable faults are the Kendang and Pateungteung-Citepus in the West and east respectively. Both faults act as the prospect boundaries on the West and East parts of the area. The Kendang fault extends to the Southwest where the neighboring vapor dominated field is situated, Darajat field. Kendang is a tensional fault that may have constructed the graben-like structure along the West part of the volcanic axis. Upon the extension of this fault zone, volcanic edifices developed. Another prominent structure is the Rim of Pangkalan caldera. The rim is about 2 km wide. The structure is shaped like a half circle and the scarp can be seen on the West to South. The North-Eastern side is unclear due to deposits of younger Cakra volcanics covering the area.

Distribution of geothermal manifestations mainly occur in the North-Eastern part of the area at the slope of the Gandapura volcanic complex. The type of manifestations found are predominantly steam heated features such as fumaroles, steaming ground, solfatara, acid sulphate hot springs and mud pools covering an area about 14 km2. Warm bicarbonate springs seeps to the surface on the creek along the Citepus fault in the North part of the area. The characteristics of the fluids are the following; the temperature of the springs are about 93-95^{o}C, close to the local boiling point, discharging large volumes of steam, the hot springs are typically acid (pH 2) and contains 1000-2000 ppm sulphate with small amounts of chloride (< 5 ppm). Isotope studies suggests that the water is of local meteoric origin. It has been heated by steam containing hydrogen sulphide which oxidises to sulphuric acid to give the waters a high sulphate concentration and low pH. The gas concentration in the vapor phase from the earliest exploration wells indicates a low content (less than 1%wt) with no significant amounts of magmatic contribution in the samples.

2.2 Existing Upflow Postulation

Geologically, the Kamojang geothermal model is controlled by a depressed structure named Pangkalan “caldera collapse” and Kamojang Crater, fault structure of Kendang Fault in the West, and Citepus-Pateungteung in the East. These structures in combination, was presumed to control the alterations and manifestations distribution, including the pattern of the MT resistive layer in the Kamojang area. The boundaries of Kamojang field laterally are limited to the West by the Kendang Fault, to the East by the Citepus fault, to the Northeast by the Gandapura-Cakra volcanic complex (which has not been delineated yet) and to the Southwest by the Ciharus volcanic crater.

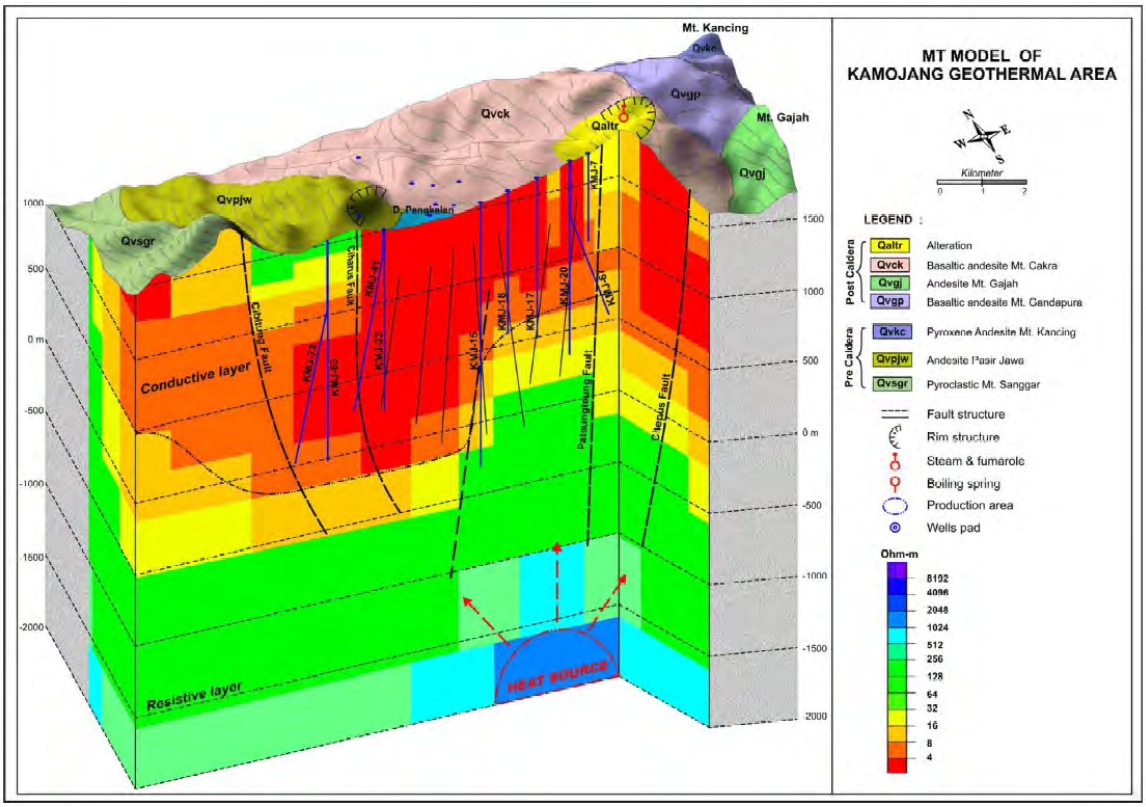

Figure 2: The thickness of the conductive and resistive zones of the Kamojang area based on MT data Geological Map of Kamojang

The Southwest and Northeast oriented sections of the geothermal tentative model were based on the integration of recent geoscience data as shown in Figure 2. Based on the gravity model, a high gravity anomaly occurs beneath the Gandapura-Cakra complex and a low anomaly beneath the Pangkalan area. Thus, it shows that a shallow intrusion is located beneath the Gandapura-Cakra that may act as a potential heat source. However, wells drilled inside and around the Pangkalan caldera rim reveal the extent of the dry steam reservoir with saturated temperatures. Consequently, the heat source may extend from Gandapura-Cakra to the Pangkalan area. The existing upflow zone interpretation is also supported by the previously observed geochemistry. The magmatic input was found on gas samples from wells located more to the Northeastern area. This is understandable since the evolution of young volcanoes are trending towards the Northeast. The wells drilled on the Northeast also shows higher temperature, pressure and productivity. The vapor fluid flowing laterally, creating a condensate layer on top of the cap rock. This condensate may move laterally and interact with shallow groundwater. One of the outflow evidence are found on the Citepus hotsprings, diluted HCO_3 water in the Southeast, away from the center of the Kamojang field. The marginal recharge from isotope data may originate from an elevation of about 1300-1700 masl.

2. Production Monitoring

Kamojang, similar with other geothermal reservoirs are monitored by observing mainly well parameter such as well pressures, flow rates, and enthalpies. Other valuable data that can be observed are the chemistry of produced fluids and micro-seismic monitoring. All monitoring data are incorporated into a geothermal reservoir management approach that continues to develop our understanding of the reservoir through all phases of its development.

2.1 Production History

The exploration of Kamojang field dates back to 1926. The initial phase of non-direct geothermal development was the generation of 0.25 MW from a mono-block unit in 1978, followed by the construction of power plant Unit 1, which went online with a capacity of 30 MW. The following years, multiple drilling campaigns were carried out to continue field expansion. Units 2 & 3 (2 x 55 MW) went online in 1987utilizing wells in the Western part of Kamojang then were followed by Unit 4 (60 MW) in 2008 and Unit 5 (35 MW) in 2015, each utilizing wells in the Southeastern and Eastern part of Kamojang respectively. After more than 40 years of development, there are currently 61 active production wells that and 6 wells active as injectors. There are also 27 other wells that are currently inactive with few acts as monitoring wells. The field is now producing 235 MW at full generation capacity from about 515 kg/s of steam production and giving an excess of 95 kg/s of condensate to reinject [Abdurachman, 2022].

2.2 Reservoir Monitoring

Since the first power plant unit deployment, a set of surveillance programs were set up to monitor the reservoir response. This paper presents the effort of data processing and analysis of the Kamojang reservoir pressure distribution that was mapped from 66 wells distributed throughout the Kamojang geothermal field over the time span of about 42 years as part of the ongoing collective works to characterize the Kamojang Reservoir and update its conceptual model. The wells used in this study are wells that are known to be free of wellbore damage or obstructions to ensure the pressure data used are representative of the normal reservoir response. The reservoir pressure data was taken from the downhole pressure and temperature survey of each well from its initial fully heated up condition together with the routine monitoring surveys. These pressure profiles taken from the selected wells are then normalized to 500 masl, the average main feedzones depth of kamojang reservoir to represent reservoir pressure. The next step is to ensure the pressure data quality by comparing the individual pressure data points with the overal pressure trend of each well within the time period and note if there is any specific well related activity that may compromise the quality of the data recorded. For example, a static downhole pressure and temperature survey that was done without the well reaching its pseudo-steady state pressure condition. Reaching the pseudo-steady state condition in a dry steam well can vary depending on the well and reservoir characteristics. Specifically in kamojang, on average, the production well requires about a month to reach steady state condition. While it is not ideal to do a downhole static pressure and temperature survey on a well still in its transient state, more than often, steam supply requirements take priority over reservoir monitoring.

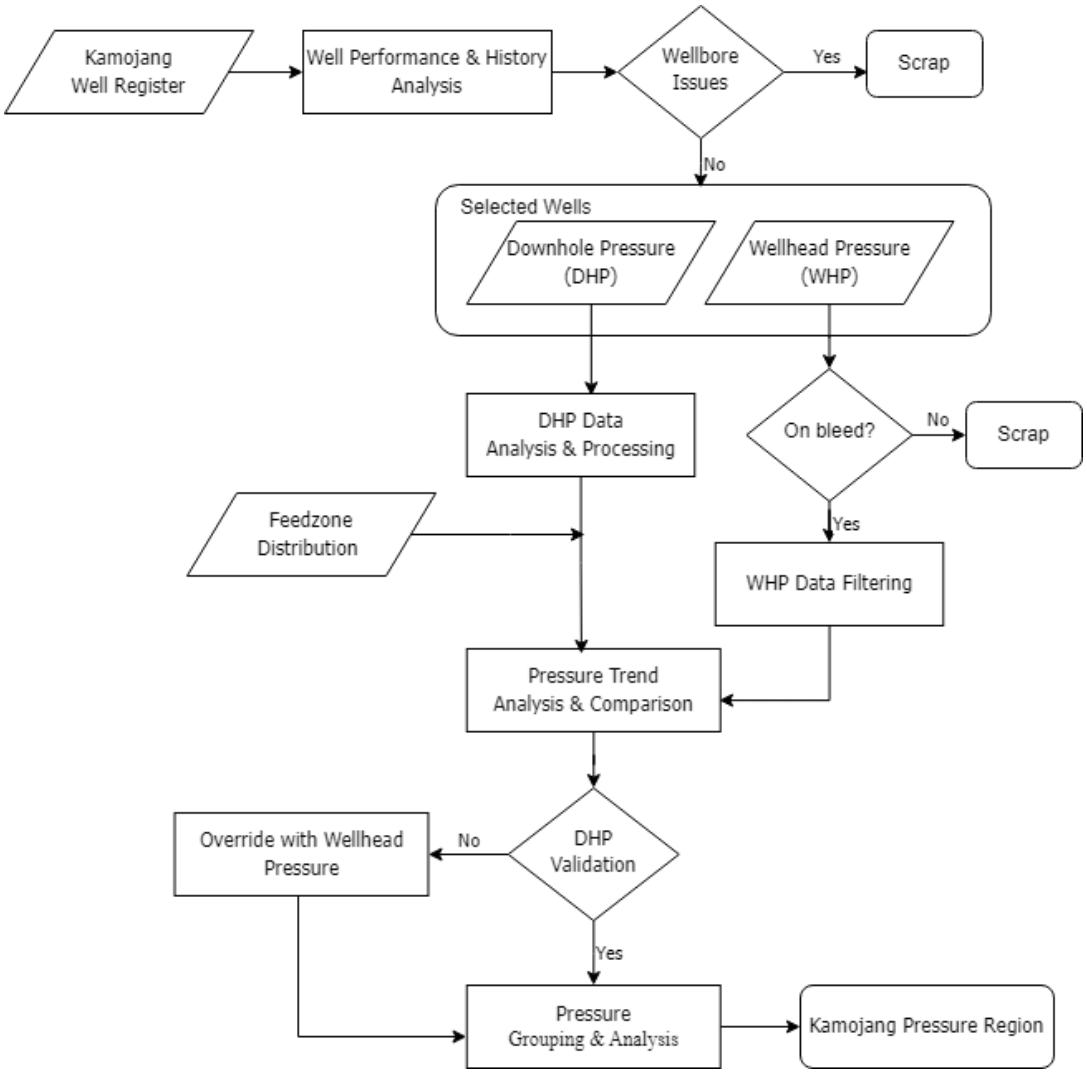

Figure 3: Workflow for Kamojang reservoir pressure data processing and analysis

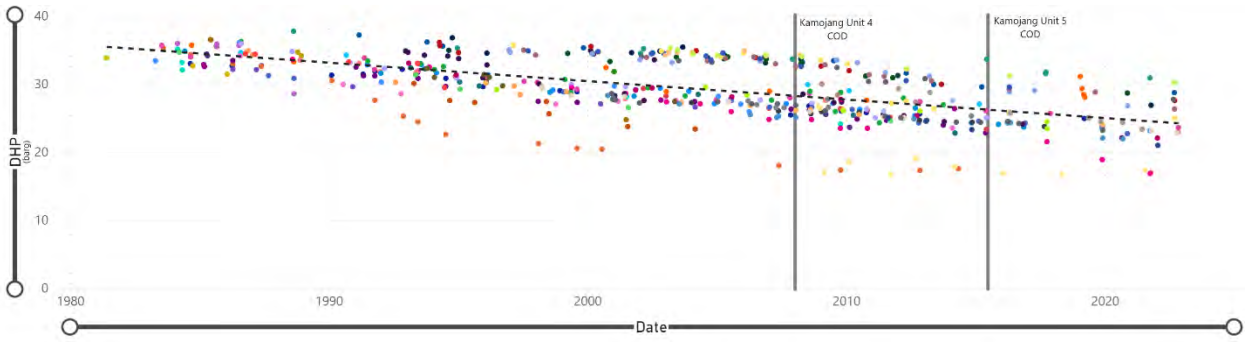

Figure 4: Kamojang collective downhole pressure in barg normalized to 500 masl depth

The last step of processing the collective pressure data is employing well head pressure data to help validate the downhole pressure. Since its a full length dry steam column inside every Kamojang well, well head pressure, adjusting for the vapor static gradient, can also be used as reservoir pressure. It has to be noted that the well head pressure used were only for wells on bleed condition. In Kamojang field, or any other dry steam reservoir field, it's a common practice to apply a very small bleed to inactive producer wells as a safety measure to vent the non-condensable gas coming from the reservoir. Furthermore, similar with the downhole static pressure and temperature survey conditions, care has to be taken to ensure that the well head pressure of the well already reached its pseudo steady state.

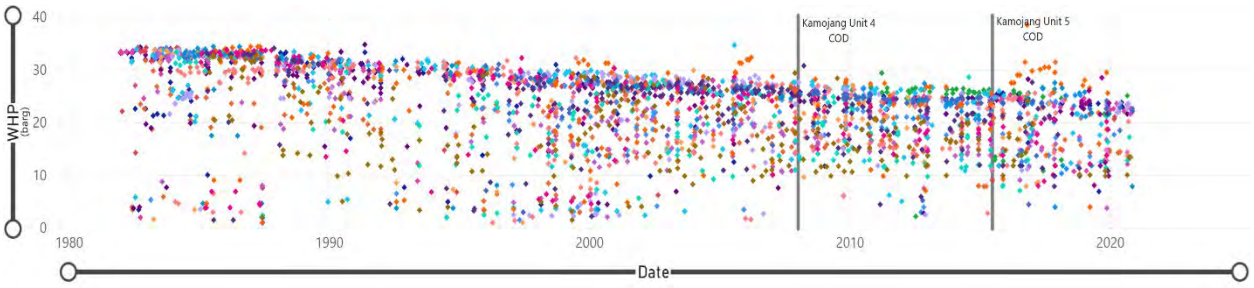

Figure 5: Kamojang Collective Well Head Pressure on Bleed in barg

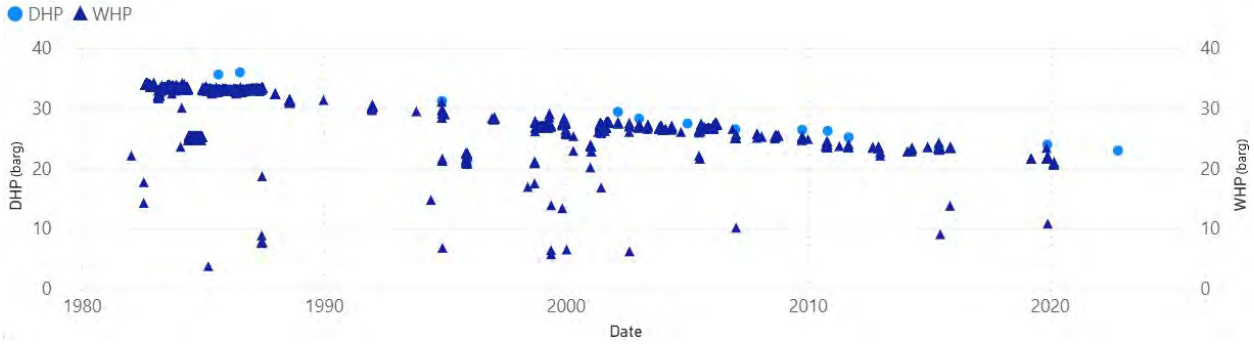

Figure 6: Comparing Downhole Pressure and Well Head Pressure in barg

Analysis of the processed reservoir pressure data set suggest there are multiple pressure regions in Kamojang. These regions are grouped by pressure trend line characteristics and simply named; high, medium and low pressure regions. The high pressure region as the name suggest is the region with the highest average reservoir pressure with 28 barg as observed in 2023 and includes most wells in the Eastern with all the wells in the Southeastern part of Kamojang. The medium pressure region has an average reservoir pressure of 24 barg in 2023 and include some wells in the central and Eastern part of Kamojang. The lower pressure region is the region with the smallest reservoir pressure of 22 barg in 2023 and includes the greatest number of wells compared to the other regions. Those wells are mainly located in the Western part of Kamojang with a couple wells in the Northern part of the field.

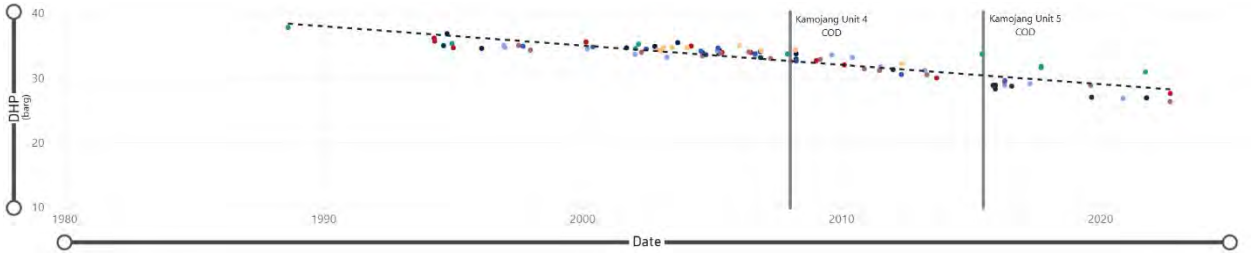

Figure 7: High Pressure Wells Grouping in barg

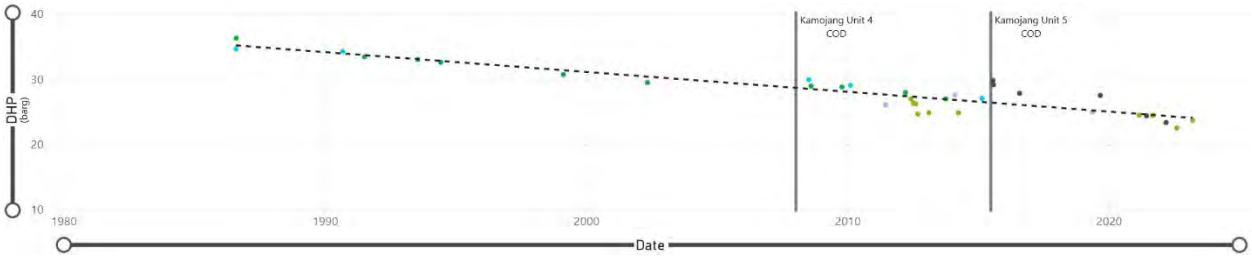

Figure 8: Medium Pressure Wells Grouping in barg

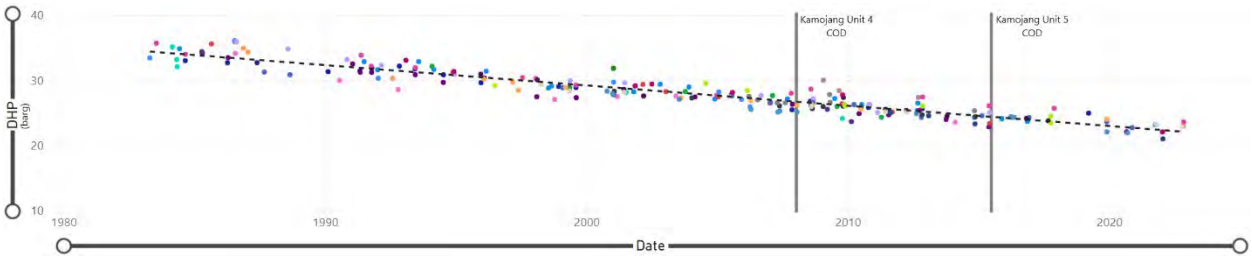

Figure 9: Low Pressure Wells Grouping in barg

Excluding wells with wellbore or reservoir issues, all the above mentioned pressure regions in Kamojang are sharing similar reservoir pressure declines ranging from 0.28 to 0.31 bar/year. While some transient declines were also observed in some of the wells due to initial production phase or power plant coming online, the observed pressure trends showshow the pressure of some wells merging with their each pressure group by the end of their transient period. Few clear examples on this phenomena were able to be observed in wells in North Kamojang that were initially deemed as high pressure wells, but are currently grouped in the low pressure region after their transient period ends. The uniform pressure decline behavior throughout Kamojang field implies two possible reasons; First is the effectiveness of reservoir lateral permeability and, second, that no subsurface structures inside the reservoir act as barriers between the defined Kamojang pressure regions.

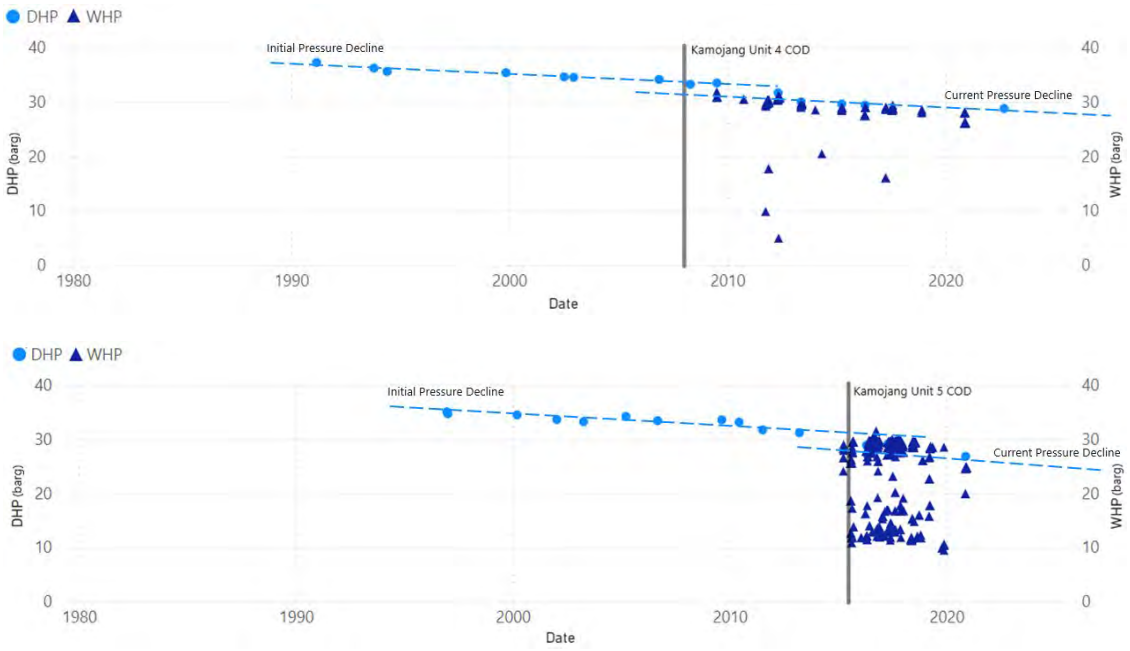

Figure 10: Transient Period During New Unit Commencing. Unit 4 (above) and Unit 5 (below) Timeline

Additional datasets were also analyzed to further test the above mentioned implication of the pressure data. Individual production rates were summed based on their respective pressure groups and observations were made to see the correlation between the cumulative production rates with the pressure decline of each pressure region. The result shows that field production changes with time does not correspond with the pressure decline trend. Pressure decline in Kamojang remain steady throughout the exploitation phases. This further supports the reasoning above on the effectiveness of the lateral permeability with no reservoir compartmentalization .

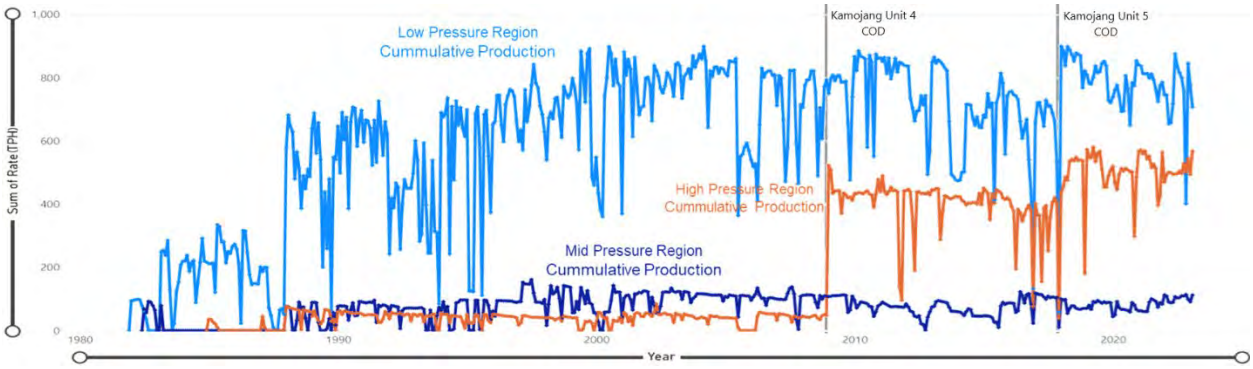

Figure 11: Kamojang Cumulative Production Rate in ton/hour per Pressure Region

2.3 Geochemistry Monitoring

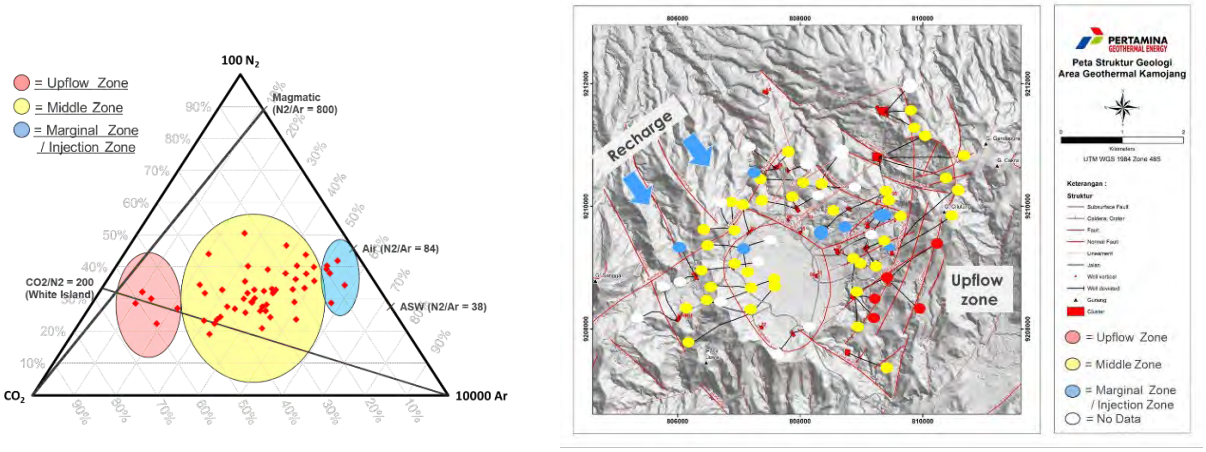

Figure 12: Kamojang Distribution Map of N2-CO2-Ar Trilinear Diagrams Plot

To determine the upflow based on geochemical data, the use of ternary diagrams is a common practice. Plot positions that are close to the magmatic line or peak of CO2 indicate that these wells are nearer to the upflow. In contrast, other wells are closer to the air point, indicating proximity to the outflow or being affected by injection, while the wells plotted in between indicate the middle zone. Geochemical gas data from Kamojang in this plot shows that wells in the upflow zone are situated in the Eastern part, while wells around Ciharus (SW area) indicate a marginal zone signature with high Ar concentration. Confirmation of the upflow and outflow positions in the Kamojang area is also supported by the CAR-HAR gas geothermometer, where wells in the upflow (Eastern part) area exhibit the highest temperatures, while wells in the Southwest area tend to have lower temperatures.

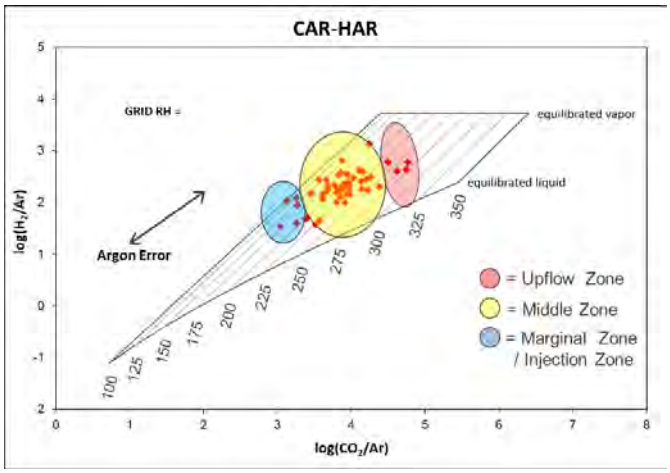

Figure 13: Gas Geothermometer CAR-HAR Shows High Temperatures For Wells in The Upflow Area

In addition to the two points above, in a steam-dominated geothermal system, NCG is also used to determine the upflow area and the edge area affected by condensation, marked by high NCG and CO2/H2S gas ratios. However, in Kamojang, these two indicators cannot be used. This is because the high NCG and the high CO2/H2S gas ratio in this area are more influenced by the high CO2 values than by a decrease in H2S values due to condensation. The CO2 values in these wells are

exceptionally high, exceeding 20,000 ppmw when compared to other wells, which have average values of 1,000-4,000 ppm. The area with this anomaly includes wells in the Eastern part and is assumed to be caused by a consistently high supply of CO2 gas in these wells, which is characteristic of the upflow zone. This is consistent with the results of the N2-CO2-Ar ternary diagram plot and the gas geothermometer, which also provide similar results, thus strengthening the hypothesis that the Kamojang upflow is located in the Eastern area.

In addition to determining upflow and outflow, the recharge zone in the Kamojang area is also identified using Oxygen-18 ($\delta^{18}O$) and Deuterium ($\delta^{2}H$) isotope data. Isotope data is collected from manifestations, wells, and shallow groundwater in the Kamojang area. These stable isotopes are commonly used in hydrology to trace the origin and movement of water, providing information about the sources and pathways of groundwater recharge. Based on isotope data in Kamojang, it is known that the recharge area is located at an elevation of 1300 masl in the SW and SSE, while the Kendang Fault is interpreted as a conduit, the entry point for marginal recharge into the Kamojang reservoir. This data is then integrated with other geochemical data and supports the hypothesis of the Kamojang outflow area being in the Southwest region

3. New Upflow Postulation

Referring to the reservoir and new geochemistry findings presented in this paper, it changes how the upflow dynamics are intepreted in the reservoir. From the previously interpreted upflow in Northeast Kamojang, beneath the Gandapura-Cakra complex, analysis and mapping of the pressure region shows that the Eastern and Souteastern parts of Kamojang is characterized with the highest reservoir pressure suggesting a new hypothesis that these are the areas with the most steam recharge likely to be interpreted as an area near the upflow. The drop of reservoir pressure from the Eastern to the Western parts of Kamojang also suggest that the steam flow is getting weaker with distance from the East of Kamojang. A similar hypothesis also comes from the new geochemistry interpretation by the N2-CO2-Ar ternary diagram and CAR-HAR geothermometer suggesting that the Kamojang upflow is located in the Eastern part of the field. However strong this hypothesis, it still needs to be integrated with the ongoing revisit of the geological and geophyisical studies to validate the new interpretation and further refine the Kamojang conceptual model.

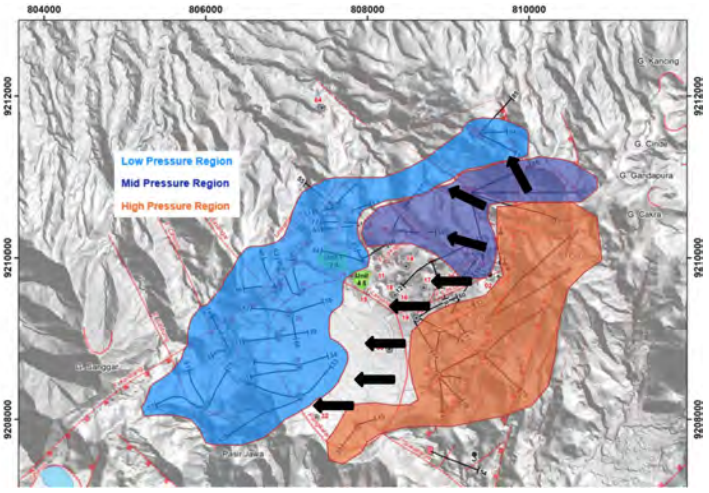

Figure 14: Reservoir Pressure Grouping of Kamojang & Suggested Lateral Steam Flow

4. Impact to Resource Assessment

Updating the Kamojang conceptual model is a continuous process, even after more than 40 years worth of data. It is a primary component in understanding the reservoir for which the upflow dynamic is still being unraveled. The newly postulated upflow will bring new constraints to the reservoir process uncertainty and ultimately affecting the resource capacity. Re-assessing Kamojang resource requires multiple stages. The first stage is the ongoing PGE effort to redefine the conceptual model where it serves as a guide in setting up the next stage. The second stage is numerical simulation. Numerical reservoir simulation has been proven as the most reliable option for geothermal resource assessment. It is a more advanced tool that models the physics of fluid flow and heat transfer and the complex nature of reservoir geometry [Ciriaco, 2020]. The existing reservoir model owned by PGE needs to be updated and re-calibrated to its natural state condition and production history following the interpreted reservoir process in the revised conceptual model. The first two stages will be fundamental to assess the Kamojang resource and support its future business decision as the last stage will be to generate production forecasts from the reservoir model to optimize the development plan further.

5. Conclusion

Processing and analyzing reservoir pressure data from the Kamojang wells suggests there are multiple pressure regions existing in the field. These regions are each grouped using pressure trend line characteristics and simply named; High, Medium and Low pressure regions. Each pressure region has its own pressure magnitude with the highest reservoir pressure in the Eastern and Southeastern Part of Kamojang and the lowest in the Western part of Kamojang. All the pressure regions are sharing similar reservoir pressure declines throughout the exploitation period.

The mapping of the pressure regions suggests a new hypothesis that the Eastern part of Kamojang is the area with the most steam recharge likely to be interpreted as an area near the upflow. The drop of reservoir pressure from the Eastern to the Western part of the field also suggests that the steam flow is getting weaker with distance from the East of Kamojang. The lateral steam flow from Eastern to the Western direction is also supported by the pressure decline characteristics. The uniform pressure decline throughout the pressure regions implies the effectiveness of the reservoir lateral permeability and that there are no subsurface structures in the reservoir acting as barriers between the defined pressure regions. Similar conclusions were also coming from the new geochemistry study suggesting that the Kamojang upflow is located in the Eastern part of the field and replaces the previous interpretation that it is located beneath the Gandapura-Cakra complex in the Northeast.

However, these newly combined hypothesis from reservoir engineering and geochemistry still needs to be integrated with the ongoing review of both geological and geophyisical studies to validate the new interpretation of the upflow dynamics and further refine the Kamojang conceptual model. The new conceptual model will be fundamental to fully assess the field resource and support its future business decision to optimize the development plans in the future.

Acknowledgement

We extend our sincerest gratitude to all those in Pertamina Geothermal Energy Reservoir and Geoscience team who have contributed to the completion of this paper. We also thank our families for their unwavering encouragement.

ABSTRACT

The Mammoth Geothermal Complex has been in operation since 1984, and during this timeframe it underwent several expansions and repowers prior to the 2022 commissioning of the Casa Diablo IV station (CDIV). Due to its proximity to population centers, groundwater wells, hot springs, and thermal creeks, a fit-for-purpose monitoring network was installed ahead of field expansion to understand potential environmental impacts. Ormat cooperated with the Bureau of Land Management, the U.S. Forest Service, the U.S. Geological Survey, and the Mammoth Community Water District to collect and analyze baseline data prior to drilling new production and injection wells to support the CDIV project. During the CDIV commissioning, this monitoring network was reviewed as output from the new geothermal production wells was ramped up in incremental steps over a four-week period. The combination of strategic downhole pressure monitoring, geochemical monitoring, temperature monitoring, and ground leveling provided confidence that there would be no measurable impacts to nearby water resources, including thermal features and municipal water supply wells from CDIV operations. Now two years into operation, the water monitoring network continues, and no impacts have been identified.

1. Introduction

Ormat operates four binary geothermal power plants located about three miles east of the town of Mammoth Lakes, California and near the Casa Diablo hot springs. The binary cycle works by using hot geothermal fluid to vaporize a secondary working fluid like isobutane, which then powers a turbine. This process not only allows an efficient extraction of energy from the lower temperature geothermal resource compared to the steam turbine design but also allows 100 percent reinjection of geothermal brine. The first power plant at the site (G-1) began operating in 1985. Binary plants G-2 and G-3 were constructed in the early 1990s. In 2022, the fourth unit, the 30

megawatt (MW) Casa Diablo IV (CDIV) binary unit began commercial operation, bringing total production to 65 MW. Figure 1 shows the total production history of the Casa Diablo/Mammoth complex from 1985 to present, highlighting periods of increase in the early 1990s with expansion of two additional binary units and again in 2022 with the CDIV expansion. Throughout this timeframe, the total thermal-water discharge into Hot Creek, located east of the geothermal operations, has not changed (Evans et al, 2018).

Exploration drilling by the United States Geologic Survey (USGS), Ormat and others determined that the geothermal system's source area was west of the original Casa Diablo development in an area known as Basalt Canyon. Deeper wells drilled in the area in 2006 (57-25 and 66-25) were higher enthalpy (up to 375° F) than the lower Casa Diablo producers, highly permeable, and hydraulically connected to the Casa Diablo area. Further drilling at the western end of Basalt Canyon in 2010 (wells 12-25 and 14-25) also encountered the resource, leading to project release of CDIV.

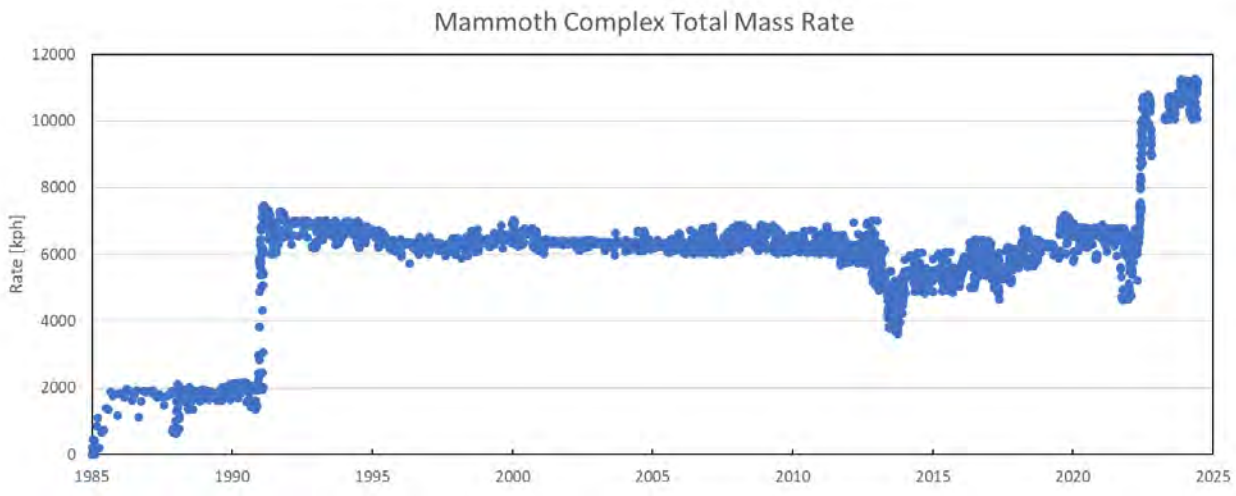

Figure 1: Total mass rate from the Mammoth geothermal complex since installation of the first binary unit in 1985 through June 2024. Flow unit is thousands of pounds per hour (kph).

A combined Environmental Impact Statement/Environmental Impact Report (EIS/EIR) was completed in 2013 that evaluated the potential impacts from CDIV development. All of the new production well sites were to be located in Basalt Canyon, closer to the town of Mammoth Lakes and to municipal water supply wells operated by the Mammoth Community Water District (MCWD). Since the community relies on these wells for drinking water and there are many stakeholders near the development, a special emphasis was placed on assessing potential impacts to that groundwater resource. Although geologic and hydrologic modeling indicated that the two systems were hydraulically disconnected and that impacts would not occur, it was decided that a fit-for-purpose groundwater monitoring and mitigation program would be implemented prior to initiating production in order to ease concerns around the development.

The CDIV Geothermal Development Project, Groundwater Monitoring and Response Plan (GMRP) was developed cooperatively by the BLM, Ormat, USGS, MCWD and the other agencies and finalized in January 2018. The purpose of this GMRP was to *"establish a monitoring program to detect any direct or indirect effects on the municipal water supply for the Town of Mammoth*

Lakes that may occur from geothermal production and injection associated with the CD-IV Project."

The objectives of the GMRP were to:

1) Identify and implement shallow groundwater aquifer, surface water resource, and deep geothermal reservoir monitoring strategies and protocols necessary to achieve this purpose, and

2) Establish a framework for determining and implementing appropriate response actions if, and when, needed to avoid, minimize, and/or mitigate potential adverse effects to the Town of Mammoth Lakes municipal water supply based on review and analysis of the monitoring data collected.

To meet these objectives, the GMRP outlined: 1) monitoring strategies, 2) data management, data reporting and plan evaluation strategies, and 3) response action strategies.

The GMRP is a cooperative, adaptive effort. An adaptive management approach was preferred because the committee recognized that hydrologic systems are dynamic and many factors can impact groundwater quality and quantity outside of geothermal production including climate, annual precipitation and its effect on aquifer recharge, variable groundwater production, regional seismic activity, and other natural source areas of geothermal fluid. As data is collected and analyzed, the monitoring strategy is reassessed, and new or refined approaches, methods or frequency are developed or optimized to ensure that the plan remains effective and practicable.

2. Geologic Setting

The Casa Diablo geothermal resource is present within a large volcanic feature known as the Long Valley Caldera. The geology of the caldera and the geothermal resources have been extensively studied and described over the past 35 years by Hildreth (2004, 2014, 2017), Bailey (1976), Sorey (1985, 1991, 1998), Suemnicht (1988), Evans (2017), and others. The following briefly summarizes these reports.

2.1 The Geothermal Resource

The geothermal resource wraps around the south and southwest margin of the resurgent dome in a hydraulically interconnected, highly-permeable zone of fractured welded tuffs belonging to two main units known as the Early Rhyolite and the underlying Bishop Tuff. The system's source area is believed to originate at great depth north of the town of Mammoth Lakes and near the Inyo Craters, another 3.5 miles northwest of Basalt Canyon. Due to difficult terrain and the depth needed to reach the resource, few wells have been drilled west of Basalt Canyon, so the exact source area remains uncertain. Figure 2 shows the regional geology and resurgent dome from Hildreth (2017).

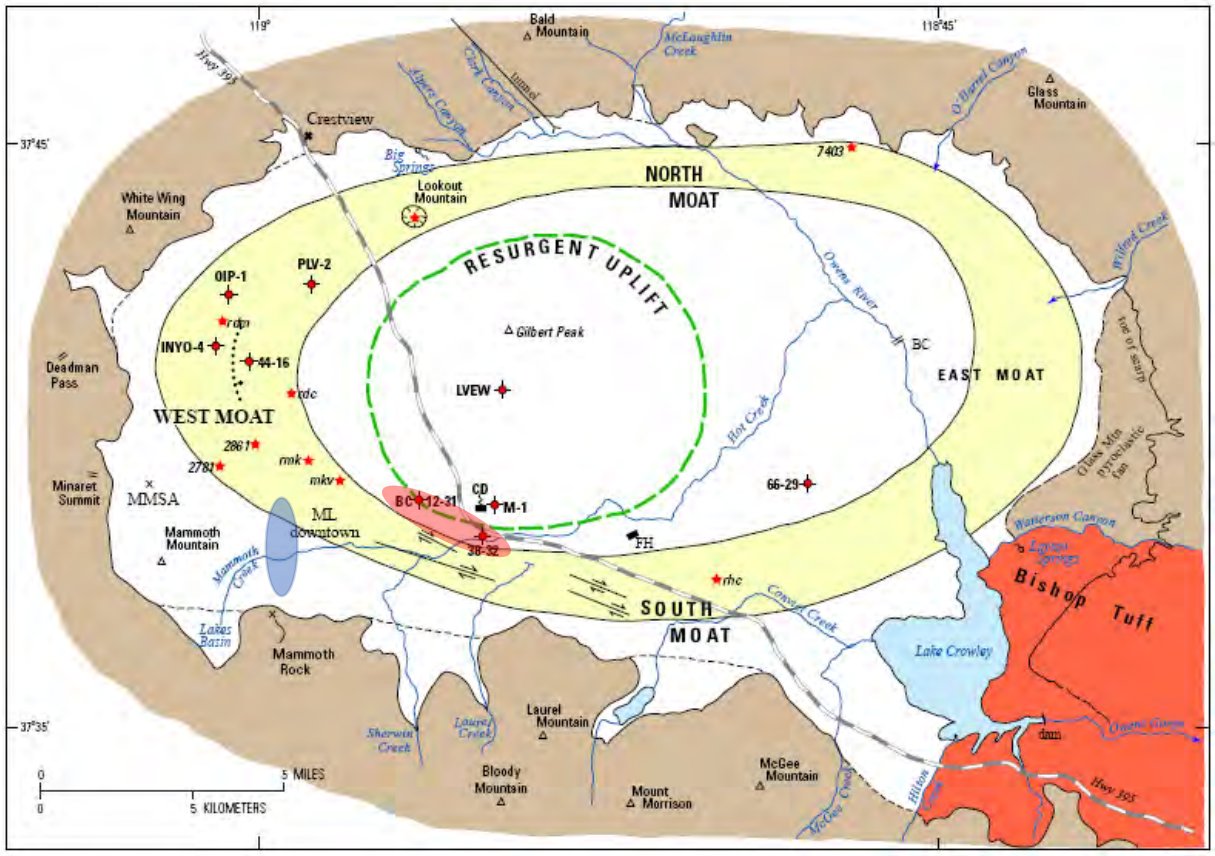

Figure 2: Figure from Hildreth (2017). The resurgent dome is comprised of Early Rhyolite, while basalt flows infill the south and west moat. General location of Ormat geothermal wells highlighted in the red oval, and groundwater municipal wells highlighted in blue oval. Legend: structural ring-fault zone (yell), Precaldera rocks (brown), Bishop Tuff ignimbrite outflow (red), dashed lines crossing caldera-wall embayments suggest continuity of basement rocks concealed beneath modern surficial deposits.

The geothermal production wells in Basalt Canyon include 57-25 and 66-25 drilled in 2005; 14-25 in 2010; 12-25 in 2011; and 47-25 (drilled next to 57-25), 14B-25 and 14C-25 (both drilled adjacent to 14-25) drilled in 2022. The wells have been drilled right up to the eastern edge of the West Moat Coulee where the system was first encountered in wells 14-25 and 12-25.

The system flows eastward through Basalt Canyon, beyond Casa Diablo, to Hot Creek where it ultimately discharges to the surface in a series of hot springs. Total system flow is reportedly 370 kg/s (about 5,500 gpm) at 220° C. The system has a relatively flat horizontal gradient due to its high permeability. In Basalt Canyon, the static water level in the production wells is about 450 feet below the surface and within the Early Rhyolite tuffs. As topography drops from west to east, the water level slowly approaches the land surface, until the system discharges into Hot Creek several miles east of Casa Diablo.

Basalt Canyon wells typically encounter high enthalpy fluids at a depth of about 1,000 ft in a moderately permeable zone in the Early Rhyolite. Below this is a thick section of tuff breccias, and clastic/lacustrine sediments and conglomerates that are essentially impermeable. These materials are underlain by the Bishop Tuff. Total lost circulation in the Bishop Tuff is limited to specific fractured zones, and is encountered at depths ranging from 1600 to 2100 ft. This lower

zone is highly productive but is generally cooler than the upper zone in the Early Rhyolite. The high permeability is likely a combination of open fractures along steep faults passing through brittle welded tuffs, and possibly along undetermined horizontal surfaces on top of individual welded tuff layers.

Cooled fluids from all production wells are reinjected into the deep Bishop Tuff at Casa Diablo near the G-2 and G-3 power plants. Injection wells 54A-32 and 54B-32 were drilled in 2021 for CDIV. There is little communication of this deep injection with the overlying production wells in the Early Rhyolite, but tracer studies in 1992, 2017, and 2023 have shown eventual migration of injection in Bishop Tuff to the Lower Casa Diablo producers.

The resource is bounded on the south by the ring fault zone which places down-dropped moat basalts against the Early Rhyolite. Geophysics indicates that the rings faults likely underlie Highway 203; however, the fault zone is entirely covered by till and younger basalt flows and is nowhere exposed, nor has it been intercepted by drilling. The mag low may be partially masked by basalt flows north of Highway 203.

A few test wells drilled south of Basalt Canyon within the moat and into the underlying Early Rhyolite have not encountered temperatures greater than 175°F. Magnetic surveys indicate that the resurgent dome forms the northern boundary to the system, but that it extends northward somewhat along the NNW-trending faults (see Figure 3). Hydrothermal alteration and small fumaroles locally extend to the surface along these faults in the vicinity of the known resource.

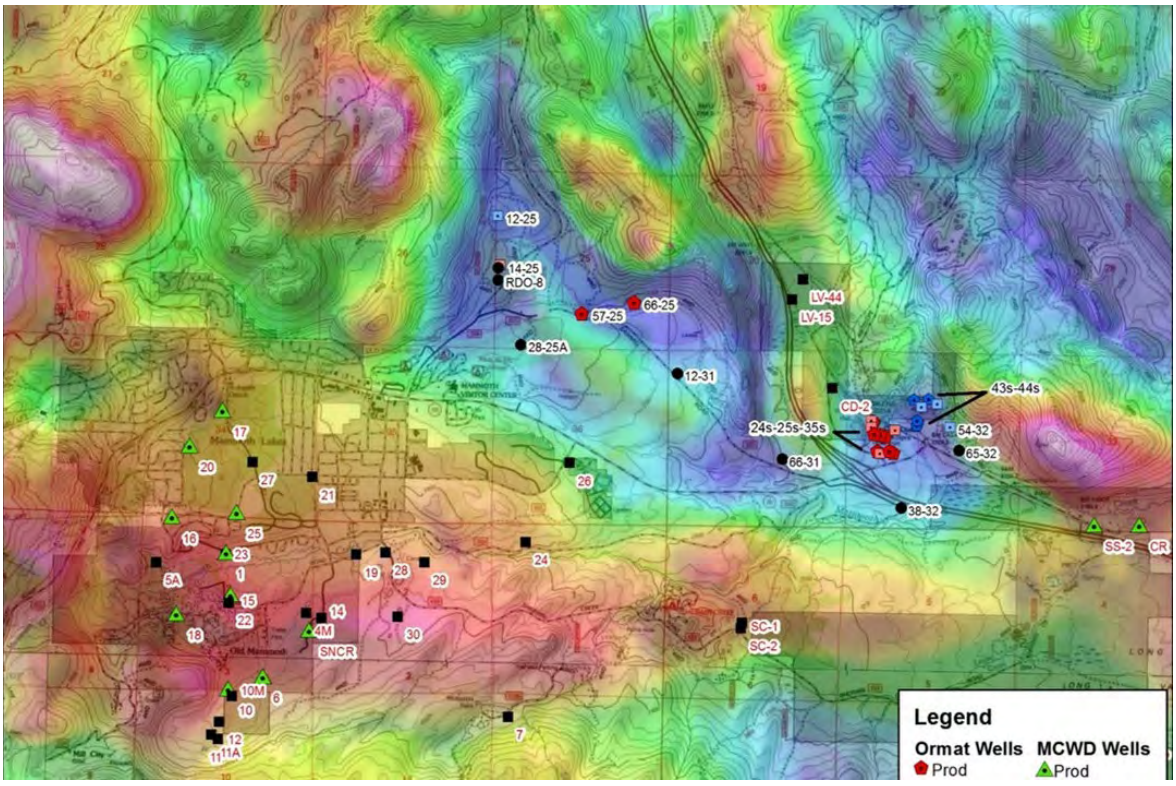

Figure 3: Location of municipal groundwater wells and geothermal wells. Background shading is natural magnetic field intensity from an aeromagnetic survey. Areas of low magnetic intensity (blue shading) map hydrothermal alteration associated with the geothermal system.

2.2 The Groundwater Resource

The municipal groundwater resource is located in the southwest moat and on the east flank of Mammoth Mountain (see Figure 2). Groundwater is produced from nine wells that are oriented in a north-south alignment. All groundwater production wells are located 1.8 miles or more from the closest Basalt Canyon geothermal production well.

The aquifer is hosted by an approximately 1,000-ft-thick sequence of mafic volcanic lavas and cinders that originated from the base of Mammoth Mountain west of the wells. Interflow glacial till is present in some wells. The aquifer is largely recharged by snowmelt and infiltration from Mammoth Creek and Mammoth Mountain. Numerous exploratory wells drilled east of the production wells within the moat had low productivity (Schmidt et al 2018).

The groundwater wells are about 700 ft deep and moderately productive. Water levels decline as pumping increases, but at variable rates due to widely varying transmissivities. Well P17 is the most productive and produces about 800 gpm with about 4 feet of drawdown. Annual operational summaries for all wells are available on the MCWD website.

Four of the wells regularly exceed the arsenic drinking water standard of 10 µg/L; three of the wells occasionally exceed the standard, and two of the wells do not exceed the standard. Well P17 water, on the north end of the field, typically contains between 86 and 150 µg/L arsenic (As). Several wells also exceed the secondary drinking water standard for iron (0.3 mg/L) and manganese (0.05 mg/L). Water temperature is highest in northern and western wells, and generally increases with increasing production and declining water levels. Well P17 is the warmest (up to 81° F), see Figure 4 for location of P17 with respect to geothermal system.

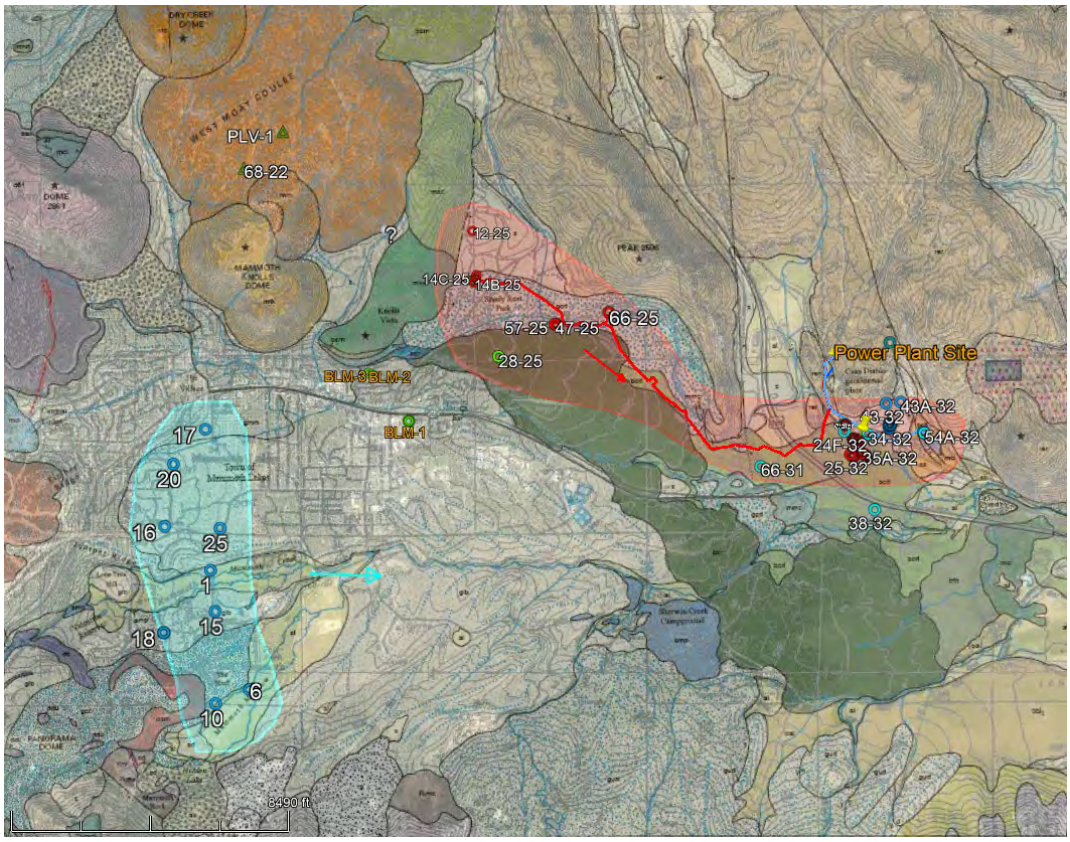

Figure 4: Geologic map showing location of MCWD (blue) and geothermal system (red). Well 17 is closest to geothermal source area and produces water containing elevated temperature and metals.

Chloride is a conservative element that is not normally present in area groundwater but is present in the geothermal fluid. As a result, it has been used to estimate that in P17, which contains the most chloride of the groundwater producers, contains about 2-3% geothermal fluid. Chloride in that well reached an all-time high of about 12 mg/L in late 2016 following three years of drought and regular production pumping. However, melting and infiltration of the large snowpack in the spring of 2017 resulted in significant recharge to the groundwater aquifer that returned chloride concentrations to lower levels by early 2020. Figure 5 shows the chloride trends for seven of the groundwater production wells including this P17 trend. Concentrations again increased during the 2020-2022 drought years. Since geothermal operations were constant during this period (see Figure 1), these responses indicate that the arsenic and chloride content in the groundwater supply wells is unrelated to the Mammoth geothermal complex operations.

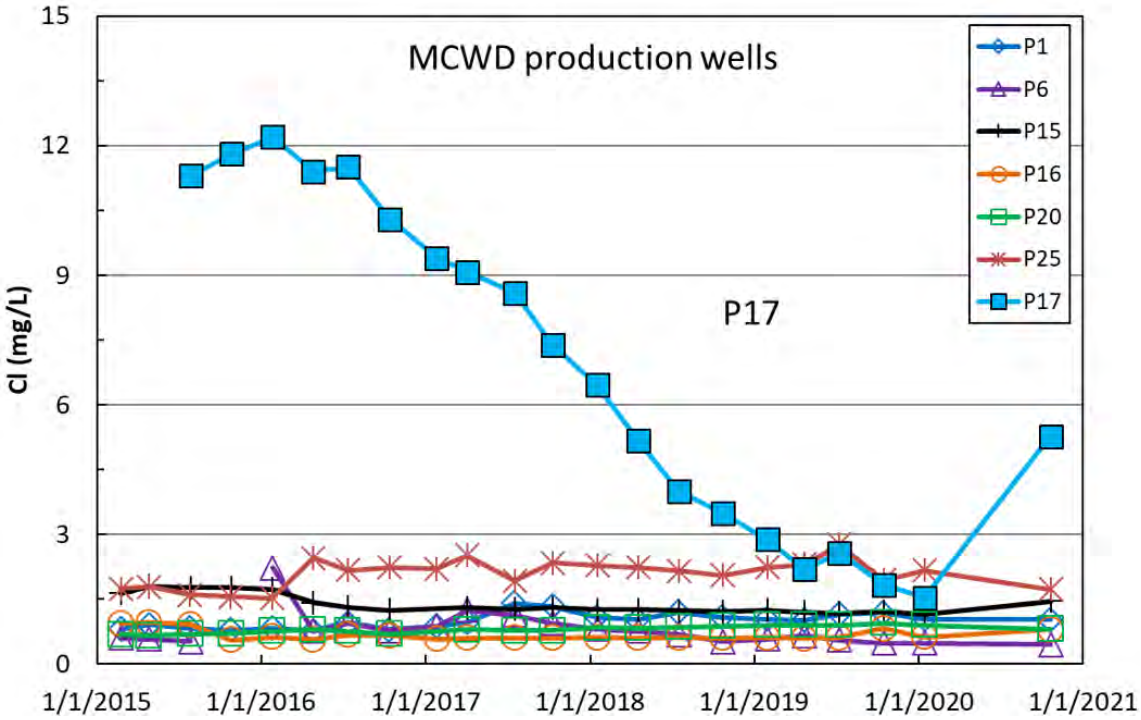

Figure 5: Groundwater production geochemistry chloride (Cl) trends from 2015 to 2021. Note decrease in sampling frequency in 2020 due to Covid-19 restrictions.

3. Monitoring Well Network

The GMRP established a baseline monitoring well network comprised of 28 sites that included a combination of shallow groundwater, dual completion (shallow and intermediate depth), and geothermal reservoir wells to be monitored for temperature, pressure/water level, and geochemical parameters, depending on well type. Tables 2 and 3 outline the types of data collected.

Since 2015, the BLM in coordination with the US Forest Service (USFS), the USGS and MCWD, has approved the installation of several wells dedicated to the CDIV Project. Table 1 summarizes the well constructions.

- 14A-25 is a 600-ft-deep, dual completion monitoring well installed by the USGS in 2015. 14A-25 is located on the well pad that hosts production wells 14B-25 and 14C-25, and standby production well 14-25. 14A-25 monitors fluid in the Early Rhyolite about 400 ft above the upper production zone.

- 28A-25 is a 600-ft-deep, dual completion monitoring well installed by the USGS in 2015. The well is 2,000 feet southwest of production wells 47-25 and 57-25, but still 1.75 miles down-gradient of the closest MCWD well. Both monitoring point are constructed in the Early Rhyolite.

- 28-25 is located next to 28A-25 and is a 1622 ft deep core hole installed by Ormat in 2017. The well measures pressure within the Bishop Tuff.

- BLM-1 is a dual completion monitoring well drilled to 600 ft by USGS in 2017. The well is completed in the moat basalts.
- BLM-2 is a 680-ft-deep dual completion monitoring well drilled by USGS in 2021 to monitor a hypothetical fault running between the MCWD wells and Basalt Canyon. Both wells are completed in the Early Rhyolite.
- BLM-3 is a 1320-ft-deep well installed by USGS in 2021, ostensibly to monitor the Bishop Tuff in a theoretical fault running between the groundwater wells and Basalt Canyon. The well, however, was completed in Early Rhyolite.

The groundwater production well group includes MCWD wells 1, 6, 15, 16, 17, 20, and 25.

Table 1. Monitoring Well Construction Summary (bolded wells indicate Moat basalts vs. Early Rhyolite completion).

Well Number	Installed by	Screen Interval	Filter Pack Interval	Geology of screened interval
14A-25 Shallow	USGS	470-490	446-496	Rhyolite tuff and obsidian. Base of basalt at 196 ft.
14A-25 Deep		575-595	555-600	Altered rhyolite tuff
28A-25 Shallow	USGS	440-460	418-481	Rhyolite xtl tuff
28A-25 Deep		575-595	555-602	USGS incorrectly logged as andesite. Core from adjacent well 28-25, has vuggy, pumiceous, pinkish grey rhyolite at this depth.

Specific conductance	microseimens per centimeter (µS/cm)
Sulfate (SO_4)	milligrams per liter (mg/l)
Temperature	°C
Temperature	°C
Non-Condensable/Dissolved Gases	
H_2S[1]	
Isotopes	
D/H ratio (Deuterium/Hydrogen)	per mil
$^{18}O/^{16}O$ ratio	per mil
Tritium (^3H)[1]	One-time sample of 14A-25, 28A-25, MCWD 26, and other select MCWD production wells (TBD) to establish existing concentrations; then, annual sampling from select geothermal production wells in Basalt Canyon (TBD); Data not yet available
Additional Constituents and Parameters	Consistent with the adaptive monitoring framework of the GMRP, additional constituents and parameters may be added for specific tests or to improve monitoring effectiveness based on new information

Notes:

[1] H_2S, rubidium, and tritium not yet incorporated into field sampling program.

[2] Laboratory calls total dissolved solids "residue."

4. Mammoth CDIV Stress Test Summary

Prior to full-time facility operations, a production stress test was performed on the new Basalt Canyon wells to demonstrate that CDIV operations would not impact groundwater wells. Data from monitoring wells 14A-25, 28-25 shallow, 28-25 Deep, BLM 1, and BLM 2 were monitored during the test for changes in water level. Four production steps, or test phases, were completed during the testing. Data from each phase was presented to the GMRP committee comprised of Ormat, BLM, MCWD, and the USGS for their review and approval prior to advancing to the next phase. Approval criteria related to the quality of data as well as the change, or lack thereof, in the water levels for each lithology.

This stress test, while instrumental in validating the environmental safety of the geothermal operations, represents a high level of scrutiny that may not be universally applicable or necessary for all geothermal projects. It is recommended that the deployment of such stress tests be considered on a case-by-case basis, taking into account the unique geological, hydrological, and ecological characteristics of each site as well as the size of the geothermal project. For projects in areas with lower sensitivity or established historical data demonstrating minimal risk, a scaled-down version of the stress test or alternative monitoring methods may be more appropriate. This approach ensures that resources are allocated efficiently, focusing intensive testing methods like those used in for CDIV on developments where the potential for environmental impact is greatest.

A full list of activities detailing the four phases of the test are outlined in Table 4. Figures 6 through 11 show the responses in the shallow monitoring wells 14A-25, 28A-25, BLM 1, and BLM 2 during the various phases. These monitoring wells show a primary response to atmospheric pressure conditions and minor, basin-wide water level decline during the summer months. Shallow well 14A-25 is located between production wells 14B-25 and 14C-25 and is constructed in hot Early Rhyolite. The USGS determined that the well exhibits poro-elastic effects on the order of less than 0.5 feet (0.2 psi) during startups of those production wells (Howle 2020). This response was also observed during the 2017 long-term flow test.

Monitoring well 28-25 Deep is completed in the Bishop Tuff geothermal reservoir and shows a direct varying response of drawdown as expected from the increase in flow. 28-25 deep also clearly displays pressure recovery equal to prior state during periods of lesser flow. Table 4 shows various events and dates which occurred during the duration of the test. Table 5 shows the change in depth of water level in ft for 14A-25, 28-25 shallow, 28-25 Deep, BLM 1, and BLM 2. Figure 12 shows the location of production and monitoring wells.

The CDIV stress test was completed in July 2022 after 6 weeks of flow variation and monitoring data analysis.

Table 4. List of events during the 2022 CDIV stress test

Date	**Event**
5/19/2022	47-25 Online
5/27/2022	14C-25 Online
6/1/2022	14C-25 offline and 47-25 online
6/2/2022	14C-25 at full capacity and 47-25 online at reduced capacity **(Phase 1)**
6/3/2022	47-25 online at full capacity; total flow ~5000 gpm
6/4/2022	All wells online, total flow ~5000 gpm
6/6/2022	Only 47-25 online
6/11/2022	All wells online, total flow ~6500 gpm (Nominal flow: **Phase 2**)
6/13/2022	All wells online, total flow ~7000 gpm (Nominal flow)
6/16/2022	CDIV down for 0.5 hours. CDIV unit started at 06:03. Test Energy/Commissioning.
6/17/2022	CDIV down for 2.3 hours. Unit started at 13:27.
6/22/2022	All wells online, total flow ~6000 gpm
6/24/2022	All wells online, total flow ~8400 gpm
6/25/2022	Flow reduced to 4000-4500gpm (50 % of full capacity) (**Phase 3**)
6/28/2022	CDIV down 10 hours. Unit online at 16:25
6/29/2022	Total flow 8700 gpm (**Full capacity**)
6/30/2022	Total flow 8700 gpm (Full capacity)
7/1/2022	CDIV down 3.8 hours
7/6/2022	End of the stress test. Total flow 8700 gpm (Full capacity)

5. Conclusions

Water quality issues, including elevated arsenic, existed in several municipal water production wells that appeared to be of geothermal origin. Previous geologic, hydrologic, and geochemical data indicated that the Basalt Canyon geothermal reservoir and the groundwater aquifer were hydraulically disconnected systems hosted in different rock formations. Because the specific source of the contaminants in these municipal water supply wells had never been identified, some

agencies were still concerned that they were related to Mammoth complex geothermal operations. To allay these concerns and to provide an early warning system should any unforeseen impacts occur, an adaptive but rigorous GMRP was cooperatively developed by Ormat and local, State and Federal agencies. The GMRP was enacted prior to and during startup of the new CDIV production wells.

The monitoring program included a network of shallow groundwater wells, intermediate depth wells, and deep reservoir wells instrumented to track water levels, temperatures, and geochemical parameters. Baseline data were collected for several years leading up to CDIV operations. Once the new production wells were drilled, a carefully designed step-rate stress test was conducted, incrementally increasing flow from the wells while closely monitoring the well network. As expected, the deep monitoring wells within the geothermal reservoir showed a direct response to the changing reservoir pressure during flow variations, but corresponding signals were not observed in either the shallow groundwater monitoring array near the geothermal system or in the municipal water supply wells.

It's important to note that the monitoring program outlined in this case study, while successful in evaluating potential environmental impacts for this development, represents an extensive undertaking that may be prohibitive for geothermal projects in early development or smaller in size. The level of baseline data collection, multi-agency cooperation, and ongoing monitoring was warranted given the proximity to the municipal water supply for Mammoth Lakes and the size of the geothermal project. However, a more streamlined process may be suitable for geothermal developments in less environmentally-sensitive areas or where the risks of groundwater impacts are lower based on preliminary studies. An appropriate balance must be struck between environmental safeguards and enabling cost-effective geothermal energy development.

Now two years into full CDIV operations at a combined complex capacity of 65 MW, the monitoring program continues and has not detected any impacts to the groundwater system to-date, and discussions regarding appropriate reductions to components of the monitoring plan have begun. The cooperative monitoring effort successfully demonstrated that the expanded geothermal operations can be conducted safely without detriment to the community's water resources. The adaptive monitoring program will remain in place going forward to provide long-term tracking and response capability should any future changes occur. This case study highlights the value of establishing comprehensive environmental baselines and monitoring programs through interagency collaboration when developing renewable energy resources in environmentally sensitive areas.

ABSTRACT

Enhanced Geothermal Systems (EGS) represent cutting-edge technologies designed to harness clean energy from the Earth's crust. However, the presence of short-circuits in certain geothermal reservoirs poses a significant threat to their sustained viability as reliable sources of clean energy. This issue arises when cold fluids injected into the reservoirs quickly traverse fractures with large apertures and directly communicate between injection and production wells without acquiring sufficient heat from the rock matrix. Effective control of flow dynamics outside the wellbore and within the reservoir is crucial to mitigate undesirable flow patterns. Polymer gels, proven successful in managing preferential flow in oil and gas reservoirs, could be adapted for controlling flow in geothermal reservoirs. Nonetheless, the absence of hydrogel products capable of withstanding the harsh conditions of geothermal reservoirs (>150 ℃) for extended periods has been a limiting factor. In response, our recent efforts have led to the development of innovative high-temperature resistant preformed particle gels (HT-PPG) specifically designed for this purpose. This study provides a comprehensive overview of our research advancements, encompassing the creation of a series of innovative particle gel products. We explore their swelling behavior, rheology, thermal stability, and plugging efficiency to fractures, highlighting their applicability in geothermal contexts, even under elevated temperatures. These products are adaptable for reservoirs with preferential fluid flow paths which have temperatures ranging from 20 to 200 °C (the reservoir could have higher temperature) and can be customized with controllable sizes ranging from micrometers to a few millimeters. Our developed products feature controllable swelling times and demonstrate commendable long-term hydrolytic thermal stability, maintaining their effectiveness for over three months. Additionally, we have designed a micromodel to observe the swelling kinetics and transport mechanisms of a representative particle gel. Furthermore, we employ numerical simulation to model particle gel injection and assess blocking performance. Overall, the HT-PPG developed in this work emerges as a reliable solution for controlling preferential fluid flow in geothermal reservoirs, addressing a critical challenge in the quest for sustainable and efficient geothermal energy extraction.

1. Introduction

Enhanced Geothermal Systems (EGS) represent a promising technology designed to tap into the Earth's vast geothermal energy resources, providing a clean and sustainable source of power. By creating man-made reservoirs in hot rock formations, EGS can potentially generate significant amounts of energy with the total estimated thermal energy above the mean surface temperature to a depth of 10 km being 1.3×10^{27} J (Lund, 2007). However, the efficiency and sustainability of EGS are often compromised by the occurrence of short-circuiting within the reservoir (McClure & Horne, 2014). Short-circuiting refers to the rapid movement of cold fluids through large fractures or direct communication paths between injection and production wells, bypassing the intended heat exchange with the rock matrix. This leads to early breakthrough resulting in the inadequate heating of the injected fluids before they are produced. This affects the thermal production temperatures resulting in suboptimal energy generation (Li et al., 2016; McClure & Horne, 2014; Zhang et al., 2024).

Addressing the issue of short-circuiting is crucial for the viability of EGS as a reliable energy source. Effective control of fluid flow dynamics within the reservoir and outside the wellbore is essential to mitigate undesirable flow patterns. In the oil and gas industry, polymer gels have proven effective in managing preferential fluid flow by blocking high-permeability pathways and diverting fluids into less permeable zones (Bai et al., 2007, 2013; Goudarzi et al., 2015; Seidy Esfahlan et al., 2021; Tongwa & Baojun, 2015). This technology offers a potential solution for controlling fluid flow in geothermal reservoirs. However, the extreme conditions typical of geothermal environments, particularly temperatures exceeding 150°C, pose significant challenges for conventional polymer gels. These gels often degrade or lose their effectiveness under such harsh conditions, necessitating the development of more robust materials (Xiong et al., 2018).

Our research has focused on developing high-temperature resistant preformed particle gels (HT-PPG) specifically designed for geothermal applications (Liu et al., 2024; Song et al., 2023). These innovative gels are engineered to withstand the challenging conditions of geothermal reservoirs, providing a reliable solution for controlling preferential fluid flow. This study offers a comprehensive overview of the development and evaluation of these HT-PPGs, highlighting their potential to improve the performance and sustainability of EGS.

2. Novel Preformed Particle Gel Development

We successfully developed two hydrogel products termed Product-1 (preformed particle gel) and Product-2 (re-crosslinkable preformed particle gel), which can be stable at 200 ^{o}C for over 6 months.

2.1 Synthesis of HT-PPGs:

The HT-PPG/RPPG was synthesized through aqueous free radical polymerization. Then the bulk gel was dried and ground into small particles, as shown in Figure 1.

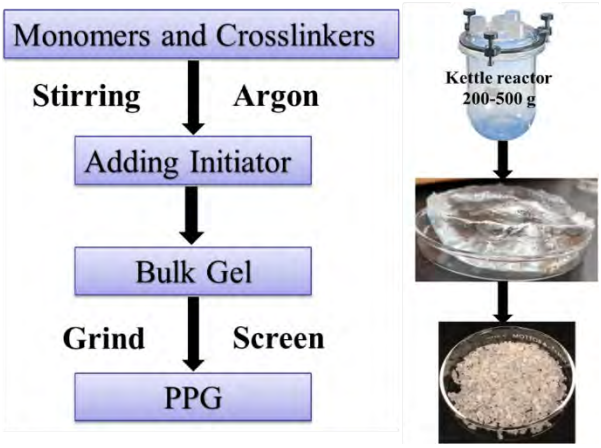

Figure 1. Synthesis procedure of HT-PPG

2.2 Evaluation Methods of PPGs

Swelling Kinetics: PPG dry particles with the size of 1 to 2 mm were used for the swelling kinetics measurements. The swelling kinetics was performed by immersing a weighed dried hydrogel sample in brine. The change in volume with respect to time was studied until the equilibrium swelling ratio was achieved. The swelling ratio of PPG is defined as the ratio of the volume of the hydrated gel to the initial weight.

Rheology Test: The rheology measurements were performed using Haake MARS III rheometer with a parallel plate geometry (PP35L Ti L) with a gap of 1 mm. All sets of rheological measurements were carried out in ambient room temperature conditions. Strain sweep tests were carried out using the oscillation strain-dependent experiment model at a fixed frequency of 1 Hz to determine the linear viscoelastic region over which storage modulus is independent of strain amplitude. The rheology measurements were performed as the oscillation time-dependent experiment model at a fixed frequency of 1 Hz and controlled strain (γ) of 1% to measure storage *modulus (G').*

Thermal Stability: The stability of the PPG was evaluated using high-pressure-resistant glass tubes with thermally stable O-rings and stainless-steel sample cylinders. The dried gel particles were swelled and sealed in anaerobic conditions. After that, the sample cylinder was aged at 150, 200 and 225 ^{o}C oven.

Core flooding tests: Sandstone cores (5 in. length, 2 in. diameter) were used for core flooding experiments, initially dried to remove residual water, vacuumed for 24 hours, and saturated with 2% KCl to calculate porosity. Matrix permeability was determined using the Darcy equation by flooding the cores with 2% KCl at varying flow rates. The cores were then halved and stainless-steel strips were glued on to represent fracture sizes. HT-PPG gel slurry was prepared by swelling dried gel particles in 2% KCl and injected into the fractures at 1 mL/min. After stabilizing the pressure gradient and sealing the cores, a post-water breakthrough test was conducted, measuring breakthrough pressure and recording stable pressures at varying flow rates to calculate the residual resistance factor.

Micromodel swelling kinetics: We designed a micromodel to observe the swelling kinetics and transport mechanisms of a representative particle gel in. In so doing, we experimentally

investigated how gel swelling and deswelling behaviors are influenced by channel size, gel particle properties, and flow conditions under high pressure and high temperature constriction channels.

3. Results

3.1 Results of PPG-1 (HT-PPG)

Product-1 is an enhanced high-temperature resistant superabsorbent hydrogel/ preformed particle gel (HT-PPG) (Buddhabhushan et al., 2021), capable of swelling without dissolving in brine solutions. Our research has demonstrated that this hydrogel remains stable at 150°C for over a year before beginning to degrade. Building on the existing gel formulation, we introduced modifications to improve the stability of the swollen hydrogel at 200°C. The evaluations included tests on swelling kinetics, rheology, and long-term hydrothermal stability.

(1) Swelling Kinetics and Rheology Behavior

Swelling kinetics were employed to measure both the swelling rate and the equilibrium swelling ratio, essential for optimizing field injection (Targac et al., 2020). The elastic modulus, or strength, is a crucial property for plugging fractures or super-K conduits. Figure 2(a) shows the swelling and rheological behavior of Product-1, which requires approximately 2 hours to reach its equilibrium swelling ratio. The equilibrium swelling ratios in 2% KCl and 1% $CaCl_2$ were 55 and 54, respectively. Figure 2(b) depicts the relationship between the swelling ratio and gel strength. The elastic moduli of Product-1 with swelling ratios of 10, half swelling, and full swelling were 960, 451, and 256 Pa, respectively. As the swelling ratio (SR) increased, the elastic modulus (strength) of HT-PPG gradually decreased. This reduction in gel strength is attributed to the absorption of more saline water at higher swelling ratios, which increases the distance between polymer chains, thereby lowering the gel strength.

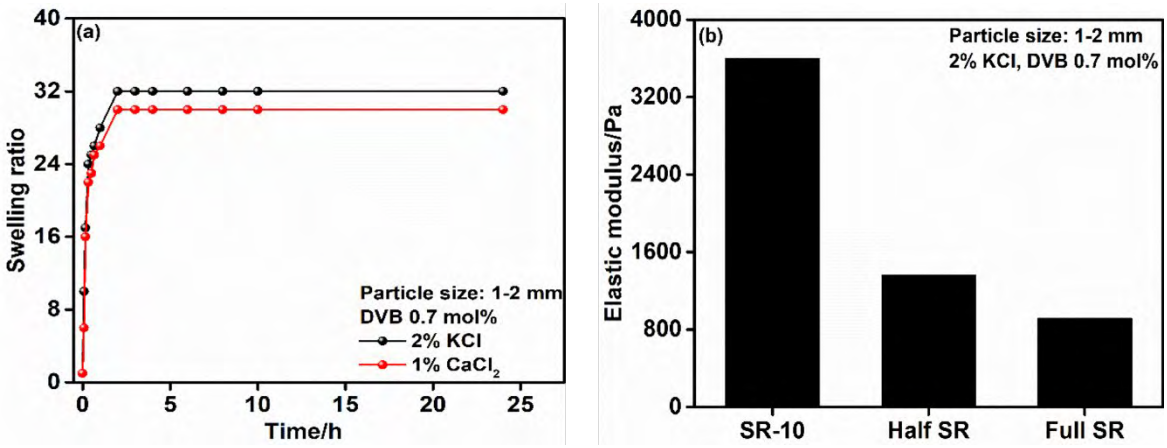

Figure 2. Effect of (a) salinity on the swelling behavior, (b) swelling ratio (SR) on the storage modulus

Figure 3 shows the effect of crosslinker concentration on the maximum swelling ratio. When the ratio of monomer to crosslinker is 996:1, the maximum swelling ratio exceeds 50. As the concentration of the cross-linker decreases, the maximum expansion multiple gradually decreases. Figure 3(b) illustrates the effects of swelling ratio and crosslinker concentration on the gel strength. As the concentration of the crosslinker increases, the strength of the gel also increases.

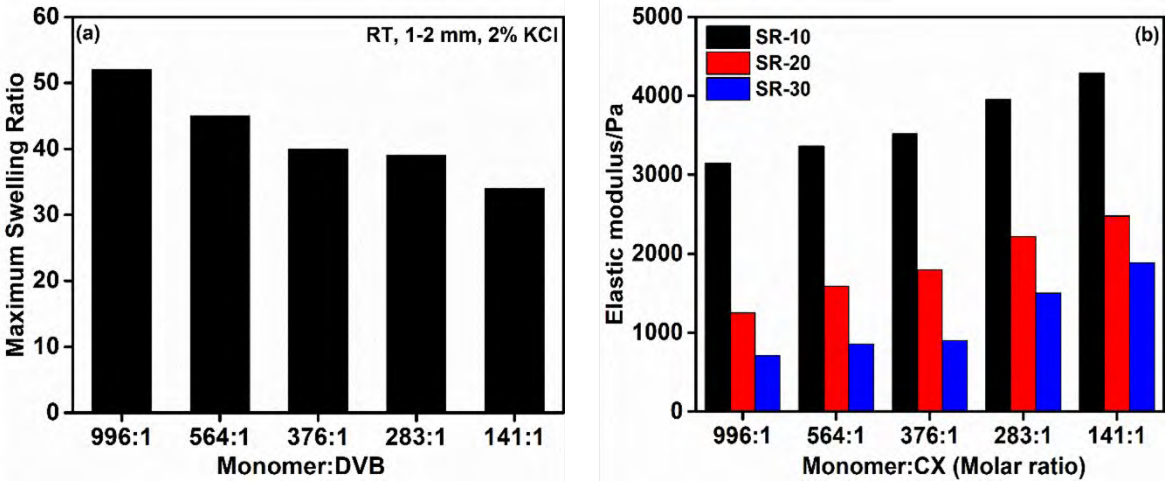

Figure 3. Effect of monomer to crosslinker ratio on the (a) maximum swelling ratio, (b) storage modulus

(2) Thermal Stability of Product-1

Figure 4 shows the stability test result at 200 °C. HT-PPG with swelling ratio 5 and 10 has excellent thermal stability and the volume loss is less than 5% for over 6 months, demonstrating the current product has excellent thermal stability at 200 °C.

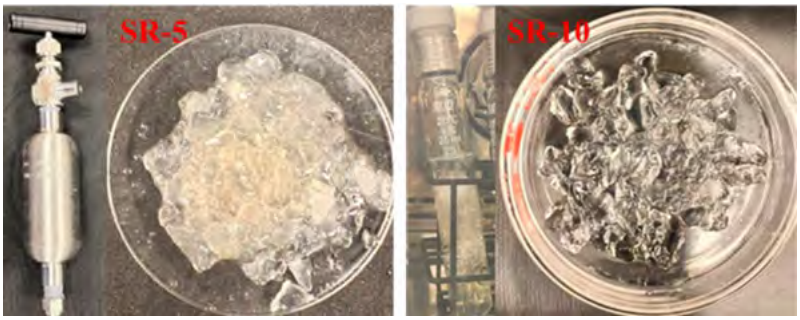

Figure 4. HT-PPG with different swelling ratio after 180 days of aging at 200 °C

3.2 Results of Product-2 (HT-RPPG)

Product-2 is a re-crosslinkable preformed particle gel (RPPG) that can self-heal to form a uniform bulk gel after swelling. This characteristic enhances its blocking performance to fracture and allows it to effectively reduce fluid flow through preferential flow path (Bai et al., 2024). We developed Product-2 by incorporating a specific clay during the synthesis of Product-1. This clay

interacts physically with the polymer backbone, imparting self-healing capabilities to the polymer gels. This method is not only cost-effective but also environmentally friendly, as it eliminates the need for toxic heavy metal ions such as Cr and Zr, as well as toxic organic crosslinkers like phenolic resins and blocked isocyanates, which are typically used in other self-healing mechanisms.

(1) Swelling Kinetics and Rheology Behavior

Figure 5 shows the swelling behavior over time and with varied concentrations of clay, and its the rheological response to swelling ratio and concentration. As shown in Figure 5(a), all HT-RPPGs can reach equilibrium swelling ratios within ten hours. As the clay concentration increases, both the swelling rate and the maximum swelling ratio decrease, with the maximum swelling ratio exceeding 120. In Figure 5(b), the gel strength of HT-RPPG increases with the increase in clay concentration and decreases with the swelling ratio, indicating that clay has a positive effect on improving rheological properties.

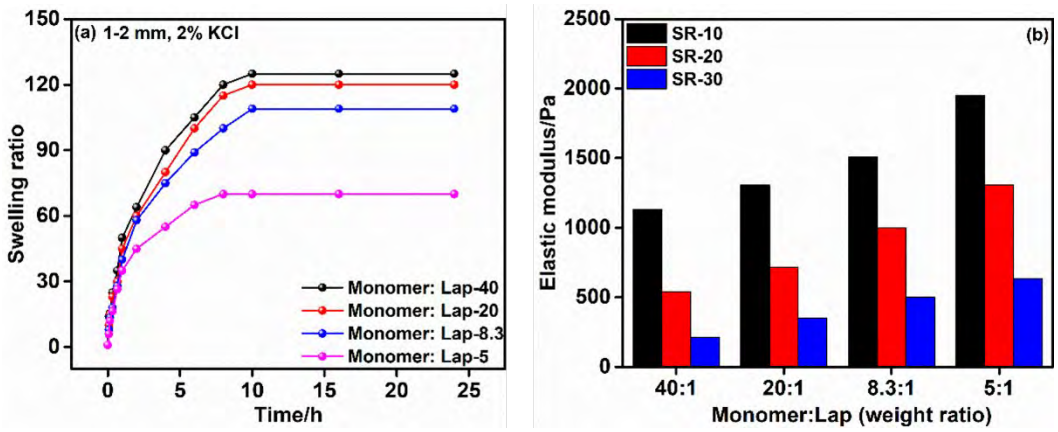

Figure 5. Effect of monomer to clay weight ratio on the (a) swelling kinetics, (b) storage modulus

Figure 6 shows the effect of clay concentration on the gel strength after fully assembling at 200 °C. The gel strength increased with the clay content. Figure 7 shows the gel appearance of HT-RPPG with different clay concentrations. As the clay concentration increases, the boundaries between particles become increasingly blurred, the gel integrity and elasticity gradually increase with clay concentrations.

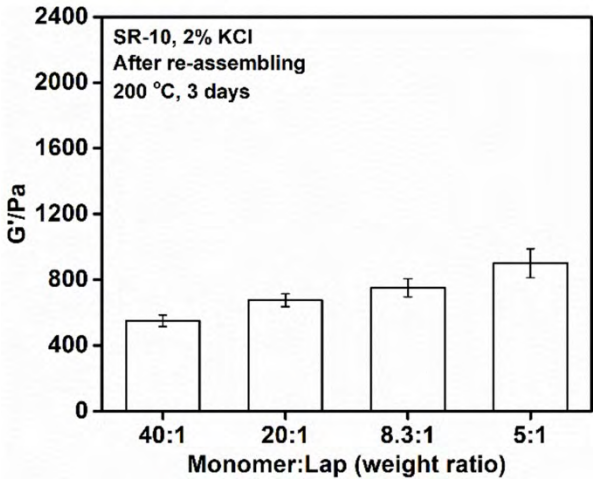

Figure 6. Effect of Clay concentration on the gel strength after fully re-assembling

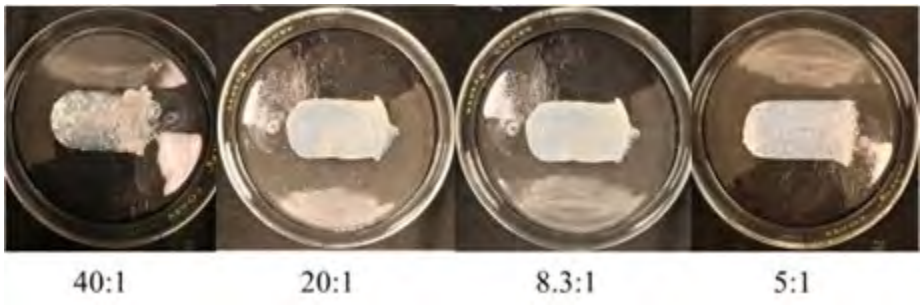

Figure 7. Gel appearance of HT-RPPG with different monomer to clay weight ratio

(2) Thermal Stability of Product-2.

Figure 8 shows the thermal stability of HT-RPPGs at 150 and 200 °C. We use transparent glass sample cylinders to monitor the gel appearance changes during the test. Bulk gel without boundaries was observed without any visible particle and flowing fluid. We also prepared several samples using the stainless-steel sample cylinder to continue studying our samples. The samples (swelling ratio of 10) in stainless-steel cylinders demonstrated excellent thermal stability at 200 °C over 6 months. We observed discoloration, but did not observe any volume loss, and no liquid existed in all cylinders.

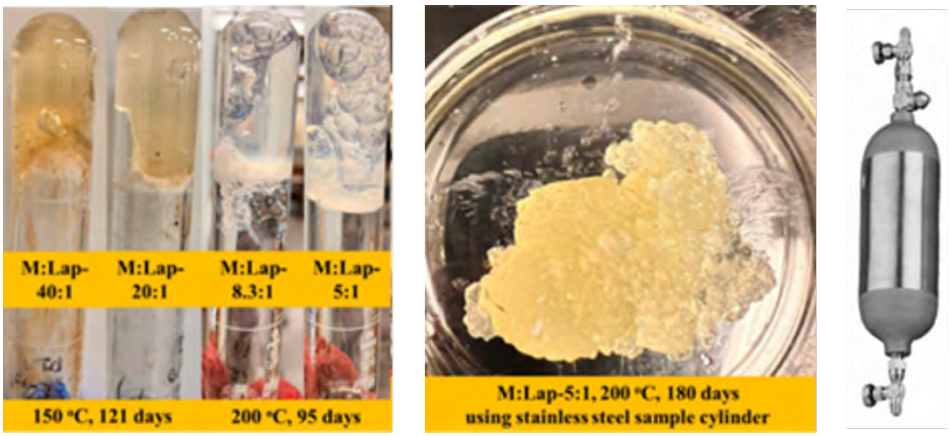

Figure 8. Thermal stability of HT-RPPG at 150 and 200 oC and stainless sample cylinder

3.4 Coreflooding Test

Core flooding tests were conducted to investigate the transport and blocking mechanisms of HT-PPG in fractures. HT-PPG slurry was prepared by swelling the dried gel particles in 2% KCl with various swelling ratios. Once the gel particles had fully absorbed the free water, the gel slurry was injected into the fracture. The core flooding setup, illustrated in Figure 9, includes an ISCO pump, accumulators, a Hassler-type core holder, and a pressure transducer connected to a computer for precise data acquisition and analysis. The test primarily consists of the HT-PPG injection phase followed by a water breakthrough phase.

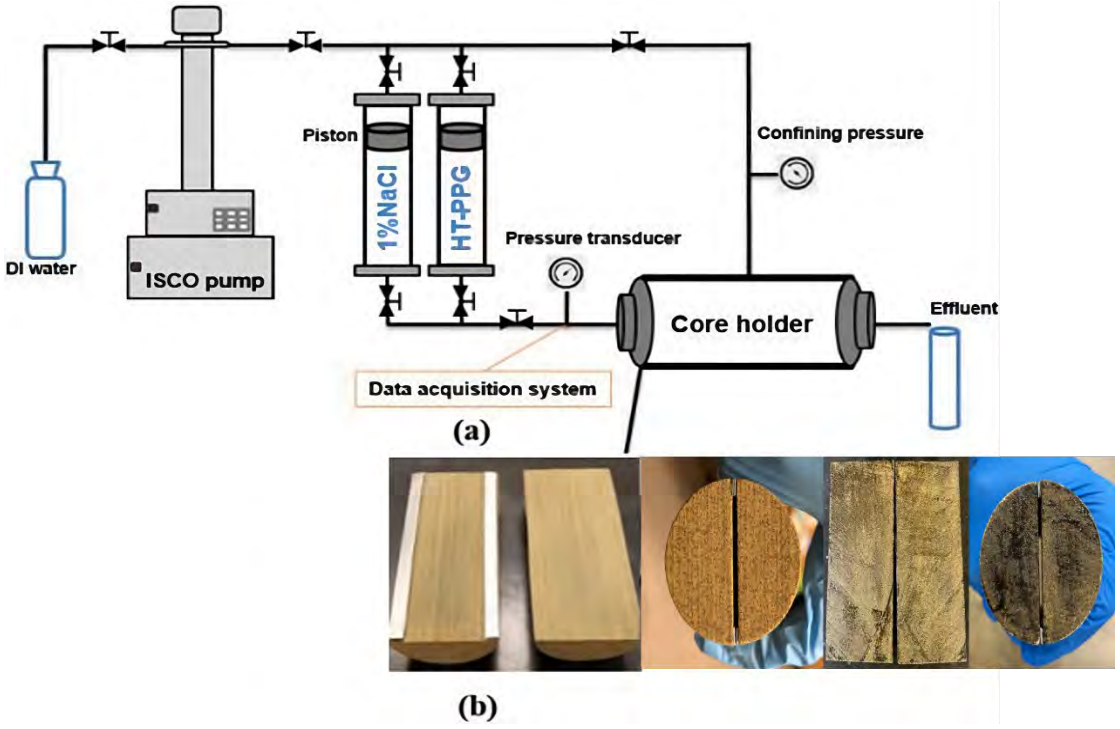

Figure 9. Core flooding setup

HT-PPG Injection: In this experiment, the fractured sandstone model is secured in the core holder, and a confining pressure is applied. The core is first flooded with 2% KCl solution. Next, the swollen HT-PPG is injected into the fracture at a flow rate of 1.0 cc/min to seal it. This injection continues until the pressure stabilizes, as monitored by the acquisition software. Figure 10 illustrates a sample HT-PPG injection profile. Following the injection, the core is sealed and aged in preparation for the breakthrough test.

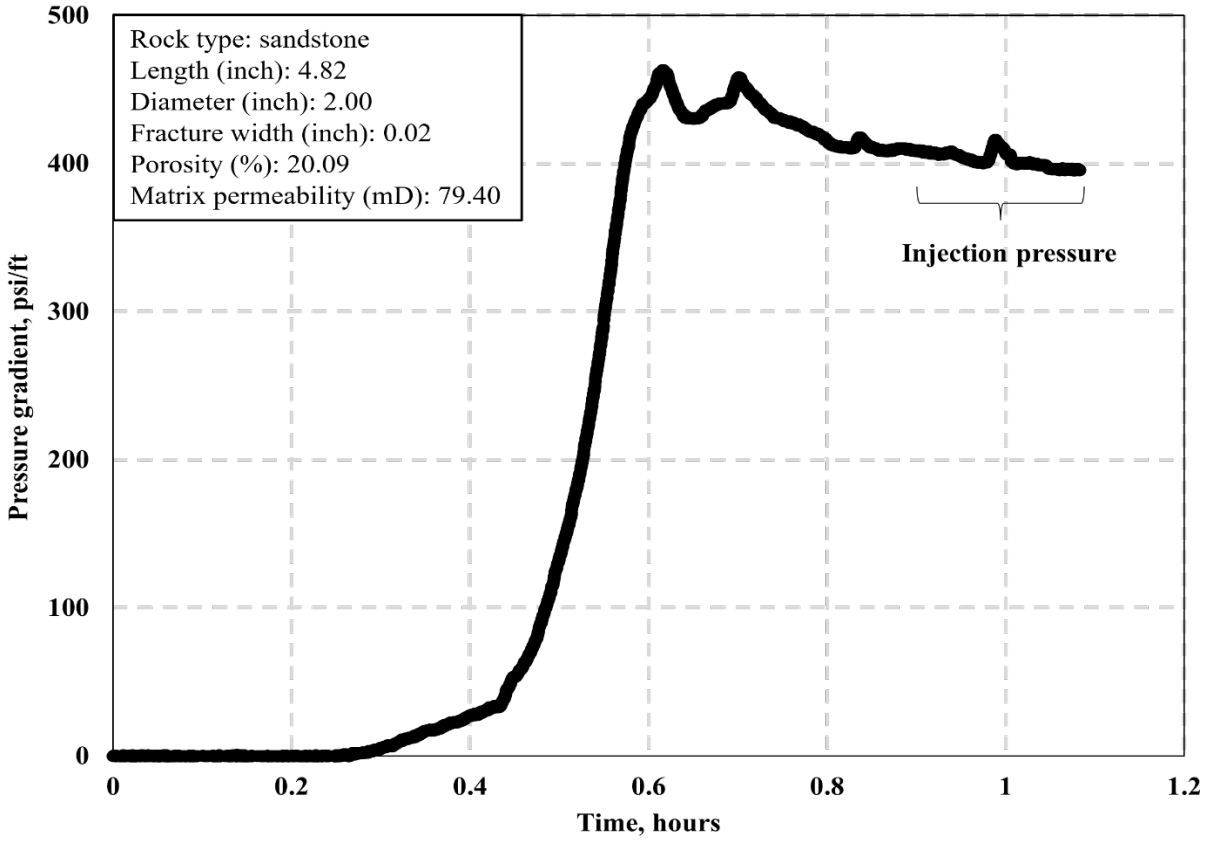

Figure 10. HT-PPG injection profile

Breakthrough pressure and plugging efficiency test: The ability of HT-PPG to reduce fluid flow channels is evaluated by determining threshold pressure and residual resistant factor (Frr). Figure 11 presents an example of the pressure response over the process. After breakthrough, brine was continuously injected at different flow rates of 0.10, 0.25, 0.50, and 1.00 cc/min until pressure reading was stabilized. Figure 12(a) shows the stable pressure readings of a representative sample and the corresponding Frr values are highlighted in Figure 12(b). The initial permeability is determined using Equation 1, while the permeability after water breakthrough is calculated using Equation 2. Frr is then calculated using Equation 3.

$$k_{\text{initial}} = \frac{h^2}{12} \quad \text{Equation 1}$$

$$k_{\text{after}} = \frac{q \times \mu \times L}{A \times \Delta P} \quad \text{Equation 2}$$

$$F_{\text{rr}} = \frac{k_{initial}}{k_{after}} \quad \text{Equation 3}$$

Where $k_{initial}$ is the initial permeability of the fracture and k_{after} is the fracture permeability after gel treatment. $k_{initial}$ and k_{after} were calculated using the above equations, h is the height of the fracture (μm), q is the flow rate (cm^3/s), μ is the viscosity of the liquid (cp), L is the length of the core (cm), A is the cross-sectional area (cm^2) of the fracture, and ΔP is the pressure change (atm).

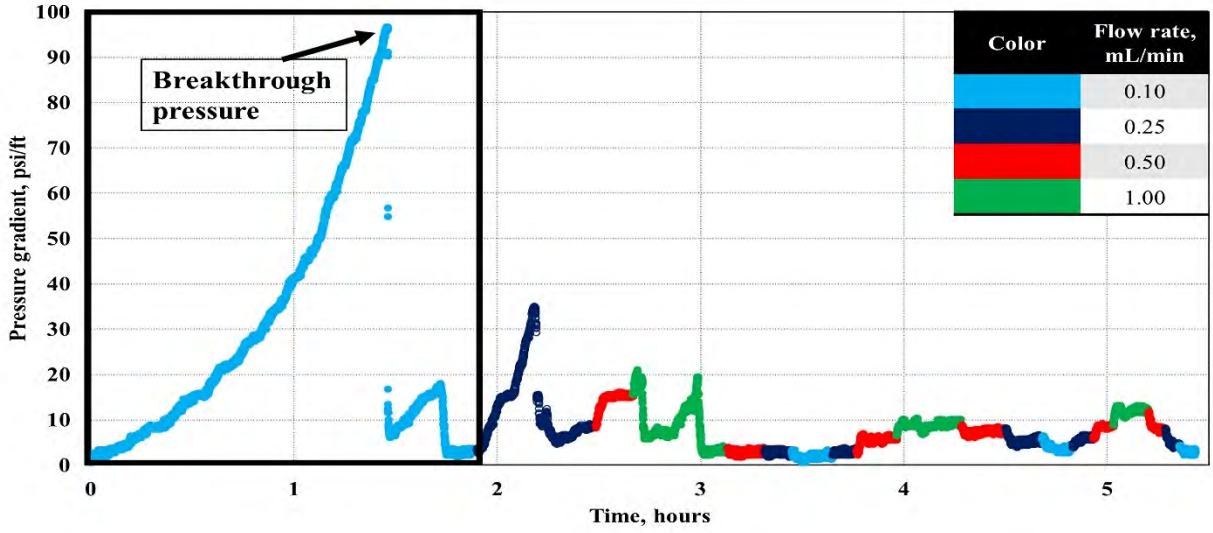

Figure 11. Water breakthrough profile

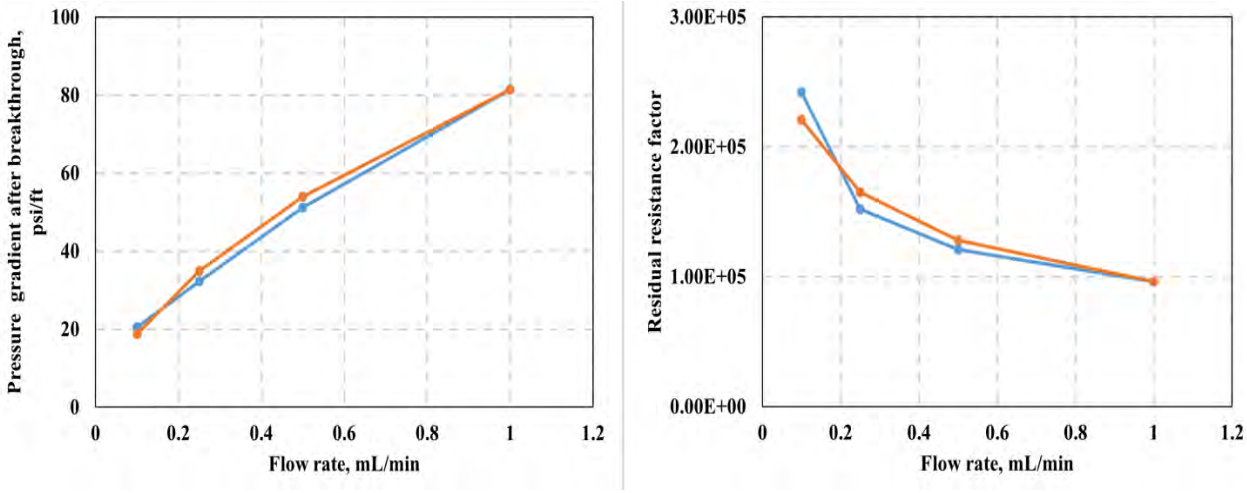

Figure 12. Pressure gradient and Frr against flow rate

We studied the effect of HT-PPG particle size, swelling ratio, and fracture width on injectivity and plugging efficiency. Based on our initial result, we conducted more experiments to further investigate the gel's injection pressure, water breakthrough pressure, and Frr. In doing so, we coated the surfaces of the core with a high temperature epoxy (HT-epoxy) to ensure that the brine used for post flooding is directed toward the HT-PPG in the fracture and not diverted into the core matrix. The HT-epoxy used has a broad service temperature range of -40 to 225 °C (-40 to 437 °F) and has extreme resistance to water and humidity.

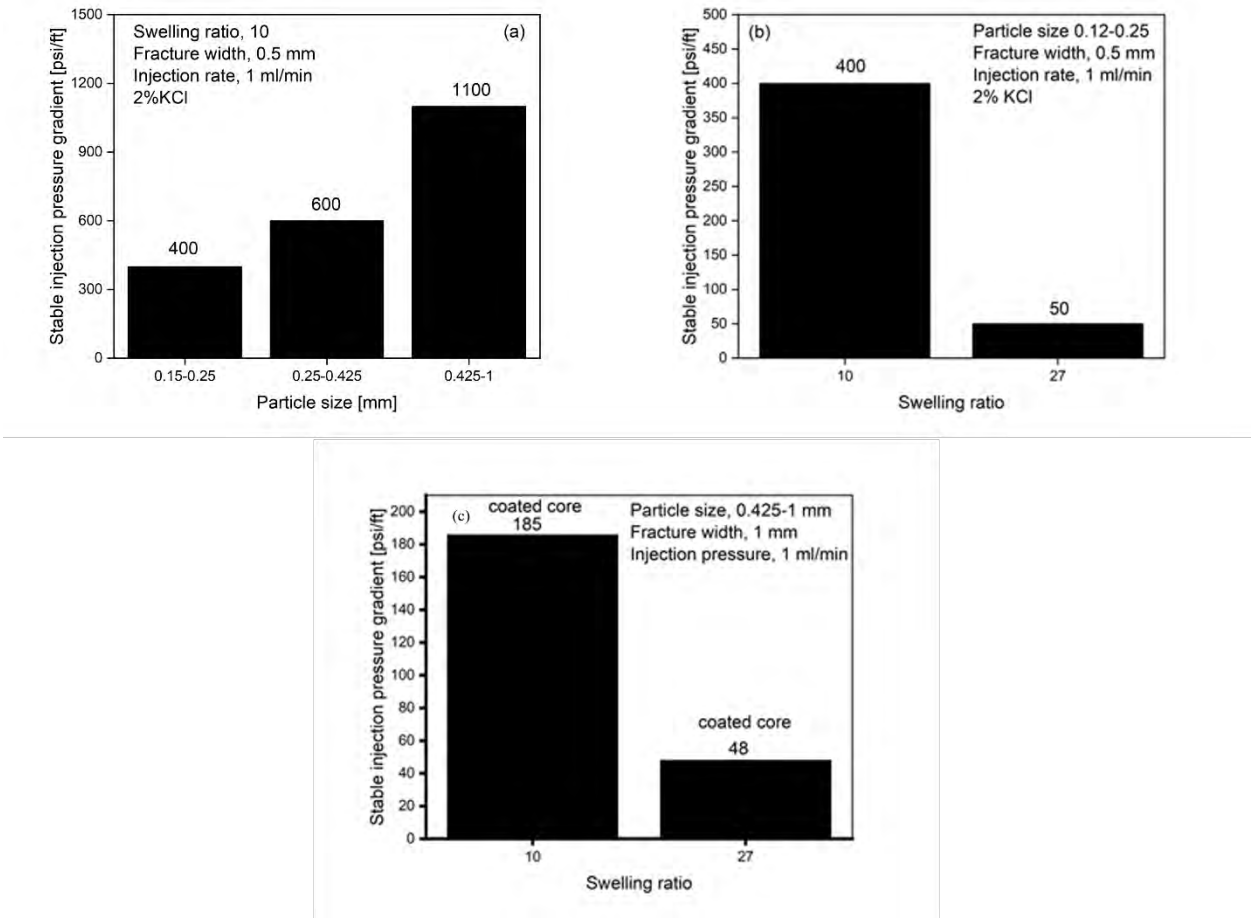

Figure 13. Effect of (a) gel particle size; (b) swelling ratio; and (c) core surface on HT-PPG injection

From our injection results in Figure 13, it is evident that at a constant swelling ratio and fracture width, the injection pressure increases as the particle size increases. It, however, decreases as swelling ratio increases. An increase in swelling ratio requires less pressure for injection into fractures as the soft particles are easier to deforms and penetrate in fractures. The uncoated cores required less pressure for gel placement as adhesion does not play a considerable role as compared to the cores with rough surfaces.

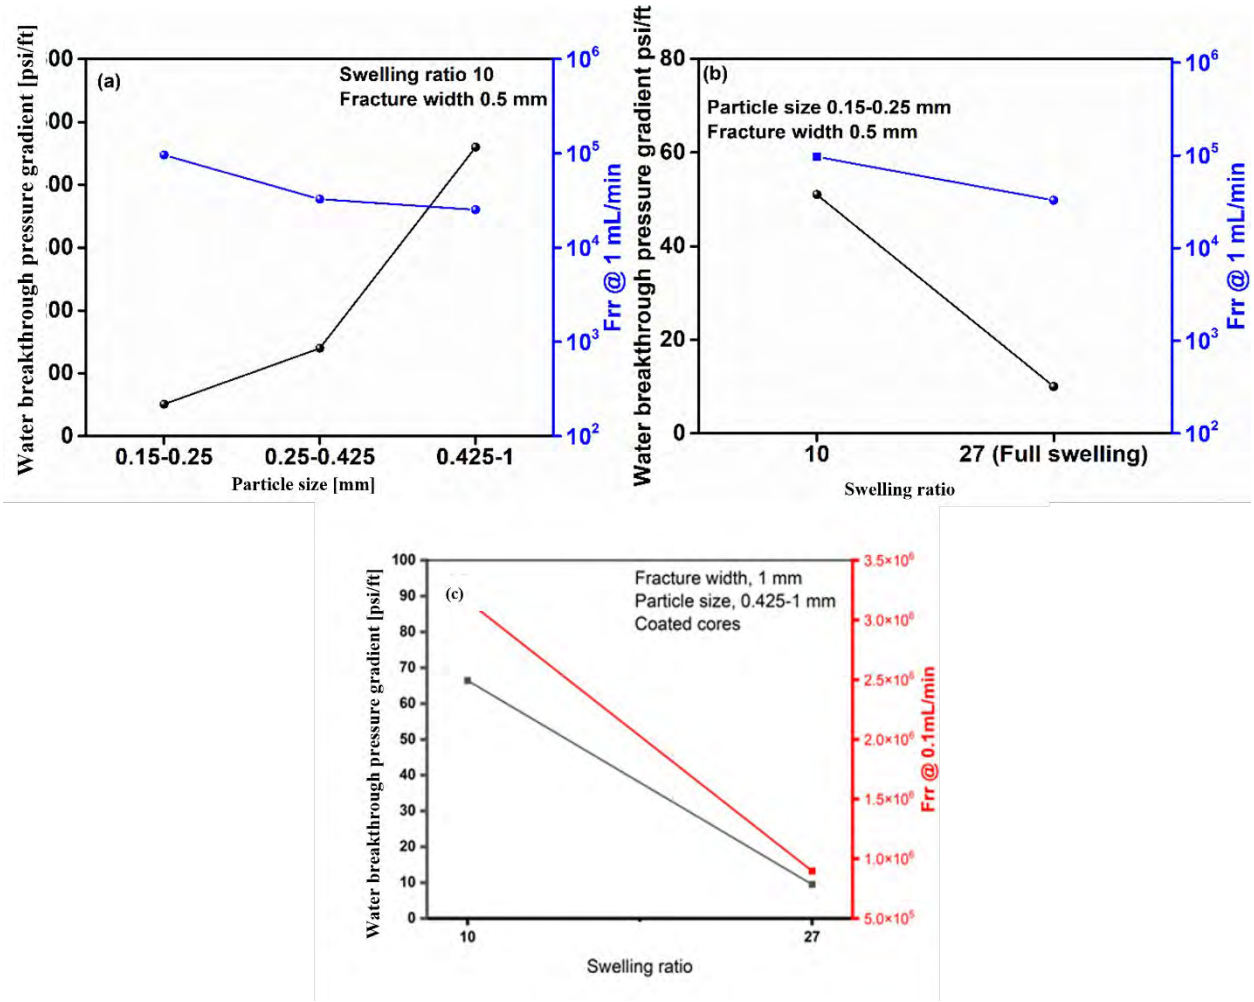

Figure 14. Effect of (a) gel particle size; (b) swelling ratio; and (c) core surface on breakthrough pressure

The effect of gel particle size, swelling ratio, and core surface on HT-PPG breakthrough pressure is summarized in Figure 14. The water breakthrough pressure increases with an increasing particle size but decreases with an increasing swelling ratio. Additionally, there is an increased Frr with the uncoated cores as compared to the coated ones.

3.3 Micromodel swelling kinetics:

We successfully developed a method to print 3D models of fractures and pores for direct visualization of the gel swelling in a confined space. This was to investigate the swelling behavior of our gels under high pressure and high temperature channel constructions. In our experiments, we discovered a novel phenomenon, depicted in Figure 15, where gel particles expand within adequately confined pores and subsequently fracture upon reaching a certain degree of swelling. This results in the formation of smaller fragments capable of blocking the pore space. Our experimental approach has enabled us to methodically investigate the circumstances under which this phenomenon occurs, scrutinize the swelling of gels under varying degrees of porous confinement, and pinpoint the conditions that lead to gel fracturing.

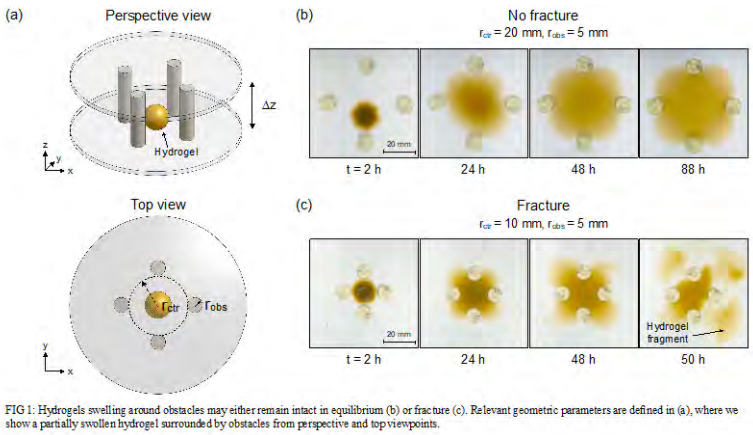

FIG 1: Hydrogels swelling around obstacles may either remain intact in equilibrium (b) or fracture (c). Relevant geometric parameters are defined in (a), where we show a partially swollen hydrogel surrounded by obstacles from perspective and top viewpoints.

Figure 15. Hydrogels swelling around obstacles may either remain intact in equilibrium (b) or fracture (c) relevant geometric parameters are defined in (a), where we show a partially swollen hydrogel surrounded by obstacles from perspective and viewpoints

The outcomes of our study are summarized in Figure 16. Each data point denoted by an 'x' represents a hydrogel experiment that culminated in a fracture, as depicted in Figure 15c. Conversely, data points symbolized by a square indicate experiments where the hydrogel reached equilibrium without fracturing, as illustrated in Figure 15b. The schematics provide a top view of the obstacle geometries corresponding to the specified trials. The shaded region in the upper left corner of the plot denotes parameters that would result in an overlap of the obstacle.

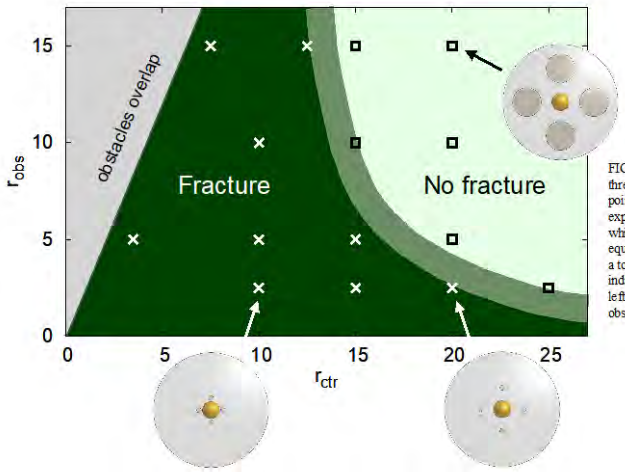

FIG 2: Hydrogel experiments reveal a fracture threshold as a function of obstacle geometry. Each point marked with an x corresponds to a hydrogel experiment that resulted in fracture (as in Fig. 1c), while points marked with a square reached equilibrium intact (as in Fig. 1b). Schematics show a top view of the obstacle geometries for the indicated trials. The grey excluded region in the top left of the plot shows parameters for which the obstacles would overlap.

Figure 16. Hydrogel experiments reveal fracture threshold as a function of obstacle geometry

Based off this finding, we intend to develop theoretical guidelines for gel swelling within confined spaces and to design a computational model for gel placement in fractured media. Additionally, we will experimentally verify how gel placement affects fluid transport pathways, using in situ measurements of pore-scale flow fields and fluid pressures.

3.4 Numerical Simulation to Characterize PPG Transport and Evaluate Gel Treatment Efficiency

We are developing swellable Preformed Particle Gels (PPG) to control preferential fluid and heat flow through fracture networks, thereby enhancing the performance of Enhanced Geothermal System (EGS) reservoirs. Our development includes creating a mathematical model and numerical simulator to simulate PPG treatments, considering coupled thermal-hydraulic-mechanical effects, gel swelling kinetics, and plugging efficiency. This approach aims to achieve an optimized gel treatment design and operation.

Our mathematical model is based on the TOUGH2-CSM formulation and code. The TOUGH2-CSM fluid and heat flow formulation extends the TOUGH2 model for multiphase, multi-component, and multi-porosity systems, incorporating the MINC and EDFM models. The TOUGH2-CSM geomechanical formulation employs the linear theory of elasticity for multi-porosity, non-isothermal media. We have modified this formulation to simulate the injection of PPG into fractures. An equation of state module for gel-water systems was developed, building on a previous TOUGH2 module designed for air and water, as PPGs are primarily water-based. Experimental studies on PPG flow through fractures informed our PPG flow formulation, modeling it as a shear-thinning fluid with yield stress (Herschel-Bulkley fluid). When injected into a permeable fracture, water leaks off through the fracture walls, depositing a more concentrated PPG as a filter cake. Additionally, the transverse pressure gradient during PPG flow can dehydrate the PPG, creating a more concentrated flowing PPG and a separate flowing water phase. These characteristics, along with the PPG's swelling behavior over time, are incorporated into our model.

We verified our simulator's features by matching them with data from experimental studies. These studies included PPG injection into open fractures, used to verify our PPG rheology and longitudinal dehydration models, and PPG injection into closed fractures, used to verify our transverse dehydration model. Finally, we applied our model to a synthetic EGS to evaluate the impact of blocking highly conductive fractures with PPG on energy production. The detail information about the simulation is reported in another paper of this same conference (Winterfeld, Bai and Wu, 2024).

Summary

We have developed a couple of novel particle gels HT-PPGs that exhibit several key properties to make them well-suited for geothermal applications. One of the most critical characteristics is their thermal stability. Unlike conventional polymer gels, HT-PPGs maintain their structural integrity and effectiveness at temperatures ranging from 20°C to 200°C. This makes them adaptable to a wide range of geothermal reservoir conditions. Additionally, the gels can be customized in size, from micrometers to a few millimeters, allowing for tailored solutions to specific reservoir requirements. This adaptability is crucial for addressing the unique challenges presented by different geothermal environments.

The performance of HT-PPGs in geothermal reservoirs is determined by several factors, including their swelling behavior, rheology, and plugging efficiency. Swelling behavior is particularly important, as it affects the ability of the gel to fill and block fractures effectively. Our research has demonstrated that HT-PPGs exhibit controllable swelling times, enabling management of the gel

expansion to optimize its blocking performance. Rheology, or the study of the gel's flow properties, is also critical, as it influences how the gel moves through the reservoir and interacts with the rock matrix. The HT-PPGs developed in our study exhibit favorable rheological properties, ensuring they can be effectively deployed in geothermal reservoirs.

Thermal stability is another crucial aspect of HT-PPG performance. In geothermal environments, where temperatures can exceed 150°C, maintaining the gel's integrity over extended periods is essential. Our HT-PPGs have demonstrated commendable long-term hydrolytic thermal stability, remaining effective for over three months. This long-term stability is vital for ensuring continuous control of fluid flow and maximizing energy production from geothermal reservoirs.

To better understand the behavior and performance of HT-PPGs, we have employed both experimental and micromodel design approaches. With the micromodel, we observe the swelling kinetics and transport mechanisms of a representative particle gel. This allows for detailed visualization and analysis of how the gels interact with the reservoir environment, providing insights into their swelling kinetics. We also developed mathematical models that can simulate PPG transport through factures and optimize PPG treatment parameters.

Overall, our research into HT-PPGs presents a promising solution to one of the major challenges in geothermal energy production. By effectively controlling preferential fluid flow, these gels can enhance the efficiency and sustainability of EGS. The development and implementation of HT-PPG could significantly improve the viability of geothermal energy as a reliable and clean energy source, contributing to a more sustainable energy future.

Pertamina Geothermal Energy

Keywords

Water-dominated, production monitoring, deliverability curve, production decline, steam supply, production variance

ABSTRACT

In the Lumut Balai geothermal field, daily well production flowrates and enthalpy measurement data are not available due to the absence of two-phase flowmeters. This condition complicates quantitative estimations regarding steam availability, steam production decline rates, and subsequently steam supply forecast. Meanwhile, a quarterly Tracer Flow Testing (TFT) has been performed to monitor individual well production flowrates and enthalpy which allows merely a qualitative evaluation of production performance. These uncertainties significantly impact reservoir management strategies.

The Steam Allocation Lumut Balai (SALB) application has been developed to estimate daily individual well production by solving mass and energy balance equations throughout the field process flow diagram and integrating operational data such as wellhead pressure, separator pressure, brine mass flow rate, steam mass flow rate, re-injected mass flow rate, and TFT. This daily monitoring facilitates a nuanced understanding of the wells and the reservoir behavior, expediting the troubleshooting and the resolution of the issues. This paper outlines the methodology employed in the SALB application and details its implementation.

1. Introduction

The Lumut Balai geothermal field is a water-dominated geothermal field located in South Sumatra, ±274 km southwest from the city of Palembang, the capital city of South Sumatra (Figure 1). Currently, it hosts a geothermal power plant with a generation capacity of 55 MWe. A second geothermal power plant unit with an identical generation capacity of 55 MWe is under construction at the Lumut Balai geothermal field. The geothermal field features wells with relatively uniform

specific enthalpy across its expanse from South to North, with reservoir temperatures spanning from 220°C to 250°C.

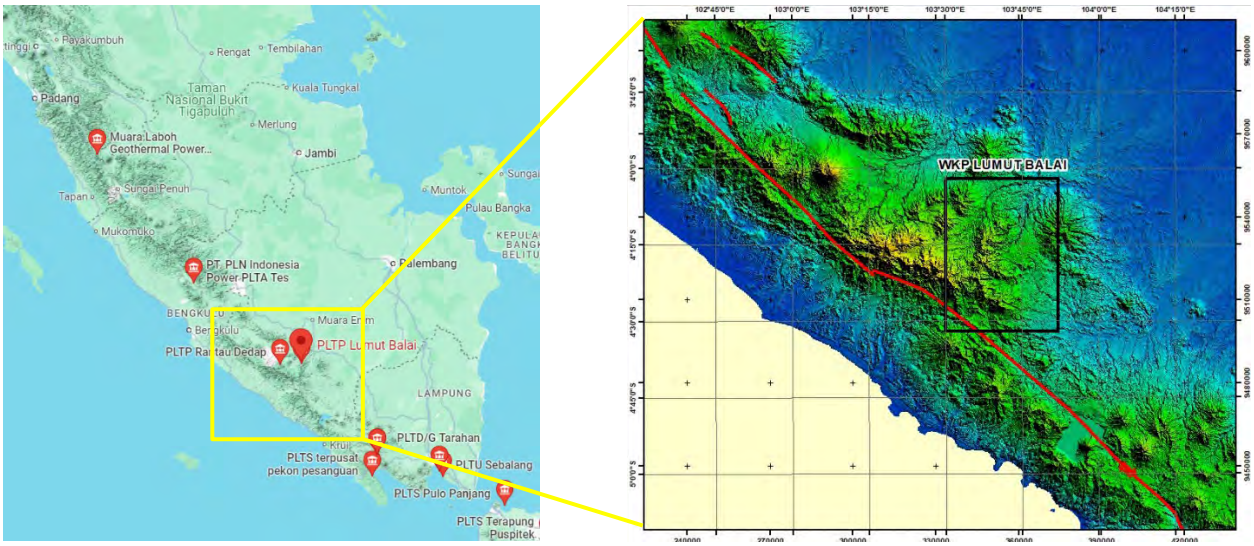

Figure 1: Location map of the Lumut Balai geothermal field.

A quarterly TFT has been employed to monitor individual well production flowrates and enthalpies. Nevertheless, operational constraints typically result in less frequent implementation of TFT. As there are no two-phase flowmeters, the information obtained regarding the reservoir conditions at the Lumut Balai geothermal field is often outdated. This temporal discrepancy between the current state of the reservoir and the most recent data available potentially leads to suboptimal reservoir management strategies.

As the second unit of power plant nearing commercialization, understanding the reservoir performance of the operational Unit 1 is crucial. Unfortunately, daily data for total mass flow rates and production fluid enthalpies from the individual wells in the Unit 1 is not readily available, leading to reliance on the quarterly TFT for steam availability and steam production decline rate calculations. Therefore, developing a technique to estimate daily production data is essential.

2. The Importance of Daily Well Production Estimation

Understanding daily well production is crucial for effective reservoir management. Production wells should provide insights into geothermal reservoir conditions. Changes in well production flow rate and specific enthalpy of well production fluid can reveal significant information about reservoir dynamics. These changes can be analyzed through alterations in deliverability curve from time to time. Figure 2 illustrates how a well deliverability curve shifts over time, indicating different reservoir conditions such as changes in reservoir pressure, temperature, or permeability, as well as well-specific issues like wellbore scaling, as described by Grant and Bixley (2011) and James (1980a). According to Grant and Bixley (2011), Curve A is the basic curve, representing the results from a water-fed well with high permeability. Curve B shows the effect of a decrease in reservoir pressure. Curve C illustrates the effect of an increase in reservoir pressure. Curve D indicates the impact of scaling in the wellbore. Curve E results when the feed is two-phase at the same pressure as for Curve A (Figure 2).

An alteration in deliverability curve of a production well leads to change in the production flow rate at high wellhead pressure, low wellhead pressure, or both. If alterations in a deliverability curve are identified belatedly, subsequent analysis and interventions regarding the conditions within a geothermal well and a reservoir will also be delayed, thereby compromising the effectiveness of reservoir management.

Understanding the most current deliverability curve of a production well is crucial for accurately determining its maximum steam supply. Geothermal wells are frequently operated in a partially open state, or "choked". Therefore, understanding the well deliverability curve enables the assessment of the well production at the maximum opening without fully opening the well, preventing steam wastage and ensuring optimal reservoir exploitation.

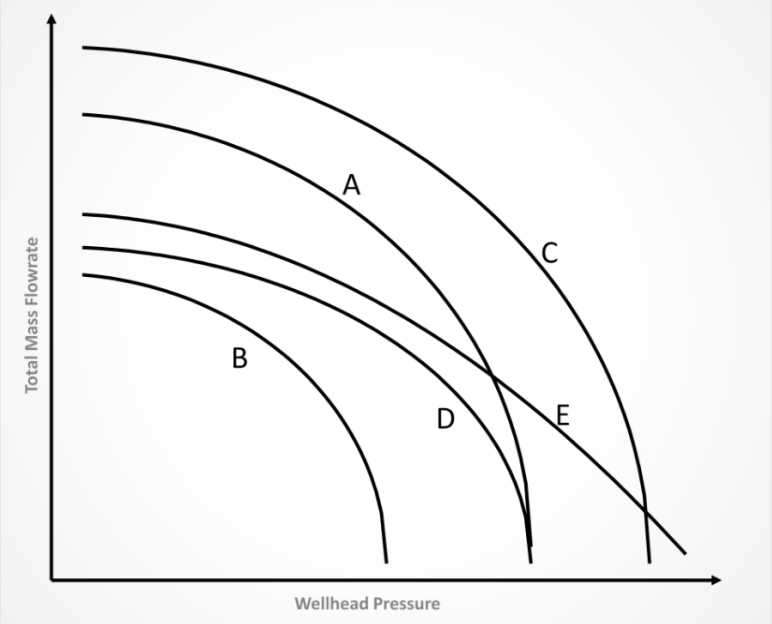

Figure 2: The variations in the shifting of the well deliverability curve over time are caused by different factors. These changes can indicate various reservoir conditions or well-specific issues.

The cumulative steam supply from all production wells within a geothermal field is determined by aggregating the maximum steam output from each production well. Since each production well exhibits a unique alteration in its deliverability curve from time to time, the production decline rate at the maximum opening will differ among production wells. This variability necessitates daily production monitoring of each production well to capture their changes in deliverability curve. The aggregate production decline from all production wells provides an estimate of the overall production decline rate for the geothermal field. The overall production decline rate serves as the basis for calculating the required timeframe to drill a make-up well, ensuring sufficient steam supply to the power plant and maintaining its operational capacity.

3. The Steam Allocation Lumut Balai (SALB) Application

The Steam Allocation Lumut Balai (SALB) application was developed to facilitate the estimation of daily production from each well, despite the absence of two-phase flowmeters in the well production lines at the Lumut Balai geothermal field. This application seeks to mitigate the lack

of well production data that occurs between the quarterly data collection intervals, which currently utilize TFT.

3.1 The Process Flow of The Lumut Balai Geothermal Field

In developing the SALB application, the first necessity is an understanding of the process flow in the Lumut Balai geothermal field. Detailed information on the number of production and reinjection wells, separators, interconnection points, condensate lines, and the availability of brine and steam flowmeters, as well as pressure gauges, is required for the algorithm development.

The Unit 1 is supplied by nine production wells, which direct flow to three separators, while the brine and the condensate from the Unit 1 are re-injected into three reinjection wells (Figure 3). The Unit 2 will receive steam from five production wells, in addition to the steam from the interconnection of wells from the Unit 1. The SALB application is currently operational only for the existing power plant unit, therefore, it does not yet encompass the wells in the Unit 2.

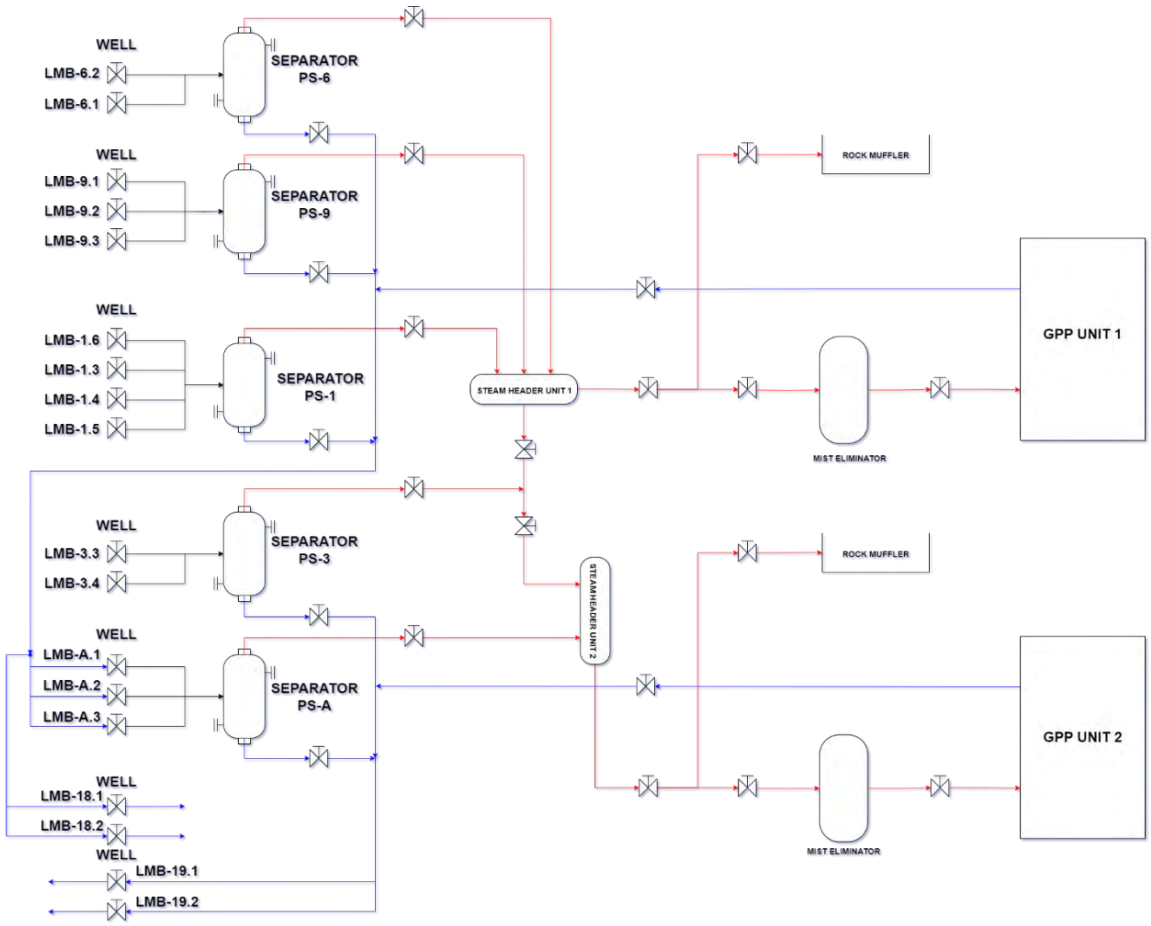

Figure 3: The process flow diagram of the Lumut Balai geothermal field. The SALB application does not yet encompass the wells in the Unit 2.

3.2 Solving Mass and Energy Balance of The Lumut Balai Geothermal Field

The SALB application is developed under the principles of mass and energy conservation. It ensures that the amount of mass and energy exiting the production wells are equivalent to those present in the separators, the steam vessels, and subsequently returned to the reinjection wells.

3.2.1 The Mass and The Energy Balance of The Lumut Balai Geothermal Field

The total mass flow balance equation, aligned with the available flowmeters at the Unit 1 production facility of the Lumut Balai geothermal field, is as follows.

$$\dot{m}_{\text{field}} = \dot{m}_{@\text{reinjector wells}} + \dot{m}_{@\text{scrubber}} + \dot{m}_{@\text{rock muffler}} - \dot{m}_{@\text{condensate line}} \quad (1)$$

Where $\dot{m}_{\text{field}}$, $\dot{m}_{@\text{reinjector wells}}$, $\dot{m}_{@\text{scrubber}}$, $\dot{m}_{@\text{rock muffler}}$, and $\dot{m}_{@\text{condensate line}}$ represent the total mass production flow rate of the field, the measured mass flow rate injected into all reinjection wells, the measured steam mass flow rate in the scrubber, the measured steam mass flow rate in the rock muffler, and the measured condensate mass flow rate in the condensate pump, respectively.

Meanwhile, the steam mass flow balance equation is expressed in the following equation.

$$\dot{m}_{@\text{scrubber}} + \dot{m}_{@\text{rock muffler}} = \dot{m}_{\text{steam}_{@\text{SEP}-6}} + \dot{m}_{\text{steam}_{@\text{SEP}-1}} + \dot{m}_{\text{steam}_{@\text{SEP}-9}} \quad (2)$$

Where $\dot{m}_{\text{steam}_{@\text{SEP}-6}}$, $\dot{m}_{\text{steam}_{@\text{SEP}-1}}$, and $\dot{m}_{\text{steam}_{@\text{SEP}-9}}$ represent the measured steam mass flow rates at the separators of Cluster 6, Cluster 1, and Cluster 9, respectively.

The brine mass flow balance equation is represented by the following equation.

$$\dot{m}_{@\text{reinjector wells}} - \dot{m}_{@\text{condensate line}} = \dot{m}_{\text{brine}_{@\text{SEP}-6}} + \dot{m}_{\text{brine}_{@\text{SEP}-1}} + \dot{m}_{\text{brine}_{@\text{SEP}-9}} \quad (3)$$

Where $\dot{m}_{\text{brine}_{@\text{SEP}-6}}$, $\dot{m}_{\text{brine}_{@\text{SEP}-1}}$, and $\dot{m}_{\text{brine}_{@\text{SEP}-9}}$ are the measured brine mass flow rates at the separators of Cluster 6, Cluster 1, and Cluster 9, respectively.

In addition to the total mass flow balance, energy flow balance is also considered to determine the enthalpy values. The energy flow balance equation, corresponding to the available flowmeters at the Unit 1 production facility of the Lumut Balai geothermal field, is as follows.

$$\dot{m}_{\text{field}} h_{\text{field}} = \dot{m}_{\text{SEP}-6} h_{\text{SEP}-6} + \dot{m}_{\text{SEP}-1} h_{\text{SEP}-1} + \dot{m}_{\text{SEP}-9} h_{\text{SEP}-9} \quad (4)$$

$$h_{field} = \frac{\dot{m}_{SEP-6} h_{SEP-6} + \dot{m}_{SEP-1} h_{SEP-1} + \dot{m}_{SEP-9} h_{SEP-9}}{\dot{m}_{field}} \quad (5)$$

Where h_{field}, $\dot{m}_{SEP-6}$, $\dot{m}_{SEP-1}$, $\dot{m}_{SEP-9}$, h_{SEP-6}, h_{SEP-1}, and h_{SEP-9} represent the weighted enthalpy of the field production fluid, the total mass flow rates at the separators of Cluster 6, Cluster 1, and Cluster 9, and the enthalpy of the production fluid at the separators of Cluster 6, Cluster 1, and Cluster 9, respectively.

3.2.2 The Mass and The Energy Balance of The Separators

In the case of the Lumut Balai geothermal field, the calibration of the total mass flow rate is performed at the separator level to achieve an accurate assessment. Each separator in the geothermal field is equipped with both steam and brine flowmeters, enabling the SALB application to perform history matching using the separator flowmeter data. The following is the total mass flow balance equation for the Cluster 1 separator, which includes four production wells.

$$\dot{m}_{SEP-1} = \dot{m}_{LMB-1.3} + \dot{m}_{LMB-1.4} + \dot{m}_{LMB-1.5} + \dot{m}_{LMB-1.6} \quad (6)$$

Where $\dot{m}_{LMB-1.3}$, $\dot{m}_{LMB-1.4}$, $\dot{m}_{LMB-1.5}$, and $\dot{m}_{LMB-1.6}$ are the total mass flow rates produced from wells: LMB-1.3, LMB-1.4, LMB-1.5, and LMB-1.6, respectively.

Each separator in the Lumut Balai geothermal field is equipped with a pressure gauge, enabling the calculation of the actual enthalpy of production fluid at each separator. Therefore, the calibration of production fluid enthalpy is also conducted at separator level. The energy flow balance equation for the Cluster 1 separator is as follows.

$$\dot{m}_{SEP-1} h_{SEP-1} = \dot{m}_{LMB-1.3} h_{LMB-1.3} + \dot{m}_{LMB-1.4} h_{LMB-1.4} + \dot{m}_{LMB-1.5} h_{LMB-1.5} + \dot{m}_{LMB-1.6} h_{LMB-1.6} \quad (7)$$

$$h_{SEP-1} = \frac{\dot{m}_{LMB-1.3} h_{LMB-1.3} + \dot{m}_{LMB-1.4} h_{LMB-1.4} + \dot{m}_{LMB-1.5} h_{LMB-1.5} + \dot{m}_{LMB-1.6} h_{LMB-1.6}}{\dot{m}_{SEP-1}} \quad (8)$$

Where $h_{LMB-1.3}$, $h_{LMB-1.4}$, $h_{LMB-1.5}$, and $h_{LMB-1.6}$ represent the enthalpies of production fluid from wells: LMB-1.3, LMB-1.4, LMB-1.5, and LMB-1.6, respectively.

3.3 Deliverability Curve and Energy Flow Rate Curve Initial Models

Equations (6), (7), and (8) involve variables for total mass flow rate and production fluid enthalpy from each well in Cluster 1: $\dot{m}_{LMB-1.3}$, $\dot{m}_{LMB-1.4}$, $\dot{m}_{LMB-1.5}$, $\dot{m}_{LMB-1.6}$, $h_{LMB-1.3}$, $h_{LMB-1.4}$, $h_{LMB-1.5}$, and $h_{LMB-1.6}$. The Lumut Balai geothermal field currently lacks instruments to measure these variables directly. Therefore, a method to estimate their values is necessary.

The total mass flow rate of a production well is related to its pressure. Wellhead is the most convenient point for measuring well pressure, as each wellhead in the Lumut Balai geothermal field is equipped with a pressure gauge. The relationship between total mass flow rate and wellhead pressure is represented by a deliverability curve. Since the Lumut Balai geothermal field is water-dominated, the wells have what is known as maximum discharge pressure. Raising the wellhead pressure beyond the maximum discharge pressure results in collapse of the flowing steam-water mixture and closure of the well, as described by James (1970).

A deliverability curve can be represented by an analytical equation that describes an ellipse situated in the first quadrant as discussed by James (1989). The presence of maximum discharge pressure shifts the elliptical axis of a deliverability curve above the x-axis. The optimal solution for this case is by using the offset elliptical equation which was solved by Davila (2017). The alternate expression of the offset elliptical equation by Davila (2017) is as follows.

$$\dot{m}_{@whp} = \dot{m}_{@mdp} + \left[\left(\dot{m}_{@whp=0\ bar} - \dot{m}_{@mdp}\right) \times \sqrt{1 - \frac{whp^2}{mdp^2}}\right] \quad (9)$$

Where $\dot{m}_{@whp}$ is the well total mass flow rate at a given wellhead pressure, $\dot{m}_{@mdp}$ is the well total mass flow rate at the maximum discharge pressure, $\dot{m}_{@whp=0\ bar}$ is the well total mass flow rate at the wellhead pressure of 0 bar, whp is wellhead pressure, and mdp is the maximum discharge pressure. $\dot{m}_{LMB-1.3}$, $\dot{m}_{LMB-1.4}$, $\dot{m}_{LMB-1.5}$, and $\dot{m}_{LMB-1.6}$ are calculated using Equation (9).

The production fluid enthalpy from a well depends on its energy flow rate. This energy flow rate is obtained by multiplying the total mass flow rate by the production fluid enthalpy. The relationship between energy flow rate and wellhead pressure resembles that of total mass flow rate and wellhead pressure (Figure 4). As a result, the equation representing energy flow rate as a function of wellhead pressure forms an elliptical curve in the first quadrant with the elliptical axis above the x-axis due to the presence of maximum discharge pressure. The analytical equation for the energy flow rate as a function of wellhead pressure is as follows.

$$(\dot{m}h)_{@whp} = (\dot{m}h)_{@mdp} + \left[\left((\dot{m}h)_{@whp=0\ bar} - (\dot{m}h)_{@mdp}\right) \times \sqrt{1 - \frac{whp^2}{mdp^2}}\right] \quad (10)$$

Where $h_{@whp}$ represents the enthalpy of the well production fluid at a given wellhead pressure, $h_{@mdp}$ denotes the enthalpy of the well production fluid at the maximum discharge pressure, and $h_{@whp=0\ bar}$ indicates the enthalpy of the well production fluid at the wellhead pressure of 0 bar.

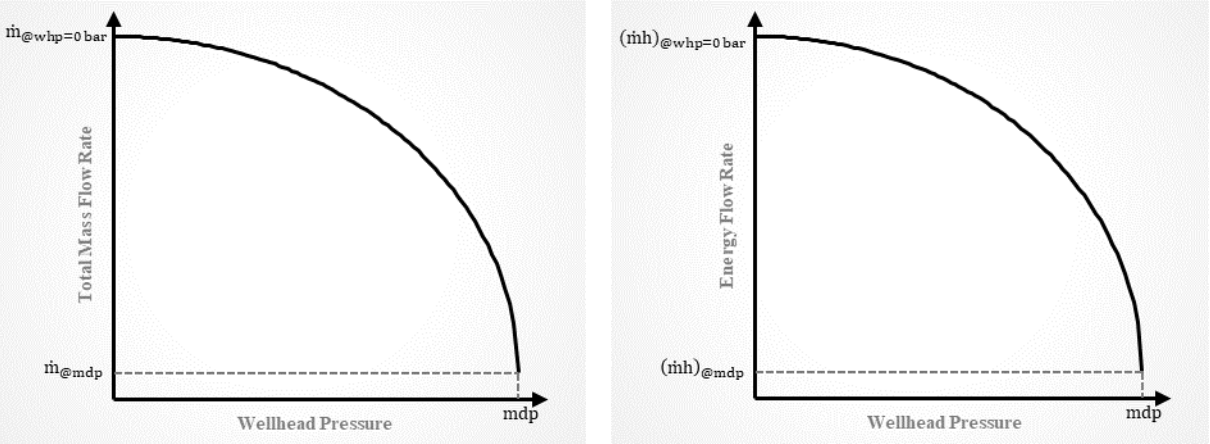

Figure 4: A well deliverability curve (left) and a well energy flow rate curve (right). The relationship between energy flow rate and wellhead pressure resembles that of total mass flow rate and wellhead pressure.

Production fluid enthalpy can be calculated using the following equation.

$$h_{@whp} = \frac{(\dot{m}h)_{@whp}}{\dot{m}_{@whp}} \tag{11}$$

$h_{LMB-1.3}$, $h_{LMB-1.4}$, $h_{LMB-1.5}$, and $h_{LMB-1.6}$ are calculated using Equation (10) and (11). Well production fluid enthalpy is necessary for calculating the dryness fraction of well production fluid using steam tables. This calculation relies on the well production fluid enthalpy value at the separator pressure. The resulting dryness fraction is then used to determine the steam mass flow rate of the production well.

Based on Equations (9) and (10), reservoir engineers will estimate the values of five variables representing the deliverability curve and the energy flow rate curve, namely $\dot{m}_{@mdp}$, $h_{@whp}$, $\dot{m}_{@whp=0\ bar}$, $h_{@whp=0\ bar}$, and mdp. Over time, the values of these five variables undergo changes, which will correspond to the alterations in both the deliverability curve and the energy flow rate curve. Before attempting to estimate changes in the values of these variables, an initial approximation is required. This approximation should reflect the original conditions of the production wells when they were initially producing together to supply electricity according to the power plant capacity. To initially approximate the values of these five variables, it is necessary to utilize production test data collected from these wells before the power plants commence commercial operation. This ensures that the initial approximation of the curve shape maintains a qualitative similarity to the shape derived from the production test data (Figure 5).

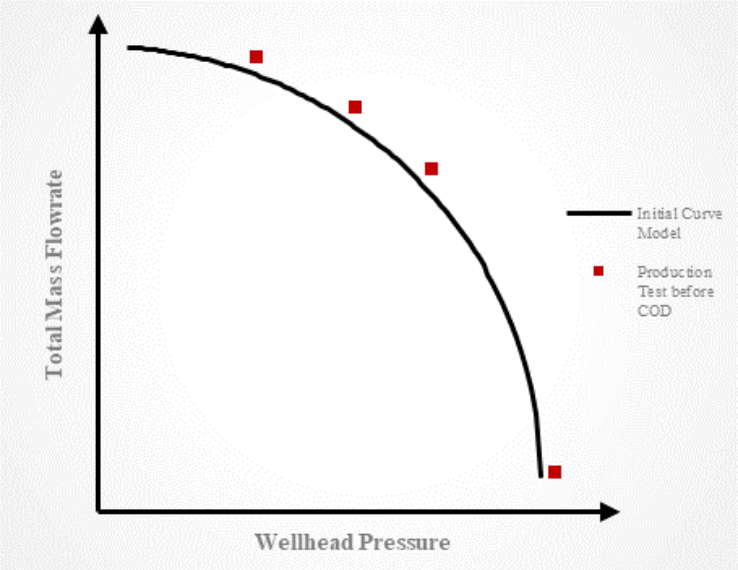

Figure 5: The initial well curve model is created to qualitatively match the shape derived from the well production test data collected before commercial operation date.

3.4 Quantitative History Matching with Separator Flowmeter Data

In the Lumut Balai geothermal field, the smallest scale of mass flow rate measurements is at separator level. Each downstream separator has flowmeters for both brine and steam, which continuously measure using sensors. Data from these flowmeters are utilized for model matching. $\dot{m}_{SEP}$ calculated by summing the mass flow rates from all production wells leading to a separator is compared with $\dot{m}_{SEP}$ obtained by adding the mass flow rates in the brine and steam lines from that separator. Similarly, h_{SEP} calculated using Equation (8) is compared with h_{SEP} obtained from steam tables, utilizing the actual data on the dryness fraction of the production fluid in the separator at the measured separator pressure.

The deliverability curve and the energy flow rate curve models from each well are used to determine the total mass flow rate and the production fluid enthalpy at a given wellhead pressure. Model matching is done daily, so data collected more frequently than daily is averaged to a daily scale.

Flowmeters installed at the separators usually have low margin of error, making it possible to perform a quantitative history matching process using their data. Three parameters will be matched with the flowmeter data at a separator: steam mass flow rate, total mass flow rate, and separator fluid enthalpy (Figure 6). This history matching process is carried out quantitatively, with a cumulative error tolerance of less than 2% for the steam mass flow rate data. Figure 7 depicts the general workflow of using the SALB application for the history matching process.

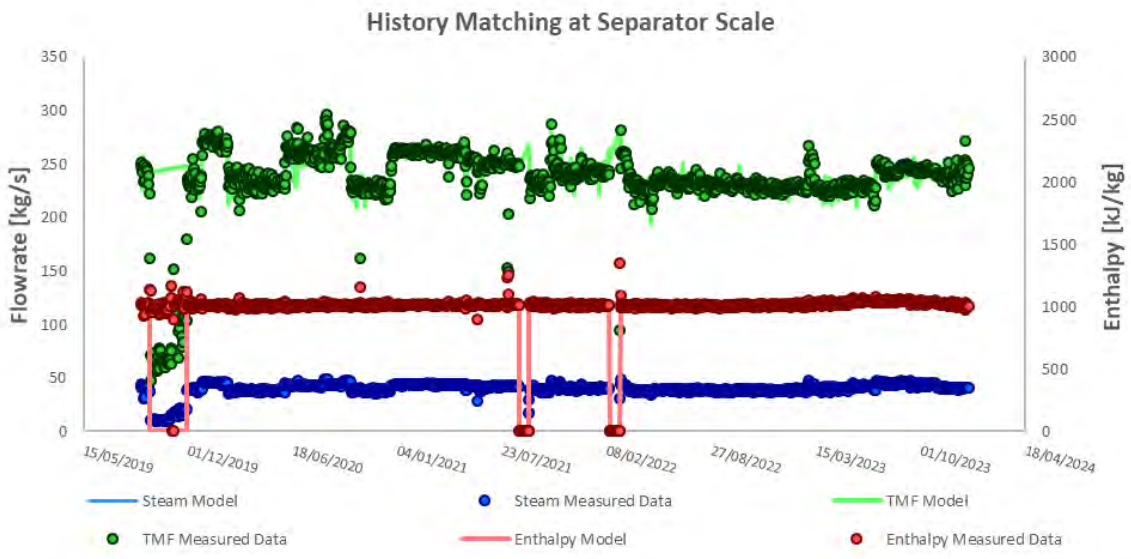

Figure 6: Three parameters are quantitatively matched with the flowmeter data at a separator: steam mass flow rate, total mass flow rate, and separator fluid enthalpy.

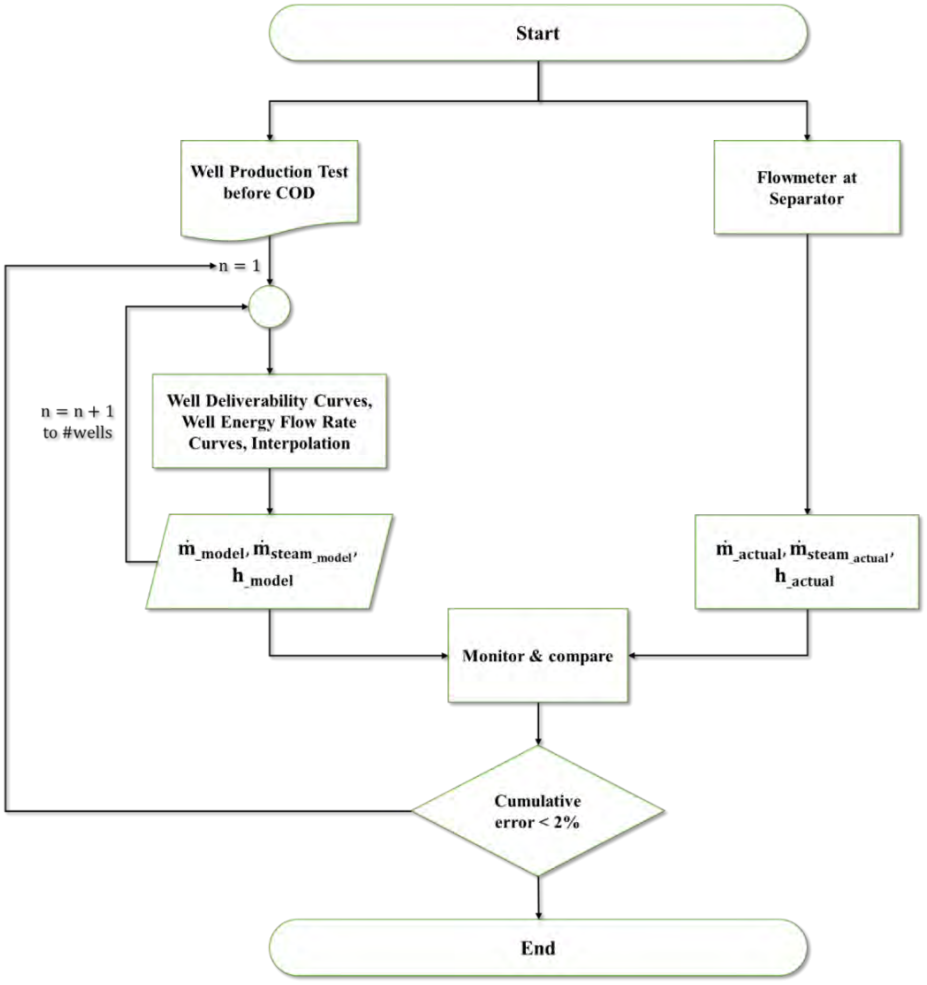

Figure 7: The general workflow of using the SALB application for the history matching process.

Unlike steam mass flow rate, which is highly accurate, total mass flow rate, calculated as the sum of steam mass flow rate and brine mass flow rate, allows for a higher margin of error. This is because brine contains many components that can clog flowmeter, leading to quicker degradation in accuracy. Consequently, since the cumulative error tolerance for the total mass flow rate is relatively large, the cumulative error tolerance for the separator fluid enthalpy values is adjusted accordingly.

3.5 Qualitative History Matching with Tracer Flow Testing Data

History matching with TFT data is qualitatively conducted due to higher error margins in chemical method measurements compared to separator flowmeter. Nevertheless, the chemical method measurements remain crucial for ensuring the credibility of the separator flowmeters. Figure 8 compares the models of total mass flow rate, steam mass flow rate, and production fluid enthalpy over time from LMB-X well alongside the TFT data. Additionally, Figure 9 presents the history matching results of the model against both the flowmeter and the TFT data for Separator-Z.

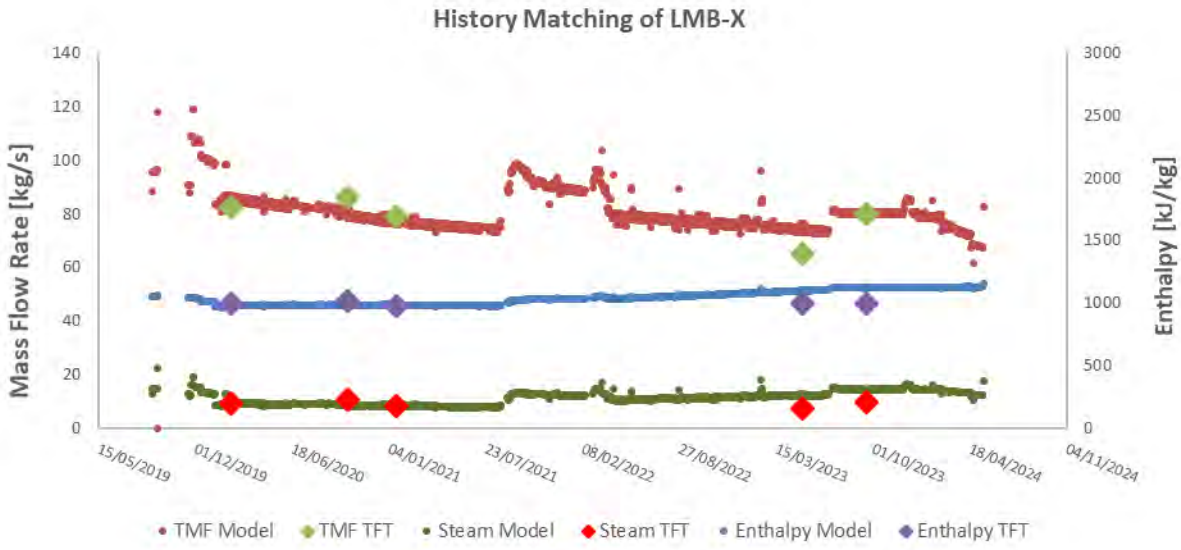

Figure 8: The models of total mass flow rate, steam mass flow rate, and production fluid enthalpy over time from LMB-X well are qualitatively matched with the measurement data obtained using the chemical method.

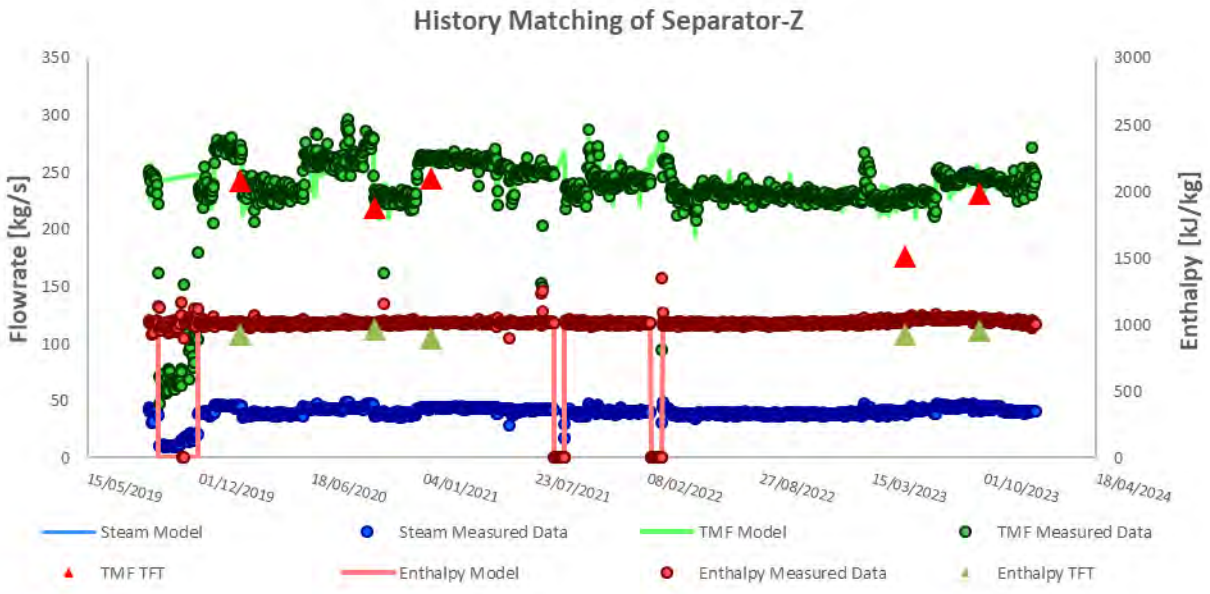

Figure 9: The history matching results of the model against both the flowmeter and the TFT data for Separator-Z.

3.6 Deliverability Curve and Energy Flow Rate Curve Monitoring

The SALB application operates with daily data, necessitating that the model aligns with the actual data on a daily basis. However, creating deliverability curve and energy flow rate curve models daily is not necessary. A critical aspect of using the SALB application is the ability to identify trends in changes to the model curves. The models generated from user input on specific days will be utilized to interpolate models for the days without model input. Therefore, new models are only required when there are significant changes in the shifting trends of the deliverability curve and the energy flow rate curve. Each well has a different timeline for model updates, so monitoring must be conducted on a per-well basis.

The timing for inputting deliverability curve and energy flow rate curve models into the SALB application is variable. Typically, the optimal time for creating a new curve model is during activities such as shutting down a well within a cluster, a major outage of a generation unit, or significantly adjusting well opening. Table 1 shows the example of historical updates for deliverability curve and energy flow rate curve models. Figure 10 illustrates the alterations in the well deliverability curve based on the parameter inputs in Table 1, while Figure 11 illustrates the alterations in the well energy flow rate curve using the same parameter inputs.

Table 1: Well deliverability curve and well energy flow rate curve model parameters inputted in the process of history matching.

Model #	Model Input Date	M_max	H_max	MDP	M_MDP	H_MDP	Remark
1	01-Sep-19	75	980	12	5	960	
2	01-Sep-19	75	980	12	5	960	Well Closed
3	14-Sep-19	75	980	12	5	960	Well Closed
4	08-Feb-20	65	980	11,5	5	960	Reduce Well Opening

6	24-Aug-21	85	980	11	5	960	
7	16-Sep-21	85	980	11	5	960	
8	01-Nov-21	85	980	11	5	960	GPP Shutdown
9	13-Feb-22	87	980	11	5	960	
10	03-Mar-22	73	980	11	5	960	Natural Decline
11	01-Jul-23	68	980	11	5	960	Natural Decline
12	08-Jul-23	72	980	11	5	960	
13	01-Jan-24	72	980	11	5	960	
14	22-Jan-24	72	981	11	5	961	
15	09-Feb-24	65	1000	11	5	965	Reservoir Boiling

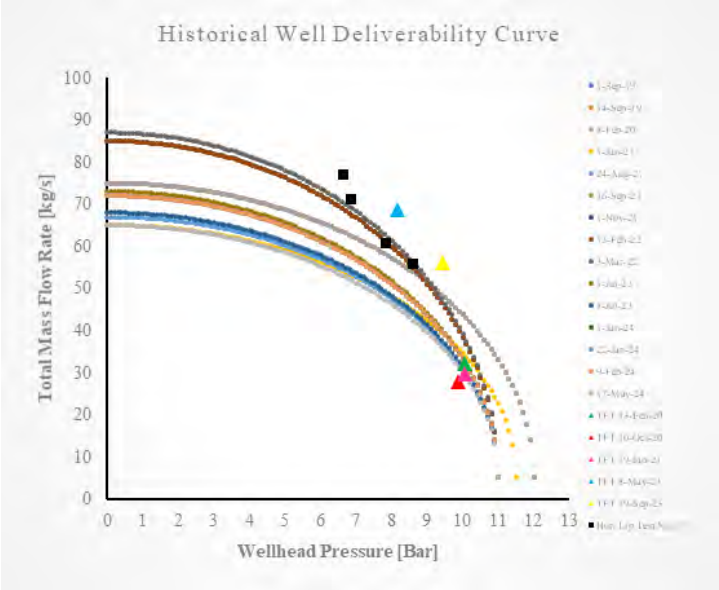

Figure 10: The deliverability curve of a production well shifts over time, leading to changing in the production flow rate at high wellhead pressure, low wellhead pressure, or both.

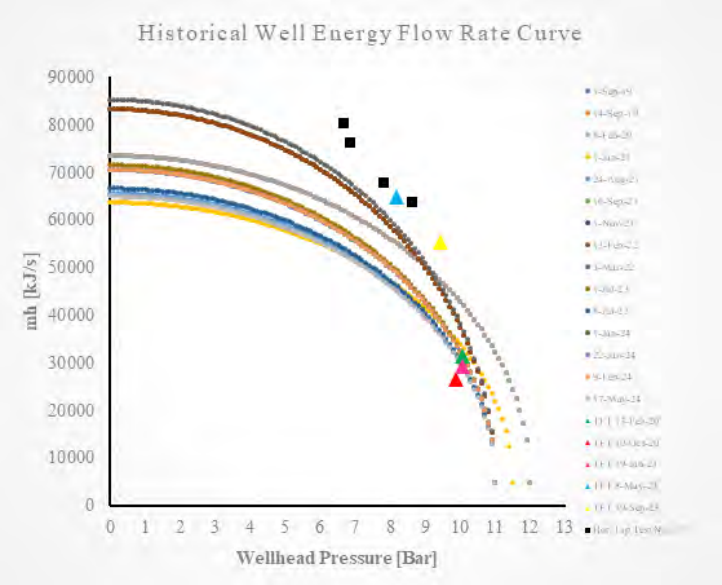

Figure 11: Energy flow rate is obtained by multiplying total mass flow rate by production fluid enthalpy. Consequently, the alterations in the energy flow rate curve qualitatively resemble that of the deliverability curve.

The SALB application inherently involves an element of estimation. The deliverability curve and the energy flow rate curve generated by the SALB application should be validated against periodic production tests data of each well. If the estimated model curves are found to be inaccurate, they can be corrected promptly based the empirical data, ensuring accurate interpretations.

3.7 Production Decline

One purpose of calculating the daily production from all the wells is to determine the field's steam availability. However, optimizing the exploitation rate of the Lumut Balai geothermal field requires choking the production wells, which limits the well production data availability on their maximum opening. This makes it challenging to accurately estimate the field's steam availability.

The SALB application uses Equations (9), (10), and (11) to determine steam production from wells at their maximum opening over time. These calculations rely on the curve models developed over time and the wellhead pressure data at the maximum opening that can be integrated into the production facility system. Figure 12 shows how production from a single well at its maximum opening changes over time, revealing decline trends for total mass flow rate, steam mass flow rate, and production fluid enthalpy. Aggregating the steam production from all the wells determines the steam availability in the Lumut Balai geothermal field. Assessing the current and the historical steam availability in the Lumut Balai geothermal field is crucial for estimating the on-stream time for makeup wells. This ensures a sufficient steam supply to the power plant, thereby maintaining its generation capacity.

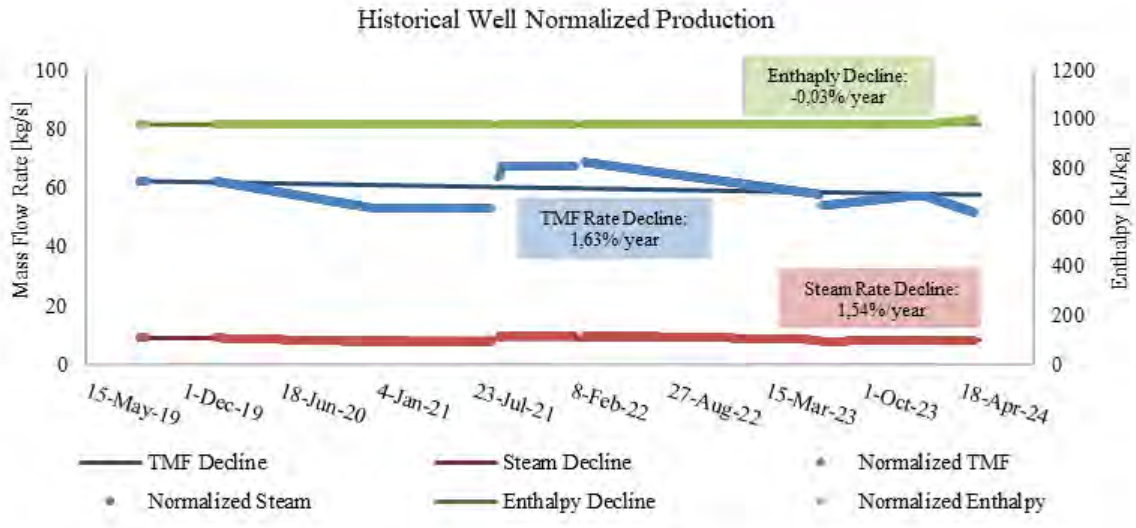

Figure 12: The well steam production at the maximum opening or the normalized condition over time is used to determine the decline rate of the field's steam availability.

3.8 Production Variance

The production variance feature is designed to highlight the disparity between the forecasted and the actual data from separator. It serves two primary functions. First, it acts as an early warning system. When the disparity between the forecasted and the actual data from a separator exceeds 10%, it may indicate abnormal well performance, prompting reservoir engineers to investigate further to identify the specific well and the cause of the high disparity.

The second function is to ensure the accuracy of the history matching models. A daily margin of error below 5% indicates that the last two curve models generated for each well are accurate (Figure 13), thus producing extrapolated curve model that remain relevant to the most recent operational data. Consequently, reservoir engineers only need to update the curve model when there is a shift in the trend for a particular well that diverges from the trend captured by the last two curve models, thereby rendering the existing extrapolated curve model obsolete.

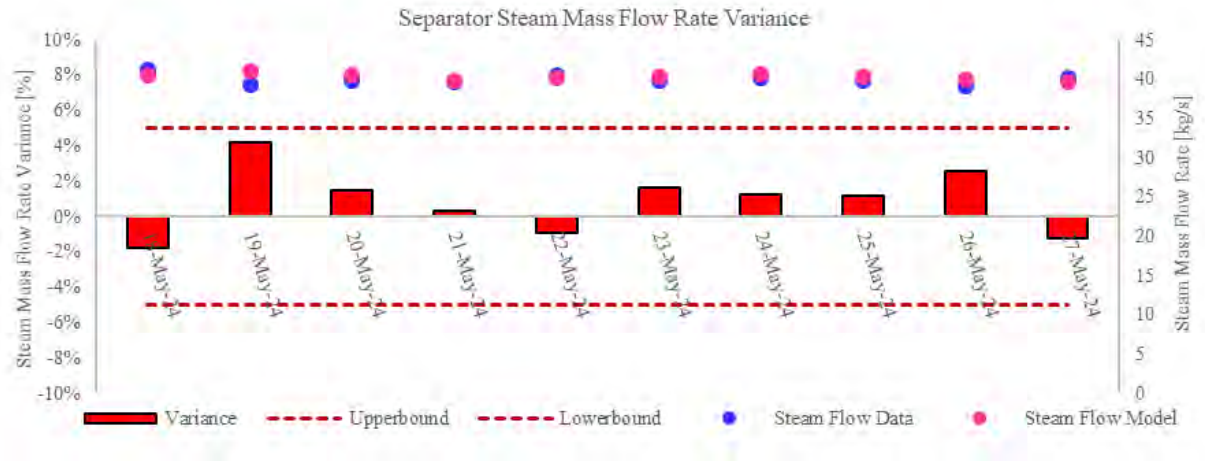

Figure 13: The production variance of Separator-Z depicts daily margin of error below 5%.

4. Conclusion

The SALB application is designed to estimate the daily production output of each production well within the Lumut Balai geothermal field. During the estimation process, the alterations in the deliverability curve and the energy flow rate curve of each well are monitored from time to time, providing insights into the behavior of the individual wells and serving as indicative of the reservoir dynamics. It is essential to validate the alterations in the deliverability curve and the energy flow rate curve of production wells against the periodic well production test data. This validation process enhances the reliability of the SALB application, which inherently relies on estimation.

The SALB application also provides the daily production value of each production well at their respective wellhead pressure at the maximum opening over time. This helps capturing the trends in the decline rate of the steam availability in the Lumut Balai geothermal field. The objective is to estimate the optimal timing for the on-stream time for makeup wells to guarantee a sufficient steam supply to the power plant, thus maintaining its operational capacity.

Acknowledgement

We extend our gratitude to Pertamina Geothermal Energy (PGE) for granting permission to publish this paper. We also highly appreciate the support of Reservoir Function and PGE Lumut Balai Area in the preparation of this paper.

ABSTRACT

Understanding and characterizing the connectivity through the induced fractured network created between injection and production wells in an Enhanced Geothermal System (EGS) is imperative to maximize enthalpy output from the system. The high temperature controls the requirements for tracer stability, and the high injection rates control the requirements for the tracers' detectability.

In this paper we will present data from a field test with extensive utilization of advanced tracer technology to gain as much understanding as possible from an enhanced geothermal system. Unique tracers were injected during each of 8 stages of fracturing in an EGS well. In addition, several tracers were injected at different times during the fracturing of one of the stages. Tracer responses were established from samples collected during clean-up. Responses from the individual zonal tracer and tracers injected at different times during the individual stage were analyzed and interpreted. After initial clean-up, and fracturing of the production well, the injection well was put into operation and a circulation tracer was added to the injected water. Sampling from the production well was then initiated. Fracture Driven Interaction (FDI) analysis was carried out on the basis of the tracer data, and the fracture communication between individual perforations and fracture networks to the production well was characterized based on the tracer results. Tracer curve analysis based on the multiple tracers injected into one particular fracturing stage was used to further enhance understanding of the fracture network complexity created in the individual stages. Residence time distribution (RTD) analysis and mass balance calculations were used to assess the different stages and characterize the volume created by the induced fracture network.

1. Introduction

Tracer testing is proven as an efficient subsurface surveillance technology and has been used extensively worldwide for applications in oil & gas, hydrology, oceanography as well as geothermal applications. Specialized tracer applications include tracking of injection fluid such as water or gas, stagnant phase quantification using the so-called single well tracer tests (SWCTT) as well as partitioning interwell tracer tests (PITT) to measure oil saturation. Tracers for subsurface applications must fulfil several important characteristics. They must be thermally, chemically and biologically stable under harsh temperature conditions and not adsorb on rock surfaces. In addition, suited tracers must be unique in the subsurface environment, have excellent analytical sensitivity and be environmentally acceptable. Typical chemical tracers are fluorinated benzoic acids for water (Galdiga and Greibrokk, 1998), or perfluorocarbons for gas (Dugstad et al., 1992; Kleven et al., 1996), or naphthalene sulfonates for high-temperature geothermal reservoirs (Rose et. al., 2000). Tracers passively follow any fluids flowing in the subsurface and therefore reflect flow dynamics. An obvious, and important information provided by tracer data is mass transport connectivity. Further interpretation, characterizing the distribution of residence time from tracer production curves, e.g. using so-called residence time distribution (RTD) analysis provide important information of the flow geometry of fractured or porous media. Even the most basic application of RTD – quantifying the produced tracer mass relative to injected at a sampling station give valuable insight of preferential flow paths and can be used to identify flow heterogeneity including fracture hits.

Enhanced geothermal systems (EGS), also sometimes called engineered geothermal systems, offer great potential to significantly expand the production of geothermal energy. Currently, geothermal power is generated from hydrothermal reservoirs. In the U.S., they are found mostly in the West. This restricts the locations of current geothermal energy developments. EGS technology will greatly expand the availability of geothermal energy resources.

The idea behind EGS is to apply methods and tools to extract heat from hot rocks below the surface which lack the same natural permeability that is required for productive hydrothermal reservoirs. This is achieved by enhancing existing fracture systems – the minute fractures and pore spaces between mineral grains so that water can be injected, heated, and produced at very hot temperatures to generate electricity in power plants on the surface.

In EGS development, two or more wells are drilled into the same volume of rock and water circulated through the hot fractured rock heats up. The volume of water injected into an EGS reservoir is very similar to the volume produced. This is different from oil and gas development where the fluids are extracted from one area of the subsurface and injected into another. The balance of water put into and removed from the ground in an EGS system minimizes the environmental impact.

Utah FORGE is a dedicated underground field laboratory sponsored by the Department of Energy (DOE) for developing, testing, and accelerating breakthroughs in EGS technologies to advance the uptake of geothermal resources around the world.

In 2020, the injection well 16A(78)-32 was drilled to a true vertical depth of 8,559 feet and a measured depth of 10,897 feet. Two years later, this well was hydraulically fractured in three stages in intervals towards the toe of the well. Microseismic monitoring mapped these fracture networks.

The production well was subsequently drilled in 2023. The two wells are parallel with lateral sections at 65 degrees to the vertical and spaced apart vertically by 300 feet. The temperature at this vertical depth reaches 225°C (435 F). Immediately following the drilling of the production well, 16B(78)-32, a brief circulation test revealed some connectivity between the two wells.

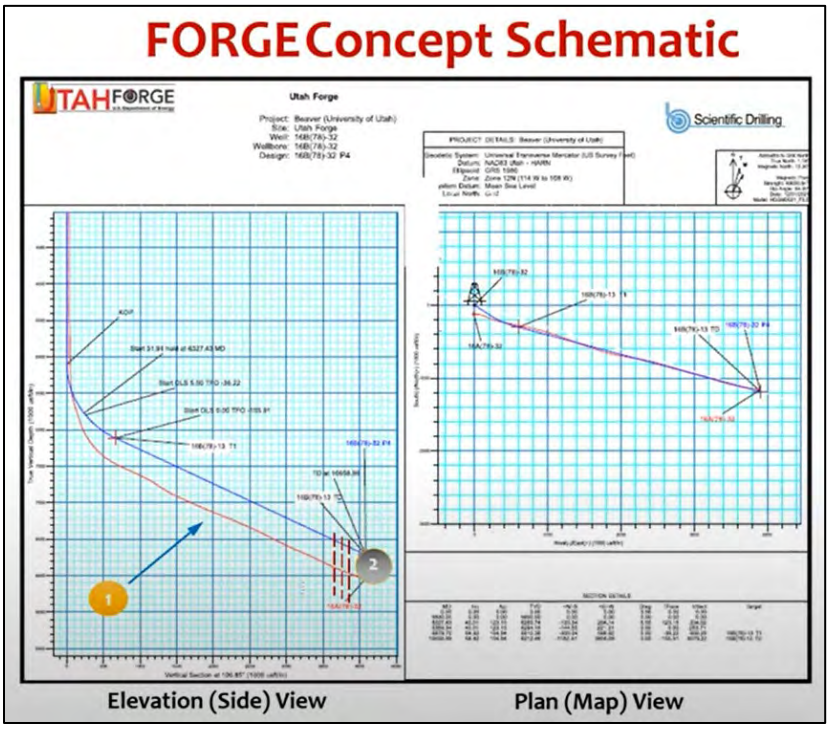

Figure 1: Injection well 16A(78)-32 (bottom) and production well 16B(78)-32 (top).

In the beginning of April 2024, commercial-scale stimulation was conducted on both wells to develop interwell connectivity. Over a period of four days, well 16A(78)-32 was hydraulically fractured in eight different stages. The three intervals previously stimulated in April 2022 were re-fractured and seven new intervals were perforated and hydraulically fractured. The fracturing fluid entering each of the intervals were traced with a unique liquid tracer, enabling increased calculation of the contribution of fluid flowed back during the clean-up of the injection well, and identification and quantification of the connectivity on a stage level. Overall, 118,000 barrels of non-potable water produced from a shallow well on the Utah FORGE site were injected. During the stimulation use of proppant, custom frac plugs, multiple clusters per stage, and different treating fluids were evaluated.

To locate fractures intersecting the production well 16B(78)-32, fiber optic cables run on the outside of the 7” production casing and cemented in place, were monitored during the stimulation of its sister well, 16A(78)-32. The recorded fiber optic signatures highlighted intervals of fracture intersection or proximity. These intervals were selected and perforated for subsequent stimulation stages that were pumped in well 16B(78)-32 (Figure 2). Stimulating both wells ensured connectivity.

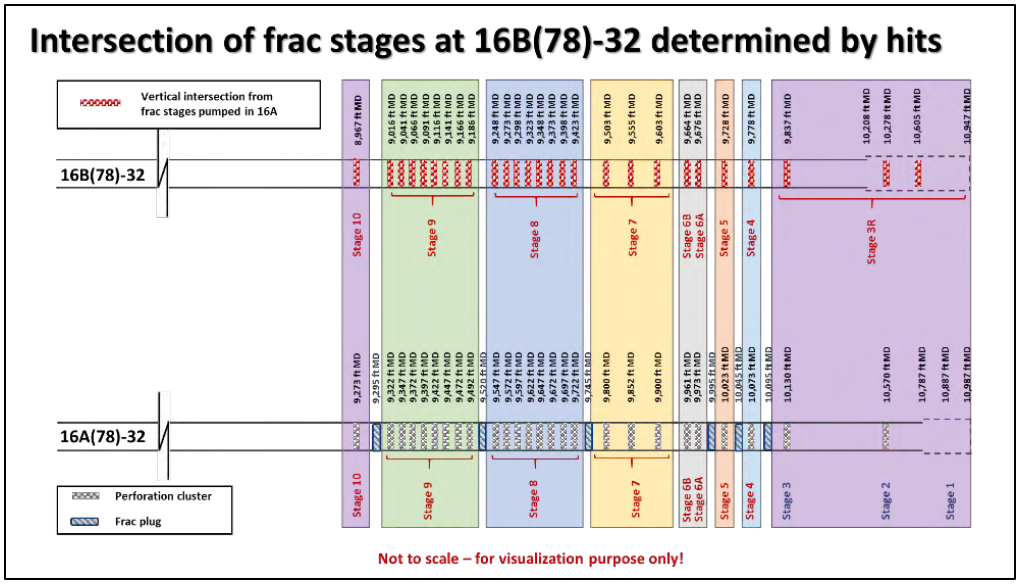

Figure 2: Schematic presentation of injection and production well with located intersections for vertical, planar hydraulic fractures.

Following the stimulation, a short circulation test was conducted. Water was injected into well 16A(78)-32 for nine hours at rates up to 16.5 barrels-per-minute (bpm). The injection led to corresponding production from well 16B(78)-32 of up to 8.2 bpm when the injection rate was 12.4 bpm, resulting in an efficiency rate of around 70% recovery. This reconfirms that conductivity between the wells was established. The temperatures of the outflow water also continually increased to approximately 139° C (282° F). Microseismic events, fiber optics data, spinner logging and tracer data showed that multiple independent flow paths had been created. The latter is described in more detail in this paper.

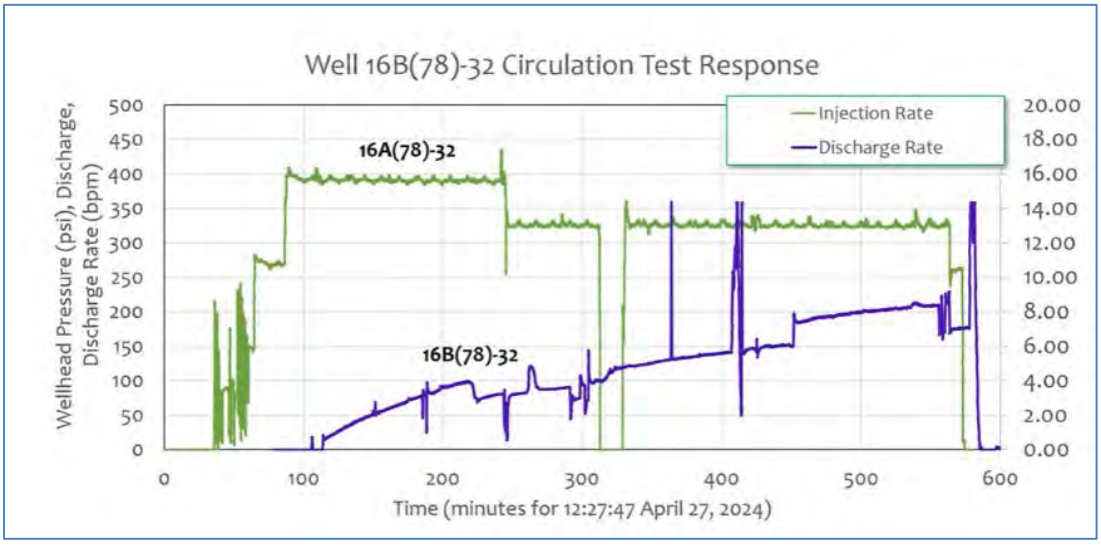

Figure 3: Injection and production rates during the circulation test.

The short circulation test capped this phase of experimentation. Hot water was produced, and the testing confirmed the potential of EGS energy production. These exciting results and the rich sets of data are being analyzed to plan additional fieldwork, including a 30-day circulation test scheduled for July 2024. All data collected are publicly available on the Geothermal Data Repository (GDR) - https://gdr.openei.org/forge.

2. Methodology

2.1 Tracer qualification

An ideal tracer for water must be thermally stable at relevant reservoir temperatures, it has to be chemically and biologically stable under reservoir conditions, the tracer should not experience sorption to rock or steel surfaces. In addition, a qualified tracer must be stable during sample storage, have excellent analytical chemical sensitivity, be environmentally acceptable and be unique in the reservoir environment. Tracer to be utilized in reservoir studies therefore must go through a rigorous testing protocol confirming that all of the above properties are met (Sanni et. al., 2015).

Due to the very high temperatures experienced in geothermal reservoirs, often exceeding 300°C, and in the case of FORGE being 225°C, the temperature-stability of the tracers is the most important parameter. Historically (Rose et. al., 2000) naphthalene sulfonates have proven stability at these elevated temperatures and have been the choice for geothermal reservoirs. Depending on availability and lab quality, the number of available tracers of the naphthalene sulfonate class is in the range of 4 to 8.

However, with the introduction of EGS with multistage hydraulic fracturing, and an objective to confirm communication between all stages of a well-pair, as well as repeated tracer usage during circulation, the required number of unique high-temperature tracers exceed the available number of naphthalene sulfonates and qualification of new geothermal tracers is required.

2.1.1 Stability testing in lab scale

A mixed tracer stock of the tracers listed in Table 1 was prepared in synthetic formation water. The tracer stock contained both newly developed tracers for geothermal as well as accepted naphthalene sulfonate tracers (2,6-NDS and 2,7-NDS) as references. The formation water tracer stock was boiled in a round bottom flask with constant addition of nitrogen gas. The mixed stock (1.5 mL) was added to inert PEEK cylinders inside steel cells and capped with nitrogen gas. All cells were sealed and placed in heating cabinets at 200°C, 220°C and 240°C. Samples were removed after 15, 21, and 34 days. Samples were analyzed and results compared to a refrigerated aliquot of the tracer stock to determine thermal degradation.
