The lab scale testing confirmed that all the tested tracers were acceptably thermally stable to be utilized at 225°C.

2.2 Field and tracer operation

2.2.1 Addition of tracers during fracturing

A unique tracer was dosed in constant concentration relative to clean fluid during the fracturing operation for each stage. The same tracer amount was designed for each stage, but due to different clean fluid volumes in each stage and operational on-the-fly changes to the planned pumping program the tracer concentration and total amount injected varied between stages. The data are summarized in Table 1. Stage 4 was extended on-the-fly to a volume larger than the safety factor taken for tracer volume, so the last ~350 bbl of the proppant stage was injected un-traced. For Stage 6 sufficient rate for sand could not be achieved and tracer dosing was stopped for periods due to the prolonged pumping time, further perforations were added (Stage 6B) but sufficient rate could not be achieved. Also, for Stage 7 sufficient rate for sand addition could not be reached. In addition to the mass balance tracers detailed in Table 1, four separate steps of Stage 8 was traced with a pulsed tracer injection according to Table 2.

Table 1 Summary of stage volumes, tracer amounts injected, and corresponding dosage concentrations.

Stage	Clean Volume (bbl)	Total sand (lbs)	Tracer name	Tracer amount (kg)	Tracer concentration (ppb)	Comment
3R	10,319	335,560	WT-17	0.86	560	
4	5,263	127,620	2,6-NDS	1.0	1,409	Minor volume un-traced
5	3,000	136,880	WT-61	0.88	1,417	
6	3,365	0	WT-102/ WT-101	0.12	1,000	Significant volume un-traced
7	12,596	0	2,7-NDS	0.60	344	
8	35,295	981,500	WT-66	0.83	196	
9	27,237	730,632	WT-60	0.67	168	
10	4,550	133,800	WT-109	0.72	1,209	

Table 2 Stage 8 pumping program with detailed information of planned step volumes and tracer amounts injected.

Step	Step name	Clean Volume (bbl)	Sand	Tracer name	Tracer amount (kg)	Comment
1	Pad	6,400	100 mesh	WT-10	1.0	Start injection after 100 bbl (10 min injection time, ~200 bbl)
2	0.5 PPA	3,200	100 mesh	WT-9	1.0	Injected at start (during 2.5 min injection time, ~200bbl)
3	0.75 PPA	3,200	100 mesh	none		
4	1.0 PPA	6,400	100 mesh	none		
5	1.0 PPA	6,400	40/70 mesh	none		
6	1.25 PPA	3,200	40/70 mesh	WT-11	1.0	Injected at end (during 2.5 min injection time, ~200bbl)
7	1.5 PPA	3,200	40/70 mesh	WT-30	1.0	Start injection 700 bbl before end (2.5 min injection time, ~200 bbl)
8	Flush	350		none		

2.2.2 Addition of tracers during circulation test

After the injection and production well had been cleaned up, a 9-hour circulation test was initiated. Water was injected into the injection well 16A(78)-32 and produced from the production well 16B(78)-32. The injection and production rates are given in Figure 3. A unique tracer was added in constant concentration to the injected fluid according to Table 3.

Table 3 Summary of stage volumes, tracer amounts injected, and corresponding dosage concentrations.

Stage	Tracer name	Tracer amount (kg)	Tracer concentration (ppb)
Circulation test	2-NS	0.174	150

2.2.3 Production and Sampling

Both injection and production wells could be routed into a geothermal separator, with a sampling point upstream of the separator. The tracer samples were collected from the upstream sampling point to avoid commingling. Sampling was executed according to a predefined sampling program designed to capture changes in tracer production profiles without the sampling personnel having to be informed on actual operational status continuously. Consequently, a large number of samples were collected, and a sub-set of these samples were selected for analysis based on actual production history. A total of ~200 samples from the clean-up of the injection well, and 23 samples from the 9-hour production test were analyzed.

Figure 4: Picture of geothermal separator and sampling point upstream of the separator.

2.2.4 Chemical Analysis

Highly sensitive and specific analytical chemical methods are needed in order to detect tracer in part per billion (ppb) and part per trillion (ppt) in complex matrixes such as produced water with additives originating from the fracturing fluid. Further, as the injected amount of a tracer is directly proportional to the limit of detection (LOD) of a tracer, a sensitive lab analysis results in a lower environmental burden and a lower carbon footprint.

The tracers listed in Table 1and Table 3 were chromatographically separated utilizing HPLC (High Performance Liquid Chromatography) using a selection of detection methods specific for each of the tracers. The limit of detection achieved in the produced water matrix was 50 part per trillion (ppt).

2.3 Interpretation of tracer signals

A significant advantage of tracer testing stems from tracer's ability to identify the origin of fluids. When unique tracer molecules are introduced and used to track fluids in the subsurface, they provide definite proof of communication based on first principles physics and mass balance considerations. Binary (yes/no) proof of communication from tracers can be expanded to assess the significance of the communication. This can be achieved by calculating the produced amount of a tracer and comparing it with the injected amount. Characterization of flow geometry is also available from tracer signals. This can be realized if we consider that added tracers yield signals containing information of characteristic timescales in a transport process.

A concrete interpretation scheme for tracer signals is to characterize the temporal moments from concentration vs. time. This can typically be done using residence time distribution (RTD) analysis (Danckwerts, 1953; Shook, 2003; Huseby et al. 2014). This analysis requires transforming tracer concentration time series, generated from concentration measurements in the sampled fluid, to a distribution of residence times for the tracers. In practice this requires multiplying concentration, $C(t)$, to fluid rate, $Q(t)$, and normalizing by the injected tracer amount, M. The resulting quantity

$$E(t) = C(t) \cdot Q_p(t)/M \tag{1}$$

is the residence time distribution. Once the residence time distribution is found, its temporal moments,

$$m_n = \int t^n E(t) dt \tag{2}$$

can be used to quantify the flow geometry. As an example, zero-order temporal moment of the residence time distributions ($m_0 = \int E(t)dt$) give the fraction of produced fluids. In a well-to-well setting, m_0 give the fraction of water produced from a specific injector. In a stagewise fracturing application it provides the amount of fluid produced back from a given stage. The first order moment $m_1 = \int t \cdot E(t)dt$ is closely related to average residence time, $\langle t \rangle = m_1/m_0$, that in turn can provide the volume of an inter-well flow geometry by multiplication with injected rate, V=$\langle t \rangle \cdot Q$. Additionally, higher order moments, such as skewness and kurtosis, carry information on the complexity of a flow. Combinations of several temporal moments is also possible. One

example is the comparison of first and second order moments used to characterize the heterogeneity of an inter-well flow, as demonstrated by Shook (2003).

3. Results and discussion

3.1.1 Cleanup of injection well 16A(78)-32

The flowback and cleanup of the injection well 16A(78)-32 was sampled to a) evaluate stage contribution and b) characterize the flow paths after the multistage hydraulic fracturing treatment. Fluid samples were collected periodically and analyzed for tracer concentration to establish tracer response curves for the 13 unique water-based tracers included in the treatment fluids as shown in Figure 5 (left). All tracers were detected at the parts-per-billion (ppb) level, with concentrations impacted by plug milling, shut in, and injection operations during cleanup.

The tracer response data demonstrates stage communication prior to milling of the plugs. At the start of cleanup operations, only stage 10 perforations were accessible due to the plug between stages 10 and 9. Tracers were detected from stages below 10. In particular, stages 9 and 8 give a strong signal, proving flow communication from those stages. However, the frac plugs that were run are, by design, flow-through plugs. This means that higher pressure from below can lift the ball off of the seat and allow flow from stages below the plug. This means that after the initial pressure reduction from the flow of Stage 10, it would be very likely that Stage 9 would start to flow through the frac plug separating stage 9 and 10. With the total amount of fluid flowed back before the start of drilling out the frac plugs in well 16A(78)-32 it is certain that fluid from Stages 8, 9 & 10 (at a minimum) would have been recovered.

This communication could a priori also be caused by flow through a micro-annulus behind casing, and/or flow through fracture connections in the reservoir. However, the strong tracer signal and the consistent observation of tracer across all stages, point to some degree of fracture network communication (e.g., far-field communication) in addition to communication through the plugs. Additional tracer interpretation is ongoing including tracer type curve analysis of the four tracer pulses in stage 8 and additional unique high-temperature tracers included in the various stages. Results of this interpretation are expected to provide additional insights into the flow profiles during cleanup operations.

The recovered masses from the cleanup of the injection well 16A(78)-32 are plotted in Figure 5 (right). Concentrations measured during cleanup were used together with production rates to calculate the amount of tracer recovered per stage and compared to the injected amount of tracer in that stage. Note that for clarity, only the 8 primary tracers added to the stages are displayed in the mass plot in Figure 5 (right).

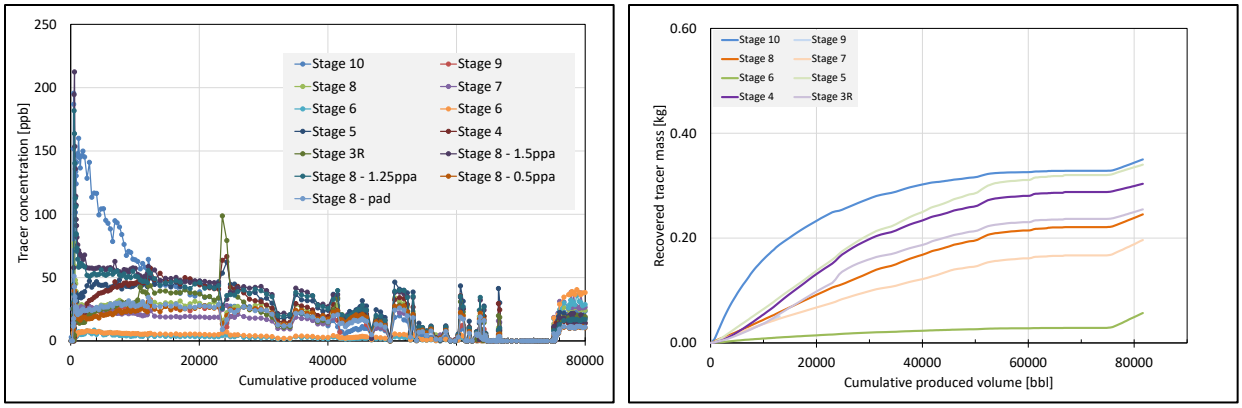

Figure 5: Tracer concentrations profiles (left) and cumulative produced tracer mass (right) during clean-up of well 16A. Eight of the injected tracer are summarized in the mass plot (right) and all 13 tracer are displayed in the concentration plot (left).

Interestingly, the fluid injected in the two unsuccessful stages; Stage 6 and Stage 7 is easily detectable even if no proppant or sand was injected in these stages. Most noticeable is the response when all plugs have been milled and the well is allowed to clean-up from all stages commingled (Figure 6).

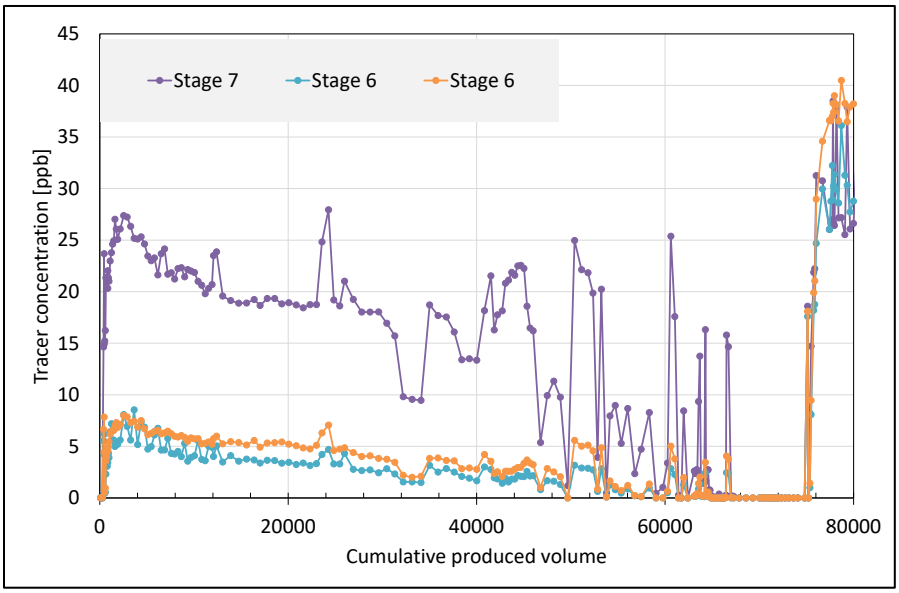

Figure 6: Tracer concentrations profiles from the two unsuccessful stages; Stage 6 and Stage 7. At about 75,000 bbl produced all plugs in the well had been milled and a clear increase in the concentration, especially for Stage 6 tracers can be observed.

3.1.2 Circulation test

Tracer concentration results for tracers injected in each of the stages in the injection well (16A(78)-32) measured in samples from the production well 16B(78)-32 are summarized in Figure 7.

Included are also the concentration profile measured in the offset well (16B(78)-32) for the tracer added to the circulation test used to verify communication and recovery during the circulation test.

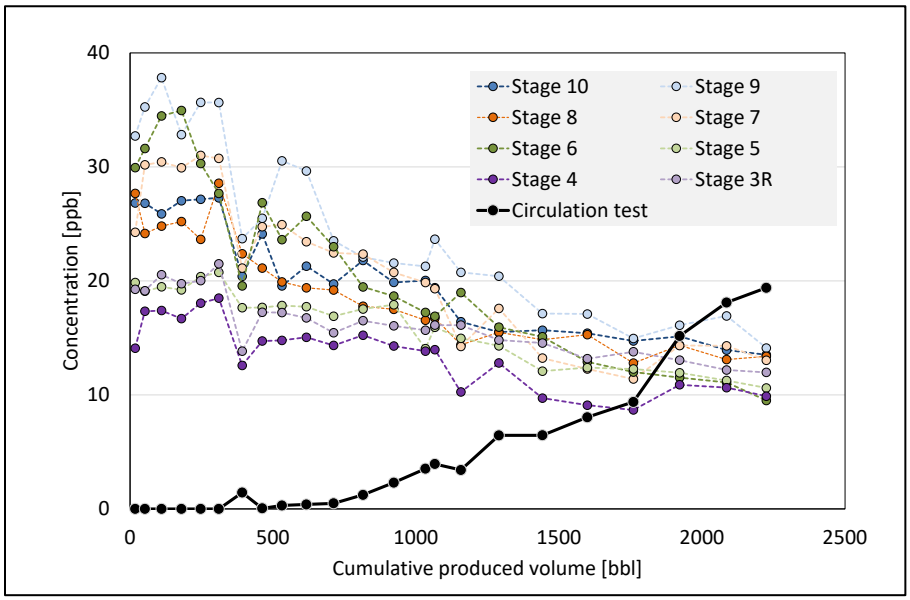

Figure 7: Tracer concentrations observed in the production well 16B(78)-32, originating from individual stages in the injection well. The circulation test tracer is also included.

An important observation from Figure 7 is that all tracers are detected at concentrations well above (~200 times) the detection limits, proving applicability of the tracer chemicals for geothermal operations at this temperature range. From the figure we see that all tracers are detected at significant concentrations at the offset well, proving communication from all stages in 16A(78)-32 towards well 16B(78)-32, even stages without proppant added (Stage 6 and Stage 7).

In Figure 7 we also observe clear correlations in the data, as well as an anticorrelation with the circulation test tracer. The circulation test tracer has a breakthrough at about 700 bbl produced volume and increased gradually after this. At the same time, the tracers from all stages decrease. The reason for this behavior is that the injected stage tracers from 16A(78)-32 are pushed towards the offset well 16B(78)-32 during fracturing and hence are found in significant amounts once the well is open for circulation. As the injected water during the circulation test arrives, the traced water (fracturing fluid) is diluted, and concentrations are declining as the circulation test water is displacing water in the fractured network. A longer duration test (30 days) was carried out in August 2024, and the continued tracer decline that is expected to be observed during that test will enable further characterization of the created fracture network.

In one of the stages (stage 8) four additional tracers were added to the fracturing fluid (Table 2). The resulting tracer profile from these tracers are plotted separately during the circulation test in Figure 8. The detection of the four pulses in the production well indicated good fracture network communication between the injection and production wells.

The concentrations measured in 16B(78)-32, together with the production rates were used to calculate the amounts recovered from each of the tracers injected across all stages (ref Equation

2). These amounts are summarized in Table 4. From the table we see that a fairly consistent amount of tracer (in the order of 0.5-1%) was recovered during the circulation test.

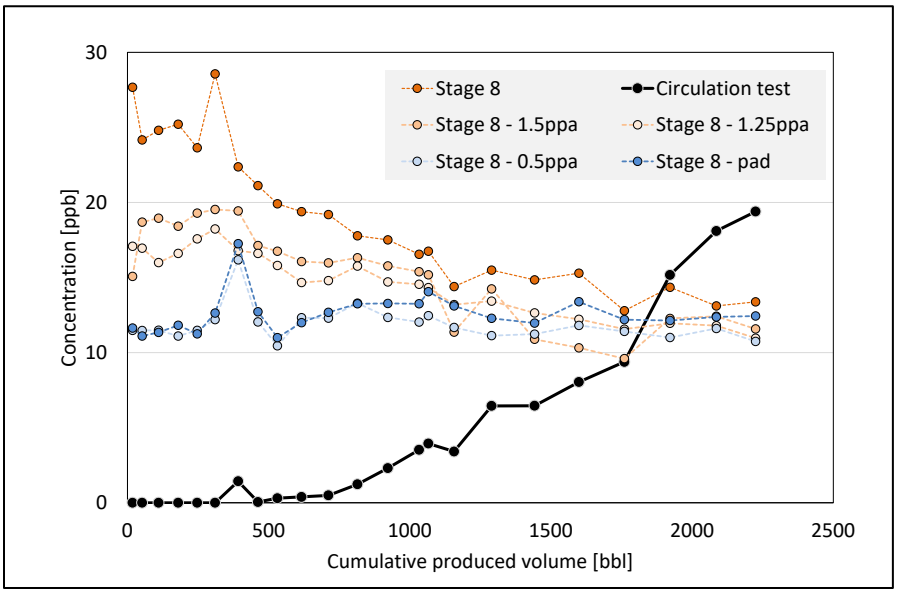

Figure 8: Tracer concentrations observed in the production well 16B(78)-32, originating from individual stages in the injection well. The circulation test tracer is also included.

Table 4 Summary of recovery of the different tracers during the circulation test.

Stage	Tracer	Injected amount (g)	Recovered amount (g)	Relative recovery (% of injected)
3R	WT-17	860	5.5	0.63
4	2,6-NDS	1,000	4.5	0.45
5	WT-61	880	5.3	0.61
6	WT-102 / WT-101	120 / 120	8.0 / 6.6	0.67 / 0.55
7	2,7-NDS	600	6.7	1.1
8	WT-66	830	6.2	0.74
8-pad	WT-10	1,000	4.4	0.44
8-0.50 ppa	WT-9	1,000	4.2	0.42
8-1.25 ppa	WT-11	1,000	4.9	0.49
8-1.5 ppa	WT-30	1,000	5.0	0.50
9	WT-60	670	7.9	1.2
10	WT-109	720	6.6	0.92
Circulation test	2-NS	174	2.0	1.2

4. Conclusions

Precise verification of fracture hits between injector and producer in a geothermal EGS well-pair was demonstrated utilizing tracer technology. Introduction of new high-temperature tracers to geothermal application enabled an increased resolutions compared to what could be achieved by the accepted naphthalene sulfonate tracers.

Calculation of recovered tracer from each stage during both clean-up and circulation enables comparison of different fracture strategies, and further interpretation of the results is expected to yield better characterization of the created fracture network.

Acknowledgement

Funding for the Utah FORGE project is provided by the U.S. DOE under grant DE-EE0007080 “Enhanced Geothermal System Concept Testing and Development at the Milford City, Utah FORGE Site.” The University of Utah thanks the many stakeholders who are supporting this project, including Smithfield, Utah Trust Lands Administration, and Beaver County as well as the Utah Governor’s Office of Energy Development.

Margrete Lie for managing and handling all lab analysis from both stability tests and field samples. Partho Giri for operational coordination and execution of tracer injection and sampling.

A Wellbore Model Approach for Scaling Prediction and Condition Assessment

Magnus Thor Jonsson

University of Iceland

Keywords

Monte Carlo Particle Filter, Wellbore Model, Scaling, Condition Evaluation

ABSTRACT

This research presents a novel approach to estimating scaling and operational conditions of geothermal wells using a Monte Carlo Particle Filter on a wellbore model. Scaling, the deposition of minerals within the wellbore, significantly impacts the operational efficiency and longevity of geothermal wells. The proposed wellbore model integrates thermodynamic and fluid dynamic principles to predict pressure drop through the well, and, using the Monte Carlo Particle Filter, estimates both scaling and bottom hole pressure.

The study begins with an overview of geothermal wells and the common challenges faced in geothermal operations due to pressure drawdown. A critical operational question is whether the drawdown is due to scaling or bottom hole pressure decrease, which determines whether the well should be cleaned or if a new well needs to be drilled. The paper introduces the Monte Carlo Particle Filter and the wellbore model, detailing their theoretical foundations and computational methodology. The wellbore model simulates the complex interactions between geothermal fluid and the wellbore environment under varying operational conditions, identifying critical factors influencing scaling.

By analyzing data from existing geothermal wells alongside simulations conducted through the model, the research validates its effectiveness in predicting scaling occurrence and bottom hole pressure drawdown. Furthermore, the model offers insights into other well parameters, such as enthalpy, pressure, and flow rate adjustments.

1. Introduction

Geothermal energy is a renewable and sustainable resource with significant potential to contribute to the global energy mix. It harnesses the natural heat generated and stored within the Earth, primarily sourced from the radioactive decay of isotopes in the mantle and crust, as well as residual

heat from the planet's formation. Effective management and utilization of geothermal energy require detailed knowledge of geothermal reservoir conditions and wellbore dynamics.

Monitoring and modeling geothermal wells are crucial for understanding reservoir behavior, optimizing production, and ensuring sustainable operation. Traditional methods of reservoir assessment and wellbore simulation often face challenges in accurately estimating subsurface conditions due to the complex nature of geothermal systems. These complexities include multiphase flow, high-temperature environments, and varying geological formations (Axelsson 2003).

A production well in a geothermal power plant serves as a conduit to the reservoir, transporting geothermal fluid to the plant. When the pressure at the wellhead decreases, it raises questions about whether the cause is pressure drawdown in the reservoir, reduced flow from the reservoir to the well, or scaling (reduced diameter) within the well.

The Monte Carlo Particle Filter (MCPF), also known as Sequential Monte Carlo (SMC), is a statistical method that provides robust solutions for state estimation problems in dynamic systems. By leveraging a set of particles to represent possible states and iteratively updating them based on new observations, the MCPF can handle non-linearities and non-Gaussian noise effectively (Doucet and Johansen 2007). This makes it an ideal candidate for estimating the conditions of geothermal wells, where the system dynamics are often complex and uncertain.

Wellbore modeling is essential for simulating the behavior of fluids within a geothermal well. It involves understanding the interactions between fluid phases, heat transfer, and pressure dynamics. Accurate wellbore models enable the prediction of well performance, identification of potential issues, and optimization of operational parameters. Combining wellbore models with advanced state estimation techniques like the MCPF can enhance the reliability and accuracy of geothermal well assessments.

This paper presents an innovative approach that integrates the Monte Carlo Particle Filter with a wellbore model, Flowell, to estimate the conditions of geothermal wells. The proposed method aims to improve the accuracy of state estimations by incorporating both real-time observational data and sophisticated modeling techniques. The following sections will discuss the theoretical background of the Monte Carlo Particle Filter, the fundamentals of wellbore modeling, and the implementation of the integrated approach. Furthermore, the paper will present case studies demonstrating the effectiveness of this method in various geothermal settings, highlighting its potential benefits for the geothermal industry.

By advancing the methodologies used for geothermal well assessment, this research contributes to the development of more efficient and sustainable geothermal energy management practices. The integration of Monte Carlo Particle Filters with wellbore models represents a significant step forward in accurately understanding and managing geothermal resources, ultimately supporting the broader adoption and optimization of geothermal energy.

This paper is structured as follows: Section 2 provides an overview of geothermal production wells. Section 3 presents the Sequential Monte Carlo or Monte Carlo Particle Filter method. Section 4 discusses the wellbore model Flowell. Section 5 presents the results of the study, highlighting parameter estimation for Flowell with both pressure drawdown and scaling or

diameter reduction. Section 6 discusses the implications of the findings and potential applications of the model. Finally, Section 7 concludes the paper with a summary of key insights and recommendations for future research.

2. Geothermal Production Wells

An important part of geothermal energy production are geothermal production wells, which serve as conduits between subterranean heat sources and surface-level energy conversion systems. Understanding the design, function, and management of these wells is crucial for optimizing geothermal energy extraction and ensuring the sustainability of the resource.

Geothermal production wells are typically drilled into geothermal reservoirs, which are areas of the Earth's crust that contain a high concentration of heat, often in the form of hot fluid or steam. The primary objective of a production well is to transport the geothermal fluids from these reservoirs to the surface, where the heat energy can be converted into electricity or used for direct heating applications as shown in Figure 1.

Once at the surface, the hot fluid and steam are directed to a geothermal power plant. There are three main types of geothermal power plants: dry steam, flash steam, and binary cycle. Dry steam plants take steam directly from fractures in the ground and use it to drive a turbine that generates electricity. Flash steam plants draw high-pressure hot fluid from deep underground into a low-pressure environment, causing the rapid vaporization or "flashing" of the fluid into steam. This steam is then used to drive a turbine. Binary cycle plants transfer the heat from geothermal hot fluid to another liquid that boils at a lower temperature than fluid; this secondary liquid is vaporized and used to turn a turbine.

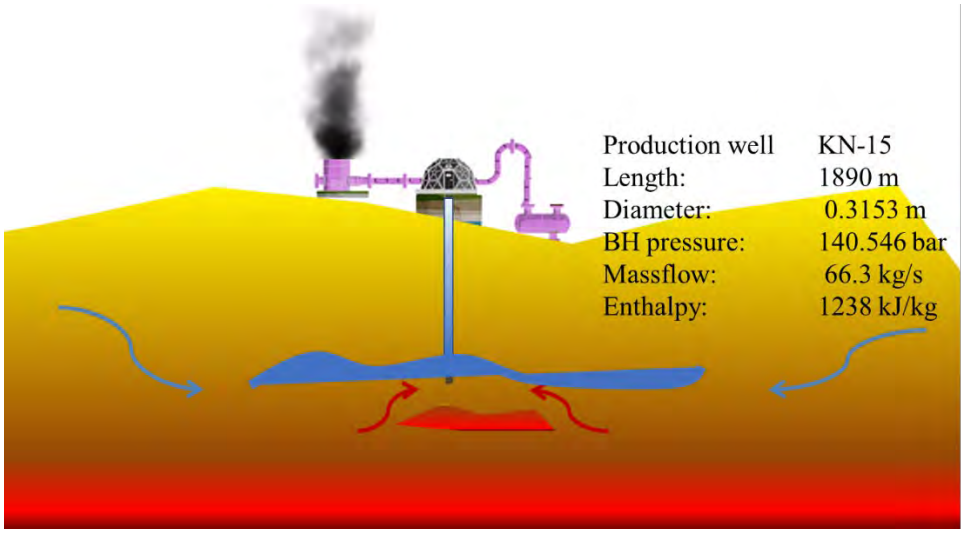

Figure 1: Production well KN-15

The construction of a geothermal production well involves several stages. Initially, exploratory drilling is conducted to locate a viable geothermal reservoir. Once a suitable location is identified, the well is drilled to reach the geothermal resource, often at depths ranging from a few hundred meters to several kilometers. The well is then cased with steel and cement to prevent the walls from collapsing and to protect the surrounding environment from contamination. The wellbore,

the actual hole drilled into the Earth, must be designed to withstand high temperatures and pressures typically found in geothermal systems.

One of the challenges in geothermal production wells is managing the pressure and flow of geothermal fluids. The pressure at the wellhead, the surface point of the well, is a key indicator of the well's performance. A reduction in wellhead pressure can signal various issues, such as pressure drawdown in the reservoir, reduced permeability, or scaling within the well. Scaling refers to the deposition of minerals from the geothermal fluid onto the inner surfaces of the wellbore, which can significantly reduce the well's diameter and impede fluid flow.

Accurate modeling and monitoring of wellbore dynamics are essential for the effective management of geothermal production wells. Traditional methods of wellbore simulation and reservoir assessment often struggle to account for the complex interactions within geothermal systems. These interactions include multiphase fluid flow, heat transfer, and the varying geological characteristics of the reservoir. Advanced modeling techniques, such as wellbore models combined with state estimation methods like the Monte Carlo Particle Filter (MCPF), offer a more robust approach to understanding and predicting well performance under different operational conditions.

Effective management of a geothermal reservoir involves precise control over various operational parameters, such as the wellhead valve openings, production rates for each well site or area, and the injection rates. The complexity of these tasks is compounded by the diversity of wells within the reservoir. Geothermal production wells are a critical component of geothermal energy systems, facilitating the extraction of heat from subterranean reservoirs. Understanding the complexities of wellbore dynamics and employing advanced modeling techniques are essential for optimizing well performance and ensuring the sustainable utilization of geothermal resources.

3. Sequential Monte Carlo

The Sequential Monte Carlo (SMC) or more specific type known as Monte Carlo Particle Filter is a method used for estimating the state of a system that evolves over time. In this study the time or the step is the location or depth of the measuring points for pressure in the well. The method uses a set of particles (samples) to represent the probability distribution of the state and updates these particles over time based on new observations (Doucet and Johansen 2007). The method used in this research is based on following algorithm:

1. Initialization

A set of N particles representing possible states of the wellbore conditions, p, for downhole pressure, $\dot{m}$ for mass flow, h for enthalpy, and d, for diameter is generated. Each particle has an associated weight based on its likelihood.

Let $\left\{p_i^{(0)}, \dot{m}_i^{(0)}, h_i^{(0)}, s_i^{(0)}\right\}_{\{i=1\}}^{N}$ be the initial particles sampled from a prior distribution.

2. Prediction Step

At each time step n ,each particle propagates through the system's model, simulating the physical processes affecting pressure and diameter. This step involves applying the Flowell model to each particle.

For a given particle i at time or step n,

$$y_i^{(n)} = f\left(x_n, p_i^{(n-1)}, \dot{m}_i^{(n-1)}, h_i^{(n-1)}, d_i^{(n-1)}\right) \tag{1}$$

where f is the Flowell function, and x_n is the input or the location, depth at step n.

3. Update Step

Observational data (measured pressure) is used to update the weights of the particles, making more likely particles represent the true state more accurately. The weights of each particle are updated based on how well the particle's prediction matches the observed data. This involves calculating the likelihood of the observation given the particle's state.

For particle i, the weight update equation is,

$$w_i^{(n)} = w_i^{(n-1)} \cdot \mathcal{L}(y_n | y_i^{(n)}) \tag{2}$$

where $\mathcal{L}$ is the likelihood function, and y_n is the observed data at step n.

Assuming Gaussian noise in the observations, the likelihood can be expressed as,

$$\mathcal{L}(y_n | y_i^{(n)}) = \exp\left(-\frac{\left(y_n - y_i^{(n)}\right)^2}{2\sigma^2}\right) \tag{3}$$

where σ is the standard deviation of the observation noise.

The weights are normlized so that they sum to 1,

$$\widetilde{w}_i^{(n)} = \frac{w_i^{(n)}}{\sum_{j=1}^{N} w_j^{(n)}} \tag{4}$$

4. Resampling Step

Particles with higher weights are sampled to form a new set of particles, emphasizing states that better fit the observational data. To avoid particle degeneracy where a few particles have all the weight, the particles are resample based on their weights. This step generates a new set of particles by sampling with replacement from the current set, according to their weights.

The resampling process involves, drawing N new particles $\left\{p_i^{(n)}, \dot{m}_i^{(n)}, h_i^{(n)}, d_i^{(n)}\right\}_{i=1}^{N}$ from the current set $\left\{p_i^{(n-1)}, \dot{m}_i^{(n-1)}, h_i^{(n-1)}, d_i^{(n-1)}\right\}_{i=1}^{N}$ with probabilities $\left\{\widetilde{w}_i^{(n)}\right\}_{i=1}^{N}$.

5. Estimation

The final step is to estimate the parameters based on the particles. The estimate of a parameter θ (e.g., $p, \dot{m}, h$ or d) at time or step n can be computed as the weighted average of the particles,

$$\hat{\theta}^{(n)} = \sum_{i=1}^{N} \tilde{w}_i^{(n)} \theta_i^{(n)} \tag{5}$$

if we use equal weights after resampling, the estimate are:

$$\begin{aligned} \hat{p}^{(n)} &= \frac{1}{N} \sum_{i=1}^{N} p_i^{(n)} \\ \hat{\dot{m}}^{(n)} &= \frac{1}{N} \sum_{i=1}^{N} \dot{m}_i^{(n)} \\ \hat{h}^{(n)} &= \frac{1}{N} \sum_{i=1}^{N} h_i^{(n)} \\ \hat{d}^{(t)} &= \frac{1}{N} \sum_{i=1}^{N} d_i^{(t)} \end{aligned} \tag{6}$$

At time $n = 1$, the algorithm performs three sequential tasks. First new particles are sampled from the initial proposal distribution. Then, the weights are given same value and normalized according to Eq.4. Finally, the particles are resampled, according to a resampling scheme, and all new particles are given equal weight. At time n > 1, the algorithm also performs three sequential tasks. First new particles are sampled from the proposal distribution. The weights are calculated according to Eq. (3) and normalized according to Eq. (4). Finally, the particles are resampled, according to a resampling scheme, and parameter estimated.

4. FloWell Wellbore Model

Flow in geothermal reservoirs, wellbores, and pipelines, involves the interaction of different phases (liquid, vapor, solids). This interaction affects energy, momentum, and mass exchange. The following sections describe the mathematical approaches used in the wellbore simulator FloWell (Gudmundsdottir and Jonsson, 2015), based on the principles of conservation of mass, momentum, and energy.

The governing equations for single-phase flow are as follows:

Continuity Equation (Mass Conservation),

$$\frac{d\rho}{dt} + \rho \nabla \cdot \boldsymbol{u} = 0 \tag{7}$$

Energy Equation,

$$\frac{d}{dt} \left(\frac{1}{2} \rho u^2 + \rho g h + \rho e\right) = 0 \tag{8}$$

Momentum Equation,

$$\rho \frac{d\boldsymbol{u}}{dt} = -\nabla p + \rho \boldsymbol{g} - f \frac{\boldsymbol{u}^2}{d} \tag{9}$$

Where f is the friction factor, calculated using Blasius equation for smooth pipes,

$$f = 0.079\,\mathrm{Re}^{-0.25} \tag{10}$$

and Swamee-Jain equation for rough pipes,

$$f = \frac{0.25}{\left(log_{10}\left(\frac{\epsilon}{3.7d} + \frac{5.74}{\mathrm{Re}^{0.9}}\right)\right)^2} \tag{11}$$

The Reynolds number Re is defined as,

$$\mathrm{Re} = \frac{(\rho\, u\, d)}{\mu} \tag{12}$$

The continuity, energy, and momentum equations for single-phase flow are combined into a single system,

$$\begin{bmatrix} \rho & u\frac{\partial \rho}{\partial p} & u\frac{\partial \rho}{\partial h} \\ \dot{m}u & 0 & \dot{m} \\ \rho u & 1 & 0 \end{bmatrix} \frac{d}{dz} \begin{bmatrix} u \\ p \\ h \end{bmatrix} + \begin{bmatrix} 0 \\ \dot{m}g + \dot{Q} \\ \rho g + \frac{\rho f}{2\,g}\, u\, u \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \tag{13}$$

In two-phase flow, both liquid and vapor phases are considered. Assuming constant pipe diameter and uniform velocity (u), the equations are:

Continuity Equation:

$$\partial \frac{\alpha\, \rho_g}{\partial\, t} + \nabla \cdot \left(\alpha\, \rho_g\, u_g\right) + \frac{\partial\left((1-\alpha)\rho_l\right)}{\partial\, t} + \nabla \cdot \left((1-\alpha)\rho_l\, u_l\right) = 0 \tag{14}$$

Energy Equation:

$$\frac{d}{dt}\left(\frac{1}{2}\rho u^2 + \rho g h + \rho e\right) = 0 \tag{15}$$

Using the mass fraction x and uniform velocity u:

$$\frac{\partial\left(\alpha\rho_g h_g \ + \ (1-\alpha)\rho_l \, h_l\right)}{\partial \, t} + \nabla \cdot (\alpha\rho_g h_g \boldsymbol{u}_g + (1-\alpha)\rho_l \, h_l \, u_l) \ = \ 0 \tag{16}$$

Where γ is:

$$\gamma \ = \frac{u_g - \ u_l}{u} \tag{17}$$

Momentum Equation:

$$\rho \frac{d\boldsymbol{u}}{dt} \ = \ -\nabla p \ + \rho g \ - \Phi^2 \frac{f \boldsymbol{u}^2}{d} \tag{18}$$

where Φ^2 is the frictional correction factor and in this study Friedel's (1979) Correction Factor is used,

$$\Phi^2 \ = \ E \ + \frac{3.24 \, F^{0.045} \, H^{0.035} \left(\frac{\rho_l}{\rho_g}\right)^{0.035} \left(\frac{\mu_l}{\mu_g}\right)^{0.045} \left(\frac{1-x}{x}\right)^{0.035}}{\left(\frac{1}{x} \ + \frac{\rho_l}{\rho_g}\left(\frac{1}{1-x}\right)\right)^{0.9}} \tag{19}$$

The void fraction, which represents the space occupied by gas or vapor, is crucial for predicting pressure behavior.

The Lockhart-Martinelli (1949) correlation:

$$\alpha \ = \frac{1}{1 \ + 0.28 \left(\frac{1-x}{x}\right)^{0.64} \left(\frac{\rho_l}{\rho_g}\right)^{0.36} \left(\frac{\mu_g}{\mu_l}\right)^{0.07}} \tag{20}$$

The continuity (Eq.14), energy (Eq.15), and momentum (Eq.18) equations for two-phase flow are combined into a following system,

$$\begin{bmatrix} \rho_l & u\frac{\partial \rho_l}{\partial p} & 0 \\ \gamma u & \frac{u^2}{2}\frac{\partial \gamma}{\partial p} & 1 + \frac{u^2}{2}\frac{\partial \gamma}{\partial h} \\ \eta \rho_l u & 1 + \rho_l u^2 \frac{\partial \eta}{\partial p} & \rho_l u^2 \frac{\partial \eta}{\partial h} \end{bmatrix} \frac{d}{dz}\begin{bmatrix} u \\ p \\ h \end{bmatrix} + \begin{bmatrix} 0 \\ g + \frac{\dot{Q}}{\dot{m}} \\ ((1-\alpha)\rho_l + \alpha\rho_g)g + \Phi^2 \frac{\rho_l f}{2\,g} \, u^2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \tag{21}$$

The one-phase and two-phase systems are solved using numerical integration, either from the bottom of the well to the top or from the top to the bottom.

4. Results

To verify the method, it was applied to well KN-15, where the pressure changes down the well has altered over a 10-year period. Measurements were first taken before the well was connected to the system on February 26, 2003. When the wellhead pressure dropped after 10 years of use, it was decided to take new measurements on June 4, 2013. The results of these measurements are shown in Figure 2.

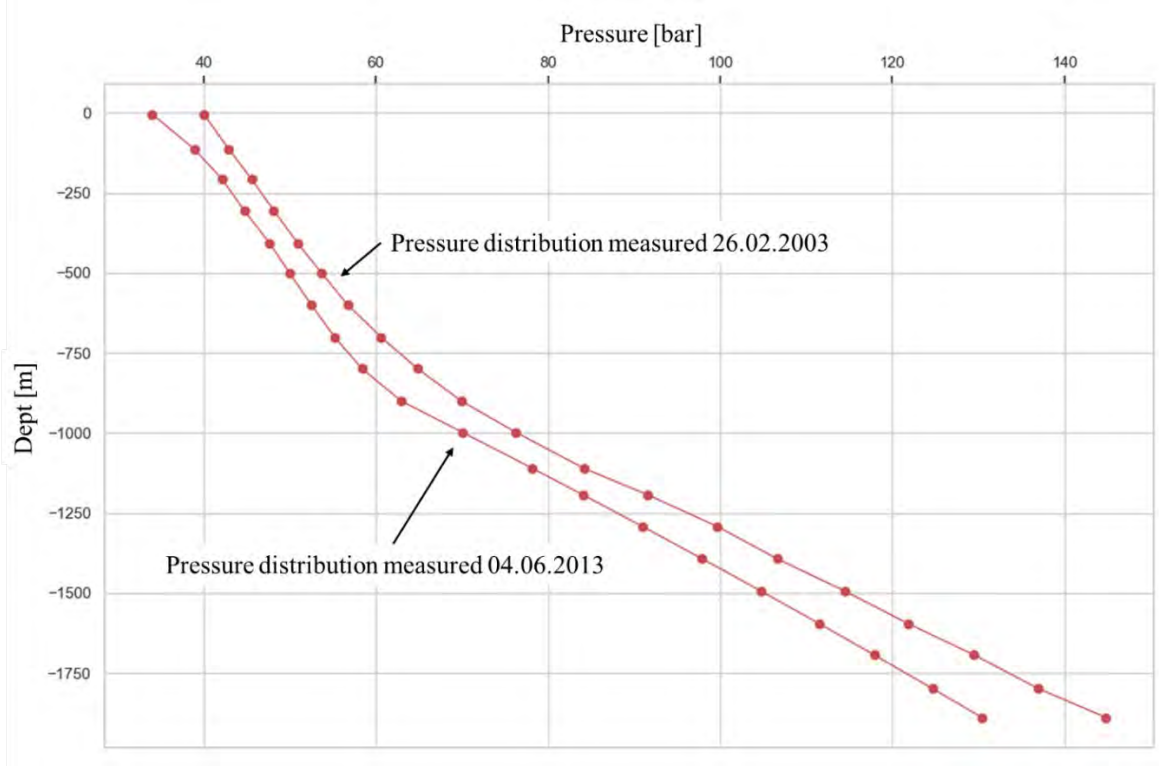

Figure 2: Pressure changes and pressure versus depth for well KN-15 measured 2003 and 2013.

The purpose of the particle filter is to approximate the uncertain values used in the Flowell wellbore model. The particle filter was set up with N = 1000 particles for each undetermined variable. The standard deviation had to be tuned for stable filter performance. If it was too high, the particle filter was unable to converge to any solution; if it was too low, the particle filter made no attempt to explore the solution domain. The pressure measurements presented in this study were obtained using a standard deviation of $\sigma = 2$ bar.

The transition model was fed predefined minimum and maximum allowed values for each particle to ensure the particles stayed within a reasonable expected range. If a particle's value after the random step was outside the range, it was forced to the corresponding boundary value.

For the results presented in this study, the specified ranges for each particle, $(p_i, \dot{m}_i, h_i, s_i)$ with minimum (x_{min}) and maximum (x_{max}) were defined as follows:

x_{max} = (147.50 bar, 69.6 kg/s, 1308.8 kJ/kg, 0.3311 m)

x_{min} = (137.67 bar, 64.9 kg/s, 1221.5 kJ/kg, 0.290 m)

Table 1 presents the key parameters of the well based on the measurement taken on February 26, 2003. To verify these values, the particle filter along with the wellbore model, was used. The corrected values are also shown in the table, and the difference is minimal.

Table 2: KN-15 Well parameters based on measurements 2003 (left) and corrected values (right).

Parameter	Value	Unit	Parameter	Value	Unit
Pressure	140.546	bar	Pressure	140.480	bar
Temp	293.5	^{o}C	Temp	293.5	^{o}C

Massflow	66.3	kg/s	Massflow	66.3	kg/s
Diameter	0.3153	m	Diameter	0.3153	m
Depth	1800	m	Depth	1800	m

Figure 3 shows a comparison between the measurement results and the wellbore model with corrected values from the Monte Carlo Particle Filter analysis.

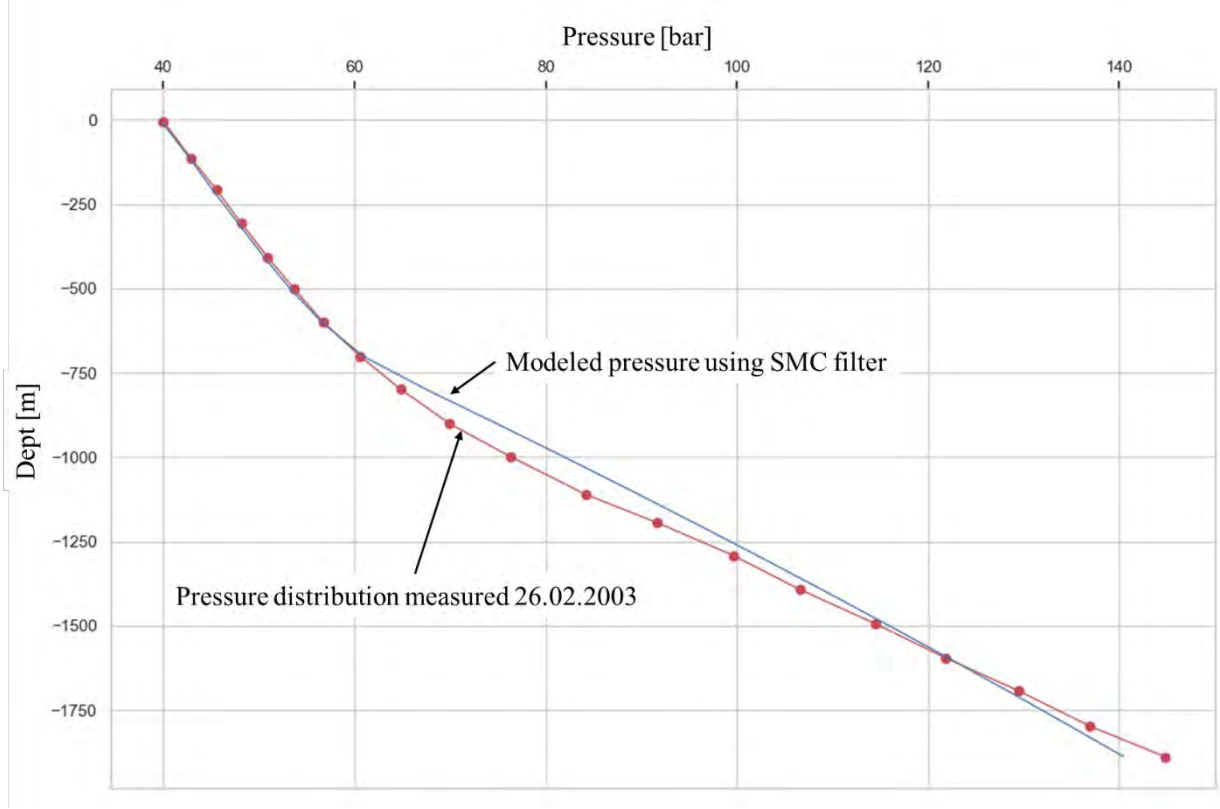

Figure 3: Measured and corrected pressure versus depth in the well KN-15 the year 2003.

Figure 4 illustrates the filter scan connected with lines between particles, showing how well the MCPF covers the area around the pressure line.

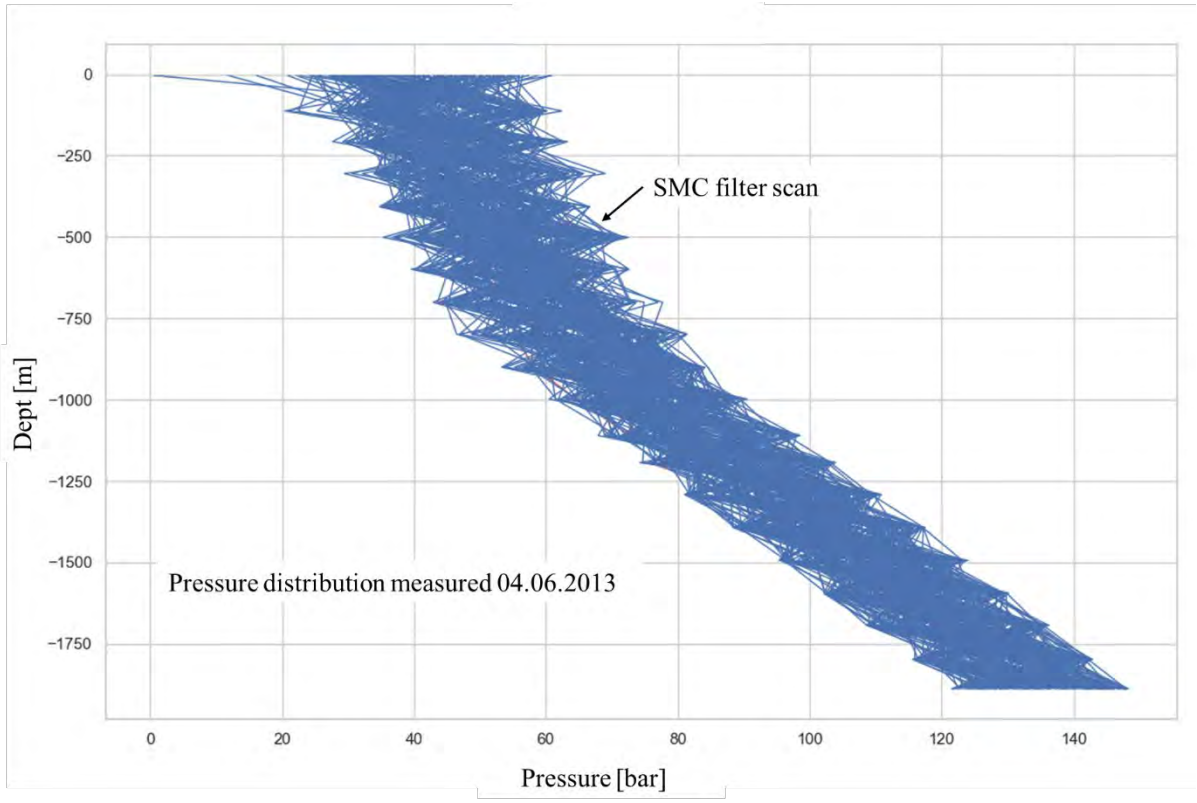

Figure 4: Particles coverage for the measurements in 2013 well KN-15.

Figure 5 presents the results where the parameters for the Flowell wellbore model have been adjusted using the filter. The results indicate that the bottom hole pressure is 137.67 bar, with a drawdown of 9.7 bar over this time period. The diameter is 0.2855 m, showing scaling of 3.5 mm. The results are detailed in Table 2. The mass flow rate is 52.7 kg/s.

Table 2: KN-15 Well parameters corrected 2003 (left) and 2013 (right).

Parameter	Value	Unit	Parameter	Value	Unit
Pressure	140.546	bar	Pressure	130.766	bar
Temp	293.5	°C	Temp	293.5	°C
Enthalpy	1238.0	kJ/kg	Enthalpy	1267.6	kJ/kg
Massflow	66.3	kg/s	Massflow	52.7	kg/s
Diameter	0.3153	m	Diameter	0.2855	m
Depth	1800	m	Depth	1800	m

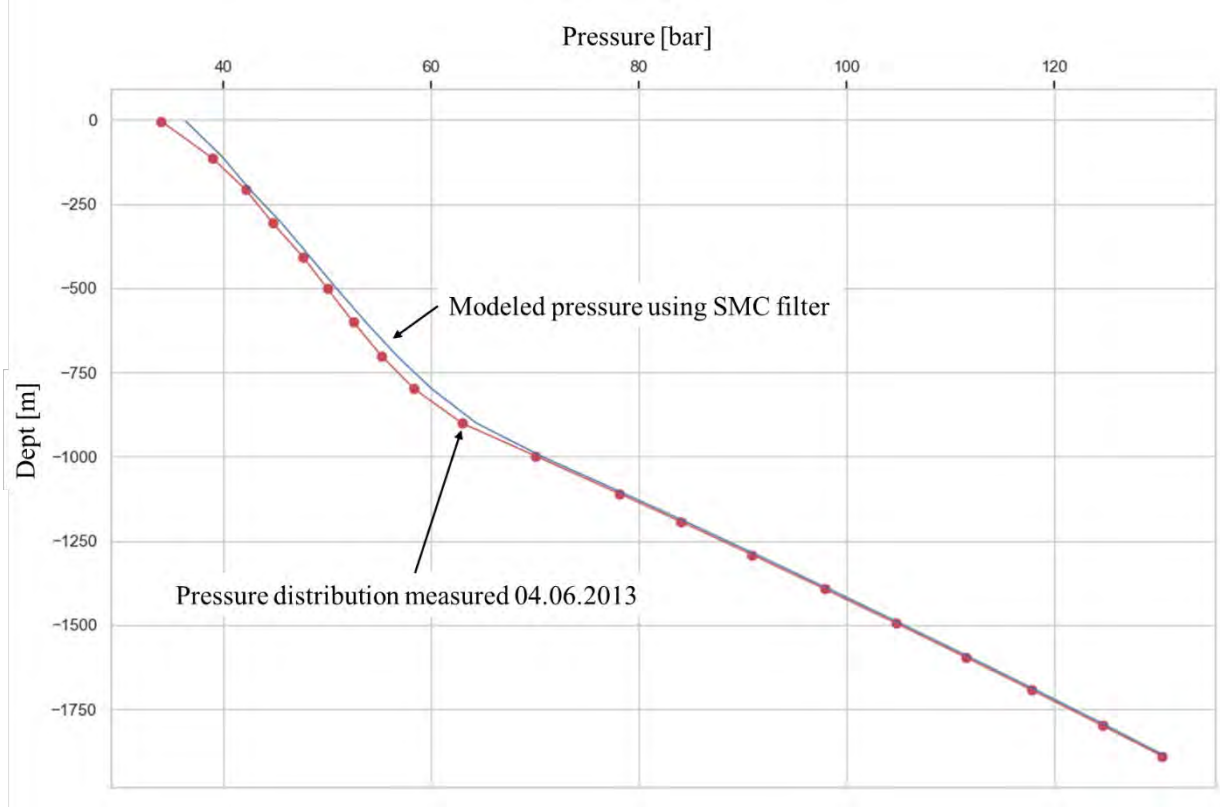

Figure 5: Measured and corrected pressure versus depth in the well KN-15 the year 2013.

5. Discussion

The results highlight the effectiveness of using a Monte Carlo Particle Filter with a wellbore model to predict downhole conditions in a geothermal well. The method successfully estimates the pressure profile and identifies changes in the wellbore diameter due to scaling. This approach provides a robust framework for real-time monitoring and management of geothermal wells.

Key advantages of this integrated method include:

- Improved accuracy in predicting wellbore conditions.

- Enhanced ability to handle non-linearities and uncertainties in the system.

- Capability to incorporate real-time observational data for continuous updating of estimates.

The case study demonstrates that this approach can significantly improve the reliability of geothermal well assessments, aiding in better decision-making for well management and optimization.

6. Conclusion

The application of Monte Carlo Particle Filter combined with a wellbore model provides a powerful tool for estimating downhole pressure and wellbore diameter in geothermal wells. The

case study confirms that this method can accurately predict well conditions and identify scaling, supporting effective and sustainable geothermal energy production.

Future work will focus on validating the approach with more extensive field data or testing the method by doing measurements with calibration before and after a cleaning process of a well. Also refining the method further by incorporating additional factors such as multi-zone scaling or piece wise blocking.

Abstract

The global consumption of electrical energy is constantly increasing and the demand for sustainable and net-zero energy is more important now than ever. In the context of energy transition, Enhanced Geothermal Systems (EGS) are emerging as a promising solution for renewable and sustainable energy production. The economic efficiency of geothermal wells depends on the production performance, which can be enhanced through various artificial lifting systems such as gas lift and submersible pumps This paper investigates the application of gas lift in liquid-dominated geothermal wells to increase the production rate of hot liquid/steam, eventually improving the enthalpy recovery per well.

A steady-state multiphase flow model is employed to simulate the impact of gas lift on the flow rate within the geothermal well. The model considers various parameters such as fluid properties, wellbore geometry, and operational conditions. Sensitivity analysis is conducted to assess the influence of different gases on gas lift performance under varying reservoir conditions. A comprehensive thermal model is developed using a finite-element modeler to analyze the thermal behavior of the geothermal well during gas lift operations. The model accounts for heat transfer mechanisms, including conduction, convection, and radiation, within the wellbore and the surrounding formation. Factors such as fluid temperature, flow rate, gas injection temperature, and thermal properties of the materials are incorporated into the model to accurately simulate thermal dynamics. Different gas compositions, including compressed air, natural gas, and CO2, are analyzed for their suitability as gas lift agents.

Application of the gas lift results in an up to 30% increase in production rates. Comparative analysis reveals that while compressed air can be utilized with compressors at any geothermal site, natural gas exhibits superior performance as a gas lift agent due to its lower density. Furthermore, the application of CO2 showed potential for commercial use in Carbon Capture, Utilization, and Storage (CCUS) projects, with caution due to the risk of carbonic acid formation, which could lead to corrosion issues in production tubing and processing facilities. Thermal modeling indicates that

an increase in gas to liquid ratio led to higher heat loss through the production tubing. However, the overall enthalpy production of the well increases due to the elevated production rate.

Overall, the combination of multiphase flow and thermal modeling, along with comprehensive sensitivity analyses, provided a robust framework for evaluating the application of gas lift in liquid-dominated geothermal wells. The findings contribute to the optimization of geothermal well performance, highlighting the potential of gas lift systems to play a significant role in the energy transition towards sustainable and renewable energy sources.

1. Introduction

The quest for sustainable and renewable energy sources is critical in addressing the growing global demand for electrical energy. Enhanced Geothermal Systems (EGS) represent a significant advancement in the field of renewable energy, offering a stable and long-term solution for electricity generation. Unlike conventional geothermal systems, which rely on naturally occurring reservoirs, EGS can be implemented in a wider range of geological settings by artificially enhancing the permeability of geothermal reservoirs (Sanyal & Butler, 2005). This innovation broadens the applicability of geothermal energy but also presents new challenges in optimizing well performance to ensure economic viability.

In the context of hydrothermal and enhanced geothermal systems, efficient production from geothermal wells is essential. Artificial lift techniques, such as submersible pumps and gas lift systems, are employed to enhance the production rates of liquid-dominated geothermal wells. Gas lift, a method traditionally used in oil and gas production, involves injecting gas into the well through annulus or coiled tubing to reduce the hydrostatic pressure of the fluid inside the production tubing and improve fluid flow from the reservoir to the surface (Oyewole & Lea, 2008; Takacs, 2005). For the case of injection through the casing-tubing annulus, a gas lift mandrel, equipment that creates a pathway for the injected gas when activated, is assembled with the completion tubular at the desired depth and placed in the well. Depending upon the reservoir deliverability, gas can be injected through the mandrel intermittently or continuously (Guet & Ooms, 2006; Julian et al., 2014). The continuous gas lift method is the most common type used in high reservoir deliverability and high gas-liquid ratio in oil-producing wells. The injected gas which is mostly methane mixes with the reservoir fluid from the point of injection up and reduces the density of the fluid inside the production tubing (Hernandez, 2016; Moffett & Seale, 2017). This assists the reservoir pressure by decreasing the hydrostatic pressure of the fluid column inside the tubing, making the fluid flow to the surface easier. Figure 1 demonstrates the schematic layout of the well with gas lift and pressure profile across the well depth.

When the reservoir pressure declines in geothermal reservoirs due to the years of production, artificial lifting becomes necessary to restore the production rates of low-performance wells. The electric submersible pumps (ESP) have proved to be very useful in oil wells with high production rates but their application in geothermal wells is hindered by the high downhole temperature, scale content, and corrosive nature of the geothermal fluid (Aydin & Merey, 2021; Turnquist et al., 2013). Although high fluid production can be achieved through proper selection and optimization of the ESPs, premature pump failure cases in real-field applications have been reported several times in the literature (Aydin et al., 2021; Aydin & Merey, 2021; Shoeibi Omrani et al., 2021; Xu, 2022). Also, the operating window of those pumps is limited up to 450°F fluid temperature. The

application of the gas lift in liquid-dominated geothermal wells, however, is not limited by the temperature and has minimal to no downhole mechanical components that might fail due to harsh reservoir conditions (Turnquist et al., 2013).

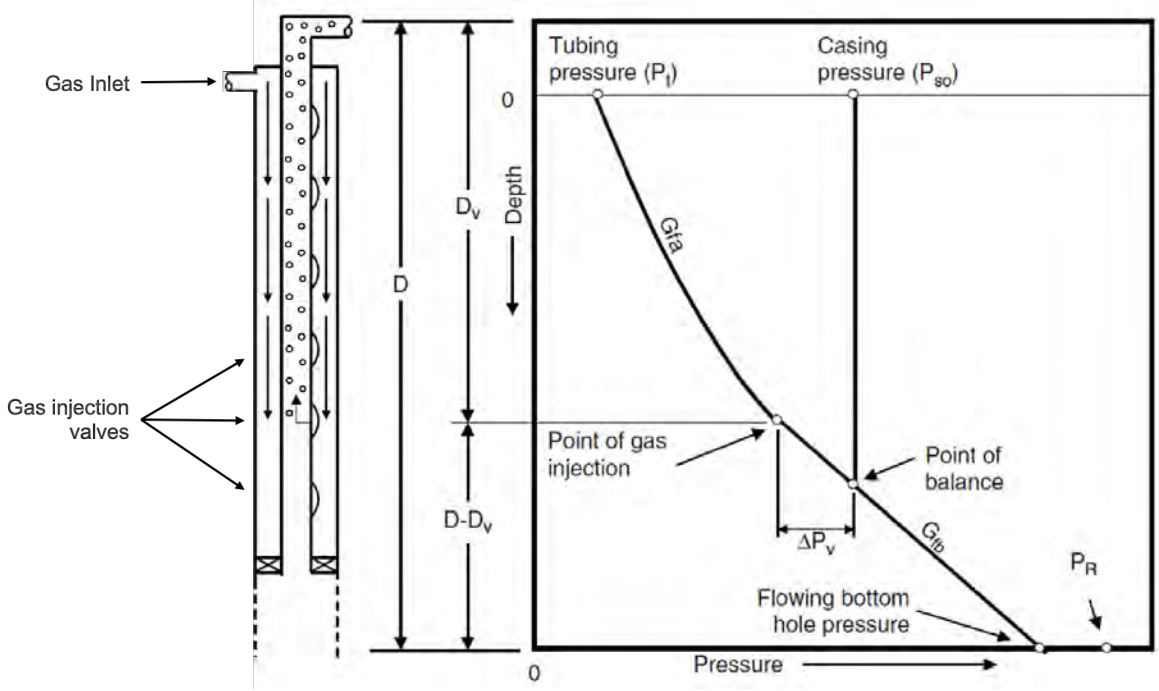

Figure 1: Schematic design of gas lift well and depth-pressure relationship (Guo, 2011). Multiple gas lift valves can be placed in the tubing string, and each can be activated separately to provide an inlet of gas at different depths in the well. At the point of injection, the pressure of the gas (casing pressure) is slightly above the pressure inside the tubing. The pressure profile changes above the gas injection due to density change of producing fluid and it results in positive wellhead pressure and transfer of fluid to the surface.

In liquid-dominated geothermal wells, gas lift production optimization can significantly enhance fluid extraction efficiency and overall system performance (Aydin & Merey, 2024). Implementing gas lift systems involves several key configurations. One common approach involves injecting gas into the annular space, which allows fluid discharge up the tubing. Alternatively, gas can be injected down the tubing to facilitate fluid discharge up the annular space. The third method employs a dual tubing system where gas is injected down one tube, and fluids are lifted in the other (Hernandez, 2016). To achieve higher flow rates without generating too much frictional pressure loss, it is required to keep the tubing diameter as large as possible. Also, producing geothermal fluid has the risk of causing corrosion on the downhole and surface well components. Thus, it is recommended to use production tubing to transfer the reservoir fluid from the well to the surface instead of using the casing alone without any tubing (Wardana & Akhwan, 2023). In the case of corrosion-damaged tubing, it can be retrieved from the well and replaced with a new one, while it is not possible to replace the damaged well casing if they are cemented in place (Song et al., 2023). Also, fiber optic cable can be installed with the tubing to record distributed acoustic and/or temperature survey that enables the producer to continuously monitor the gas lift performance and liquid level inside the tubing, as well as detect any tubing and casing leaks due to heavy corrosion (Khankishiyev et al., 2024 (a)).

The initial steps in designing a continuous-flow gas lift system include determining the optimal gas injection point, calculating the required gas volume, and establishing the necessary injection pressure (Takacs, 2005). This careful planning ensures that the system operates efficiently and effectively. In an intermittent gas lift system, a high-pressure gas bubble or slug expands and ascends to a low-pressure outlet, effectively lifting the geothermal fluid. The control of pressure and volume expansion of gas entering the tubing is managed by a valve with a large port. This valve can regulate the lift of the accumulated fluid head above it with maximum velocity to minimize slippage or control liquid fallback by fully ejecting the fluid to the surface with minimal gas usage. Intermittent gas lift is often complemented by a surface time controller to optimize the injection cycles (Kamari et al., 2014).

Depending on the availability of the gas around the geothermal site, compressed air, methane, nitrogen, and carbon dioxide can be used as injection gas. First proposed by Aqui (1996), nitrogen gas was injected in five geothermal wells in the Sibayak field in Indonesia field from 1993 until 1995 using coiled tubing. Due to its low solubility, non-corrosive, and non-toxic characteristics, nitrogen was preferred as the injection gas in more wells consequently with around 70% success rate (Buñing et al., 1998). However, this method did not prove to be economical due to the cost of coiled tubing service and nitrogen gas (Siega et al., 2006).

Carbon dioxide (CO2) has been previously proposed for use as a working fluid in closed-loop geothermal systems in several modeling studies (Beckers et al., 2022; Khankishiyev et al., 2024 (b); Rajabi et al., 2021). It can also be applied in geothermal well gas lift applications as an injection gas. This creates another commercial use for Carbon Capture, Utilization, and Storage (CCUS) projects. However, carbon dioxide has a higher density compared to air, nitrogen, and methane which limits the hydrostatic pressure reduction through gas lift inside the tubing. Another challenge is the risk of carbonic acid formation from the reaction of CO2 and water under high temperatures, which could lead to corrosion issues in production tubing and processing facilities (Mubarak et al., 2023; Sonke et al., 2022). Thus, careful consideration of every aspect of CO2 as a gas lift agent is necessary.

Air and methane have been used as a gas lift agent in oil production wells for decades. They provide sufficient hydrostatic pressure drop to achieve economic oil production rates when the injection rate and pressure are selected properly (Kamari et al., 2014). Compressed air was injected into the well using coiled tubing to initiate the discharge of geothermal fluid in Philippine geothermal wells in 1998 (Buñing et al., 1998) while there is no published record of the application of methane as a gas lift agent in geothermal wells. Overall, the air can be taken from the atmosphere around the geothermal site, compressed, and injected into the well, while methane and nitrogen must be transported from the provider to the geothermal site. The carbon dioxide can either be transported from the provider or captured around the site if the carbon capturing facility installed nearby the geothermal wells.

Gas lift offers significant advantages in geothermal wells over other artificial lift techniques, primarily due to its cost-effectiveness and operational efficiency. It has low operating costs as it utilizes methane, air, or nitrogen as compressor fuel, which is economical and readily available (Turnquist et al., 2013). Once the injection gas is introduced to the system, the same gas will be separated from the produced fluid in the two-phase surface separator, compressed, and injected back into the well, with very minimal loss during the surface separation process. The system requires minimal downhole equipment, reducing both installation and maintenance costs. With

few moving parts, gas lift systems are easy to maintain and repair, leading to lower overall downtime. Additionally, gas lift valves can be easily and inexpensively replaced without the need for a workover rig, making it a flexible and reliable method for enhancing geothermal production performance (Julian et al., 2014).

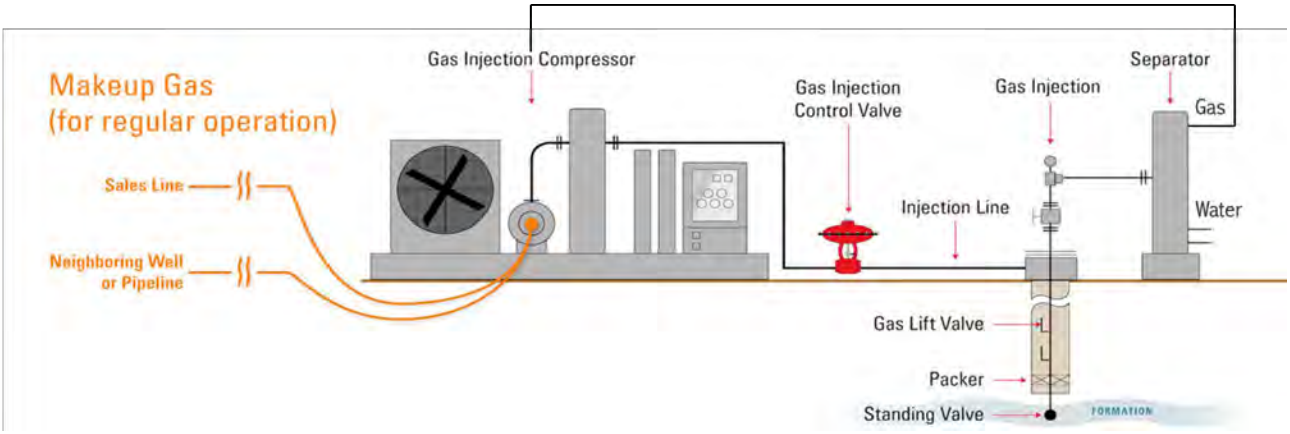

Figure 2: Gas lift well surface equipment (Andrews 2023). The main component of the system is the gas injection compressor. The gas can be provided to the compressor either from neighboring wells and pipelines or transported from the gas provider on the market. The flow of the gas is regulated by the surface control valve. After the injected gas is produced at the surface with geothermal fluid or steam, it is separated from the mixture using a surface separator to be fed into the compressor next.

The surface equipment and process for a gas lift system involve several key components. A compressor is used to pressurize low-pressure gas, which is then injected into the well through a gas injection valve. This valve regulates the flow of gas into the casing-tubing annulus, where it travels down to the gas lift valves. These valves open in response to specific gas pressures, allowing the gas to aerate the fluid column and reduce its density, facilitating easier flow to the surface. Additional equipment such as standing valves and packers ensure the system operates efficiently by maintaining fluid levels and preventing gas from escaping into the formation (Mubarok & Zarrouk, 2017). Figure 2 shows the surface components of the gas injection system.

The application of gas lift in geothermal wells requires specialized modeling and analysis due to the unique thermal and fluid dynamics involved. This study aims to explore the potential of gas lift systems in enhancing the productivity of geothermal wells by developing robust thermal and flow models that simulate the performance of various gas lift scenarios, offering an alternative to downhole pumps. The methodology for gas lift design depicted in this study is described in the subsequent section and includes using inflow performance curves (IPR) and tubing performance curves (TPR) to determine the optimal gas injection rate and liquid production rates, employing well-established methods such as the modified Hagedorn and Brown method for multiphase flow calculations and the Chen method for friction factor determination. The thermal section of the model considers heat transfer through conduction, convection, and radiation within the wellbore and the surrounding formation. Factors such as fluid temperature, flow rate, gas injection pressure, and the thermal properties of the materials are analyzed using sensitivity analysis to find the optimized set of parameters for a given geothermal well design. The results of the simulations are provided in the discussion section and the necessary findings are outlined in the conclusions.

2. Methods, Procedures, Process

This section describes the dynamic flow and thermal modeling details of the geothermal well with gas lift in a commercial steady-state multiphase flow simulation. The well design including casing size, setting depth, and deviation is based on the Well 16B(78)-32 drilled in the Utah Forge site (McLennan et al., 2023). The bottom of the well is at 10208 ft depth, while the completions are placed in 9700-9850 ft intervals. The packer is placed at 9500 ft depth to isolate the annulus from formation fluid and the gas lift inlet point is at 9100 ft. The diagram of the well developed in the model is given in Figure 3 and Table 1 shows the dimensions of the casings and tubing, including setting depth and diameters. The well deviation survey, rock temperature, and thermal conductivity are given in Table 2 below.

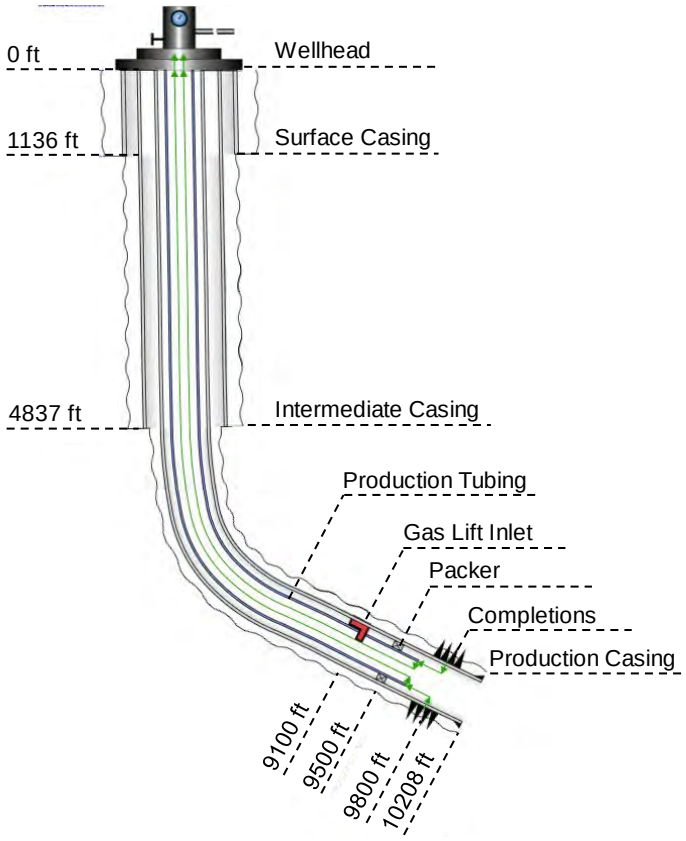

Figure 3: Schematic diagram of the well-developed in the steady-state flow simulator. The given in the diagram is measured depth MD). The green line extending from the completions to the surface is the flow pathway of produced fluid. Surface facilities were not included in the model. Only one well was used for flow and thermal modeling.

The ground temperature at the surface is set to 65°F and the ambient temperature at 8400 ft TVD is set to 425°F. The average thermal gradient and the rock-specific heat capacity are 0.043 °F/ft and 0.2 Btu(lbm.degF) for the whole interval respectively. The thermal conductivity of the rock is set to 1.73 Btu/(h.degF.ft) from the surface to 5000 ft TVD and 2.17 Btu/(h.degF.ft) to 8400 m TVD, which is close to the thermal conductivity of granite. The reservoir pressure was set to 4000 psi and the productivity index was assumed to be 100 lb/(hr.psi) to model the inflow performance relationship. The surface pressure in all simulations was set to 200 psi to consider the pressure losses within the surface facilities and power generation turbines.

Table 1: Dimensions and thermal conductivity of the casing and tubing.

Section type	From MD, ft	To MD, ft	ID, in	OD, in	Roughness, in	Thermal conductivity, Btu/(h.degF.ft)

Intermediate Casing	0	4837	10.772	11.75	0.001	27
Production Casing	0	10208	5.92	7	0.001	27

Table 2: Well deviation survey, subsurface temperature, and rock thermal conductivity.

MD, m	TVD, m	Horizontal length, m	Angle, deg	Rock temperature, °F	Rock thermal conductivity, Btu/(h.degF.ft)
0	0	0.0	1.06	65	1.73
1000	1000	18.4	1.09	108	1.73
2000	2000	37.4	1.02	151	1.73
3000	2999	55.3	0.68	194	1.73
4000	3999	67.1	1.38	237	1.73
5000	4999	91.2	9.76	280	1.73
6000	5985	260.7	43.62	322	2.17
7000	6709	950.5	67.06	353	2.17
8000	7098	1871.5	62.93	370	2.17
9000	7553	2761.9	64.21	390	2.17
10000	7988	3662.3	64.82	409	2.17
10947	8391	4519.3	64.98	424	2.17

The thermal conductivity of the carbon steel casings and liner are set to 27 Btu/(h.degF.ft). The gas is pumped through the annulus and the gas/fluid mixture is produced through the insulated tubing that has a thermal conductivity of 0.05 Btu/(h.degF.ft). There are several commercially available vacuum-insulated tubing (VIT) products provided by different manufacturers with very low thermal conductivity. The cement around the surface and intermediate casing is two inches thick while it is set to one inch for the production casing. The thermal conductivity value for the cement is set to 0.9 Btu/(h.degF.ft) according to the commonly used H and G class cement in the well construction. Since cement has higher thermal conductivity than water and drilling mud, the annulus between casings is filled with cement up to the surface.

The steady-state multiphase flow simulator incorporates a wide variety of industry-standard multiphase flow correlations that have been developed through decades of research, as well as industrial data collection and analysis. The model enables the calculation of pressure losses, flow

velocities, and flow regimes at any node given in the system. The heat transfer modeling part of the simulator provides an accurate estimation of the heat transfer from the rock to the circulating fluid through cement and casing. The model recalculates the temperature and pressure-dependent fluid properties during the simulation at any given depth in the well to achieve accurate flow and thermal modeling. The simulator carries out comprehensive energy-balance calculations accounting for convection, conduction, Joule-Thomson cooling and heating, and frictional heating (SLB, 2022).

Four gases, air, methane (CH_4), carbon dioxide (CO_2), and Nitrogen (N_2), will be used in the simulations to determine the impact of gas on multiphase flow and thermal performance of the geothermal fluid/steam production. Table 3 provides the properties of each gas. The chemical compositions of the reservoir fluid and injected gas including the names and mole fractions are provided in Table 4. Although geothermal reservoir fluid usually contains a lot of components such as salts, scales, acids, and rare earth minerals, its composition was kept simple during simulations in this study. The H_2S and CO_2 were added to the composition to account for the corrosion taking place during production.

Table 3: Some properties of four gasses used in the multiphase steady-state simulation model as gas lift agents

Property	Air	Methane (CH4)	Carbon Dioxide (CO_2)	Nitrogen (N_2)

3. Results and Discussion

3.1 Impact of reservoir pressure and gas injection rate on the operating point

The gas injection method is not recommended to be applied to all types of geothermal wells. In the wells where reservoir pressure is enough to overcome the pressure of the hydrostatic column in the well and provide sufficient pressure at the surface, injecting the gas will provide a very slight increase in production rate, while increasing the temperature loss across the well. To check the impact of reservoir pressure on the Inflow Performance Relationship (IPR) and injection rate Tubing Performance Relationship (TPR) curves, a nodal analysis was performed by setting the reservoir pressure to 2500, 3000, 3500, 4000 psi and gas injection rate to 0, 1, 2 and 3 mmscf/d. The methane was used as a gas lift agent and surface pressure was set to 200 psi. The gas was injected at 9100 ft MD from behind the casing into the production tubing. The productivity index was kept constant at 5 STB/(d.psi). The node was placed at the bottom of the well where the completions are located. The results of the simulation are shown in Figure 4, where negative-slope lines show the IPR curves and positive-slope lines are the TPR curves. The blue dots are the operating point for each scenario that indicates the pressure and flow rate at the bottom of the well.

With increasing reservoir pressure, the inflow curve moves up, and increasing the gas lift injection rate, the outflow curve moves down. When the reservoir pressure is 2500 psi, the well produces only 1350 STB/day liquid without any gas lift, while a 4050 STB/day flow rate can be achieved by injection of 1 mmscf gas per day at 9100 ft MD. Raising the injection rate to 2 mmscf/d provided an additional 150 STB/d and 55 STB/d increase at 3 mmscf/d. A production increase of 35% was estimated for the case of 3500 psi reservoir pressure by injecting 1 mmscf methane per day and an additional 5% can be realized by increasing the injection rate three times. The production rate boosted by the injection rate was relatively smaller at 4000 psi reservoir pressure (20%). The plot indicates that gas lift provides less production rate assistance at high reservoir pressures. In addition, the production rate increase slows down significantly at higher gas lift rates, while causing more heat loss and smaller surface production temperature.

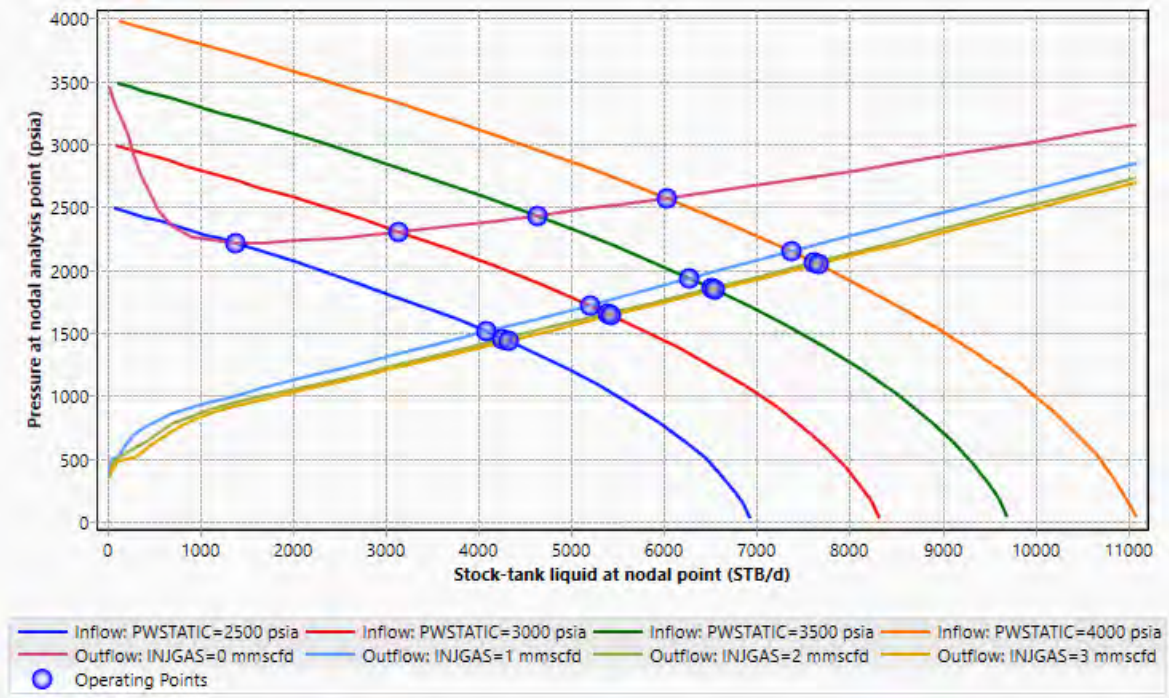

Figure 4: Nodal analysis of Inflow Performance Relationship (IPR) and Tubing Performance Relationship (TPR) curves. The reservoir pressures were set to 2500, 3000, 3500, and 4000 psi which impact the IPR curves. The methane gas injection rates were set to 0, 1, 2, and 3 mmscf/d that impact the IPR curves. At higher rates, the gas lift has minimal influence to increase the production flow rate. The gas injection rate relationship with the production rate increase is not linear and after a certain gas injection rate, the production rate does not increase further.

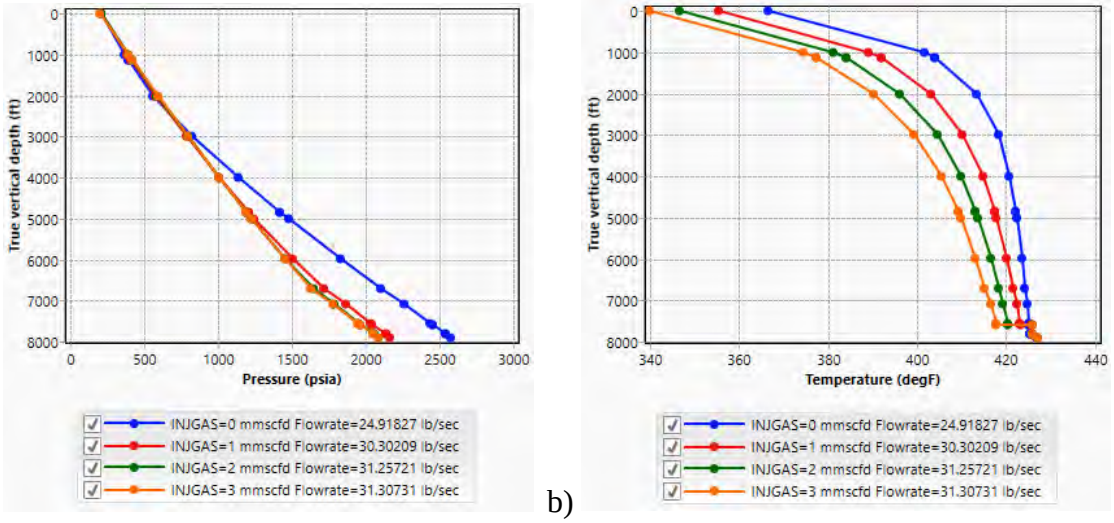
3.2 Pressure, temperature, and flowrate profiles with different gas injection rates

In this section, pressure, temperature, and flow rate profiles within the wellbore under varying nitrogen gas injection rates are examined. For this analysis, wellhead production pressure is maintained at 200 psi, reservoir pressure at 4000 psi, with an injection point at 9100 ft MD and 7600 ft TVD. The nitrogen injection pressure is set to 2500 psi with an injection temperature of 75°F. It was observed that applying 1 mmscf/day nitrogen injection dropped the bottomhole flowing pressure by around 12% (300 psi). Increasing the injection rate from 1 mmscf/day to 3 mmscf/day resulted in another 3.5% decrease in bottomhole flowing pressure. The surface production temperature dropped by around 10°F as a result of 1 mmscf/day nitrogen injection. Overall, there temperature of the produced liquid drops from around 420°F to 355°F as the heat loss occurs through the tubing. The simulation results are displayed in Figure 5.

The flowing liquid and gas flow rates across the well with varying nitrogen injection rates are shown in Figure 6. The application of gas lift led to a 20% increase in liquid production and up to a 200% rise in gas flow rate, the big majority of which is injected gas. At the bottom of the well, the liquid flow rate is at its maximum while the gas flow rate is at its minimum. As the multiphase fluid moves up the well, the gas expands and accelerates, causing the flowing liquid flow rate to drop by around 10% compared to the bottomhole flow rate.

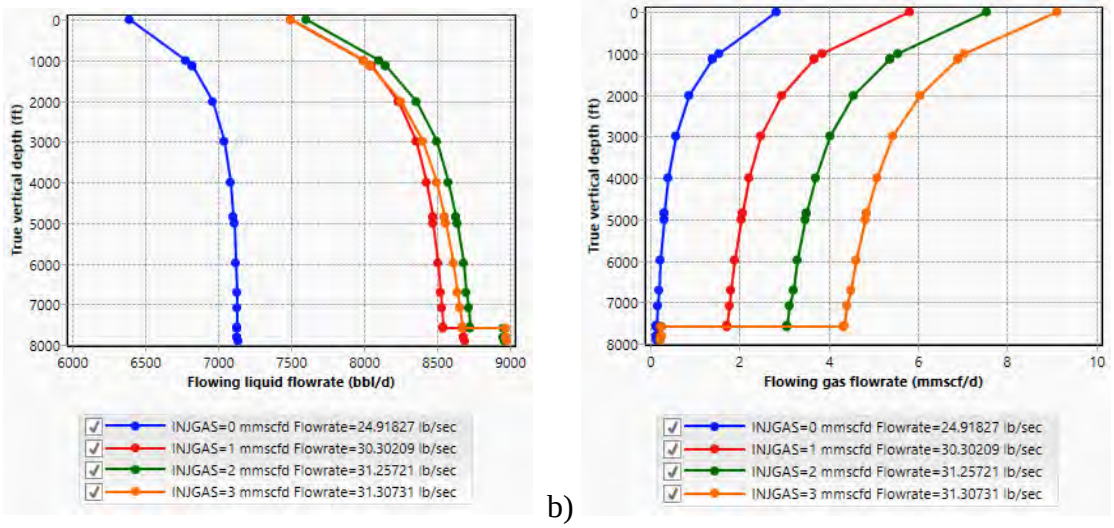
In Figure 7, the flowing liquid and gas heat capacity of the multiphase fluid flowing inside the production tubing from bottom to top with varying nitrogen injection rates is illustrated. The injection of nitrogen resulted in approximately a 10% drop in the heat capacity of liquid water and

gas, indicating that more temperature drops will occur as the fluid travels up the well. Therefore, insulation of the top part of production tubing is more necessary to prevent heat loss.



a) b)

Figure 5: Pressure (a) and temperature (b) profiles across the well with varying Nitrogen injection rates. Increasing the injection rate from 1 mmscf/d to 3 mmscf/d decreased the bottomhole pressure by 3.5% and the surface temperature dropped by 4.5%.



a) b)

Figure 6: Flowing liquid (a) and gas b) flow rates across the well with varying Nitrogen injection rates. Application of gas lift provided 20% increase in liquid production and up to 200% rise in gas flow rate. The liquid flow rate is maximum at the bottom of the well and the gas flow rate is the minimum. As the multiphase fluid moves up the well, the gas expands and speeds up while the liquid flow rate drops by around 10%.

3.3 Impact of injected gas type and rate on production performance

Nitrogen, compressed air, carbon dioxide, and methane were tested as a gas lift agent at different injection rates while keeping the injection pressure and temperature at 2500 psi and 75°F, the injection point at 9100 ft MD, the wellhead production pressure at 200 psi. Figure 8 illustrates the impact of gas injection rate on liquid and gas flow rates at the wellhead for all four gas types. It was observed that the liquid production rate reaches its maximum value at the injection rate of 1.5 mmscf/day, after which it declines. Among the gases tested, methane injection provided the most

support for liquid production, yielding the highest flow rates (max. 7680 bbl/day). The injection of air, primarily composed of nitrogen and oxygen, produced similar results to the injection of nitrogen alone with the highest production rate of 7600 bbl/day, indicating no significant difference between these two gas types in terms of liquid production performance. Carbon dioxide injection exhibited the lowest performance (max. 7420 bbl/day), resulting in the least liquid production. Interestingly, the gas type did not significantly affect the gas flow rate at the wellhead, regardless of the injection rate. As more and more gas enter the tubing above 1.5 mmscf/day injection rate, they expand and prevent liquid from flowing from the reservoir up the tubing. The diminished liquid production rate also decreases enthalpy production. Although gas production seems to be increasing, the majority of it is injected gas and not steam. This means that higher gas lift injection rates do not provide any advantages in terms of power production.

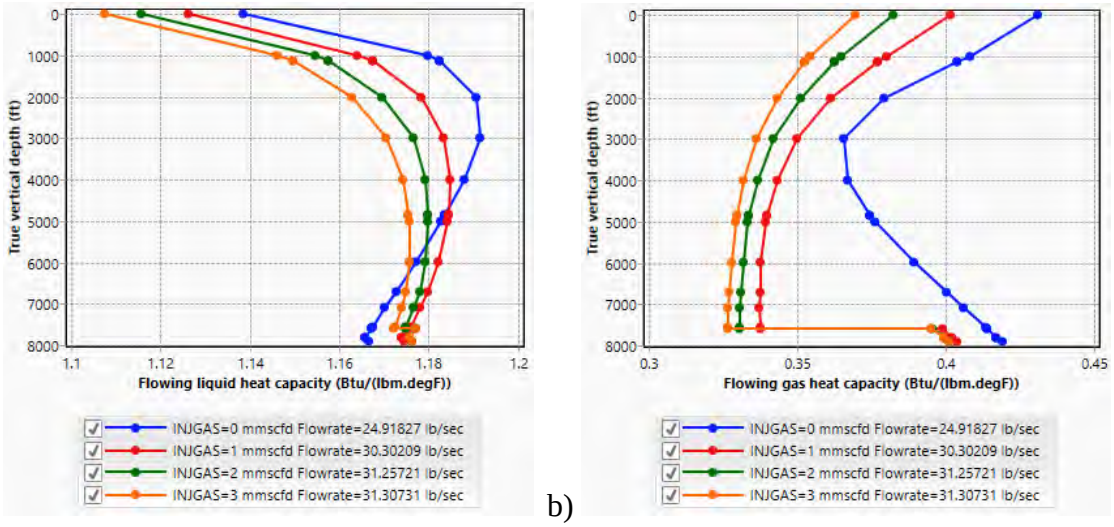


Figure 7: Flowing liquid (a) and gas (b) heat capacity of the multiphase fluid flowing inside the production tubing from bottom to top with varying Nitrogen injection rates. Overall, the injection of nitrogen dropped the heat capacity of liquid water by around 10% which means more temperature drop will occur as the fluid travels up the well.

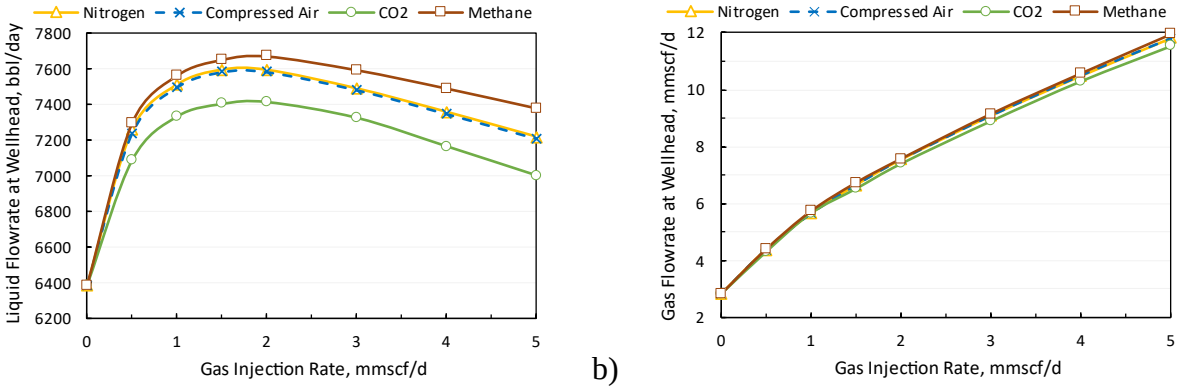

Figure 8: Liquid (a) and gas (b) flow rates at wellhead vs. gas injection rate. The liquid production reaches the maximum value at 1.5 mmscf/d gas injection after which it drops to lower values. Methane injection provided the most support for liquid production. The injection of air that consists mostly of nitrogen and oxygen and the injection of nitrogen alone showed the same results for liquid production. The lowest performance was observed during the injection of carbon dioxide. No considerable difference was observed in the produced gas flow rate at the wellhead no matter which gas type was injected.

The produced heat is a function of the mass production rate, temperature, and heat capacity of the fluid, and it must be considered to find the most effective gas injection rate to achieve the best techno-economic performance. Figure 9 shows the produced heat for different injection rates and gases calculated based on the temperature, flow rate, and liquid and steam heat capacity values taken from the simulation. The produced fluid temperature dropped by around 35°F as the injection rate increased from 0 to 5 mmscf/day. However, the gas type had almost no considerable impact on temperature up to a 2.5 mmscf/day injection rate. The produced heat plot showed that the optimal gas injection rate is around 1.5 mmscf/day, and further increases in the injection rate harmed the production performance. Methane injection resulted in the highest produced heat (13 MW), while air and nitrogen-assisted heat production was slightly lower (12.8 MW). CO2 injection resulted in the lowest heat production (12.6 MW). A reduction of 0.6 MW produced heat was estimated when the gas injection rates increased from 1.5 mmscf/day to 5 mmscf/day. It was concluded that injection above the optimum point not only decreases the produced heat but also increases the capital costs of providing the injection gas and the operating cost of the chiller and compression stations.

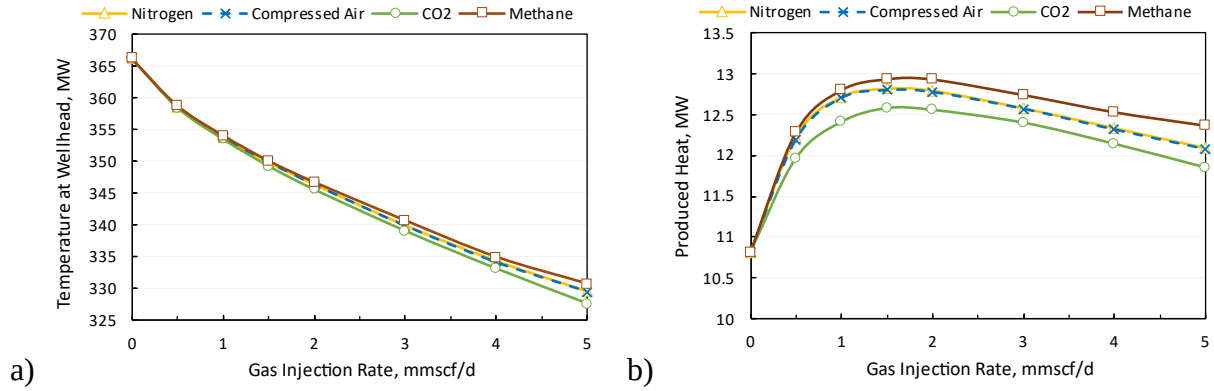

Figure 9: Temperature at the wellhead (a) and Produced heat (b) with varying gas injection rates and types. The produced fluid temperature dropped by around 35°F as the injection rate increased from 0 to 5 mmscf/day. However, the gas type had almost no considerable impact on temperature up to 2.5 mmscf/day injection rate. The produced heat plot showed that the optimal gas injection rate is around 1.5 mmscf/day and further increase of the injection rate had negative impact on production performance. Methane injection resulted in the highest produced heat while air and nitrogen-assisted heat production was slightly under that. CO_2 injection resulted in the lowest heat production.

It is necessary to determine other aspects of the gas lift application to determine which gas is the most suitable. One of such factors is the availability of gas around the geothermal field. Although the methane and nitrogen gases showed superior performance in terms of produced heat, their transportation from the market to the field might be costly. The air and CO_2 on the other hand can be captured from the atmosphere right where the geothermal wells are located and compressed to inject in the well. However, there is a corrosion risk associated with the injection of air and carbon dioxide. The corrosion rate evaluations showed that the injection of air containing 21% oxygen doubled the corrosion rate (Figure 10. a). Without air injection, the corrosion rate was 0.005 in/year on average and after injection of 3 mmscf/day air, the average corrosion rate was estimated to be around 0.01 in/year. The corrosion rate with the CO_2 injected was even more severe (Figure 10. b). Under high pressure and temperature, the CO_2 and water forms carbonic acid that speeds up the corrosion process significantly. The corrosion rate was estimated to increase by at least 150% (from 0.005 in/year to 0.012 in/year) with 1 mmscf/day CO_2 injection by around 8 times with 3

mmscf/day CO_2 injection. Although the application of CO_2 for gas lift in geothermal wells might create commercial use for CCUS projects, the integrity of the geothermal wells would be compromised in the long term.

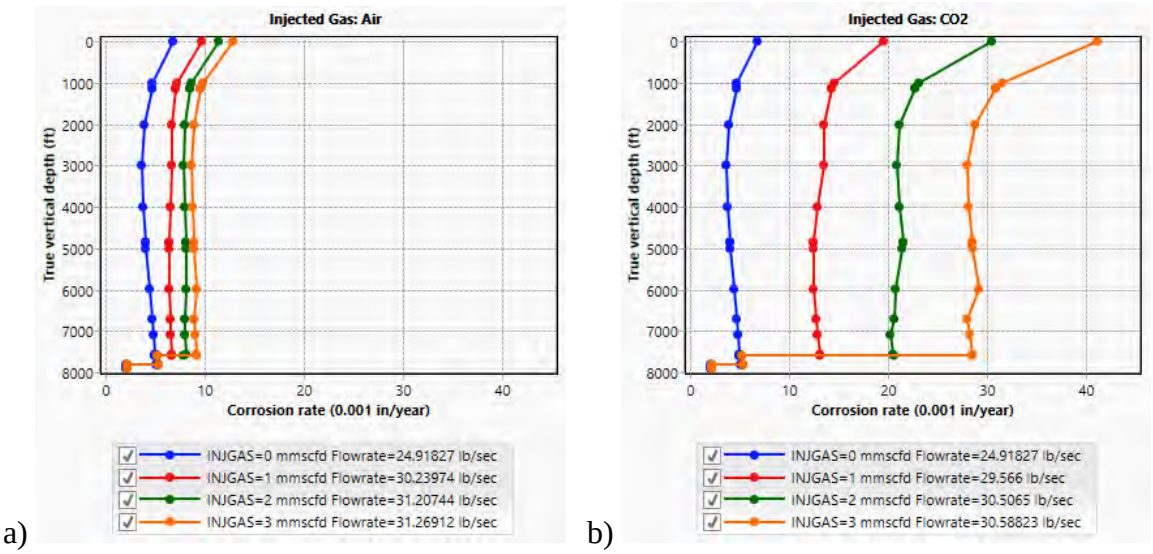

Figure 10: Corrosion rate of production tubing in case of air (a) and CO_2 injection (b) with varying injection rates. Carbon dioxide is estimated to cause three times more corrosion compared to air. To put into perspective, 0.1 inch of the tubing wall would corrode away within 5 years of production using 1 mmscf/day CO2 injection.

These findings highlight the importance of selecting an appropriate gas type and injection rate to optimize geothermal well performance. Although obtaining the air and CO_2 around the geothermal site, injecting them into the well for the long term was estimated to cause irreversible corrosion damage to the tubing and surface facilities. Methane proved to be the most effective gas for maximizing both liquid production and heat output, making it a preferable choice for gas lift operations in geothermal wells. It should also be considered that methane is flammable and any leaks during compression, injection, and production might cause environmental damage and safety hazards. The results also highlight that while increasing the injection rate can initially enhance production, there is a threshold beyond which the benefits diminish and production efficiency declines. Therefore, careful optimization of gas injection parameters is crucial for achieving the best techno-economic outcomes in geothermal energy production.

3.4 Impact of gas injection depth on production performance

Injection pressure does not influence production mass flow rate and wellhead temperature considerably. However, it must be above the pressure of the fluid at the injection point in the well so that it can enter the tubing and mix with the geothermal fluid. The injection depth, on the other hand, impacts the liquid flow rates considerably. To evaluate this impact, gas injection points were set to different depths ranging from 3500 ft TVD to 7500 ft TVD. Air was used as a gas lift agent with an injection rate of 1.5 mmscf/day. The surface injection pressure was kept constant at 2500 psi and the wellhead production pressure was set to 200 psi. The results, illustrated in Figure 11, demonstrate that the deeper the gas lift injection point is installed in the well, the more significant the impact on the mass production rate. This is because a deeper injection point results in a longer hydrostatic column mixing with the gas, which decreases the fluid density and therefore the hydrostatic pressure. Consequently, changing the depth of the injection point from 3500 ft TVD

to 7500 ft TVD resulted in a 13% increase in mass production rate. The temperature of the produced fluid, however, showed very little improvement, only about 2°F. While deeper injection points enhance production rates, they also necessitate higher surface gas injection pressures. This increase in required pressure directly correlates with higher surface gas compression costs, which must be factored into the overall economic analysis of the gas lift system. It is crucial to balance the benefits of increased production with the additional costs associated with deeper gas injection. In practical applications, the selection of the optimal gas injection depth should consider both the technical and economic aspects. The increased production rate and its impact on the levelized cost of electricity (LCOE) must be weighed against the added costs of deeper injection points and higher injection rates. This comprehensive evaluation ensures that the gas lift design maximizes the economic efficiency of geothermal energy production.

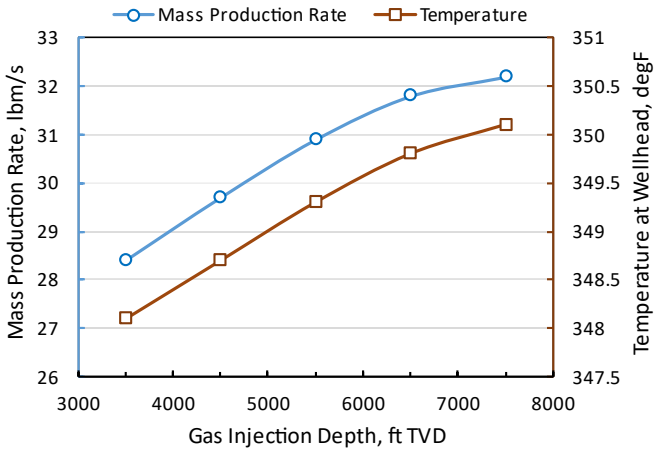

Figure 11: Mass production rate and temperature at the wellhead impacted by the air injection depth. The deeper the gas lift injection point is installed in the well, the longer the hydrostatic column will mix with the gas, decreasing density and therefore the hydrostatic pressure. Changing the depth of the injection point from 3500 ft TVD to 7500 ft TVD resulted in a 13% more mass production rate. It had very little impact on the produced fluid temperature (only 2°F improvement). However, placing the gas lift mandrel deeper means the surface gas injection pressure must be higher and that increases the gas compression costs. The cumulative impact of it on the LCOE needs to be considered.

Conclusion

The comprehensive study on the application of gas lift technology in liquid-dominated geothermal wells yielded significant insights into optimizing geothermal energy production. The following key findings and recommendations are concluded from the analysis:

- Gas lift technology is most beneficial in geothermal wells with lower reservoir pressures. In wells with sufficient natural reservoir pressure to overcome the hydrostatic column pressure, gas lift provides minimal production enhancement and increases temperature losses.
- Optimal gas injection rates must be carefully determined to balance production gains against increased heat loss and operating costs. For methane injection, the production rate benefits were evaluated to diminish beyond an injection rate of 1.5 mmscf/day, and higher rates lead to excessive heat loss and reduced surface fluid temperature.
- Increased nitrogen injection rates resulted in decreased bottomhole pressure and lower surface production temperatures. The maximum liquid flow rate occurs at the bottom of the well, decreasing as the gas expands and accelerates up the well.

- The injection of gases into the tubing reduces the heat capacity of the multiphase fluid, necessitating the insulation of the upper sections of the production tubing to minimize heat loss.
- Methane proved to be the most effective gas lift agent, yielding the highest liquid production and produced heat. The flammability and potential environmental hazards of methane must be considered as well. Nitrogen and air showed similar performance, while CO2 injection was the least effective. CO2 and air injection were estimated to accelerate the corrosion process, compromising the integrity of the well.
- Optimal injection rates (around 1.5 mmscf/day for the case studied in this paper) are crucial for maximizing produced heat and minimizing operational costs. Exceeding this rate results in diminished returns and higher capital expenditures.
- Deeper gas injection points enhance production rates by reducing the fluid density and hydrostatic pressure. However, this requires higher surface gas injection pressures, increasing operational costs.
- The optimal depth for gas injection should balance the production rate benefits against the added compression costs, considering both technical and economic factors.

In summary, the successful implementation of gas lift technology in geothermal wells requires a balanced approach that considers reservoir characteristics, gas type and availability, injection parameters, and long-term economic impacts. The findings of this study provide a solid foundation for optimizing geothermal energy production, contributing to the sustainable and efficient use of geothermal resources.

Sorik Marapi; Numerical Reservoir Model; Conceptual Model; Natural State; History Match

ABSTRACT

The Sorik Marapi Geothermal Field is a volcano-hosted geothermal system, located in North Sumatra, Indonesia. As the field development and operations have expanded over the past several years, the conceptual model has been continuously updated to represent the geologic data from new drilling and well testing results. The numerical reservoir model has also been updated to incorporate the geoscientific understanding from the conceptual modeling work, drilling and well testing results, and field operations. The numerical model was developed within the iTOUGH2 framework for automatic calibration, and a joint inversion of steady-state data (i.e., natural state) and transient production data was performed to adjust model input parameters. The calibrated numerical model demonstrates reasonable matches against the natural state pressures and temperatures and the available monitoring data during wellfield operations. The current numerical model provides a suitable basis for assessing the production capacity of the resource area and will be used to forecast the reservoir response to various development scenarios.

1. Introduction

PT Sorik Marapi Geothermal Power (SMGP), a project of KS Orka Renewables Pte. Ltd. currently has 190 megawatts (MW) installed capacity at Sorik Marapi Geothermal Field (SMGF) adjacent to Sorik Marapi volcano in Northern Sumatra. SMGF was developed in phases: Phase 1 (45 MW) online October 2019, Phase 2 (45 MW) online July 2021, Phase 3 (50 MW) online October 2022, Phase 4 (27 MW) commissioned December 2023, and Phase 5 (23 MW) in planning stage for August 2024. SMGP has confirmed a commercial geothermal resource at ~245 – 320°C by drilling and testing 43 deep exploration and development wells in a 3 km (N-S) × 2 km (E-W) area within the Sumatra Fault System (Figure 1).

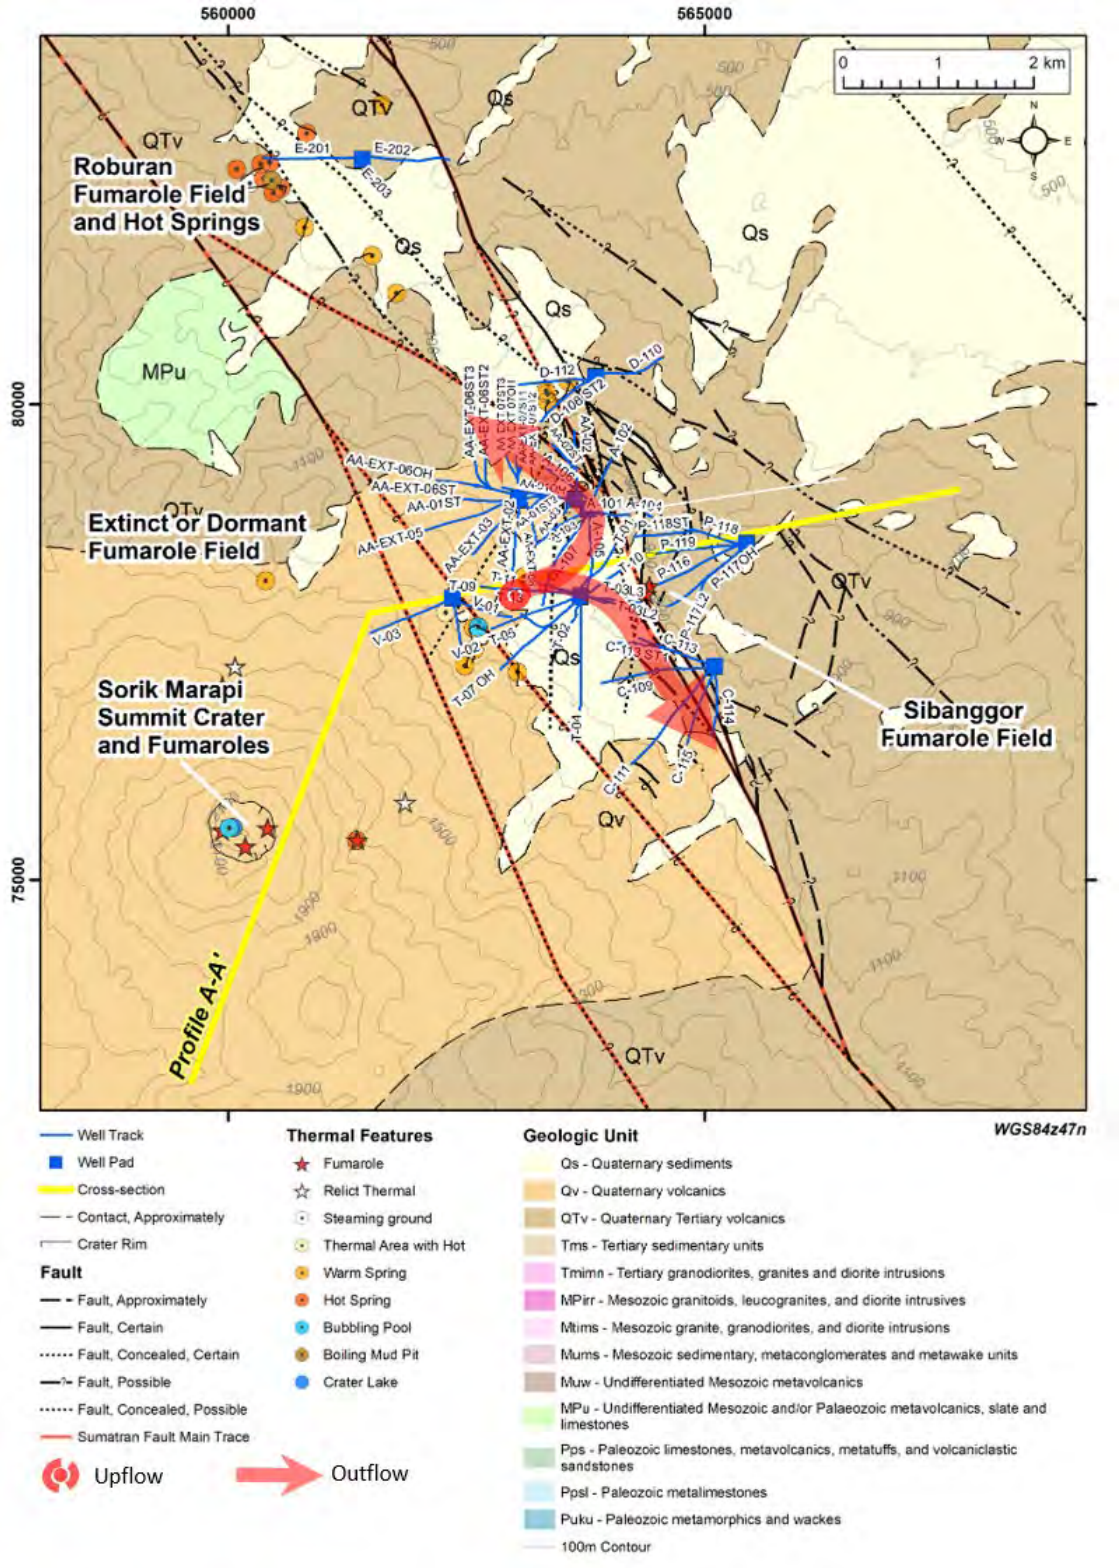

Figure 1: Map of the Sorik Marapi geothermal field. Upflow (red circle) and outflow pathways (red arrows) are shown. The A-A' conceptual model profile line corresponds to the cross-section in Figure 2.

As the field development and operations have expanded over the past years, the conceptual model has been continuously updated to include the geologic data from new drilling and well testing results. The temperature, geologic, geophysical, geochemical, and structural data are integrated into the conceptual model that represents details of upflow, outflow, reservoir rock, and cap. The up-to-date conceptual model shows that the reservoir is elongated along NNW-ESE and is bound on the east by the main strand of the Sumatra Fault System, and a deep ≥320°C upflow is located near the bottom of wells T-05 and T-09, which feeds the shallower productive reservoir to the NE, E and SE (see the arrows in Figure 1). The top of the reservoir (ToR) in the Pad A wells area starts at -50 mASL and deepens to the southwest reaching about -1250 mASL near the TD of T-09 (Figure 2).

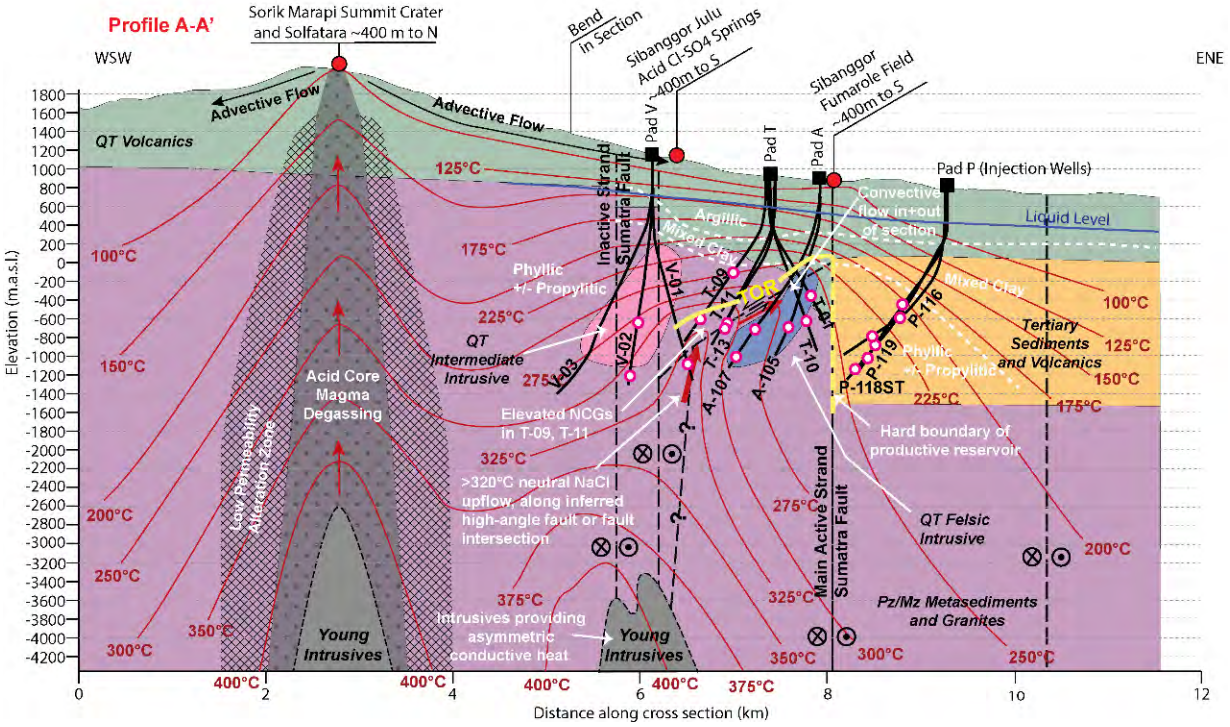

Figure 2: A cross-section of the conceptual model of the Sorik Marapi Geothermal Field along Profile A-A' (ENE-WSW) in Figure 1. The key features of the model include simplified geologic units, temperature isotherms, the top of the reservoir (ToR) shown as a yellow line, major structures (dashed black lines), and hydrothermal alteration (white dashed lines and text). Well courses are solid black lines, and major feedzones are shown as open red circles.

A 3D numerical reservoir model was initially developed using the early-stage conceptual model and calibrated against the pre-production pressure and temperature data (Kim et al., 2021). The updated conceptual model forms the basis for revising the geologic and hydrogeologic setting of the numerical reservoir model, which incorporates lithologic geometry and properties, temperature distribution and fluid flow within the reservoir, and boundary conditions such as upflow and outflow. In addition, natural-state data, field operation (i.e., production and injection history) and reservoir monitoring data are used to constrain the numerical reservoir model.

This paper presents the revised numerical model, model calibration process, and natural-state and history match simulation results compared with the field measurements. The revised and calibrated numerical model provides a suitable basis for assessing the production capacity of the resource area. The calibrated numerical model can be used to forecast the reservoir performance for various development scenarios.

2. Model Description

The computational domain of the numerical model with dimensions of 10 × 11 × 3.5 km is discretized into a three-dimensional structured grid with higher resolution within the well field. The grid origin is at 563,351.73 mE, 70,863.33 mN and -2,500 mASL, and the X-axis is rotated 32.71˚ north of east to be aligned with the orientation of the Great Sumatran Fault zone (Figure 3).

The original numerical model, described in Kim et al. (2021), was constructed based on the iTOUGH2 simulation-optimization framework (Finsterle et al., 2017; Finsterle, 2020), where a single-continuum model set up was employed to perform the natural-state simulation. This paper presents the natural-state and history match simulations, for which the mesh grid has been refined with a dual-continuum (fracture and matrix) model (Pruess and Narasimhan, 1982, 1985) for the elements within the main resource area.

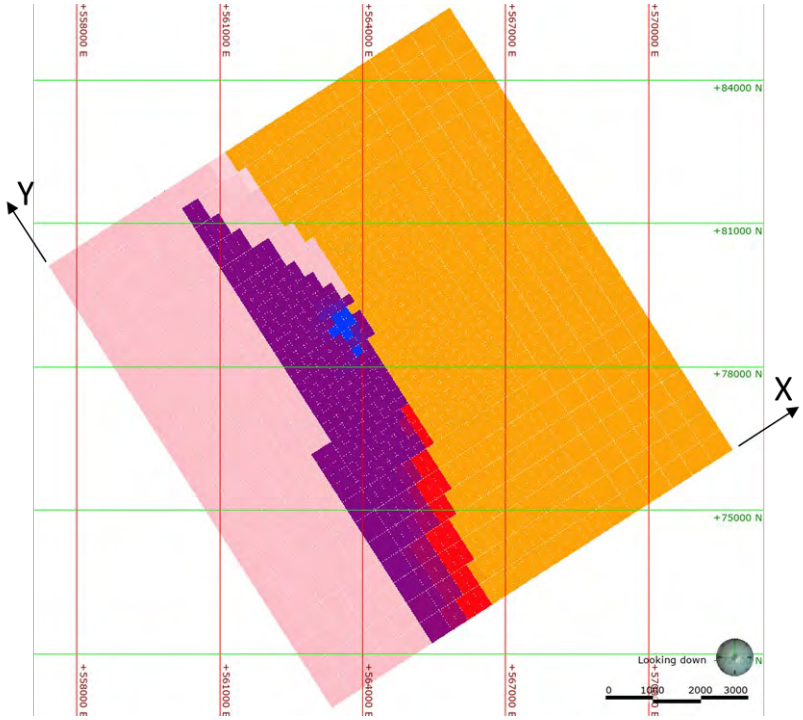

Figure 3: Computational domain and grid orientation.

The updated conceptual model and new drilling and testing data obtained through October 2023 are visualized in the Leapfrog geologic framework, which is adopted as the basis for assigning lithology to the elements of the numerical grid. Further revisions for local element rock types are made to improve the model matches to the observed natural-state and production history data,

which include 1) enhanced local connections to the permeable area; 2) an engineered barrier introduced to weaken the connection between injection and production areas; 3) a uniform lithologic volume subdivided into various rock units; and 4) the upflow chimney extended and inclined towards wells T-09 and T-13 (where the highest static temperature and flowing enthalpy were measured). The revised numerical model has 16 lithologic units. Figure 4 shows map and section views of rock type distributions.

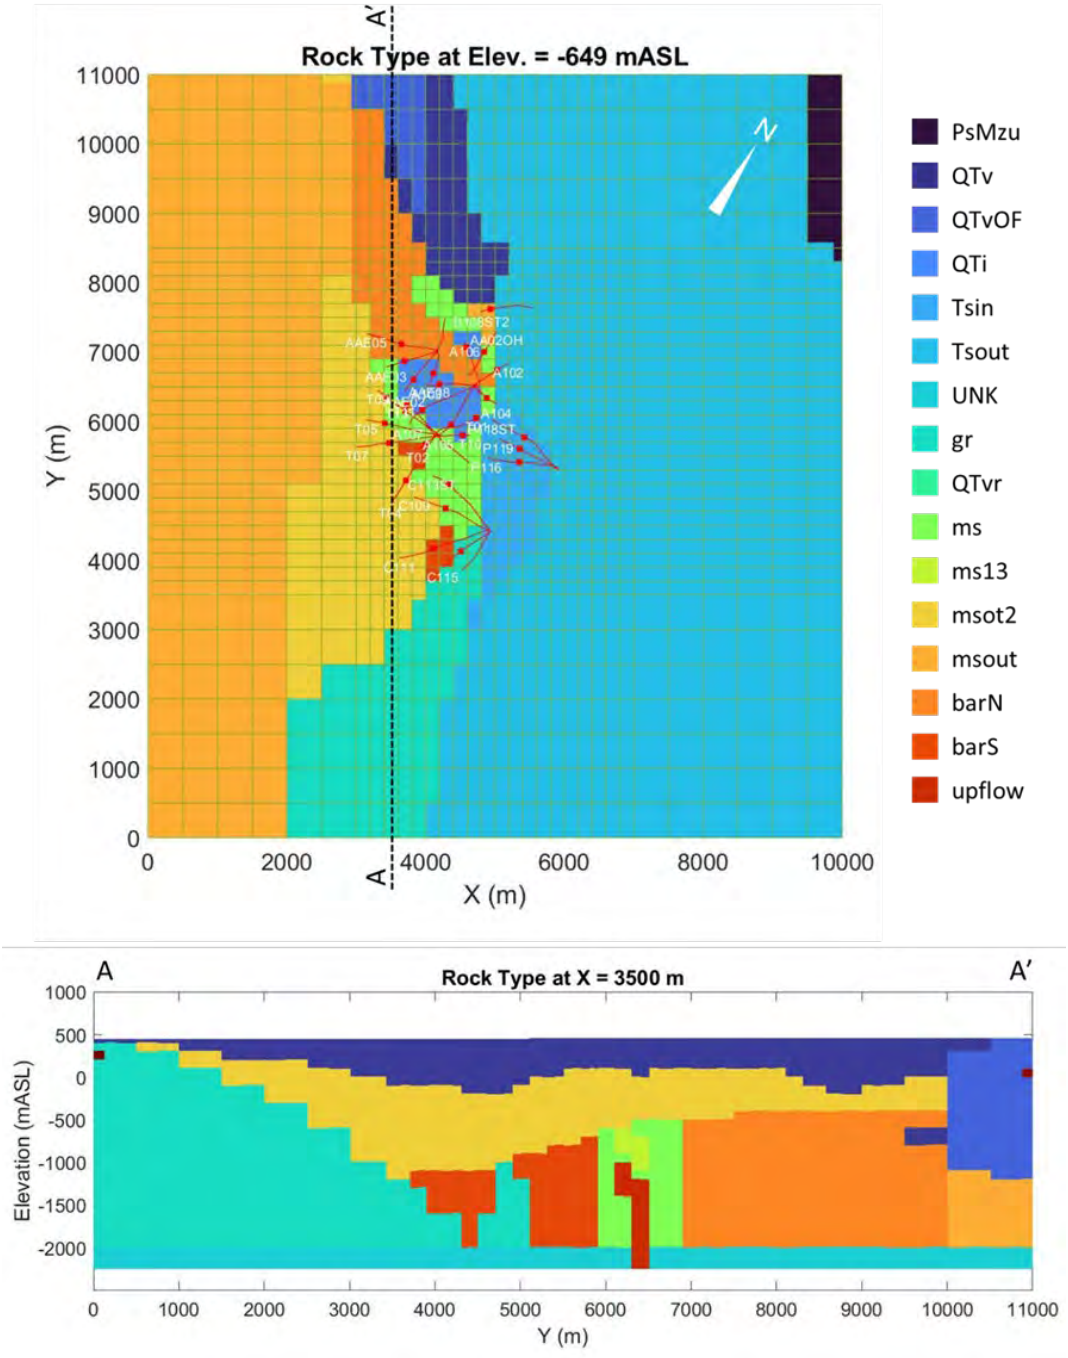

Figure 4: Rock type distributions in the numerical model. Red dots in the map view (upper plot) indicate the intersections of individual well tracks on the plane at the elevation of -649 mASL.

Constant pressure and constant temperature boundary conditions are specified at both the top layer (i.e., water level) at 550 mASL and the bottom layer at -2500 mASL. The boundary pressure and temperature values at these boundaries are determined as part of automatic model calibration. Note that heat flux across these boundaries is conduction-dominated. In addition, hot water flows into a narrow channel at the bottom of the model and connects to the high-permeability upflow chimney west of well T-09. The rate and enthalpy of this mass upflow is determined during model calibration. All side boundaries are impermeable and thermally insulated, except two outflow windows that allow for relatively shallow lateral flow from the center of the reservoir along the major strand of the Sumatra Fault System to the southeast and northwest. The pressures and temperatures at these two outflow windows are adjustable parameters for model calibration.

The revised numerical reservoir model was calibrated via inverse analysis for the natural state and the production history of the well field. A total of 78 parameters, including the rock properties (e.g., thermal conductivities, permeabilities, and porosities) and boundary condition values, are adjustable parameters for the iTOUGH2 automatic inversion. Depending on the importance of a calibration point and the reliability of measured data, the residuals are appropriately weighted in the objective function. The inverse problem solution (i.e., calibrated model results) minimizes the objective function of residuals between measured data and computed values. The following sections present the calibrated model results for the natural-state and history match simulations.

3. Natural-State Model

The numerical reservoir model is run to steady state. The resulting temperature distribution is compared to measured temperature profiles in wells that are considered to have stabilized and to represent natural-state conditions. Moreover, static feedzone pressures in some of the wells are also available for natural-state calibration.

Figure 5 shows the comparison between measured (blue lines) and computed (red lines) static temperature profiles for individual wells, where the measured temperatures are interpolated to the element coordinates for calibration points (indicated by yellow squares). Figure 6 presents the computed pressures compared to the feedzone pressures for the Pad A and Pad C wells from the pre-production period. The computed temperatures and pressures closely fit the measured data; therefore, the model is appraised as a good representation of the natural-state reservoir conditions.

4. History Match Simulation

Transient simulations with the numerical model were performed, from which the simulated dynamic behavior of the reservoir was fit to the monitoring data during the field operation (from August 2019 to November 2023). The production and injection rates for individual wells are specified as sink and source terms in the model.

Figure 7 shows the comparison between the computed production enthalpies and the estimated enthalpies based on the tracer flow test (TFT) results for individual production wells. Heat loss from the fluid in the well to the formation is accounted for by adding 25 kJ/kg to the TFT-based enthalpy measured at the wellhead, which is compared to the computed enthalpy at the feedzone grid block. The simulation results show good matches to the field measurements in terms of the overall level of enthalpies in various production wells, and the timing of steam development in well A-101.

Figure 8 compares the computed pressure changes with the observed pressure changes (i.e., shut-in pressures over the production period – natural state pressures) for Pad A, AAE, C, and T wells. While the computed pressure changes are slightly overestimated, the overall trend of pressure changes in the simulation accords with the measurements.

5. Conclusions

The numerical reservoir model of the Sorik Marapi Geothermal Field has been updated to incorporate geologic features from the updated conceptual model and information from new drilling and testing data. In addition, local element rock types are revised to improve the model matches to the observed natural-state and production history data. The updated model with a dual-

continuum (fracture and matrix) set up for the main resource area has been calibrated against the natural-state temperature and pressure and the production enthalpy history and reservoir pressure changes measured over the production period (from August 2019 to November 2023). The simulation results indicate that the calibrated model provides a reasonable representation of the pre-production field condition (i.e., natural state) and the transient reservoir response to the well field operation. The calibrated numerical model will be used to forecast the reservoir performance for various development scenarios and assess the resource and production capacity of the field.

ABSTRACT

Surface thermal features, most notably hot springs and geysers are increasingly being recognized in the U.S. for their importance to ecosystems, indigenous cultures, agriculture, recreation, and tourism. Combined with an unprecedented push to develop renewable energy projects across the U.S., concerns about impacts to these features from geothermal energy projects has resulted in development of tensions, an increase in regulatory scrutiny, and greater stakeholder opposition to geothermal energy development in some locations. Opposition and increased permitting and monitoring requirements have largely resulted from historical examples of negative impacts, most of which were associated with flash steam plants developed prior to 2000 that caused significant fluid/mass and losses from the reservoirs. However, since 2000, nearly all geothermal capacity additions have been binary plants which re-inject 100% of produced geothermal fluids back into the reservoir. With this trend expected to continue, impacts to surface thermal features will be significantly reduced, and possibly eliminated when field development exclusively uses technologies that minimize water losses (e.g., binary cycle power plants), and reinjection strategies that incorporate preservation of surficial flows as a management factor.

Current regulatory requirements for assessing and managing risks to surface thermal features during permitting, exploration, development, and operations are somewhat inconsistent and

unpredictable across different geothermal fields. In some cases, potentially excessive or unnecessary monitoring requirements that may be limited in their ability to provide meaningful insights have led to uncertainty and increases in exploration risk for geothermal energy developers including project delays, cancellations, or hesitation to commit. Varying regulatory requirements can also influence public perception and foster confusion, distrust, and opposition to geothermal projects. This comes at a time when there is an increasing urgency for reliable sources of clean energy, and geothermal can provide a net-zero, renewable solution. Continued integration of geothermal energy into the national energy roadmap can be facilitated through consistent and predictable permitting, providing regulators the framework they need, giving developers a clear path forward, and creating the transparency that the public deserves to feel sure that these resources are being protected.

This project, currently in its beginning phases, seeks to address this important issue by providing a technical basis from which to build a preliminary protocol for assessing and managing potential impacts from new or existing geothermal energy projects to surface thermal features and their associated ecosystems. Development of this preliminary protocol will be informed by (1) literature reviews of well-documented case studies in the western US and internationally to understand the range of conditions that exemplify geothermal-surface thermal systems; (2) development of illustrative conceptual numerical models to quantify, understand, and predict the first-order controls (e.g., pressure and permeability) on surface flows; and (3) additional independent case studies using industry-provided and publicly available data to understand and demonstrate the risk profiles and cause-and-effect relationships between geothermal power production and impacts to surface thermal systems.

Learning from the successes of the process used to develop the Induced Seismicity Management Protocol (ISMP), we ultimately aim to use these initial efforts as a springboard for establishing a surface thermal feature management working group that will collaboratively refine the protocol as well as co-develop recommended best practices for implementation. We envision that the working group will be composed of representatives from diverse stakeholder groups (e.g., regulatory entities, industry, government agencies, Tribes, academia, national laboratories), and will include regular engagement with community organizations and environmental groups to understand and meaningfully incorporate their input into the final protocol and best practices for implementation. This will help ensure broad acceptance and implementation of the protocol, which will facilitate a more consistent, and efficient regulatory process, and ultimately help to ensure that geothermal energy continues to provide a reliable source of clean energy and a pathway to achieving greater energy equity in the U.S.

1. Introduction

Over the last several decades there has been an increasing awareness of the significant importance of hot springs, geysers, and other surface thermal features (Figure 1) to ecosystems, indigenous cultures, agriculture, recreation, and tourism. Combined with an unprecedented push to develop renewable energy projects across the United States (U.S.) this has resulted in development of tensions, an increase in regulatory scrutiny, and greater stakeholder opposition to geothermal energy development in some locations (e.g., Richter, 2019; U.S. BLM, 2022; Newberger, 2023; Coates, 2023; Donnelly, 2023, U.S. DOE, 2024). Opposition to development and increased permitting and monitoring requirements have largely resulted from historical examples of negative

impacts, most of which were associated with flash steam plants developed prior to 2000 that caused significant fluid / mass losses from the reservoir and subsequent pressure and/or groundwater elevation decreases (e.g., White, 1998; Sorey, 2000; Barrick, 2005; White and Hunt, 2005; Allis and Larsen, 2012; Chen et al., 2020; Martinez, 2024). However, since 2000, nearly all new geothermal capacity additions in the U.S. have been binary plants which re-inject 100% of produced geothermal fluids back into the reservoir (U.S. EIA, 2020; Robins et al., 2021). With this trend expected to continue (e.g., Robins et al., 2021), impacts to surface thermal features will be significantly reduced, and may be eliminated when field development exclusively uses technologies that minimize water losses (e.g., binary cycle power plants), and reinjection strategies that incorporate preservation of surficial flows as a management factor (Kagel et al., 2007; Heasler et al., 2009; Kaya et al., 2011; Ratouis et al., 2017; Kamila et al., 2020).

Figure 1. Collection of images depicting examples of surface thermal features. ***Source: Kagel et al., 2007***

Currently, there is a lack of consistency or predictability in permitting and monitoring requirements across different geothermal fields (e.g., U.S. BLM, 2009; U.S. OIG, 2013; Young et al., 2014, 2019; U.S. DOI, 2022; Levine et al, 2013, 2022; U.S. DOE, 2024). Section 3102 of the Energy Act of 2020 requires that the U.S. Secretary of Interior establish a national Renewable Energy Coordination Office (RECO) and State, district, or field offices, as appropriate, to improve federal permit coordination for geothermal, solar and wind projects occurring on federal lands. Section 3102 also allows for the Secretary of Interior to temporarily assign qualified staff to RECOs to expedite the permitting of eligible projects (Levine and Smith, 2023). In response, in 2022 the U.S. Secretary of Interior entered into a memorandum of understanding (MOU) with Secretaries of several other federal agencies, including the U.S. Department of Energy (DOE) to establish RECOs that will:

> *"…implement improved coordination among agencies, help avoid and resolve potential conflicts and bottlenecks, identify best practices, accelerate information sharing, and promote efficient and timely reviews to support smart agency decision-making*." (U.S. DOI, 2022).

For geothermal projects, one of the contributing factors for the inconsistencies in permitting and monitoring requirements is the lack of shared understanding between industry, regulators, and other potentially impacted stakeholders of what general and site-specific conditions drive risk to surface thermal features during exploration and operation, and what mitigative approaches (including characterization, monitoring, and reinjection strategies) are most appropriate for identifying and managing those risks (e.g., Young et al., 2019). This is leading to potentially unsustainable increases in economic risk for geothermal developers (e.g., Neupane and Adhikari, 2022) which derive largely from project delays or potentially excessive or unnecessary site characterization requirements during permitting (i.e., before a developer can drill a single test well to assess economic viability), and during monitoring of operating systems. Importantly, in some cases the additional site characterization or monitoring data being required by regulators may be limited in their ability to provide meaningful insights into the system dynamics or cause-and-effect relationships that exist at a given site. Regulatory inconsistencies may also lead to decreased public trust and increased public opposition which leaves the geothermal industry more vulnerable to legal challenges that can result in project cancellations (e.g., Richter, 2019; U.S. BLM, 2022; Newburger, 2023; Coates, 2023; Donnelly, 2023). This comes at a time when there is a heightened urgency to expand reliable clean energy options that can combat the climate crisis and provide pathways to greater energy equity and environmental justice in the U.S. (U.S. DOE, 2023). Ostensibly, geothermal should be among the best options in the clean energy space, due to its low land use and mineral requirements, as well as the value it adds to the grid in the form of clean, baseload power (e.g., Bromley et al., 2010; U.S. DOE, 2019; Soltani et al, 2021; Vargas et al., 2022).

2. Overview of Regulatory Landscape

Development of geothermal energy must undergo regulatory review similar to other energy resources. If a proposed project may have impacts to human health or the environment and is deemed a federal action (i.e., occurs on federal lands, or federal funds are contributed to the project), then at the highest-level, developers must comply with the National Environmental Policy Act (NEPA). NEPA requires an evaluation of potential impacts from a proposed action and offers a tiered approach that includes a review of the proposed project by an assigned staff member who may either issue a categorical exemption (CX) to the NEPA process or indicate the need to perform an environmental assessment (EA) of the proposed action. The result of the EA may either be issuance of a finding of no significant impact (FONSI), or a finding that the proposed project will significantly affect the quality of human health or the environment. In the latter case, this could then trigger the need for a full environmental impact statement (EIS). For an EA or EIS, compliance with NEPA includes a formal process of public disclosure of potential effects. Importantly, most geothermal energy resources in the U.S. (approximately 90%) are on federally managed land, making NEPA considerations a major factor in present and future geothermal development projects (U.S. BLM, 2005; Young et al, 2014).

Implementation of the NEPA process also includes considerations of various other federal laws, and geothermal development efforts may have to account for many general federal statutes including the, Clean Air Act (42 U.S.C. §7401 et seq.) Clean Water Act (33 U.S.C. §1251 et seq.), Endangered Species Act (16 U.S.C. 1531-1544), National Historic Preservation Act (16 U.S.C. §§470a-470w-6 et seq.), and others as well as resource-specific laws including the

Geothermal Steam Act as amended (30 U.S.C. §23). State and local governments also regulate development and monitoring within their jurisdictional boundaries.

In 2009, the U.S. Department of Interior's (DOI) Bureau of Land Management BLM and U.S. Forest Service issued their final, joint Programmatic EIS (PEIS) for leasing, permitting, exploration and utilization of proposed geothermal projects in the western U.S (U.S. BLM, 2009). The value of a PEIS is to provide early information that can be considered during planning which can be used to inform, and responsibly expedite implementation of site-specific NEPA analyses and permitting. Multiple NEPA analyses are typically required for the development of utility-scale geothermal projects (Young et al., 2014; Neupane and Adhikari, 2022; U.S. BLM, 2023). Figure 2 (modified from Young et al., 2014) provides an example timeline of the multiple NEPA analyses that are or may be required during the stages of geothermal permitting and licensing. However, U.S. federal land and resource management agencies are de-centralized in structure, which has largely left implementation of these NEPA requirements to regional and local offices. Variance, or in some cases, contradiction in agency mission within site offices also contributes to regulation and environmental review process variability, adding another level of complexity to the regulatory landscape that is difficult to anticipate (Levine et al., 2013, 2022).

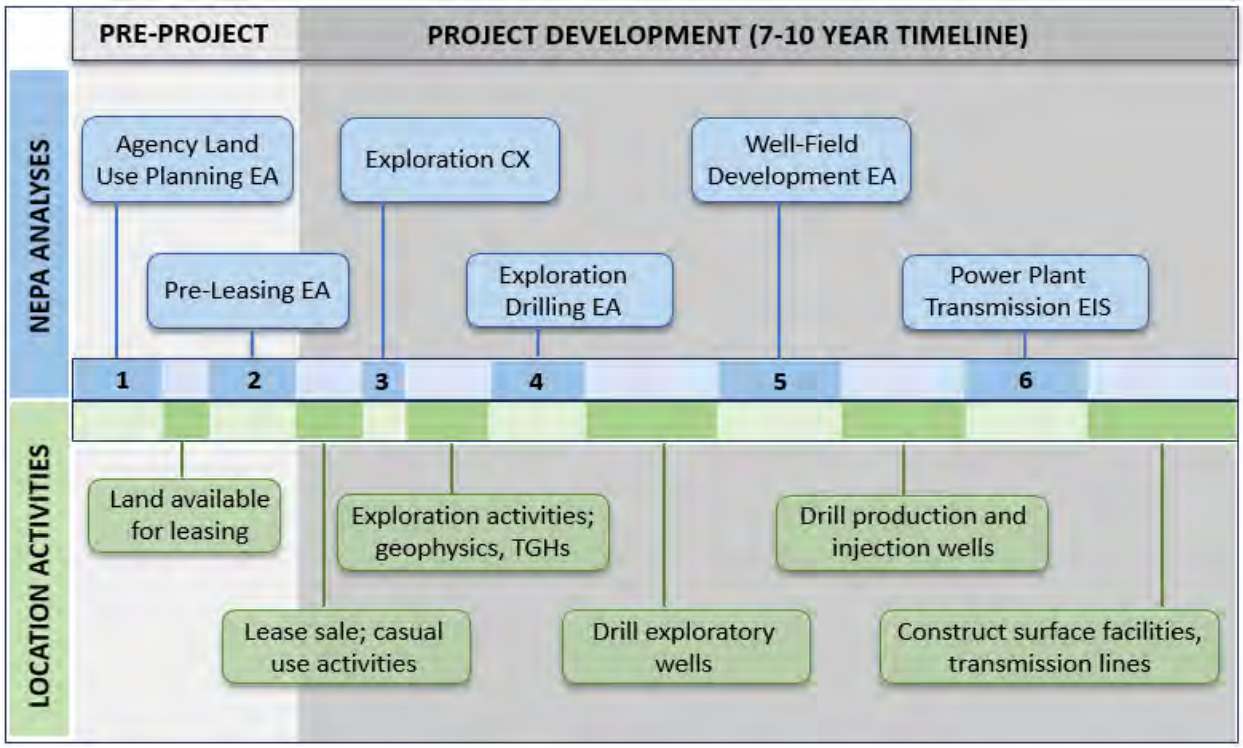

Figure 2. Example of a timeline depicting permitting requirements for geothermal resource project located on federal lands. The example demonstrates that a NEPA analysis (blue timeline) could be triggered as many as six times during permitting benchmarks (green timeline). EA: Environmental Assessment; CX: Categorical Exemption; EIS: Environmental Impact Statement; TGHs: Thermal Gradient Holes *Modified from Young et al., 2014.*

3. Project Goals and Objectives

The *near-term objective* of this project is to establish a preliminary protocol for assessing and monitoring potential impacts to surface thermal features during geothermal permitting and operation. Establishment of this preliminary protocol will be rooted in (1) a review of well-documented case studies in the western U.S. and internationally that are able to illustrate the range of conditions that exist in geothermal-surface thermal systems; (2) development of illustrative conceptual numerical models to quantify, demonstrate, and predict the first-order controls (e.g., pressure and permeability) on surface flows; and (3) conduct additional independent and scientifically rigorous evaluations of geothermal-surface thermal system case studies from the western U.S. that includes analysis of publicly available information as well as data provided by industry through data-sharing agreements.

The *long-term objectives* of this project are three-fold:

1) Establish a working group comprised of individuals representing diverse interests within the geothermal community writ large (e.g., regulatory bodies, industry, academia, government, special interest groups, Tribes, and communities) to collaboratively review stakeholder concerns, technical challenges, and ultimately finalize the preliminary surface thermal feature management protocol and co-create best practices for implementation.
2) Facilitate wide-spread acceptance and adoption of the protocol and best practices throughout the geothermal community.
3) Improve or renew public trust and confidence in geothermal energy projects and establish a strong social license to operate.

Combined, meeting these near-term and long-term objectives will contribute to the realization of *the fundamental goal* of this effort, which is to standardize regulatory requirements associated with understanding and managing impacts to surface thermal features during geothermal energy operations, and to ensure geothermal energy can continue to provide a reliable source of clean energy that the Earth needs, as well as help advance U.S. energy equity and environmental justice goals that underserved communities deserve.

4. Establishing the Technical Foundation for Preliminary Protocol

As illustrated in Figure 3, to meet our near-term objective of establishing a preliminary protocol for managing potential impacts to surface thermal features during geothermal permitting activities and operations, we will perform the following tasks: (1) complete a literature review with key stakeholders to understand the range of domestic and international geothermal circumstances and experiences, both pre- and post-2000; (2) develop a series of illustrative conceptual numerical models to demonstrate the controlling role of pressure and permeability on hot spring and geyser flow; and (3) conduct case study analyses on several additional geothermal systems in the western U.S. using publicly available and industry-provided data. The following sections provide additional information about each of the three near-term objectives.

4.1 Literature review and knowledge capture

The primary overarching objective of this task is to develop a baseline understanding of the range of conditions that might exist in geothermal-surface thermal feature systems, and to assess the known or likely first-order controls on observed or potential impacts to these features from

geothermal development. A literature review will be conducted to collate existing knowledge related to these systems using several well-documented geothermal systems and fields in the U.S. and internationally that are able to clearly demonstrate the relationships. This includes locating and reviewing scientific studies, environmental impact assessments (EISs), industry reports, and regulatory guidelines from around the world. We are also assessing:

- Cases when changes in flow, pressure, temperature, or chemical regime of surface thermal features have resulted in negative impacts to associated ecosystems.
- Impacts to surface thermal features with respect to geothermal plant operational designs.
- The evolution of the geothermal permitting, exploration, and management regulatory requirements, and the potential site-specific drivers behind those requirements.
- Existing mitigation strategies employed to minimize impacts on surface thermal features and associated ecosystems. This may involve wellbore design considerations, pressure monitoring protocols, limitations on water withdrawal, and reinjection strategies.
- Satellite imagery to visually assess the stability of surface thermal features over time, particularly as it relates to industrial or agricultural development.

Importantly, this effort may include interviews with geothermal energy experts, practitioners, regulatory entities, and community organizations, as appropriate, to better understand the diverse perspectives, drivers, and experiences related to assessing and managing potential impacts to surface thermal features. While some of these interviews may only point to anectdotal information or evidence that would not be appropriate to include in any quantitative assessments, this information could provide important qualitative insights that may inform improvements to our quantitative approaches.

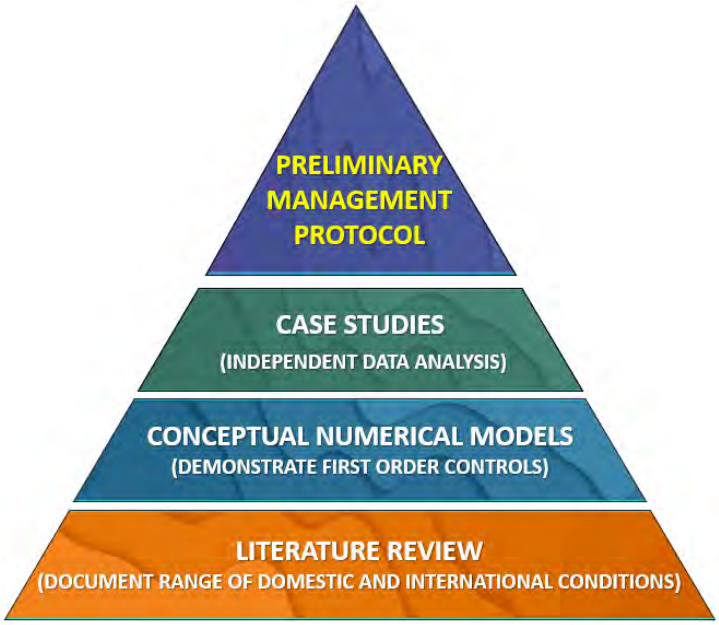

Figure 3. Illustration of the near-term activities that will form the basis for development of a preliminary surface thermal feature management protocol. Future activities include establishment of a surface thermal feature management working group comprised of diverse stakeholders what will co-refine and finalize the preliminary protocol as well as co-create best practices for protocol implementation during permitting and/or monitoring of new or existing geothermal power plants.

4.2 Development of illustrative conceptual numerical models

A series of simple illustrative conceptual numerical models are currently being developed using STOMP-GT (Subsurface Transport Over Multiple Phases-Geothermal) to clearly illustrate first-order cause-and-effect relationships between geothermal field operations and surface flows given a set of basic assumptions about subsurface features. STOMP is a suite of numerical simulators for solving multidimensional, nonlinear problems, including those involving nonisothermal conditions and dual permeability (i.e., fracture-controlled and porous media) using coupled flow and transport processes in variably saturated geologic media (White and Oostrom, 2006; STOMP Online User Guide). The STOMP simulations and models will include parametric evaluations that assume a realistic range of vertical and horizontal permeabilities, with 70% to 100% fluid reinjection, as well as a baseline scenario of 0% reinjection, over a 20- to 50-year period. Depth level of interrogation will initially be constrained to a production-injection depth of >500 to 2000 meters. Examples of models that may be constructed include the following:

- Scenario 0. Isotropic permeability with no fluid reinjection (baseline scenario).
- Scenario 1. Isotropic permeability, 70-100% fluid reinjection.
- Scenario 2. Anisotropic permeability, partial to complete vertical barrier to fluid flow (i.e., a fault), 70-100% fluid reinjection.
- Scenario 3. Anisotropic permeability, partial to complete horizontal barrier to fluid flow (i.e., a fault or low permeability stratigraphic feature), with 70-100% reinjection.

Boundary conditions for these simple scenarios will be established using real-world conditions found in the western U.S. and will be combined with additional assumptions related to permeability, pressures, hydraulic gradients, and heat flow regimes to provide first-order quantification of the effects of pressure drop propagation and on piezometric/water table levels that control hot spring or geyser discharge in a given production/injection regime (e.g., White and Hunt, 2005; Ratouis et al., 2017). We may also conduct sensitivity and uncertainty analyses on each of these scenarios to identify thresholds beyond which geothermal production activities could have significant negative impacts to surface thermal features. These thresholds can then be used to help establish clear guidelines for surface thermal feature management protocol.

4.3 Case studies enabled through publicly accessible and industry-provided data

The project team will evaluate several case studies from the western U.S. using site-specific data that is available in the public domain and that is provided by industry through data-sharing agreements. The intended primary use of these data is to evaluate the time-histories of pressure, temperature, flow rates, and aqueous geochemistry of production/injection fluids and associated surface thermal features, and to assess whether any observed changes in surface thermal feature conditions may be correlated to geothermal energy production. We will also consider the potential influence that natural phenomenon (e.g., seismic activity) or other nearby agricultural or industrial activities may also have on these features. The illustrative conceptual numerical model parameters (refer to Section 3.2) will be updated to be representative of the site-specific conditions at each case study location to improve the correspondence between the simulation results and field observations. This will allow for a greater understanding of the controls on these specific systems as well as identify what information is required to accurately predict observed changes in the geothermal-hydrothermal system. The team has identified four initial case studies and has begun receiving data from industry. To date, industry data received includes:

- Production and injection well coordinates.
- Wireline logs (including image logs, and pressure / temperature flow meter results)
- Raw brine and injectate aqueous chemistry (including pH, conductivity, temperature, pressures, major and minor ion concentrations, isotopic composition of water, dissolved gas concentrations and other gas indicators).
- Underground Injection Control (UIC) O&M manuals.

Additional data that we anticipate receiving from industry or are locating from publicly available sources include:

- Production and injection well depths.
- Permeability of key stratigraphic units.
- Time-series groundwater, surface water, and surface thermal feature data (preferably both before and after geothermal operations) including:
    - Hydrologic parameters (e.g., water levels, photographs, hydraulic gradients, flow rates).
    - Field parameters (e.g., temperature, pH, conductivity).
    - Aqueous chemical composition (e.g., total and dissolved major ion composition, trace metals concentrations, and elemental / molecular and isotopic composition of water and dissolved gases).
    - Visual documentation (photographs or satellite imagery) of changes to surface thermal features and surrounding land.
- Information related to ecosystems that are present and any sensitive flora or fauna that may be dependent on the geothermal/hydrothermal system to thrive.
- Plant permitting, exploration, development, and operational histories.
- Regulatory histories for each plant over time.

Access to these high-quality data from multiple sites expands and diversifies the types of systems we can consider. This provides a more complete understanding of the commonalities and differences in cause-and effect relationships, what conditions pose the greatest risk to surface thermal features, and what the most appropriate approaches are for assessing and managing those risks. This significantly strengthens the quality of the study, enables greater generalizability of the results, and creates a strong, evidence-based foundation for the establishment of preliminary protocol for protection of surface thermal features.

Importantly, a key element of our case studies includes detailed reviews of the regulatory requirements for each site over time, specifically as it relates to assessing or monitoring impacts to surface thermal features. This review will provide an assessment of what is driving the additional requirements, and the degree to which the data requested are able to provide meaningful insights into the risk profile or cause-and-effect relationships. This assessment will build on insights from the literature review, results from the illustrative conceptual numerical models and any findings from the time-history evaluations of geothermal production and flow regimes in the surface thermal features.

4.4 Development of preliminary surface thermal feature assessment and management protocol

The insights gained from the tasks described in sections 3.1, 3.2 and 3.3 will ultimately be integrated to develop a preliminary protocol for assessing and monitoring potential impacts to surface thermal features from geothermal power plant permitting, development, and operation. We envision that this protocol can ultimately be used by geothermal operators, regulators, and other stakeholders to responsibly evaluate and monitor the potential impacts of geothermal development on surface thermal features, without imposing unnecessary regulatory requirements on geothermal developers that may hinder the development of this clean energy resource. We expect that this preliminary protocol will include a clear decision-making framework that will guide geothermal energy developers, regulators, and potentially impacted communities through a more consistent and predictable permitting and monitoring process.

5. Establishing a Surface Thermal Features Management Working Group

One of the long-term objectives of this project is to promote the wide-spread acceptance, adoption, and confidence in these practices and guidelines across the geothermal community. Creation of a surface thermal features management working group will allow diverse stakeholders with unique backgrounds and expertise to collaboratively refine and finalize the protocol and co-create a set of best practices for implementation. We also envision potential co-development of a web-based tool that will allow stakeholders to navigate and implement the protocol and guidance more effectively, which will further optimize implementation of NEPA requirements and reduce barriers to geothermal permitting.

Learning from the process successes of the Induced Seismicity Management Protocol (ISMP) (U.S. DOE, 2012), as well as the Geothermal Interagency Collaboration Task Force (Levine and Smith, 2023), we envision that the surface thermal feature management working group will include representatives from industry, federal and state regulatory entities, other federal agencies (e.g., DOE), Tribes, academia, and national laboratories. It will also engage early and often with local or state governments, community stakeholders and special interest groups (e.g., environmental groups) to ensure that input from these groups is meaningfully incorporated, and issues and concerns are addressed to the greatest extent possible.

Successful co-development of the final protocol and best practices that includes meaningful inclusion of input from many voices offers many important benefits (e.g., Keeys and Huemann, 2017, Rossi and Tuurnas, 2021). First, it helps to ensure that the final products can effectively and equitably address the needs of all impacted or potentially impacted stakeholders. Second, it can lead to development of protocol and procedures that are more comprehensive, practical, and relevant to the real-world context. Third, it can build trust among stakeholders which in turn will foster greater acceptance of the protocol and best practices and increase the probability for wide-spread adoption.

6. Summary and Future Perspectives

The lack of consistency in geothermal permitting, and monitoring requirements, specifically as it relates to assessing and monitoring potential impacts to hot springs and geysers and other surface thermal features has greatly increased exploration risk and permitting costs for geothermal developers. This comes at a time when there is an increased urgency and demand for the clean

energy and renewable power generation that geothermal energy can provide. This paper describes the project team's approach to standardizing regulatory requirements and reducing barriers to permitting and geothermal development. Our near-term objective is to develop a preliminary protocol for assessing and managing potential impacts to surface thermal features using scientifically rigorous and independent analyses that are informed, in part, by site-specific data provided by industry through data sharing agreements. These studies will offer improved understanding of the cause-and-effect relationships that exist in geothermal-surface thermal feature systems, and the primary risk factors to consider when evaluating potential impacts to surface thermal features. Our long-term objectives are to establish a surface thermal features management working group comprised of diverse stakeholders and Tribes from across the geothermal community to refine the preliminary protocol, establish agreed-upon best practices for implementation, promote widespread acceptance and adoption of the protocol and best practices, and build trust within communities. The goal of these efforts is to standardize regulatory requirements associated with mitigation of potential impacts to surface thermal features, and to help ensure that geothermal energy can continue to provide a reliable source of clean energy and a pathway to achieving greater energy equity in the U.S.

ABSTRACT

Geothermal energy, a sustainable and renewable resource, plays a vital role in the global energy supply. To guarantee peak performance and longevity of geothermal wells, it is essential to implement a wellbore operation and maintenance strategy.

A fundamental component of this strategy is scale management attributed to mineral precipitation from the brine during the reinjection and production process. The accumulation of scale deposits significantly impacts the lifespan and efficiency of geothermal wells by restricting fluid flow, thus reducing wellbore performance. To address these impacts in a geothermal district heating (GDH) system, it is important to administer forward-looking maintenance plans before manageable fluids become unmitigated outages.

The GDH system in the Town of Lakeview, Oregon plays a critical role to heat local schools, the community hospital, the emergency services station, and a dental clinic. By using geothermal energy, Lakeview offsets the expense and environmental impact of traditional fuels like propane, ensuring cost-effective and sustainable heating for the community. The functionality of the GDH was impacted by severe iron oxide-hydroxide scale deposits that had developed over time. In recent years, the scaling drastically reduced the flow rate from 160 gallons per minute (gpm) down to 88 gpm. To efficiently meet the needs of these community buildings, a production rate of 130 gpm is required.

To restore these essential services, various methods for scale removal were considered and electro-hydraulic pulse technology was applied. The targeted pulsing technology in Lakeview achieved

breakthrough results in scale removal, leading to an increased production rate of 206 gpm. The Lakeview case study underscores the importance of regular maintenance and innovative solutions to improve the well production and increase the lifespan of geothermal wells.

1. Introduction

In the global energy portfolio, geothermal energy plays a vital role as a sustainable and renewable resource. As the geothermal industry continues to grow, operators seeking to increase production generally have two primary strategies: embark on capital-intensive drilling campaigns to initiate new wells or optimize and extend the productivity of existing wells. The financial outlay and inherent risks associated with drilling new wells often overshadow the benefits, making it critical for operators to implement a strategic wellbore maintenance plan.

A fundamental component of this strategy is scale management, as geothermal brines typically contain dissolved minerals that can precipitate out of solution during the reinjection and production process. The accumulation of scale deposits significantly impacts the lifespan and efficiency of geothermal wells by restricting fluid flow, thus diminishing wellbore performance. To address these impacts in a geothermal district heating (GDH) system, it is important to administer forward-looking maintenance plans before manageable fluids become unmitigated outages.

A prime example where the fluid flow has been restricted, thus reducing well performance, is the GDH system in the town of Lakeview. The operator’s producer well was severely affected by untreated scale deposits. Given the community's reliance on the geothermal heating system for local schools, the dental clinic, hospital, and emergency services station, it was vital to find an effective and economical solution. By using geothermal energy, Lakeview offsets the expense and environmental impact of traditional fuels like propane, ensuring cost-effective and sustainable heating for the community. When the system was unable to operate to meet the heating demand, buildings had to use propane as the back-up energy source or be shut down until the accumulation of scale deposits were removed through wellbore cleaning treatment.

If an appropriate wellbore maintenance strategy is implemented, then ideal fluid flow can be maintained for improved energy production because of the removal of flow impediments within the geothermal system. A proactive approach for regular wellbore cleaning will extend the operational life of geothermal wells, reduce unplanned downtime, and ultimately enhance the economic viability of a geothermal project.

2. Method

During the utilization of geothermal resources, geothermal wells and surface equipment are susceptible to scale deposition due to various factors that include changes in temperature, pressure, and flow velocity, pH level, degree of supersaturation and presence of ions in solution. Silica, carbonates (calcite, aragonite), and iron-based corrosion products are the most common types of scale in geothermal wellbores.

Developing a wellbore operation and maintenance strategy requires the consideration and evaluation of several factors. These factors include: specific wellbore conditions, operational requirements, regulatory constraints, economic considerations, and various scale removal techniques.

In this case study, the town of Lakeview (operator) initially reviewed conventional chemical and mechanical scale removal techniques. Key considerations for the operator included:

- A rigless operation due to the added mobilization costs to get to their rural locality
- Wellbore integrity by not damaging the completion equipment
- A solution with low health and safety risk

In order to meet these requirements, they decided to pursue, an innovative method, the electro-hydraulic pulsing technology,

The geothermal producer well contained goethite (iron oxide-hydroxide) scale that had been building up over a period of 14 years shown in Figure 1(a) and 1(b). With goethite being a challenging type of scale to remove, the electro-hydraulic technique was important to deploy to ensure an effective cleanout while maintaining the wellbore integrity of their geothermal system.

Figure 1(a): Goethite (Iron Oxide-Hydroxide) scale found in Lakeview producer wellbore. 1(b) SEM photomicrograph of goethite scale particle. Red arrow indicates FeO-OH-rich surface; blue arrow shows black Fe_3O_4 sub-surface (Hudspeth, et al., 2023).

3. Results

Through the strategic maintenance plan for the town of Lakeview, the electro-hydraulic pulse technology was deployed. The technology involved utilizing a small amount of energy that is released over an extremely short timespan to generate powerful electro-hydraulic pulses downhole. The hydraulic pulses propagated outwards (compressional force), reflected off the casing, and traveled back inwards (tensile force). Since scale has high compressional strength and low tensile strength, this push-and-pull motion peeled the scale from the sides of the wellbore.

The pulsing technology targeted specific intervals totaling 105 feet of permeable water-bearing zones that were partially obstructed by scale deposits. The repetition of pulses effectively broke up the goethite scale (iron oxide-hydroxide) in the wellbore to eliminate any flow impediments.

Four years ago, the production rate was 160 gallons per minute (gpm), which had declined to a rate of 88 gpm due to flow impediments. To efficiently meet the needs of the buildings, a production rate of 130 gpm has been recommended. Following the targeted pulsing treatment, the production rate increased to 206 gpm as shown in Figure 2.

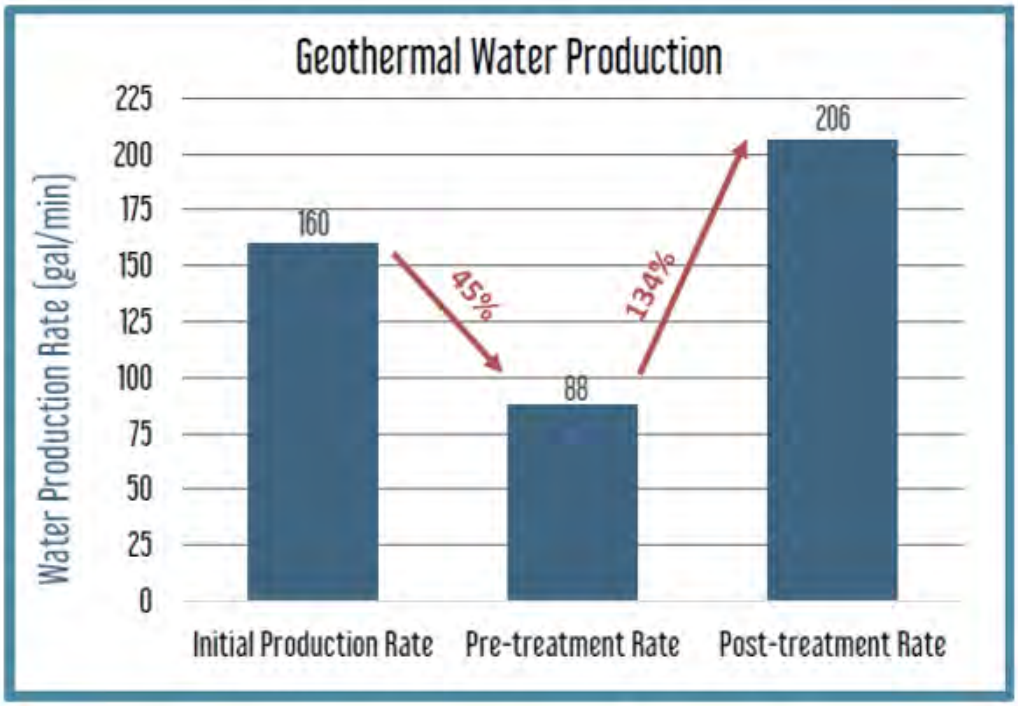

Figure 2: Geothermal production rate of 160 gal/min in 2020, followed by 88 gal/min (pre-treatment) and 206 gal/min (post-treatment) in 2024.

4. Conclusion

The use of this technology in Lakeview achieved breakthrough results in scale removal, leading to increased fluid flow and well productivity. The heat was successfully restored to the town, providing energy security, with a production rate to support the heating of additional buildings as needed. The Lakeview case study underscores the importance of regular maintenance and innovative approaches to managing geothermal wells.

Acknowledgements

The project benefited immensely from the collaborative efforts of the Town of Lakeview, Blue Spark Energy, Jacobs Solutions, and Di Drill Survey Services. The study acknowledges the valuable technical insights from these industry experts, whose contributions have been pivotal in addressing the challenges of scale deposition in GDH systems. Most importantly, the support of the local community and Scott Langum for taking the lead to pursue an innovative approach to scale removal.

Optimizing Geothermal Resource Management: Insights from Stock Reservoir Modeling Analysis in Icelandic Fields

Arkaitz Manterola Donoso[1], María Gudjonsdottir[1], Hlynur Stefansson[1], Egill Júlíusson[2]

Reykjavik University[1], Artic Green Energy[2]

Keywords

Sustainable Energy Engineering, Geothermal Utilization, Stock Reservoir Model, Interconnected Production Modeling.

ABSTRACT

It is essential to optimize the sustainable utilization of geothermal resources, considering the current growth trend of the geothermal energy sector, to achieve long-term sustainability and profitability. This involves aligning with market demands, optimizing field management and increasing efficiency, which includes maintaining reservoir pressure, optimizing well production, and minimizing environmental impacts of the utilization.

This study aims to increase the understanding of the production from geothermal reservoirs by using production history data and well characteristic curves to analyze the impacts on the resource by using stock reservoir modeling. This mathematical modeling technique can predict how the reservoir might behave over time in response to production activities. These models can be useful for optimizing production strategies, such as the need for drilling make-up wells, reinjection, and scheduling to ensure energy production and long-term resource sustainability.

The main goals of the research are 1) to apply stock modeling to a variety of wells with different characteristics and production histories to better understand the method's versatility and 2) to analyze the applicability of using stock reservoir modeling for wells with interconnected productions. Specifically, wells from the Þeistareykir geothermal field in North Iceland and the Hverahlið geothermal field in Southwest Iceland are used as case studies to gain insights into their unique characteristics and production histories by applying the model to them.

1. Introduction

Current trends show that most energy sectors, including the geothermal sector, aim to reduce greenhouse gas emissions and enhance sustainability. Geothermal is a renewable energy source that provides relatively clean and reliable electrical and thermal energy. However, although they are closer to being carbon neutral than fossil fuels, there is room for improving geothermal resource utilization to reduce emissions and minimize the impacts on the reservoir.

In this study, a methodology is proposed that uses stock reservoir modeling (SRM) to study the effects of production on geothermal reservoirs. This data-driven approach employs well data to simulate production impacts and characterize each well's production. This modeling tool defines parameters that combine well mass flow rate, thermal output, and wellhead pressure to generate 3D surface diagrams to study production over time. SRM was first presented by Júlíusson E., and Axelsson G., 2018, and was further studied in Manterola Donoso A., et al, 2024; Manterola Donoso A., et al, 2023, Manterola Donoso, A., 2022; which analyzed the technical and financial aspects of geothermal utilization applying SRM.

This study further examines the methodology by applying this mathematical modeling technique to various wells with different characteristics and production histories to understand its versatility and applicability. Specifically, wells from the Þeistareykir geothermal field in North Iceland and the Hverahlið geothermal field in Southwest Iceland are studied to gain insights into their unique characteristics and production histories. Moreover, this study goes further by analyzing the potential of using SRM to study the production of different production wells simultaneously, for wells showing a high interconnection in their output. This method could lead to a novel approach for studying multiple production and reinjection wells using a single SRM.

2. Methodology

Stock reservoir modeling (SRM) is one of the three main geothermal reservoir modeling techniques, together with grid-based numerical reservoir models (Franco A, Vaccaro L., 2014) and lumped parameter reservoir models (LPRM) (Klüpfel S, Gunnarsson G, 2021). These models are important for estimating geothermal resources and understanding production impacts. Each reservoir modeling approach uses different data inputs to generate the models, with numerical models using both physical and operation data, LPRM using mostly physical data, and SRM using only operation data. The models usually also have a different scale and focus. Numerical models and LPRM are usually used to study a whole geothermal field, however, lumped models are usually simpler and have a higher solving speed which comes to the cost of lower accuracy if compared to numerical models, which need more data for their generation, are more complex and provide a more detailed picture of what the geothermal reservoir might look like. SRM, as LPRM, is a faster-solving and simpler modeling approach which, so far, has been used to analyze production impacts on a well-by-well basis instead of studying a geothermal field in its entirety (Júlíusson E., and Axelsson G., 2018, Manterola Donoso A., et al, 2023, Manterola Donoso, A., 2022).

As SRM has yet to be applied more commonly, this study aims to analyze various wells individually in different geothermal systems using the pre-established methodology (Manterola Donoso A., et al, 2023, Manterola Donoso, A., 2022) and to develop further SRM to study production from interconnected wells. This second goal presents a change in formulation, as it requires a more complex stock model than for studying individual wells, which presents a challenge due to the method's reliance on production history data to study well production capacity in geothermal systems.

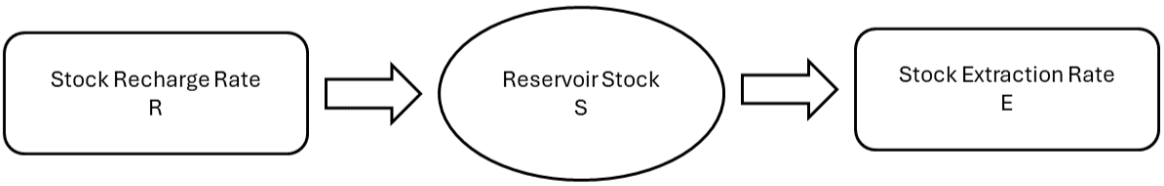

Figure 1: Individual well stock model (Adapted from Júlíusson, E., & Axelsson, G., 2018)

The methodology to study production from additional wells is presented in (Manterola Donoso, A., et al, 2023) where the SRM methodology for individual wells was developed and described. The model minimizes the difference between actual and estimated extraction data by history matching to set stock parameters that characterize a well's production characteristics. These parameters define the maximum energy output of a well (Q_{MAX}) in MW, maximum wellhead pressure (P_{MAX}) in bars, maximum stock (S_{MAX}) in MWyr and maximum recharge (R_{MAX}) in MW of a well. These variables are based on stock changes (S), defining a well's energy availability, calculated based on the model presented in Figure 1, where the geothermal system's extraction (E) and recharge (R) impact the reservoir's energy availability. The model details, including all parameters, equations, and bounds, are described in (Manterola Donoso A., et al, 2023).

The previous SRM methodology must be updated to study the production of interconnected wells. This study considers only the simplest version, where only two production wells are considered, and no reinjection well is in place. This model simulates the production behavior of two different production wells to study the relationship between their production and analyze the possible impacts on the general reservoir they might share. Moreover, this model intends to study how the system is recharged. However, for a more simplistic first look, the authors do not consider that a reinjection well in place. In a future study, reinjection data and tracer test data might help to estimate the connectivity between recharge and production, to compare these estimates with the optimizer's calculations to validate the method and increase its accuracy.

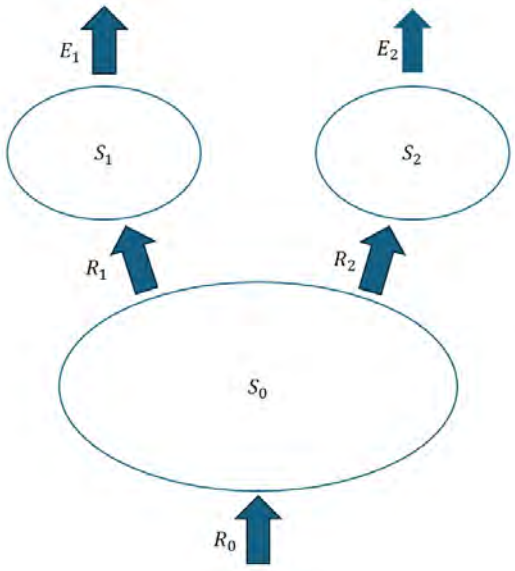

Figure 2: Interconnected stock model for two production wells

Figure 2 shows an interconnected geothermal system with two production wells, each with its stock (S_1, S_2) which will change depending on the extraction (E_1, E_2) and recharge (R_1, R_2) of each well.

This system depicts the simplest possible configuration between interconnected wells to allow for the addition of other wells to study production patterns together. However, as the goal is to study the connection between wells, an additional stock (S_0) must be considered where each well recharges from. This figure also considers the recharge (R_0) of the S_0, which for this simplified model only includes the effects of natural recharge.

To examine the connection between wells, redefining concepts such as reservoir storability and well-to-well transmissibility is essential. These concepts are already used in numerical or lumped parameter modeling, and establishing parallel concepts can be useful in describing and comparing models. Storability defines the total thermal energy the geothermal reservoir or well can produce; transmissibility describes the relationship between well productions. SRM already defines storability using the stock (S) parameter, but transmissibility needs to be added as an additional variable to study the relationship between wells.

The model depicted in Figure 2 uses SRM functions as those defined in a pre-study (Manterola Donoso A., et al, 2023). Said equations define the Extraction (E), Recharge (R), and Stock (S) parameters in Equations 1, 2 & 3 respectively which help analyze the productivity of a well over time. To be able to define the model presented in Figure 1, the model defines said parameters not only for each well in the geothermal system ($\mathrm{E_i}, \mathrm{R_i}, \mathrm{S_i}\ \forall\ i \in N$) but also for the connecting reservoir (S_0). As such, the model includes an additional equation (Equation 4) defining the connecting reservoirs stock (S_0), which is dependent on the recharge ($\mathrm{R_i}\ \forall\ i \in N$) of each production well and the general recharge of the system (R_0). The R_0 parameter could consider both natural recharge and reinjection recharge, but for the simplicity of this study, Equation 5 only considers natural recharge.

$$E_{i,t}\left(P_{i,t}, S_{\mathrm{i,t}}\right) = Q_{i,MAX} \cdot S_{\mathrm{i,t}}/S_{i,MAX} \cdot \sqrt{1 - \left(P_{\mathrm{i,t}}/P_{i,MAX}\right)^2} \forall\ i \in N \tag{1}$$

$$\mathrm{R_{i,t}}\left(S_{\mathrm{i,t}}\right) = R_{i,MAX} \cdot \left(\left(S_{i,MAX} - S_{\mathrm{i,t}}\right)/S_{i,MAX}\right) \forall\ i \in N \tag{2}$$

$$S_{\mathrm{i,t}} = S_{i,(\mathrm{t}-\Delta t)} - \mathrm{E_{i,t}}\left(P_{\mathrm{i,t}}, S_{i,(\mathrm{t}-\Delta t)}\right) \cdot\ \Delta t + \mathrm{R_{i,t}}\left(S_{i,(\mathrm{t}-\Delta t)}\right) \cdot \Delta t\ \ \forall\ i \in N \tag{3}$$

$$S_{0,\mathrm{t}} = S_{i,(t-\Delta t)} - R_1\left(S_{1,(t-\Delta t)}\right) \cdot \Delta t - R_2\left(S_{2,(t-\Delta t)}\right) \cdot \Delta t + R_0\left(S_{0,(t-\Delta t)}\right) \cdot \Delta t\ \forall\ i \in N \tag{4}$$

$$R_0\left(s_{\mathrm{T},t}\right) = R_{0,MAX} \cdot \left(\frac{S_{0,MAX} - S_{0,t}}{S_{0,MAX}}\right) \forall\ i \in N \tag{5}$$

where $E_{i,t}$, $P_{i,t}$, $S_{i,t}$, $R_{i,t}$, $Q_{i,MAX}$, $P_{i,MAX}$, $S_{i,MAX}$, $R_{i,MAX}$, $S_{0,t}$, $R_{0,t}$, $S_{0,MAX}$, $R_{0,MAX}$, t, Δt, i, N represent calculated extraction, wellhead pressure, stock, recharge, maximum output, maximum wellhead pressure, maximum stock, maximum recharge, general tank stock, general tank recharge, general tank maximum stock, general tank maximum recharge, time step, time differential between time steps, well index, and total number of wells respectively.

To better study well transmissibility, the recharge from each well is not independent, but rather connected through the general reservoir stock (S_0). Equation 6 defines the recharge for the non-

primary well, to be selected by the user considering lower well productivity and parametrized using α, which represents well-to-well transmissibility as the connecting factor between wells. Therefore, α connects how each well recharges from the general reservoir considering the other production wells in a system. This equation replaces the definition on Equation 2 for all wells defined as non-primary.

$$R_{2,t}(R_{1,t}) = \alpha \cdot R_{1,t} \tag{6}$$

Where $R_{1,t}$, $R_{2,t}$, α are primary well recharge, secondary well recharge and well-to-well transmissibility, respectively.

The model defines an objective equation (Equation 7) aimed to optimize the well variables that describe the geothermal system ($Q_{i,MAX}, P_{i,MAX}, S_{i,MAX}, R_{i,MAX}, S_{0,MAX}, R_{0,MAX}$). Equation 7 determines the error between the measured values and the extraction estimations made by the model. By comparing and minimizing extraction, the model determines which are the optimal parameters that define each production well, as well as the connecting reservoir.

$$\underset{Q_{i,MAX},P_{i,MAX},S_{i,MAX},R_{i,MAX},S_{0,MAX},R_{0,MAX},}{minimize} \sum_{\tau} \left(Ed_{\mathrm{i},\tau} - E_{\mathrm{i},\tau}(P_{\mathrm{i},\tau}, S_{\mathrm{i},\tau})\right)^2 \ \forall\, i \in N \tag{7}$$

Where $Ed_{i,\tau}$, $E_{i,\tau}$, $P_{i,\tau}$, $S_{i,\tau}$, τ, i, N represent calculated extraction rate, extraction rate data, wellhead pressure, stock, time of measurement, well index and number of wells respectively.

Finally, the variables require at least lower bounds. All variables have a lower bound greater than zero, as all parameters in a geothermal system should be positive. There is no need for an upper bound unless to prevent errors from low recharge or high stock. Upper bounds might need to be applied by the user when required, for example, to reduce local minima errors or if the “optimal” results show, for instance, a seemingly impossible infinite maximum recharge value.

3. Data Collection

Having defined the stock model to characterize production impacts, this section describes the data used in the study. To apply SRM to more wells, the authors study the production data from the Þeistareykir and Hverahlið geothermal fields in Iceland, which include wells with varying outputs and histories. These differences are key for understanding how production patterns and characteristics affect the individual well stock parameters. As aforementioned, the model in Manterola Donoso A., et al, 2024, defines these parameters.

The data used for this study includes information on the wells' measurement date, wellhead pressure, and thermal energy output. Due to confidentiality, the well name, history data, and characteristic curves are not shared, but a short description of each analyzed well is provided. Wells from the Þeistareykir field (wells ÞG-A to D) in the North of Iceland include non-continuous and non-periodical data. They include between 83 and 106 data points, over a period of 4 years. Wells from the Hverahlið field (wells HE-A to D) in Southwest Iceland include daily and/or weekly measurements. They include between 730 and 2922 data points, over 8 years. See below a description of each well:

- Well ÞG-A: Well with a high and continuous production that shows a slow decline through production.

- Well ÞG-B: Well with high and continuous production, with small changes in the operation wellhead pressure, that shows minimal decline through production.
- Well ÞG-C: Well with a high production closed for a year and a half halfway through the studied production period.
- Well ÞG-D: Well with non-constant production, not used in regular production.
- Well HE-A: Well, with fast declining production, only in production for two years.
- Well HE-B: Highly productive with a constant decline in production.
- Well HE-C: Well with a high production. After an initial decline, it was very constant and highly productive.
- Well HE-D: High productivity well, with slight changes to its production and a small output decline.
- Well HE-E: High productivity well, with a high correlation between wellhead pressure and output production.

Moreover, to study well interconnection, two sets of wells with a combined production pattern have been generated instead of using real data to simplify the expected result and to make the model easier to apply. This approach does not validate the model but rather aims to demonstrate whether SRM can be applied to identify, and study impacts between linked production wells. The model is solved using two sets of production wells: one without output decline and another with decline. This comparison aims to highlight the necessary future improvements required in the methodology.

The data for the generated synthetic wells (A-01 to A-04), includes a set of weekly values for wellhead pressures, enthalpies and flows. Wells A-01 and A-03 represent a main production well with continuous production and a short period with reduced production, with A-03 having a decline in production. Wells A-02 and A-04 represent a secondary production well, which is only used for a short period.

Considering the applied wells, an additional constraint (see Equation 8) nullifies the secondary production well's recharge in case its stock is higher than the estimated initial stock. This is applied to negate the unnecessary recharge if production is null.

$$S_{2,t} \geq S_{2,MAX} \rightarrow R_2 = 0 \tag{8}$$

To apply the interconnected model, these wells are first studied individually by applying SRM to each of the wells to characterize the individual stock parameters. Then, these are applied as starting production parameters for the interconnected SRM presented in Section 2.

4. Results

This section presents the study's results on individual and interconnected well analysis using stock reservoir modeling.

First, the results of the individual stock reservoir models are presented in Table 1, which shows all the different stock parameters for the studied wells. The results show the different values for the maximum pressure (P_{MAX}), stock (S_{MAX}) and recharge (R_{MAX}) parameters of each well. To protect sensitive information, the maximum output parameter (Q_{MAX}) is not shown. Table 1 also shows the squared error between the extraction data and the simulated extraction and the corrected error,

which has been adjusted considering the number of data points used to compare results from different fields better.

Table 1. Stock parameters and history match errors for the selected wells.

WELL	P_{MAX} (bar)	S_{MAX} $(MWyr)$	R_{MAX} (MW)	Error	N° of points	Corrected error
ÞG-A	97.17	3656.99	793.97	70.37	87	0.88
ÞG-B	26.87	733.92	1131.53	2887.4	83	34.79
ÞG-C	93.01	182.86	534.77	917.64	65	14.11
ÞG-D	16.18	48.03	133.24	3140.94	106	29.63
HE-A	49.03	125.04	56.59	2987.00	730	4.09
HE-B	66.25	2709.36	38.58	33115.73	2858	11.58
HE-C	83.78	178.91	262.08	72902.93	2922	24.95
HE-D	84.75	5154.04	455.15	193015.22	2893	66.72
HE-E	91.97	570.51	264.28	155374.20	2099	74.02

To support these results, the authors present the following sets of curves to understand better how SRM simulates the production in the studied wells. Figures 3 to 11 show changes in extraction rate, recharge rate, and energy availability or stock. These figures also include a 3D surface diagram that links a well's productivity rate and wellhead pressure with its output, considering the reservoir stock. The figures include data points to show the correlation between the data and the simulation. The output values are shown as a percentual value to protect any sensitive information.

Next, the results concerning the interconnected sections are presented. To apply the methodology developed in Section 2, we first apply individual SRM analysis to each well to estimate their stock parameters individually. Table 2 shows all stock parameters and the squared error between the generated values and the model's estimations for each well. Figures 12 to 15 describe the stock, recharge and extraction curves and the extraction data for each set of curves after applying SRM.

The interconnected model is solved using the individual SRM parameters as initial values for the interconnected SRM. Tables 3 and 4 present the optimized stock parameters for each set of wells. The model without decline has a square error of 244.06, adjusted to 0.52 considering the number of data points. For the model that accounts for the decline, the square error is 157.16, adjusted to 0.33.

5. Discussion

The study aimed to apply SRM to a wider range of wells to better understand its versatility and to examine its applicability for studying interconnected well production. The results show the model being applicable to individual wells in different Icelandic geothermal fields and an interconnected synthetic model that considers production from one connected reservoir.

The results show SRM's applicability to many wells with different production patterns, power outputs, and characteristic curves. Overall, wells show a strong correlation between the measured extraction data and the estimated extraction. Generally, more data points result in more reliable results with fewer outlying points. Comparing results from the Þeistareykir and the Hverahlið fields reveals that unless production is highly linear (as in the case of ÞG-A), having more production data increases accuracy.

Wells ÞG-B and ÞG-D show the highest error rates for the Þeistareykir field (see Table 1). Despite having different characteristics, this discrepancy between the model and the data might be due to uneven data distribution. Specifically, well ÞG-B shows minimal output variation over time without any changes in WHP. Consequently, as the estimated extraction correlates with the wellhead pressure change, not having a high correlation between the pressure and output greatly impacts the results. Similarly, well ÞG-D shows two different production stages, each with varying outputs despite comparable wellhead pressures, contributing to a higher error.

In the Hverahlið geothermal field wells HE-A, HE-B & HE-C have an overall low error rate, outlining the benefits of having continuous data when using SRM. However, even then, due to changes in well productivity without pertaining changes in wellhead pressure, slight differences show between the estimated and the measured extraction values for certain periods of the data. This discrepancy is shown more often for wells, HE-D and HE-E, where the adjusted error is higher than the rest. This is believed to be mostly due to the provided data not being consistent in certain time periods where the wellhead pressure does not change while the estimated output changes.

All in all, most wells and their respective 3D surfaces show low error, strong correlation and efficient computation time, as all models were solved in under five minutes. This makes SRM a versatile tool that can assist with successfully analyzing geothermal well production impacts based solely on production data. However, the model can still be improved in future iterations by incorporating additional parameters and constraints. For example, considering the high impact of scaling on a well's output, it would be of high interest to include the decline in production not only by the change in energy availability but also by scaling. This could also help improve the characterization of the stock variable. Moreover, the study's current consideration of one single extraction equation and recharge equation proves to be limiting. Considering the different characteristics of geothermal wells, applying the model using alternative equations could enhance result accuracy.

Regarding the application of interconnected SRM, the study proves successful in further using SRM to study production wells connected via an additional reservoir tank. Despite using synthetic data, the study shows SRM's capability to analyze interconnected wells by minimizing error between estimated and simulated extraction rates for each well. Furthermore, the model successfully defines well-to-well transmissibility consistently, regardless of well decline,

highlighting the connection between these wells. Moreover, it helps establish the minimal initial stock and recharge parameters essential for sustaining the presented production.

Comparing the two sets of wells and their results reveals that considering decline or not does not have much of an impact when calculating the maximum pressure (P_{MAX}) and maximum output (Q_{MAX}) in both individual and interconnected SRM (see Tables 2, 3 and 4). However, this differs for stock (S_{MAX}) and recharge (R_{MAX}) parameters. The individual model highlights how wells with higher decline show a higher stock value and a lower recharge in comparison to those without any decline. In contrast, the interconnected model's understanding of energy availability changes due to having the additional general tank.

Although successful in applying the model, this study represents only the first iteration of interconnected SRM, outlining many areas of improvement required to increase its applicability to more geothermal systems. Currently, the model is not able to appropriately estimate the general tank's stock (S_0), which functions more as an infinite recharge source. This is represented when comparing each well's stock (S_1, S_2) and recharge (R_1, R_2) with the estimated max stock (S_{MAX}) and recharge (R_{MAX}) for the individual models, which have a much higher value. This discrepancy is due to the general tank providing the required energy to maintain a recharge equal to the extraction, as shown in Figures 16, 17, 19 and 20. As long as the general tank's stock remains nonzero, this infinite recharge on wells continues. Future iterations should address these issues by improving the definition of equations 2 and 6 to include the impact that the energy availability in the general stock might have.

This effect is further enhanced by the absence of data on reinjection or recharge. As the recharge of the general tank is not parametrized, the model chooses a suitable recharge parameter to have continuous production. However, if reinjection data was included and the effects of reinjection were compared with how the reinjection might affect the production wells, the model's accuracy in defining energy availability could be improved.

When comparing individual and interconnected models, adjusted error values vary based on the data. Models with continuous data, like those from the Hveralið field or the synthetic data, show more accurate production impacts. Although future work is needed for the interconnected model, it already shows low error, even if helped by synthetic data. Nevertheless, as it considers extraction errors from multiple wells, the total error was expected to be higher. Despite such expectations, the interconnected model's error is comparable to or even lower than some individual SRM results, indicating that, for certain geothermal systems, analyzing well productions together may better assess production impacts.

6. Conclusions

Overall, in this study, SRM was successfully applied both to individual wells and to an interconnected system of wells. Individual SRM results highlight the method's versatility when understanding the production impacts of geothermal wells using 3D surface diagrams, generated by estimating the well characteristics using production history data. Interconnected SRM results show that the proposed method can be applied to systems with more complex production and well configurations. The low error of using interconnected SRM also suggests that analyzing well productions simultaneously for multiple wells can improve the understanding of the production impacts for certain geothermal systems.

These results demonstrate that SRM can be a tool that can consistently help define different types of wells and systems to make more informed decisions in well utilization to further increase the sustainability and good use of geothermal resources. As a fast-solving and easy-to-recalculate method, it allows the operators to include additional data when available or to consider different bounds and constraints that might better recreate the real geothermal system.

Finally, the authors want to outline the challenges that this methodology presents. For instance, regarding individual SRM, the methodology does not consider a changing maximum wellhead pressure for different stock values or the possibility of using different equations to define the extraction and recharge parameters, which could improve the accuracy of the model for certain wells with non-ordinary production patterns. As for the interconnected model, much work still needs to be done when it comes to connecting the production wells between each other and the general tank. Various possibilities arise, such as including reinjection data to simulate the impacts of production in the general reservoir or improving the definition of the system's equation to better simulate the effects of the production.

Acknowledgment

This study received financial support from the Rannis Technology Development Fund (project: 2321574-601) and the Landsvirkjun Energy Research Fund.

The authors also would like to acknowledge Landsvirkjun and Orkuveita Reykjavikur, who provided the required data to perform the work.

Puna Geothermal, Permeability, Numerical Modeling, Well Testing, Reservoir Engineering, Case Study

ABSTRACT

The Puna Geothermal Venture (PGV) power plant was restarted in 2020 following the 2018 Kilauea eruption, providing a unique opportunity to quantify the impacts of this eruption on permeability, temperature, and pressure in the geothermal reservoir. Permeability was quantified using multiple datasets which show reduced permeability in some production fractures but overall good permeability remaining in others.

A numerical model was developed which simulates the pre-eruption and post-eruption reservoir behavior. The numerical model was calibrated to historical reservoir performance and the unique effects of the eruption, including temperature recovery and changes to the permeability distribution. The resulting model accurately matches the post-eruption temperature recovery and the reservoir pressure response to the plant restart under the modified permeability regime.

1. Operational History of the Puna Geothermal Venture

The first exploration wells in Puna were drilled in the early 1960s by Hawaii Magma Power. The Hawaii Geothermal Project conducted federal and state funded research and drilled several wells in the 1970s. The Hawaii Geothermal Project – Abbot (HGP-A), an experimental 3 MW power plant, was completed in 1981 and operated until December 1989 (Kim, 2018).

The Puna Geothermal Venture (PGV) was founded in 1981. Three wells were drilled from 1981 to 1985. A 25 MW power sales contract was signed with Hawaii Electric Light Company (HELCO) in 1986. More wells were drilled in 1991 and power production began in 1993 using steam in a combined cycle (steam turbine with binary condenser) air cooled plant with 100% reinjection of produced fluid. Wells were drilled in 1993, the contract was increased to 30 MW in 1995, and more wells were drilled from 2001 to 2010. The contract was increased to 38 MW in 2012 and a bottoming unit was constructed to generate power from hot water produced with the steam.

The Lower East Rift Zone of Kilauea erupted in May 2018. Earthquakes became frequent on May 1st and the plant was shut down on May 3rd after lava began erupting in nearby Leilani Estates.

Bridge plugs and cement were installed in production wells, piping was removed, and the wellheads were covered with cinders. Lava continued flowing until August 8, 2018. Three wellheads were covered with lava and the substation was destroyed. Recovery work began in 2019 after which a total of six wells were drilled and five pre-eruption wells were worked over. The 2022-2023 drilling campaign consisted of three additional wells after which the plant generated over 32 MW.

2. Reservoir Pressure and Temperature Response to Eruption and Shut-In

During the process of safely securing the wellfield and then preparing for restarting the plant in 2020, downhole surveys were conducted which showed the response to the plant shut-in and eruption. Wellhead pressure observations during the eruption showed increases to over 1840 psig in KS-14 and dissipated to 1100 psig over one day (Spielman et al., 2020). In October 2018 a pressure survey was conducted which showed indications that pressure had reduced significantly, about 3 bar above pre-development conditions; a survey in late April 2020 in KS-18 showed that after two years of no production, the reservoir pressure had returned to pre-development conditions.

Temperature also showed a significant recovery and increase during the eruption. Tracer flow test (TFT) data collected in wells KS-14 and KS-16 prior to the eruption showed enthalpy declines to 1270 kJ/kg, which was interpreted to represent liquid reservoir conditions around 290 °C. This interpretation was supported by a flowing pressure/temperature survey of KS-16ST in 2015 which showed a liquid reservoir feedzone at 292 °C. This section of the reservoir had therefore declined in enthalpy in response to production, as initial reservoir temperatures in the production zones were > 310 °C, based on downhole survey and a flowing enthalpy of 1450 kJ/kg in KS-14. In April 2019, after drilling KS-14RD2, a static survey measured 330 °C in the production reservoir. After plant startup, a survey in KS-18 measured a flowing temperature of 311 °C indicating that the temperature impact of the eruption was to effectively "reset" these temperatures, undoing the temperature declines observed during the first 25 years of operation. Based on a reservoir engineering interpretation of static and flowing temperature surveys and flowing enthalpies, an interpreted post-eruption temperature was compiled for the production reservoir. This compiled temperature is shown in Figure 15 and was used for the numerical model calibration for the production reservoir.

Well KS-15, east of the production area was also impacted by the eruption. While the maximum temperature measured in KS-15 prior to the eruption was 278 °C, a survey in October 2018 showed temperatures as high as 310 °C at the depths of the production reservoir. A subsequent survey in March 2019 measured only 213 °C at these depths, suggesting that although there was a significant heat input, it was not sufficient to permanently alter the temperature distribution beyond the natural conditions observed prior to the PGV development or the impact of long-term injection into KS-15.

The injection area (northwest of production, separated by 200-300 m) was at similar temperatures to the production area prior to the PGV plant startup. Limited equilibrated survey data was able to be obtained in the injection area following the eruption, but the data that was collected did not show a recovery to natural state temperatures in the feedzones. This suggests that the heat input from the eruption was not sufficient to reverse the long-term impact of cool injection in this area. The 2018 eruptive fissures were 200 – 400 meters south of the production area (Lundblad and

Anderson, 2020), and further from the injection area, and the lack of temperature recovery is consistent with the increased distance from the input of magmatic heat.

3. Characteristics of Permeability at the Puna Geothermal Venture Before and After the 2018 Eruption

Permeability in the Puna geothermal reservoir is primarily characterized by discrete fractures in a NE-SW orientation. Wells in the production field are deviated south from the plant area, crossing one to three fractures depending on depth and deviation direction. These fractures are named according to wells that first encountered permeability in those fracture. In the western portion of the production reservoir, these are the KS-8, KS-14, and KS-5 fractures from north to south. Figure 1 shows a map view at surface with the key fractures shown. Further details on the geologic model are provided in Spake et al, this volume. Prior to the 2018 eruption, the KS-14 and KS-5 fractures were the primary sources of production, with the KS-14 hosting very high permeability. Following the 2018 eruption, wells crossing the KS-14 fracture have shown zero to low permeability in that zone. In contrast, well KS-18 (drilled post-eruption), encountered significant permeability in the KS-8 fracture. Deep drilling has also brought significant production success post-eruption, with the majority of production now sourced from the KS-5 fracture at elevations near -1500 mRSL.

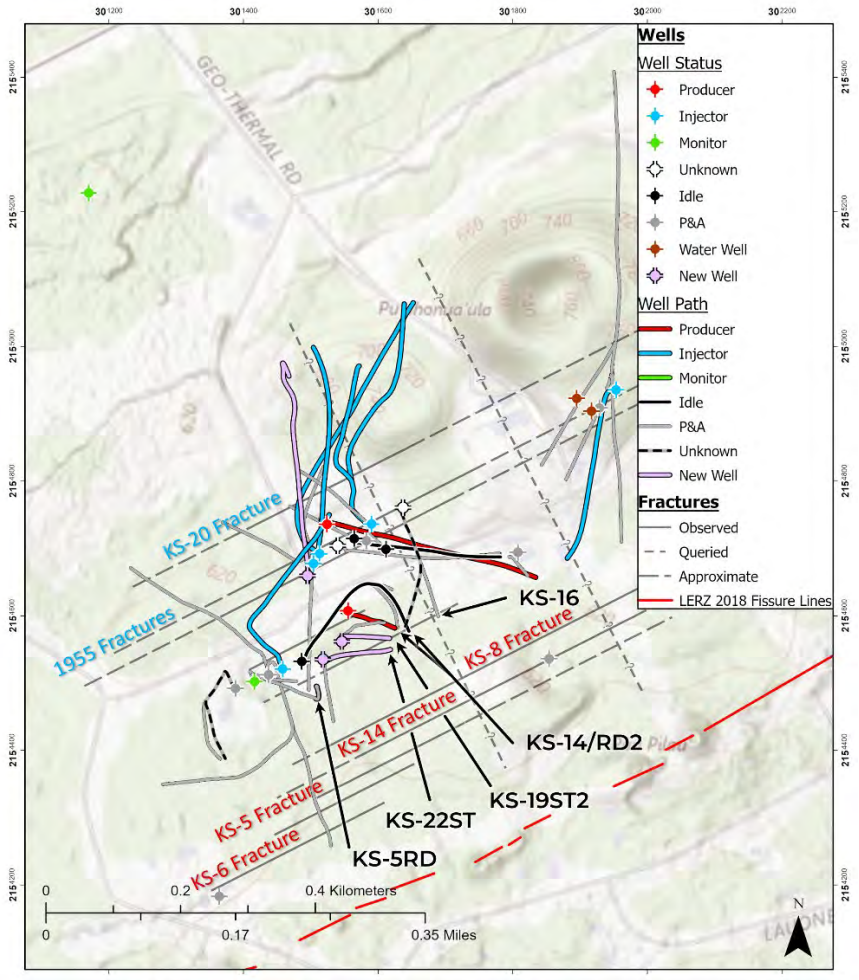

Figure 1: Summary Map of the Puna Geothermal Venture (adapted from Spake et al, 2024)

Four key datasets allow for quantification of permeability in the production reservoir at PGV. Firstly, wells undergo a rig injection test which provides a step-rate injectivity index and a fall-off test on which pressure transient analysis can be conducted. Secondly, interference testing was conducted during a 2023 completion test which gives a supporting dataset for the reservoir permeability. Thirdly, pressure decline over the period of months to years as measured by static downhole pressure surveys measures the bulk reservoir response to production and injection. Productivity index during long-term production provides a fourth dataset. Although complicated by two-phase effects in this high-temperature reservoir, wells with liquid feedzones give a good measure of the productivity index for comparison with other datasets.

3.1 Quantifying Permeability: Injectivity Testing and Productivity

Figure 2 summarizes step-rate injection testing at PGV from six wells drilled into the production reservoir. Conducted after drilling, these tests measure downhole pressure near the primary feedzones while increasing injection rate (although KS-5 pressure was measured at the surface, the measurement is a reasonable proxy for downhole pressure at low rates with negligible frictional effects). Three wells drilled pre-eruption (KS-16, KS-14, and KS-5RD) showed injectivity indexes from 6.5 kg/s per bar to infinite (no change in pressure while injecting). Comparatively, three wells drilled post-eruption (KS-19, KS-22, and a re-drill of KS-14) measured injectivity indexes from 0.9 to 2.5 kg/s per bar, a significant decrease. All post-eruption wells cross the KS-14 fracture which hosted the very high permeability in KS-14 and KS-16. Despite crossing the KS-14 fracture, wells KS-19 and KS-22 primarily feed from the KS-5 fracture. These repeated injection tests show a stark decrease in permeability after the 2018 eruption. Quantifying productivity in a similar way is more complicated, due to the effects of two-phase flow in the reservoir. Using downhole flowing surveys in wells with liquid feedzones, the pre-eruption wells (KS-16 and KS-14) had very high productivity indexes on the order of 25-400 kg/s per bar, with no drawdown observed in flowing surveys, whereas post-eruption wells with liquid feedzones (KS-18 and KS-22) have productivity indexes on the order of 5 to 15 kg/s per bar. Although the post-eruption wells are strong producers, they do not demonstrate the extremely high productivity observed in the KS-14 fracture prior to the 2018 eruption.

An interesting feature of this dataset is the relationship between injectivity and productivity in post-eruption wells tested at PGV wherein the productivity for liquid feedzones is roughly 5-10 times the injectivity during completion testing of those same feedzones. This differs from many geothermal fields where the inverse relationship is observed. A study by Grant et al. (2013) over several high temperature reservoirs found an average 3.5:1 ratio of injectivity from completion testing to productivity. Pressure transient analysis of completion tests and an interference test at PGV give insight to the nature of this relationship and also to the actual permeability of the KS-5 fracture at PGV.

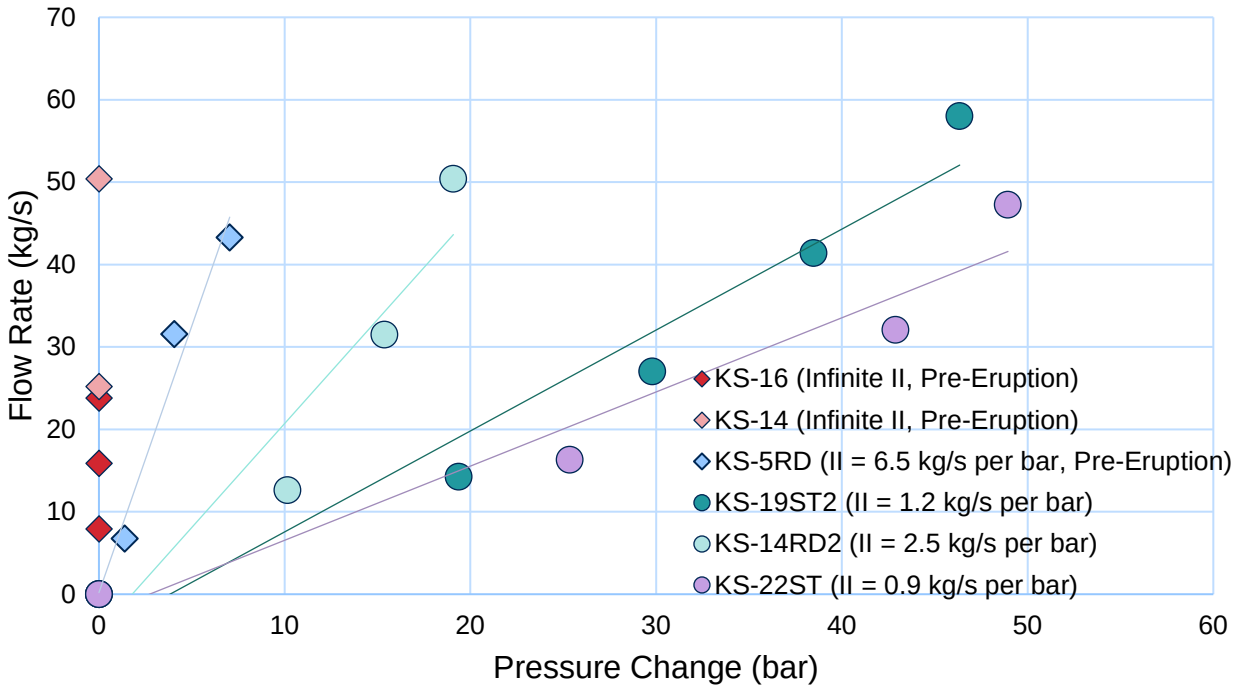

Figure 2: Summary of Injectivity Testing at PGV

3.2 Quantifying Permeability: Pressure Transient Analysis of Fall-Offs and Interference

Figure 3 shows the pressure transient analysis of the fall-off in well KS-19ST2, which is typical of wells at Puna post-eruption. No similar data was available for the pre-eruption wells; with near-infinite injectivity the temperature effects dominate and prohibit meaningful pressure transient analysis. This analysis was conducted using equations for pressure transient type curves which rely on multiple parameters: permeability, thickness, well storage, skin, porosity, and compressibility as described in Kuchuk and Kirwan (1987). The time of pressure transient is corrected using the Agarwal method, appropriate for a fall-off after injecting, and the times are given in Aragwal time (Agarwal, 1980). After shutting injection off, pressure was measured near the feedzone for 1.8 hours, with an overall pressure change of 46 bar. Qualitatively, the majority of the pressure change occurs in the first 0.25 hours (44 bar), after which the pressure nearly stabilizes. This suggests very high skin, and indeed the matching model shown uses a high skin (100), and a moderate permeability-thickness of 17.5 darcy-meters (5.7E-4 md-ft).

During KS-22ST testing, an interference test was also conducted, with downhole pressure measured in KS-19ST at a horizontal spacing of 30 meters in the KS-5 fracture. The fall-off pressure in KS-22ST was similar to KS-19ST2 and very high, 52 bar, whereas the interference measured was small (0.5 bar), suggesting that the permeability of the formation is very high. This data can be matched with a pressure transient analysis using the Theis solution (1935) and the same permeability thickness of 17.5 darcy-m as was estimated from the KS-19ST2 fall-off test (Figure 4). One adjustment was needed: an increase to the compressibility to delay the onset of pressure response slightly. This could be reflecting the impact of colder, high-viscosity injection (discussed below), or a slightly two-phase reservoir. The eventual productivity of KS-22ST is closely predicted by the permeability-thickness; projecting the radial flow pressure response out to one year without skin returns a productivity index of 8.7 kg/s per bar, a good prediction of the

~10 kg/s per bar that has been calculated for these wells from flowing surveys and wellbore simulation (Figure 5).

The high skin is most likely an impact of near-wellbore cooling, a source of skin caused by the higher-viscosity cold fluid surrounding the well in a high-temperature/low-viscosity reservoir. This effect has been demonstrated by numerical modeling of injection tests (McLean and Zarrouk, 2015). Pressure transient analysis can also show the effect, with the same permeability-thickness applied to a reservoir of 49 °C, the long-term pressure response to the same flow rate is 6 times higher, predicting a productivity index of 1.4 kg/s per bar, of similar magnitude to the injectivity and the expected result if the whole reservoir were at the near-wellbore temperature after drilling. One possible explanation for the large skin/temperature effect at Puna is the discrete nature of the permeability. With a single dominant fracture contributing to permeability, the cool fluid circulated while drilling can effectively cool the fracture, whereas in reservoirs with more distributed permeability the cooling should extend less far into the reservoir.

3.3 Quantifying Permeability: Reservoir Pressure Decline

The above tests quantify the short-term pressure responses to flow at PGV, and show that certain fractures in the pre-eruption reservoir hosted extremely high permeability, whereas the key fractures in the post-eruption reservoir host a more moderate but sufficient permeability. The longer-term pressure response to production also demonstrates a reduction in permeability. Figure

6 shows the pressure response at a representative reservoir datum (-1510 mRSL) from static surveys collected over the field history. This figure shows the initial pressure level around 132 bara, declining to a range of 102 to 112 bara as production is ramped up in the pre-eruption configuration, with the range representing operational fluctuations. The last two pre-eruption points measured in KS-14 and KS-16 are the most comparable to current conditions; at this time most of the production was coming from the same area of the PGV reservoir that is also producing post-eruption. During the plant shut-in during and after the eruption, pressure recovered to natural state levels, as discussed in the next section of this paper. In post-eruption operations, the reservoir pressure has declined to a similar range (again impacted by operational fluctuations). Normalizing these pressure changes to flow is instructive. As shown in Figure 7, the pressure change per flow in bar per kg/s was around 0.15 when producing mostly from the prolific KS-14 fracture (pre-eruption), whereas the same reservoir area post-eruption shows a decline of around 0.22 bar per kg/s (about 1.5x the pressure impact for a given total reservoir flow). When the KS-5 area was being produced earlier in the operational history the impact was similar, prior to the discovery and production from the most permeable area (KS-14 fracture) of the production area.

The story of any operating field is complex, with variations in production and injection strategies and production locations. On the whole, the data from PGV shows that the impact of the 2018 eruption was a decrease in individual well productivity and bulk reservoir permeability in the main production area. Key fractures, specifically the KS-8 and KS-5 fractures, remain permeable and highly successful production wells have been drilled post-eruption.

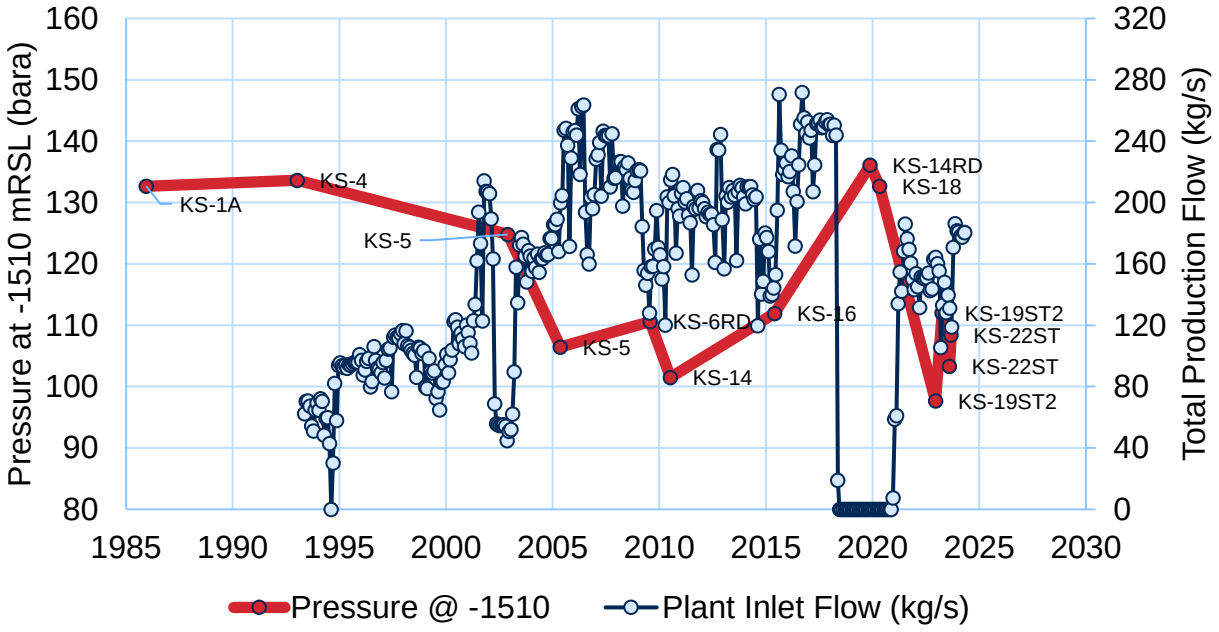

Figure 6: Reservoir Pressure and Total Flow History

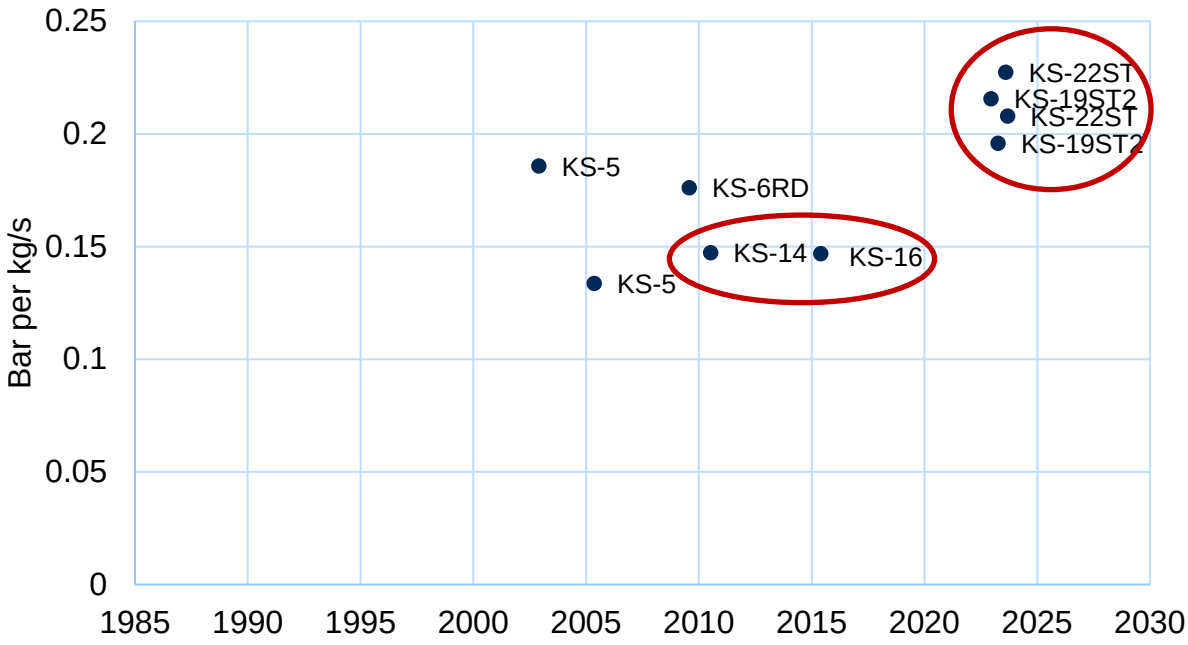

Figure 7: Reservoir Pressure Change Over Total Flow (bar per kg/s)

4. Numerical Reservoir Modeling

Due to the unique history of the PGV field, numerical reservoir modeling was conducted in three phases. (1) Pre-eruption natural state and operations, (2) a transient period of heat and mass input to simulate the impact of magma near the production area during the eruption, and (3) the post-eruption plant startup using an altered permeability structure, reflecting the changes measured in drilling, testing, and operations. Numerical modeling at Puna utilizes a combination of the Tetrad reservoir simulator (Vinsome and Shook, 1993) and the Volsung simulator (Franz et al., 2019).

4.1 Initial State Temperature Model

In the pre-eruption model, the natural state was characterized by a hot upflow centered on these permeable production fractures. Wells KS-1A and KS-3 encountered this upflow most directly, with a maximum temperature of 345-351 °C. KS-5 and KS-4 represent the productive western margin, with maximum temperatures of 337 °C and 325 °C, respectively. The impermeable margins of the system (characterized by conductive temperature gradients below -500 mRSL) are constrained by well SOH-1 to the northwest and Lanipuna 1 to the south. Permeable volcanic rocks overlay the capped geothermal reservoir. Cooler flowing fluid, predominantly a mix of meteoric and altered seawater, effectively sweeps heat leading to cooler temperatures from surface to the reservoir top which is encountered between -500 and -1000 mRSL. Figure 8 shows the natural state temperatures measured in key wells along with the simulated temperature from the calibrated model. Measured data is selected from the available surveys to best represent equilibrated reservoir conditions; in the case of Lanipuna 1, three surveys were used to generate a composite profile. Figure 9 shows the measured and simulated pressure in KS-1A, which has the best dataset to constrain reservoir pressure. In the reservoir at -1510 mRSL, reservoir pressure is 133 bara.

4.2 Permeability Models

The pre-eruption permeability model is shown in Figure 10, with a maximum permeability of 8000 md assigned to the KS-14 fracture. High permeability is used as a damage zone around this feature. As described above, the effect of the 2018 eruption was a significant decrease in the permeability of the KS-14 fracture. The KS-8 fracture hosts a feedzone in KS-18 but has not been successfully targeted again, suggesting a high degree of heterogeneity. The KS-5 fracture is highly permeable, as quantified by well testing in the previous section. The modified permeability distribution is shown in Figure 11. Note NW-SE fractures exist at depth connecting injection to production. The nature of the disconnection between east and west sectors of the production reservoir is uncertain, earlier tracer testing suggested a moderate disconnection, whereas post-eruption testing shows that the east and west are more strongly connected. This may be due to the re-activation of the KS-8 fracture, which was the basis for increasing the permeable connection as shown in Figure 11.

4.3 Temperature Calibration and Heat Input during 2018 Eruption

The evolution of simulated temperature is shown in Figure 12 to Figure 14. The initial state temperature corresponds to the calibrated model in Figure 8. During plant operation, injection wells to the northwest of production cooled those fractures and moderately cooled production. This temperature decline is observable in enthalpy and the resulting subsurface temperature distribution is shown in Figure 13.

Figure 14 shows the same depth slice after the thermal input from the eruption. The impact of the eruption, as described above, was a reset of temperatures in the production area. In the numerical model, this was accomplished using a heat input to the permeable rock types. During the calibration period, it was determined that the heat input was likely sufficient to heat both the fractures and the surrounding matrix, due to the persistent nature of the heat recovery. If the fractures alone had been heated, the remaining low-temperature matrix would have tended to quickly cool the fractures after the end of the eruption, whereas observed enthalpies and flowing temperatures show that the higher temperatures persisted.

There was no clear evidence of significant heat recovery in the injection area. Over two years of plant-shut, the lack of injection did allow for some reheating in this area of the model, from temperatures near the injection temperature up to temperatures in the range 100-200 °C. Such temperature recovery is typical of geothermal systems when injection is shut-off, regardless of eruptive heat input.

Figure 15 shows the interpreted, measured, and simulated temperatures corresponding to the post-eruption conditions. The bold red squares in the production wells represent a composite profile reflecting the best data from downhole static and flowing surveys and flowing enthalpy. This was interpreted to be generally uniform across the production area. Where available, select actual static surveys are shown, although these generally differ from the interpreted composite profile and are impacted by circulation during drilling/workovers, injection, and transient effects.

In the simulated curves, the blue dashed line represents the simulated pre-eruption conditions. This is heavily cooled in the injection feedzones, and moderately cooled in the production feedzones. This cooling was greater in KS-5RD than KS-14 based on observations; as KS-17 and KS-18 were drilled after the eruption, no data was available to constrain the pre-eruption conditions in those

wells. KS-17 is known to have a strong connection to KS-15, so the cooled zone in the simulated blue line for that well shows the effect of long-term injection into KS-15.

The black lines, solid and dashed, represent the simulated fracture and matrix temperatures at the end of the simulated heat input period. These closely match the composite profile for production wells. The profiles for injectors show a small degree of heat-up.

4.4 Pressure Response Calibration

As described in Section 3.3, above, the reservoir pressure history of PGV can be constructed from selected static surveys throughout the operating history. Figure 16 shows the measured and simulated pressure response. Up to plant restart in 2020, the pre-eruption permeability model is used, and a good match is achieved to the measured data. The difference between measured and simulated pressure in KS-5 in 2002 is due to that well's feedzone being located further west than most of the production during that period of operations, whereas the simulated data is taking from the central production reservoir. For the pressure decline observed after plant restart in 2020, the post-eruption permeability model is applied. The good match to the observed data lends support to the modeled permeability distribution and the interpreted impact of the permeability reduction in the KS-14 fracture.

5. Conclusion

With over 31 years of commercial power production at the Puna Geothermal Venture power plant, the field lends itself to robust analyses of permeability and a well-calibrated numerical model. The 2018 Kilauea eruption resulted in a two-year pause in operations, and the data gathered during recovery and restart give unique insights to the impact of the eruption on the geothermal system. The Puna reservoir remains highly productive following the eruption. The KS-14 fracture, previously a source of very high permeability in the production reservoir, has diminished significantly, with the majority of production now coming from the KS-8 and KS-5 fractures. Numerical modeling and calibration to the reservoir performance requires an adjusted permeability model to represent the post-eruption reservoir.

Temperature, which had undergone moderate declines in the production area during the first 25 years of commercial operations, recovered in the production areas during the eruption and plant shut-in. Numerical modeling of this temperature recovery utilized direct heat input of a sufficient magnitude to heat both the fracture and matrix domains of the model. Temperature in the production area remains elevated compared to the pre-eruption conditions, supporting the conclusion that the eruption and shut-in reversed the impact of temperature decline due to production and injection. After an initial period of elevated pressures, as observed from wellhead pressures during the eruption, the reservoir returned to initial (pre-development) pressure following two years without production and injection. The bulk permeability of the reservoir is somewhat lower after the eruption, as quantified by the moderately higher pressure decline in response to production and injection, compared to pre-eruption observations.

ABSTRACT

Atmospheric cleanout flows and flow tests are standard practices at geothermal projects around the world. These tests are typically conducted after new wells are drilled and act both to cleanout drilling debris from permeable zones and provide initial indications of well performance and reservoir characteristics. However, cleanouts and flow tests have not been conducted at the Puna Geothermal Venture field since 2006 due to complex permit requirements and risks associated with hydrogen sulfide gas and related abatement chemicals. This challenge led to the practice of starting new wells directly to the power plant, which resulted in issues with both well performance and plant equipment. In 2022 an upgraded flow test facility was designed and following completion of two new production wells in 2023, atmospheric cleanouts were safely and successfully conducted using the upgraded facility and improved abatement practices. The tests were completed within permit constraints and ultimately led to increased power generation and improved well performance.

1. Introduction

The Puna Geothermal Venture (PGV) power station is located on the east side of the Island of Hawai'i. The PGV power station began generating power in 1993 with an Ormat-supplied 30 MW capacity plant consisting of 10 nominal 3 MW units utilizing the produced steam only. Ormat

acquired PGV in 2004 and in 2012 added two new plant units with an additional total 8 MW of installed capacity utilizing the brine phase and Ormat Energy Converter (OEC) technology.

The PGV power station was taken offline in May 2018 as a result of the 2018 Kilauea eruption. PGV resumed power generation in late-2020 following the completion of three new geothermal wells and one redrill. Three additional wells were drilled in 2022 and 2023, including new production wells KS-19 and KS-22 which were successfully flow tested utilizing an upgraded flow test facility.

Flow testing is a crucial step in the well completion process for geothermal projects. It involves evaluating the performance and characteristics of a geothermal well by allowing the hot fluid (water or steam) to flow from the reservoir to the surface in a controlled manner. This testing phase provides valuable data on the well's productivity, temperature, pressure, and fluid composition (Hole, 2008). By analyzing this information, engineers can assess the potential energy output of the well, determine the optimal flow rates, and identify potential issues. Flow testing also helps in designing and sizing the surface equipment, such as pipelines, heat exchangers, and power generation facilities, to ensure efficient and sustainable energy production from the geothermal resource (Axelsson, and Steingrímsson, 2012). Additionally, it aids in estimating (and optimizing) the long-term sustainability of the geothermal reservoir and guides future well drilling and field development strategies.

Initial flow testing following drilling completion also assists with well development by cleaning the wellbore and permeable fractures of drilling debris (Grant and Bixley, 2011). This drilling debris typically consists of formation cuttings and remnant drilling fluid which should be cleaned out prior to flowing to power generating facilities. If drilling debris is not properly removed from the wellbore and productive fracture system during flow testing, it can result in negative impacts on both power generating facilities and long-term well performance, both of which have been observed at PGV. To avoid these issues following completion of new wells, PGV worked with Two-Phase Engineering & Research, Inc (TPE) and West Coast Geologic Inc (WCG) to design upgraded testing facilities and implement updated abatement practices. The upgraded facilities and practices were developed with the goals of safely handling the high enthalpy reservoir fluid, safely managing the hydrogen sulfide gas (H_2S) in produced reservoir fluid, minimizing gas emissions, and adhering to unique regulatory requirements.

Use of the upgraded PGV flow test facility proved very effective in achieving desired goals, with brine carryover effectively eliminated and H_2S concentrations in the testing area remaining below 1 part per million by weight (ppmw) for the duration of the flow tests. Total H_2S emissions were more than 17 times below the regulatory limit during the first 2023 test and more than 200 times below the regulatory limit during the second 2023 test. Steam velocity was successfully measured with a constant temperature anemometer designed for wet/condensing gasses, allowing a direct enthalpy calculation.

Overall, the two tests completed in 2023 confirmed atmospheric testing can be safely conducted at PGV with conditions maintained well within the permit limits. Completing atmospheric cleanout flows for new wells provides significant value to the PGV reservoir and power generating facilities. Flow through the upgraded flow test facility allowed the production fracture system to be cleaned of drilling debris prior to initiating flow to the plant, resulting in improved long-term performance of the production wells. The drilling debris was successfully managed by the flow

test facility and later safely disposed of, instead of flowing through the plant gathering system where it can cause equipment fouling and down-time for maintenance. Further, between 2006-2022, prior to the reimplementation of atmospheric cleanouts, starting new wells at PGV was a challenging process requiring generation to be reduced to a minimum as the new wells came online. Use of the upgraded flow test facility allows wells to be put into service seamlessly, with no negative impact on plant generation.

2. Background

Completing atmospheric cleanout flows and flow tests is standard practice at geothermal projects around the world. These tests are typically conducted after new wells are drilled and act to both clean out drilling debris from permeable zones and provide initial indications of well performance and reservoir characteristics (Grant and Bixley, 2011). However, cleanouts and flow tests have not been conducted at the Puna Geothermal Venture field since 2006 due to complex permit requirements and risks associated with hydrogen sulfide gas. As a result, between 2006-2021, new production wells were started directly to the plant. Starting new production directly to a power plant is not common practice for geothermal facilities around the world due to several key risk factors:

1) Drilling debris including cuttings and residual drilling fluid is not fully cleaned out of the wellbore or fracture system. This can result in reduced near-wellbore permeability and impaired production well performance over time.
2) Drilling debris that does flow to the surface during initial well startup is flowed into the gathering system and power plant equipment. This material can cause fouling of plant equipment, specifically in heat exchangers that utilize the separated brine phase.
3) In some cases, the drilling debris can make its way through the surface equipment and damage the permeability of injection wells.
4) Starting new wells directly to the plant typically requires generation to be reduced to a minimum to allow the well to heat slowly and begin production at commercial temperatures and pressures.

Following the 2019-2020 drilling campaign, new PGV production wells were started directly to the power plant without a period of atmospheric cleanout flow. This direct-to-plant startup procedure resulted in all four of the points above being observed to some degree. To avoid these issues in the future, Ormat and PGV completed background research to better understand why flow tests had not been completed in recent years and determine if they could be safely conducted for future wells.

Prior to the 2023 testing, the last atmospheric flow test completed at PGV was in 2006. Atmospheric cleanout flows were not conducted for new wells at PGV post-2006 due to stringent permit regulations that limit the duration of the flow test and require complex installations to abate H_2S in the geothermal fluid. From 2021-2022 Ormat, TPE, and WCG investigated the permit requirements and determined the following key requirements could be met with an upgraded flow test facility design:

1) Total H_2S emissions to be maintained below 2.27 kg/hr (5 lbs/hr).
2) Four-hour maximum duration of flow to atmosphere per day.

3) Hydrogen sulfide concentrations at the local air monitoring stations are not to exceed 10 parts per billion by weight (ppb) on a 24-hour rolling average or 25 ppb on a 1-hour average. Note: local air monitoring stations A1, B1, and C1 are located near the PGV lease boundary between 0.8 km and 1.1 km linear distance from the planned muffler location (Figure 1).
4) Hydrogen sulfide concentrations must be measured upstream and downstream of the abatement location at least twice during the 4-hour flow period to determine the abatement efficiency and ensure emissions remain below the permitted level.
5) Hydrogen sulfide abatement equipment must consist of a cyclonic muffler or other equivalent device designed to minimize particulate and brine aerosol emissions, and direct venting into a vertical direction.
6) A minimum sodium hydroxide (NaOH) treatment mole ratio of four (4) to one (1) ($NaOH/H_2S$) must be used initially and the abatement efficiency monitored.

These requirements are further detailed in PGV's noncovered source permit number 0008-02-N, a publicly available document issued by the Hawaii Department of Health Clean Air Branch. Following review of the flow test permit requirements, Ormat, TPE, and WCG began design work in 2022 with the goal of having equipment ready to test wells completed during the 2022-2023 drilling campaign.

3. Flow Test Facility Design

An upgraded flow test facility was designed by Ormat, TPE, and WCG with the goals of optimizing H_2S abatement and ensuring redundancies for both critical surface equipment (e.g., high pressure abatement pumps) and abatement dosing locations (e.g., primary and secondary ports for adding abatement chemicals). To increase abatement efficiency, ensure the abatement system is comprehensive, and improve collection of testing data, several upgrades were made to the facility design. The relevant upgrades are discussed below.

The Low Emission Atmospheric Metering Separator (LEAMS, Jung and Howard, 2000) was procured from Drill Cool Systems Inc. The LEAMS was designed by TPE in the 1990s and is used in place of a traditional cyclone separator to provide high brine/steam separation efficiency, effectively eliminating carryover of caustic brine in steam. The LEAMS was tested by Sandia in 2000 (Finger et al., 2000) with results indicating superior separation efficiency and minimal brine-carryover compared to a traditional cyclone separator at a similar flow rate and enthalpy conditions. The LEAMS design met the goals of the upgraded design for PGV flow testing.

In place of a James Tube (James, 1962), steam velocity is planned to be measured at the muffler outlet using high-temperature anemometers. Compared to a traditional cyclone muffler, the LEAMS has a relatively constant velocity profile along the muffler outlet. This allows a representative steam exit velocity to be recorded from a point source at the LEAMS outlet. The steam exit velocity can be used together with the brine flow rate from the weir box and atmospheric separation conditions to facilitate a direct calculation of the steam mass flow rate, total mass flow rate, and total flow enthalpy. Two different types of high-temperature anemometers were selected for testing. The first was a mechanical vane anemometer with a temperature rating of 100 ^oC, and the second was a constant temperature anemometer designed for condensing gasses with a temperature rating of 125 ^oC.

Figure 1: The figure above shows the PGV lease boundary as the light-blue line with the air monitoring station locations indicated as A1, B1, and C1. Straight line distances from the planned flow test location to the air monitoring stations are indicated.

A secondary abatement manifold was designed by TPE and installed on the LEAMS. This manifold allows the steam between the two LEAMS demister sections to be treated with NaOH solution (see Figure 2), effectively abating any H_2S remaining in steam following primary abatement of the two-phase flow upstream of the control valve (see reaction equation (1)). The goal of the secondary abatement manifold is to ensure H_2S emissions at the muffler outlet are maintained at a minimum, ideally well below the permit limit of 2.27 kg/hr.

$$H2S(g) + NaOH(aq) \rightarrow NaHS(s) + H2O(aq) \quad (1)$$

A basic schematic of the LEAMS muffler with the secondary abatement port locations and the planned positioning of the high-temperature anemometers is shown in Figure 2.

A static mixer assembly designed by TPE is installed on the 3-inch bypass to increase the abatement efficiency of potential gas slugs that could be encountered during the initial well startup. The static mixer is designed to provide efficient mixing of NaOH solution with dry gas or gas-saturated condensate that may be encountered during initial well discharge through the 3-inch bypass (bleed) line.

Amber HS (a chelated zinc-sulfate solution, Amber Chemical, Inc.) will be pumped into the weir box and weir box drain line to the lined sump to ensure H_2S precipitates out of solution as zinc sulfide, following the reaction shown in equation (2). Precipitation out of solution as zinc sulfide ensures H_2S gas will not break out of solution while brine is stored in the lined sump prior to safe disposal.

$$H2S(aq) + ZnSO4(aq) \rightarrow ZnS(s) + H2SO4(aq) \quad (2)$$

Two real-time H_2S sensors are installed on opposite sides of the LEAMS outlet to allow continuous reading and recording of H_2S concentrations in vented steam. Collection of real time data allows the NaOH pumping rates to be optimized and ensures the emissions remain below the permit limit and are minimized for the duration of the test.

Finally, a portion of the permanent plant piping tie-in will be used as part of the flow test flow line. This ensures the well can be controlled or shut-in by a remote operated control valve and allows all pressure control safety equipment used during long-term operation to be used during the flow test (e.g. two 12-inch 1500 master valves, one 12-inch 1500 side isolation valve, and two 8-inch 1500 remote operated control valves). The full flow line and flow test facility setup are further detailed in Section 4.

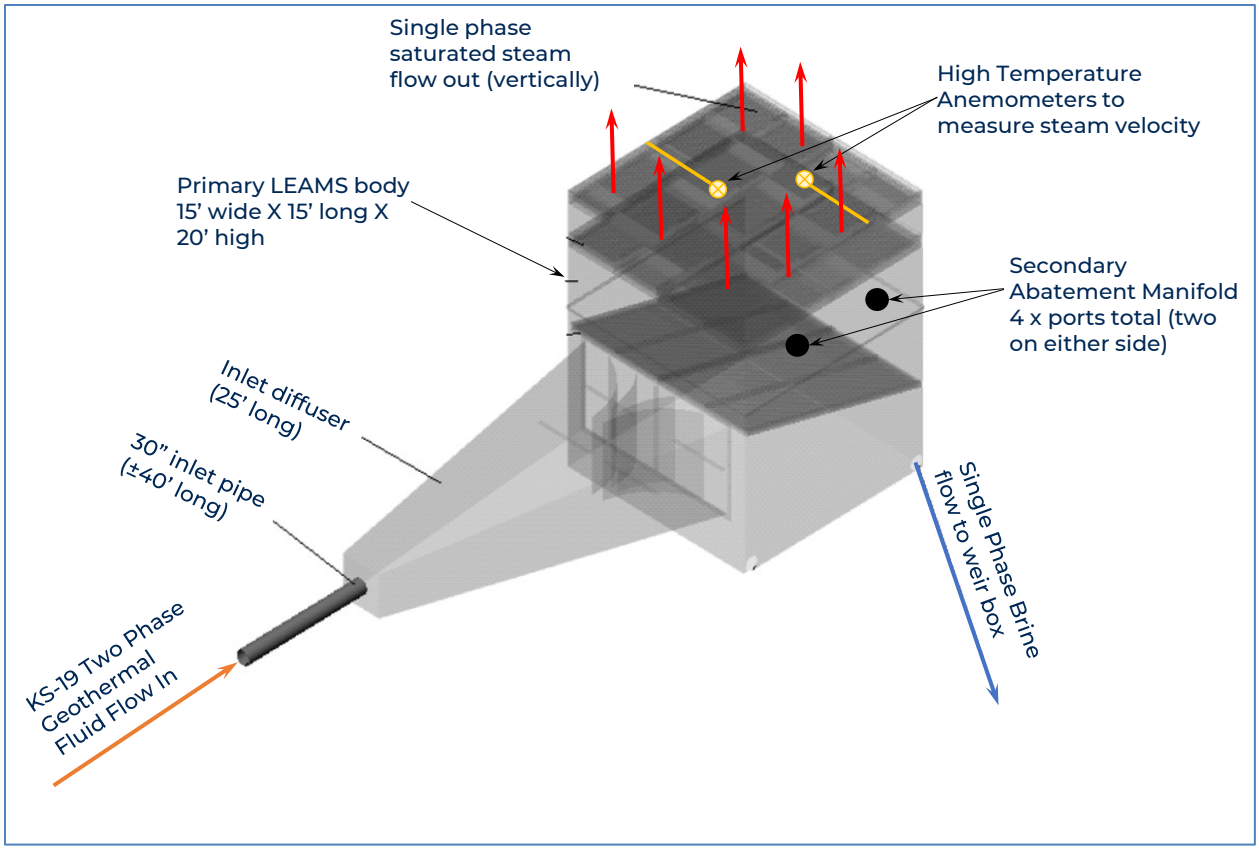

Figure 2. Basic schematic of the Low Emissions Atmospheric Metering Separator (LEAMS) used for PGV flow testing and cleanout flows. Planned locations of the secondary abatement manifold ports and high-temperature anemometers are indicated. Figure modified from Jung and Howard, 2000.

4. Flow Test Equipment Installation

Following completion of KS-19 drilling, Ormat proceeded with installation of the permanent pipeline from the well to the main two-phase production header. At PGV the permanent pipeline from the well to the main header includes two separate branches and four primary 8-inch control valves (CVs), two on each branch (Figure 3). To ensure proper control of the well is maintained during the flow test, the flow test setup is planned to incorporate one of the two permanent branches and two of the four primary control valves. The permanent production wellhead stack is also used during the flow test. This includes a robust design made up of two 12-inch 1500 master valves separated by a 12-inch 1500 kill spool with two 3-inch 1500 side outlets. Above the upper master valve a 12-inch 1500 flow cross is installed with 12-inch isolation valves installed on the two lateral outlets and 1500 class rock catchers attached to the isolations valves. Figure 4 and Figure 5 detail the wellhead arrangement for KS-19, typical of PGV production wells.

The KS-19 flow test setup is detailed in Figure 3, Figure 4, and Figure 5 which identify key valves and abatement injection ports to be used during the flow test. Note that the KS-22 setup is identical, but off the east branch instead of the west. The key valves to be used during KS-19 flow testing include the following:

- Valve #1: Lower 12-inch 1500 master valve (Figure 4)

- Valve #2: Upper 12-inch 1500 master valve (Figure 4)
- Valve #3: West branch 12-inch 1500 Velan Valve (Figure 4)
- Valve #4: 3-inch 1500 gate valve on the bleed line adjacent to the wellhead (Figure 5)
- Valve #5: 8-inch fisher control valve (remote operated). There are redundant 8-inch valves, both may be opened to increase flow following initial well startup (Figure 3).
- Valve #6: The 16-inch 300 gate valve isolating the temporary flow test flowline from the permanent plant flow line (Figure 3).
- Valve #7: The 3-inch 1500 gate valve just upstream of the static mixer (Figure 3)
- Valve #8: The 3-inch 1500 gate valve isolating the static mixer from the downstream plant bleed system (Figure 3).

Valves #1 through #5 are all components of the permanent wellhead installation and flow line to the plant. The CV noted as valve #5 is remotely operated from the PGV control room to ensure the well can be isolated remotely in the case of an emergency. Following the 4-hour testing period of KS-19 through the west-branch, flow will be transitioned to the plant using the east-branch. This allows the west-branch to be isolated with valve #3 so the permanent west-branch flow line and CVs can be cleared of debris produced during the flow test. Also note that a spectacle blind flange is installed on the west-branch just downstream of valve #6. This ensures the dead-leg of the permanent west-branch does not become filled with drilling debris during the flow test period. Once the west-branch is out of service following the test, the spectacle blind is rotated as part of the post-flow test maintenance, so the west-branch can be put in plant service when needed.

The 3-inch static mixer designed by TPE is installed on a tee coming off of the primary bleed line of the well, which is connected to the wellhead below the lower master valve and completely isolated from the primary flow line (see Figure 3 and Figure 5 for additional details).

During the flow testing period, the two-phase geothermal fluid is treated with 50% sodium hydroxide solution (NaOH) through the primary abatement ports located upstream of the CV (ports #1 and #2, Figure 3). Port #2 is to act as a standby backup port in the case there is an issue with injection into port #1. There are also primary and backup high-pressure abatement pumps attached to ports #1 and #2 respectively, providing a fully redundant system to ensure constant NaOH dosing at the primary abatement location for the duration of the testing period. The flow is further treated with NaOH through the secondary abatement manifold installed on the LEAMS muffler to ensure maximum abatement efficiency (ports #5 through #8, Figure 3).

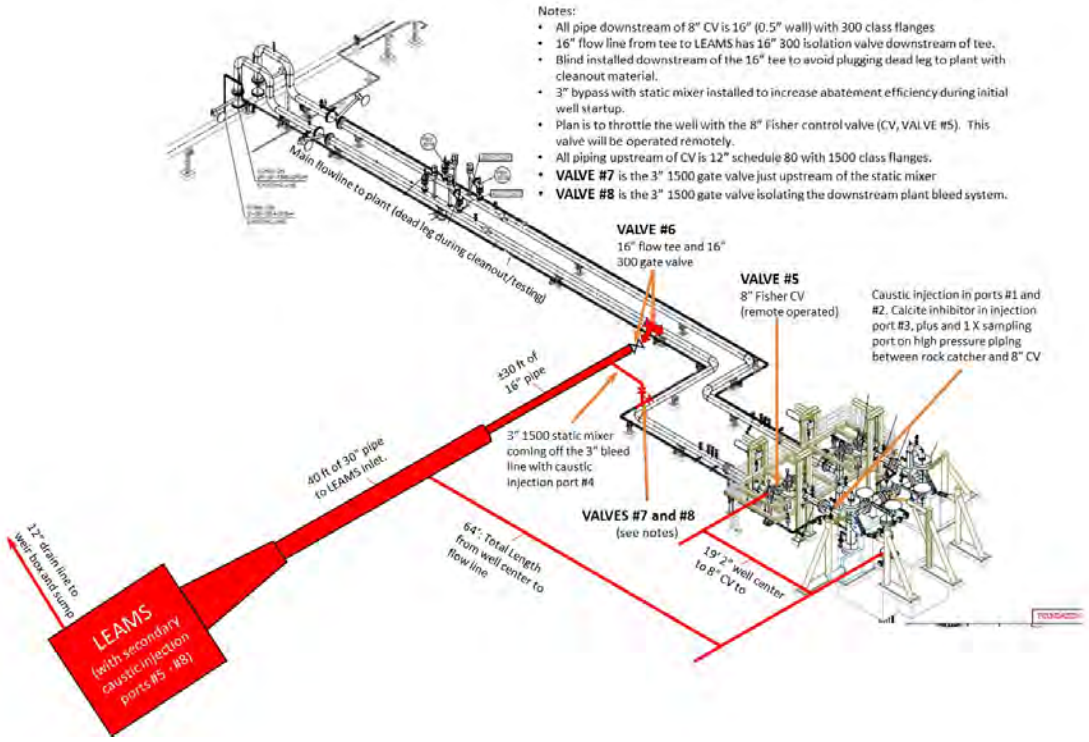

Figure 3. Sketch of the flow test facility as installed for KS-19 testing showing positions of key valves and caustic abatement injection ports.

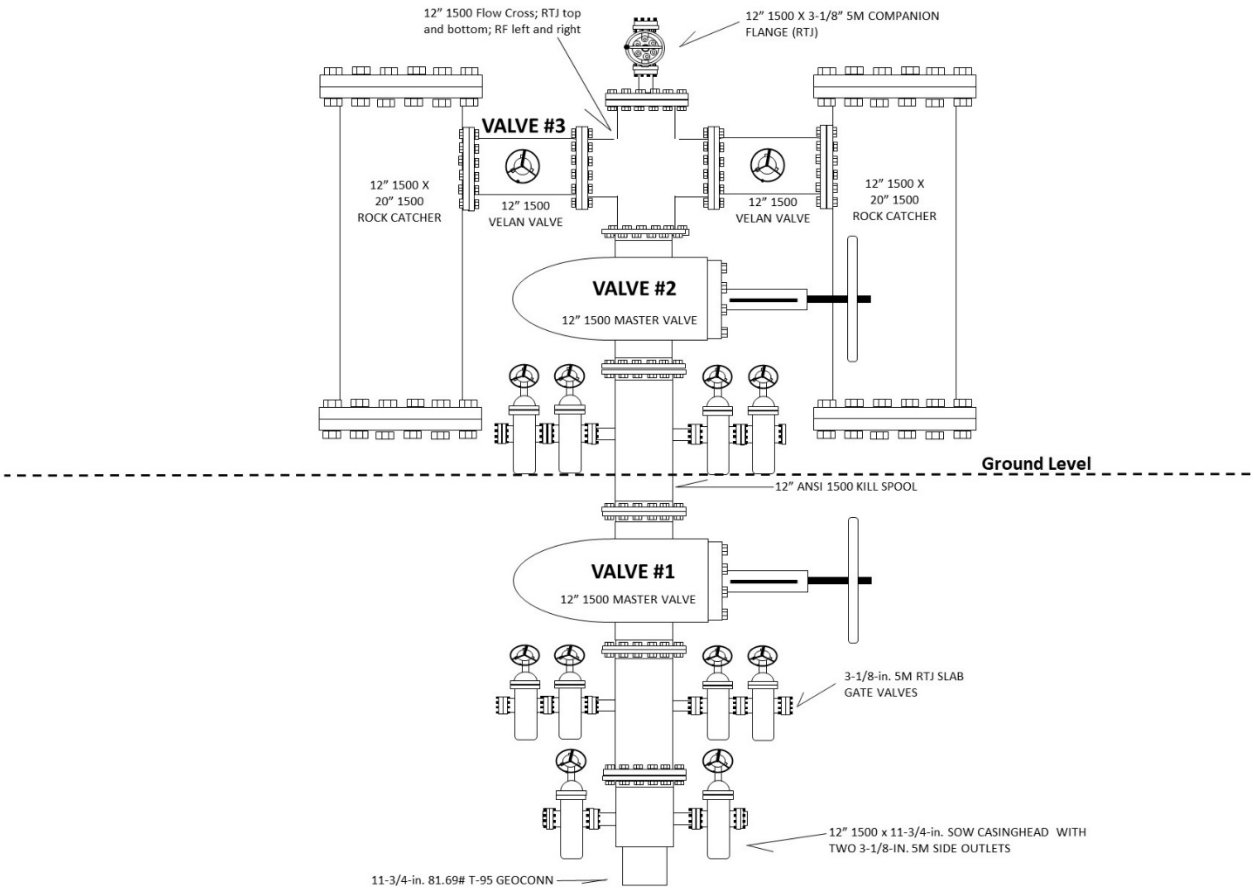

Figure 4. KS-19 wellhead assembly with Velan side-isolation valves and rock catchers included (note: bleed line not shown).

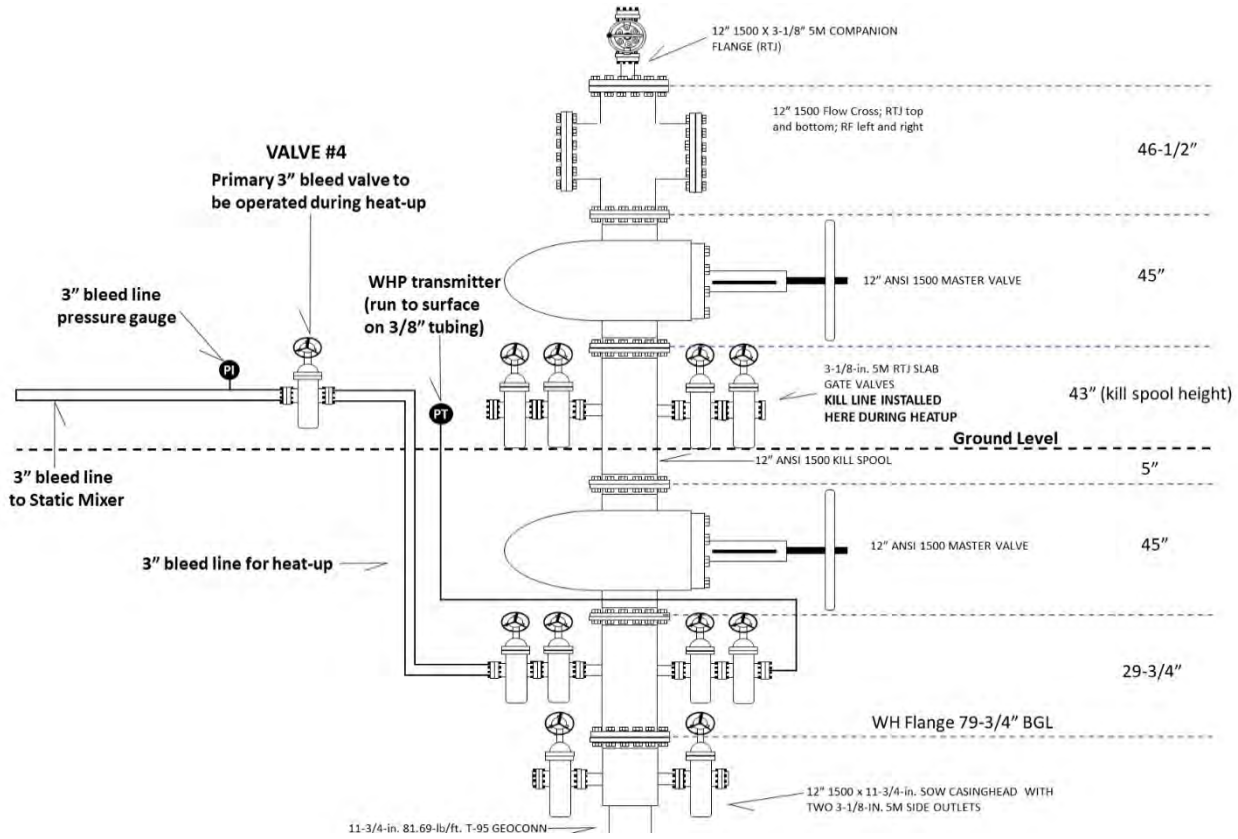

Figure 5. Simplified KS-19 wellhead assembly with bleed line emphasized (note: rock catchers not shown).

5. Hydrogen Sulfide Abatement Calculations

During the four-hour clean-out period, all flow is directed to the LEAMS. The vapor phase is vented to the atmosphere, and the liquid flows through the weir box and into a lined pond, where it is stored until it can be safely disposed. The maximum expected steam flow rate to be vented during the clean-out is approximately 28 kg/s (220 thousand pounds per hour (kph)) based on flow test equipment capacity. The steam phase is assumed to have an initial maximum H_2S concentration of 1000 ppmw based on measured geochemical concentration of other wells at startup. The maximum estimated rate of H_2S production in steam is therefore given by:

$$\frac{220{,}000\ lb\ steam}{hr} * \frac{1000\ ppmw\ H2S}{10^6} = \frac{220\ lb\ H2S}{hr} \quad (3)$$

H_2S abatement efficiency is conservatively estimated to be 98%. Previous test results indicate that efficiencies of 99% or greater are readily achievable using the upgraded abatement equipment designed for the PGV flow testing. The amount of H_2S to be removed based on 98% efficiency is:

$$\frac{220\ lb\ H2S}{hr} * 0.98 = \frac{215.6\ lb\ H2S}{hr} \quad (4)$$

Therefore, at the maximum anticipated flow rate and H_2S concentration, this level of abatement is estimated to result in a maximum emission rate of 4.4 pounds per hour of H_2S to the atmosphere during the clean-out period. This is below the permitted rate of 5 lbs/hr, even based on the most conservative assumptions for maximum steam flow rate, H_2S concentration, and abatement efficiency. Note that average H_2S concentrations in steam during normal operation are typically in the range of 200 – 600 ppmw.

Permit requirements state that a minimum mole ratio of 4 to 1 (NaOH to H_2S) is required for abatement during flow testing to an atmospheric muffler. To be conservative, Ormat, WCG, and TPE determined a mole ratio of 8.4 to 1 (NaOH to H_2S) would initially be used to ensure the required abatement efficiency of 98% is achieved. This mole ratio determines the abatement solution pumping rate required as follows:

$$\frac{8.4 \text{ mole NaOH}}{1\ mole\ H2S} * \frac{40 \text{ lb NaOH}}{1 \text{ mole NaOH}} * \frac{1 \text{ mole H2S}}{34 \text{ lb H2S}} * \frac{1 \text{ gal 50\% NaOH solution}}{5.32 \text{ lb NaOH}} * \frac{220 \text{ lb H2S}}{\text{hr}} = \frac{409\ gal\ 50\%\ NaOH\ solution}{hr} \quad (5)$$

The installed pumping capacities for the two primary pumping units are 500 gallons per hour (gph) each of 50% sodium hydroxide solution for a total capacity of 1000 gph. Therefore, a large excess capacity for abatement is available, including a fully redundant backup system at the primary abatement location to the two-phase flow line upstream of the control valve.

Further, during the 4-hour flow test period, an additional 150 gph of 50% NaOH solution will be added to the secondary abatement manifold to treat the steam phase in the LEAMS and ensure a minimum of 98% abatement efficiency is achieved.

Flow from the well will be initiated through the static mixer on the 3-inch bypass line. Just upstream of the static mixer assembly is port #4 for NaOH injection. 450 gph of 50% NaOH will be added to this port 5-minutes before initiating flow from the well. Flow will be started through the 3-inch bleed line and static mixer assembly to ensure efficient mixing of caustic abatement chemicals with dry gas or gas-saturated condensate that may be encountered during initial well discharge. Flow through the 3-inch static mixer is planned to proceed for roughly 15-min to ensure proper abatement of the initial discharge. Flow will then be transitioned to the primary two-phase flow line once wellhead conditions are stable and saturated steam is observed exiting the top of the muffler and brine observed in the weir box.

6. Procedure for Initiating Flow from Well

Prior to the initiation of flow, the well is to be on back heat from an adjacent active production well. This process is started roughly a week before the planned flow test date with heat being added to the well in a slow, controlled manner to avoid rapid thermal cycling and ensure the wellbore is properly heated before initiating flow. The flow test facility has been installed according to the information presented above and in Figure 3 through Figure 5.

Flow from the well is initiated using the following procedure:

1) All flow for the KS-19 cleanout to the LEAMS is through the west-branch (note: flow initiation procedure is the same for KS-22, but through the east-branch). The KS-19 east-branch Velan should remain closed at all times to keep the branch isolated until flow begins to be transferred to the plant through the east-branch.

2) Valves identified in Figure 3 through Figure 5 should be in the following positions:
    a. Valve #1: OPEN (Lower 12-inch 1500 master valve)
    b. Valve #2: OPEN (Upper 12-inch 1500 master valve)
    c. Valve #3: OPEN (West leg 12-inch 1500 Velan Valve)
    d. Valve #4: OPEN as the well will be on back heat until flow is initiated (3-inch 1500 gate valve on the bleed line adjacent to the wellhead).
    e. Valve #5: CLOSED (8-inch remote operated fisher CV).
    f. Valve #6: OPEN (16-inch 300 gate valve to the LEAMS flow line)
    g. Valve #7: CLOSED (3-inch 1500 gate valve just upstream of the static mixer)
    h. Valve #8: OPEN to allow back heat into the well (3-inch 1500 gate valve for isolation of the static mixer from the downstream plant bleed system).
3) If any leaks in wellhead equipment are encountered during the startup or test operations, shut-in the well and tighten bolts to fix the leaks. Then restart the startup procedure from point #1 above.
4) Ensure that NaOH and abatement pumps are setup to pump at the following rates and ports:
    a. Port #1 (primary caustic port upstream of CV): 50% NaOH at 450 gph
    b. Port #2 (secondary caustic port upstream of CV): 50% NaOH at 450 gph
    c. Port #4: (caustic port on 3-inch bypass line upstream of static mixer) 50% NaOH at 450 gph
    d. Ports #5 through #8 (secondary caustic abatement ports in LEAMS) 50% NaOH at 150 gph total.
5) Make final notification to the control room that test is beginning.
6) Close valve #8 to isolate the back heat flow from adjacent production well.
7) Begin abatement flow into port #4 on the static mixer at 450 gph.
8) Slowly open valve #7 to 20-30% to begin flowing the well through the static mixer and into the LEAMS.
    a. Caustic injection into port #4, should be started 5-minutes before valve #7 is opened. This location will be used for caustic injection until steam flow reaches 2.5-5.0 kg/s and flow is transferred to the primary two-phase flow line.
    b. Caustic injection into ports #5 through #8 will be initiated at this time at 150 gph.
    c. As soon as brine flow begins coming over the weir, begin dosing with Amber HS to complete abatement reaction. Amber HS pumps are rated for 180 gph at pressure up to 40 psi.
9) Well Test Engineer and Geochemist to immediately verify the following parameters before continuing or increasing the by-pass flow:
    a. A pH of 12.0 or more is required for water from weir box.
    b. A temperature at the static mixer of 100 ^{o}C or greater if the temperature at the wellhead is 100 ^{o}C or greater.
    c. A temperature at the static mixer within 10 ^{o}C of the temperature at the wellhead, if the wellhead temperature is less than 100 ^{o}C.
    d. H_2S monitor readings from all stationary and portable devices indicating less than 10 ppm on LEAMS outlet and zero on the ground in the vicinity around the LEAMS. The designated safety supervisor will be roving with a mobile gas sniffer and at this time should be immediately downwind of the muffler and fully masked-up with SCBA working.

e. If any above parameters are not met, immediately close valve #7 and evaluate the cause. Proceed after the situation is fully understood and the process corrected as necessary.

10) If the above parameters are met, slowly increase flow through the 3-inch bleed line to 100% open on valve #7. Continue to monitor the parameters above and close valve #7 if they cannot be maintained.
11) Once stable steam flow has been established through the bleed line, use data from the two H_2S sensors on LEAMS outlet to ensure H_2S emissions are below 2.27 kg/hr (5 lbs/hr).
12) Assuming H_2S emissions are below 2.27 kg/hr, begin injecting 50% NaOH in port #1 at 450 gph.
13) Once the chemical injection rates are established in port #1, change the valve positions in the following order:
    a. Ensure the high-pressure piping has equalized and begin to slowly open valve #5 (8-inch CV) to flow through the primary two-phase flow line into the LEAMS.
        i. Since valve #5 is a remote-operated Fisher CV, coordinate with control room on desired valve position. Flow test engineer to coordinate and confirm all CV position changes.
    b. Valve #6 should already be opened 100% and the well should be controlled and throttled with valve #5.
14) Once flow is established through the main flow line, close valve #7 and stop caustic injection into port #4.
15) Collect fluid samples upstream of the caustic injection ports as needed to determine pre-abatement H_2S concentrations through onsite titration per regulatory requirements.
16) With flow established through the main flowline, continue injection of 50% NaOH at 150 gph into ports #5 through #8 to control H_2S concentrations (i.e. the secondary abatement ports on the LEAMS).
    a. NaOH injection rates into the secondary abatement manifold should be optimized to minimize H_2S concentrations at the muffler outlet.
17) Once stable flow is established through the main flowline, continue to monitor H_2S emissions. Flow test engineer will provide steam flow rate based on available instrumentation to facilitate a running calculation of the hourly emissions.
18) Assuming the H_2S emission rate is 1 kg/hr or less, slowly open valve #5 to a maximum measured steam rate of 28 kg/s (220 kph).
19) If H_2S emissions approach 2.27 kg/hr, reduce flow from the well to stay below this limit. Ensure proper operation of all abatement pumps.
20) Continue the clean-out for a cumulative period of up to 4 total hours. Begin shut-in of the west-branch and transition flow to the plant at 3.5 hours.

7. Results

The upgraded PGV flow test facility was safely and successfully utilized for new production wells KS-19 and KS-22. Both tests stayed well within regulatory limits, with H_2S concentrations remaining below 1 ppmw at the ground-level monitoring stations located in a 5 m radius around the LEAMS. Average H_2S concentrations at the LEAMS outlet briefly reached 5 ppmw during the KS-19 test, though this was due to a temporary issue with an abatement pump which was quickly resolved by transitioning to the standby backup pump. Even considering the temporary abatement pump issue, the maximum hourly H_2S emission during the KS-19 test was 0.32 kg H_2S.

Total emissions for the 4-hour test period were 0.51 kg compared to the maximum allowable 9.1 kg. During the KS-22 testing, abatement pumps functioned properly for the duration of the 4-hour test, and H_2S emissions for the full test were less than 0.041 kg, over 200 times below the regulatory limit of 9.1 kg (i.e. 2.27 kg/hr * 4 hr). Both tests maintained H_2S emissions significantly below the regulatory limit of 2.27 kg/hr. Even KS-19 with slightly higher emissions was more than 17 times below the regulatory limit for the full 4-hour period. Figure 7 shows the total emissions during the flow tests of both KS-19 and KS-22.

Metering of the flow rates during the test went generally according to plan apart from the mechanical vane anemometer failing 15-minutes into the KS-19 test because the wire connecting it to the base station was unintentionally stepped on, removing it from the instrument at the top of the muffler. The constant temperature anemometer successfully measured the steam exit velocity for the duration of both tests, providing values within the expected range of steam flow rates.

At the end of the 4-hour period, the maximum flow rate from KS-19 was 81 kg/s with steam flow rate of 28 kg/s and brine flow rate of 53 kg/s. At PGV atmospheric separation conditions, this provides an enthalpy value of 1200 kJ/kg. This is within the expected range for the well given that the flow test period was only 4-hours. Given the complex reservoir dynamics, PGV production wells typically start production a relatively lower enthalpy than the observed long-term stable enthalpy. Enthalpy increases over-time until the well stabilizes within the first 2-3 months of production. For reference, stable enthalpy for KS-19 after 3-months of production was 1600 kJ/kg.

At the end of the 4-hour period, the maximum flow rate from KS-22 was 72 kg/s with steam flow rate of 28 kg/s and brine flow rate of 44 kg/s. At PGV atmospheric separation conditions this provides an enthalpy value of 1287 kJ/kg. This is within the expected range for the well given that the flow test period was only 4-hours.

Figure 6 shows the flow rate and enthalpy plots for both KS-19 and KS-22.

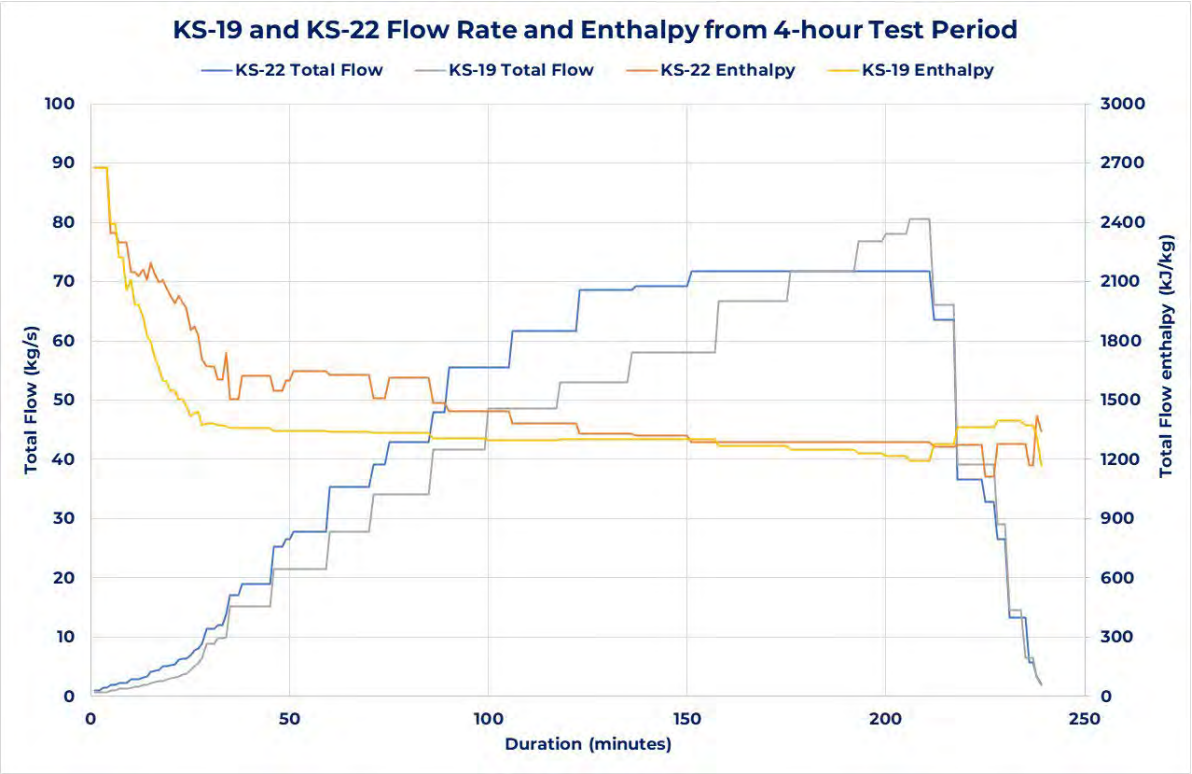

Figure 6: Four-hour flow test measurements of total flow rate and total flow enthalpy for both KS-19 and KS-22 flow tests through the LEAMS.

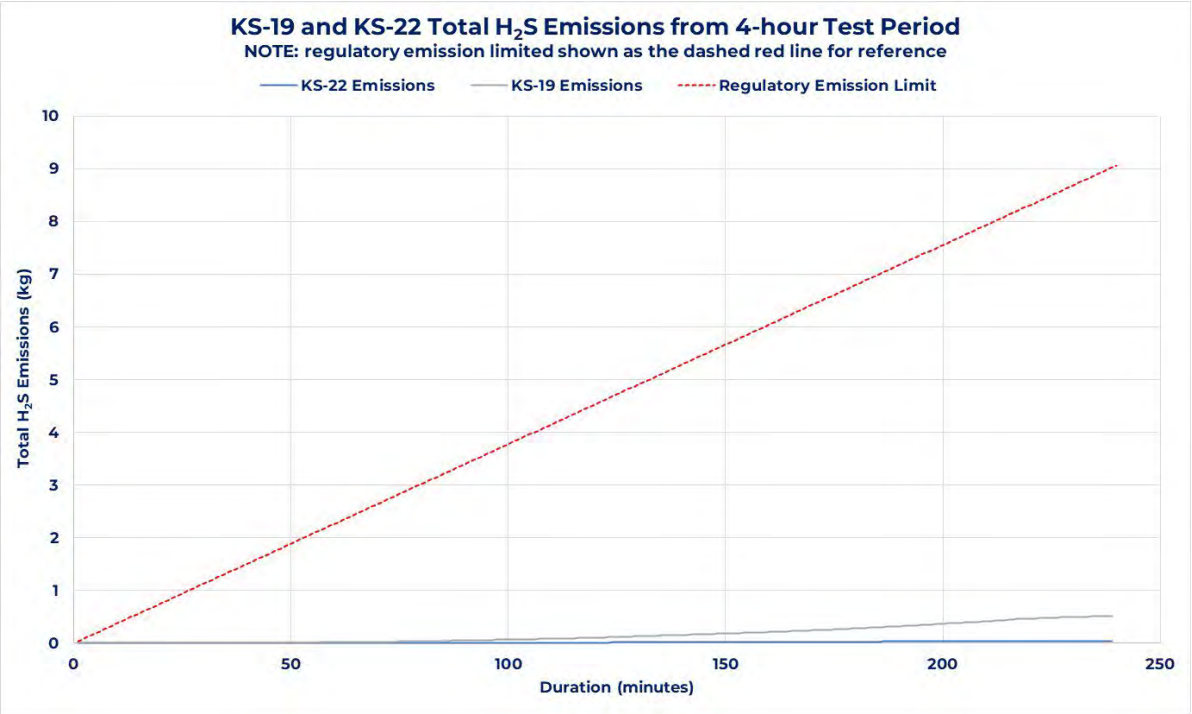

Figure 7: Total emissions of H_2S during the four-hour flow tests for both KS-19 and KS-22 through the LEAMS. For reference, the regulatory emission limit is shown as the dashed red line.

Figure 8: Aerial image of KS-22 flow test in 2023.

7. Conclusions

Overall, the two tests completed in 2023 confirmed atmospheric testing can be safely conducted at PGV with conditions maintained well within the required permit limits. Completing atmospheric cleanout flows for new wells provides significant value to the PGV reservoir and power generating facilities. Flow through upgraded flow test facilities allowed the production fracture system to be cleaned of drilling debris prior to initiating flow to the plant, resulting in improved long-term performance of the production wells. The drilling debris was safely managed by the upgraded flow test facility and later safely disposed of, instead of flowing through the PGV plant gathering system where it has previously been observed to cause equipment fouling requiring down-time for maintenance. Further, between 2006-2022, prior to the reimplementation of atmospheric cleanouts, starting new wells at PGV was a challenging process requiring generation to be reduced to a minimum as the new wells came online. Use of the upgraded flow test facility allows wells to be put into service seamlessly, with no negative impact on plant generation.

Following startup of KS-19, plant generation improved by a factor of roughly 100%, and following startup of KS-22 generation increased by a factor of 150%, indicating significant value in starting new production wells through the upgraded flow test facility. It has now been ten months since KS-22 was started and power generation remains stable with total plant generation 120% higher than observed prior to well start-up, indicating good long-term performance of the new wells.

However, even following the permitted 4-hour clean out flow periods, some fouling of plant equipment from drilling debris was still observed. This indicates the permitted 4-hour flow test period does not provide sufficient time for the well and local fracture system to fully clean out all drilling debris. A longer duration flow test period of up to 12-hours would provide significant value for future PGV production wells and the power generating facilities. Note that at other geothermal projects around the world new wells commonly flow to atmosphere for weeks, or even months at a time during long-term testing (Sanyal et al., 1987; and. Oikawa et al., 2001).

Aside from the duration, the 2023 PGV flow tests met the desired goals of safely conducting the tests within the permit requirements. The upgraded flow test facility and abatement practices further proved that H_2S emissions could be maintained well below the regulatory limit, supporting the idea that a longer testing period could be achievable without any significant modification to the currently permitted emission limits.

Acknowledgment

Special thanks to Doug Jung and Two-Phase Engineering & Research for reviving the LEAMS and providing invaluable insight on the equipment design, setup, and use. Another special thanks to West Coast Geologic for their assistance in preparing for and safely executing the flow tests.

Salton Sea Geothermal Field, conceptual model, high-temperature, high-salinity, double-diffusive convective system, lithium

ABSTRACT

The Salton Sea Geothermal Field (SSGF) is known for its high-temperature, high-salinity brine, the existence of a low-salinity reservoir above the hypersaline reservoir, and complex thermodynamic behavior. Previous conceptual models have generally described homogeneous reservoir architectures with minor variations along known depths (-4,000 to -9,000 ft ASL). This paper presents an alternative view that highlights the interaction of structurally controlled permeability and permeability barriers with the laterally extensive stratigraphically hosted reservoir, while also addressing thermo-chemical barriers that explain the vertical distribution of salinity and temperature in the system.

The model presented here incorporates the key elements of a conceptual model of a hydrothermal system; heat source, permeable pathways, fluid recharge, characterized reservoir, and fluid discharge. Each of these elements are resolved with data sets obtained on the eastern margin of the field, with their implications extended regionally to the rest of the field, informed by observations from previous studies. On the fields' eastern margin, lateral permeability barriers marking the edge of the economic resource are recognized in large offset faults imaged in depth migrated seismic data. Well temperatures from the eastern side of these faults are significantly colder than temperatures encountered in wells on the west side, supporting the demarcation of the resource's edge. The resource top is defined by a thermo-chemical interface where density compensation achieved by a decreasing temperature and salinity gradient gives way to background shallow hydrology. This "brine interface" marks the top of the convecting system and the base of the shallow hydrologic system. The behavior below this interface has been described in other works as a "double-diffusive convective system", and its characteristics in the Salton Sea are discussed at length based on temperature and salinity data presented here.

The conceptual hydrothermal model presented here also accounts for highly permeable zones in transitional metamorphic depths of the Salton Sea reservoir and surface manifestations like mud-pots of the system through discreet vertical pathways (faults and fractures) that rupture the thermochemical cap intact over the rest of the reservoir.

1. Introduction

Different studies, (e.g. Hulen 2002, 2003, and Kaspereit, 2016) have been published to describe the Salton Sea geothermal system. The system exists in a propagating continental rift that has

resulted in divergent sea floor spreading to the south in the Gulf of California while propagating northward along trans-tensional elements stemming from the transform plate boundary to the East and North. The Salton Sea is located at the northern tip of the Gulf of California and hosts extensional and trans-tensional structures that have thinned the crust, elevated the thermal gradient, and enabled intrusive and extrusive magmatism. The permeable structures, (meta-)sedimentary rocks, and heat hosted in this setting provide the basic elements of the geothermal system.

Multiple commercial geothermal projects have come to completion on the southern edge of the Salton Sea in the so-called "Salton Sea Geothermal Field" (SSGF). Data from wells in these fields, as well as regional geologic and geophysical data sets have supported iterations of conceptual hydrothermal models (CHM) described in the literary review section of this paper. The CHM presented here is informed by these previous iterations but is refined by data obtained in the Southeastern margin of the field at the Hudson Ranch Power I project. The model presented here also expands to contemplate interactions between the geothermal system and shallow ground water, as wells as thermal and chemical stratification in the reservoir that results in a perhaps uncommon constant density condition in the main reservoir. This "Double-diffusive convection system (DDCS) was developed by Fournier et al. (1990) and is summarized and applied to our CHM in the sections that follow.

2. Literature review

The CHM outlined in this work builds on key elements previously developed by other authors. The following section highlights the essential geological and hydrothermal findings from previous studies and explains how they are incorporated into our interpretation and proposed model.

2.1 Regional Geology

The SSGF is located in a tectonically active sedimentary pull-apart basin known as the Salton Trough (Kasperit, 2016). Lying at the southern tip of the San Andreas fault system, the Salton Trough borders a continental rift zone between the Pacific and North American plates as the San Andreas fault system steps-over to the right (Figure 1). This zone is dominated by a series of subsiding pull-apart basins, with elevated heat flow, seismicity, and volcanism (McKibben, 1991). The multiple pull-apart basins connect to right-stepping, primarily dextral faults, striking northwest.

The San Andreas fault system, the Imperial fault, and the San Jacinto fault zone play an important role in the formation of the SSGF (Kasperit, 2016). While the step-over from the San Andreas fault to the Imperial fault likely plays a more significant role in the SSGF system, the San Jacinto fault zone runs up the west side of the Salton Sea before joining the San Andreas fault to the north where it impedes northern movement of the Pacific Plate. This northern movement is transferred to the west of the San Jacinto fault zone allowing for rotation to expand over a larger area within the step-over and in turn forming two spreading centers. Extensional forces are the primary control on the location of most active parts of the geothermal field, however, a component of rotation along the faulted blocks may provide additional permeable drilling targets where fault tips intersect. Furthermore, extension creates crustal thinning coinciding with igneous intrusions and volcanism providing a means for the elevated heat flux to support the SSGF (Kasperit, 2016).

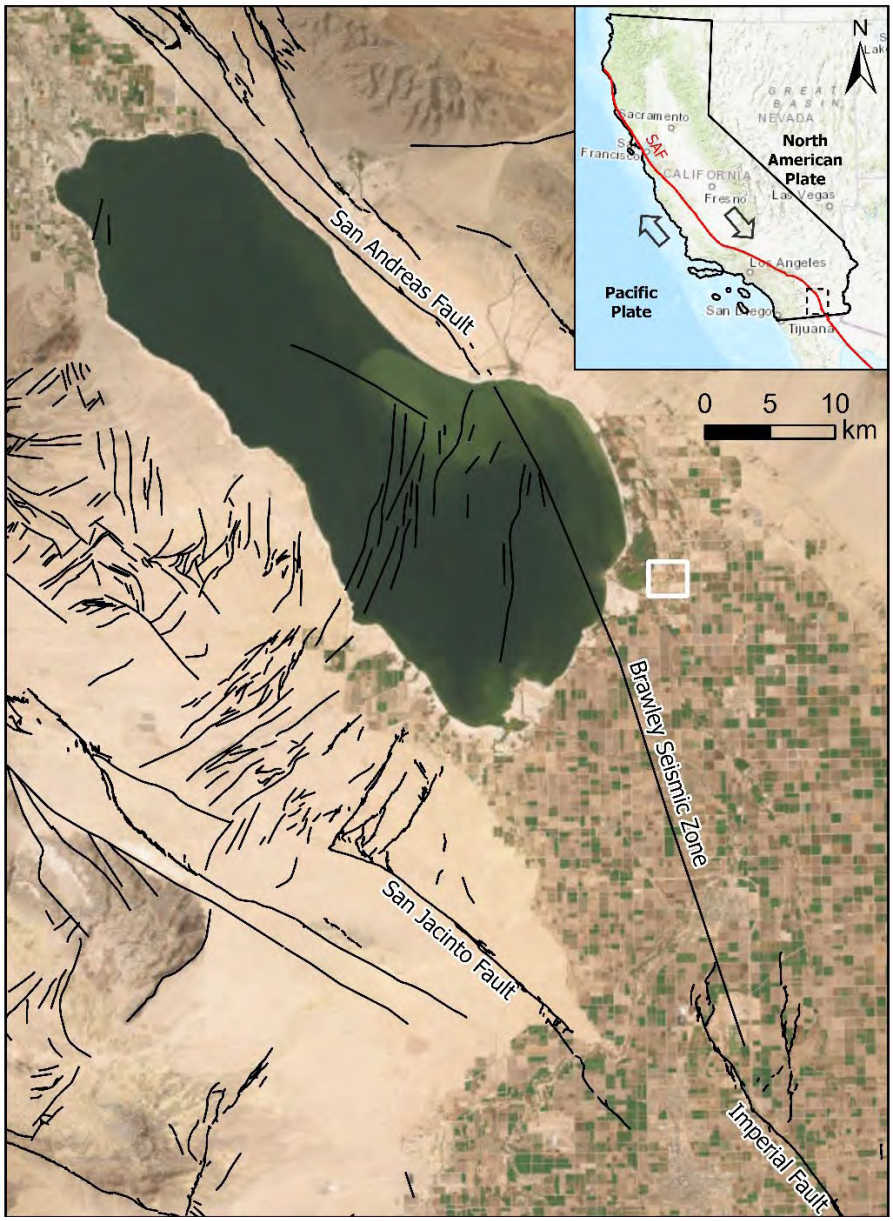

Figure 1: Location of HRP1, outlined in white, in respect to the Salton Sea Geothermal field. Satellite imagery overlain with USGS Quaternary faults. Inset map depicting San Andreas Fault (SAF) with relative sense of motion.

Due to the nature and amount of hydrothermal activity in the SSGF a 'recently' emplaced igneous intrusion is suggested to produce a robust heat source (Norton and Hulen, 2006). A detailed gravity survey of the Imperial Valley conducted in 1971 identified a gravity high extending NW and SE along the axis of the Salton Trough (Biehler, 1971). There are two possible explanations for the anomaly that may not be mutually exclusive; sediment densification through hydrothermal alteration and/or an igneous intrusion at depth (Younker et al., 1981). The intrusion hypothesis also potentially explains a linear magnetic high extending about 18 miles northwest from Calipatria into the Salton Sea (Griscom and Muffler, 1971). Estimates for the intrusions' size are roughly 12,000 ft thick and 15,000-26,000 ft wide. It is suggested that the intrusion was emplaced within ~5km of the surface within the last 50,000 years (Norton and Hulen, 2006). Localized Quaternary

volcanism and upwelling of hydrothermal fluids in the SSGF elevate heat flows to >500mW/m^2 (Sass et al., 1984). High heat flow in the region leads to mineralogical changes at depth that are prolific throughout the Imperial Valley as recorded by numerous boreholes (Norton and Hulen 2006). Within the SSGF greenschist metamorphism can generally be divided into three major zones; chlorite-calcite zone (~190-325°C), biotite zone (325-350°C), and clinopyroxene-amphibole zone (>350°C) (McDowell and Elder, 1980; Han et al., 2016b; Cho et al., 1988).

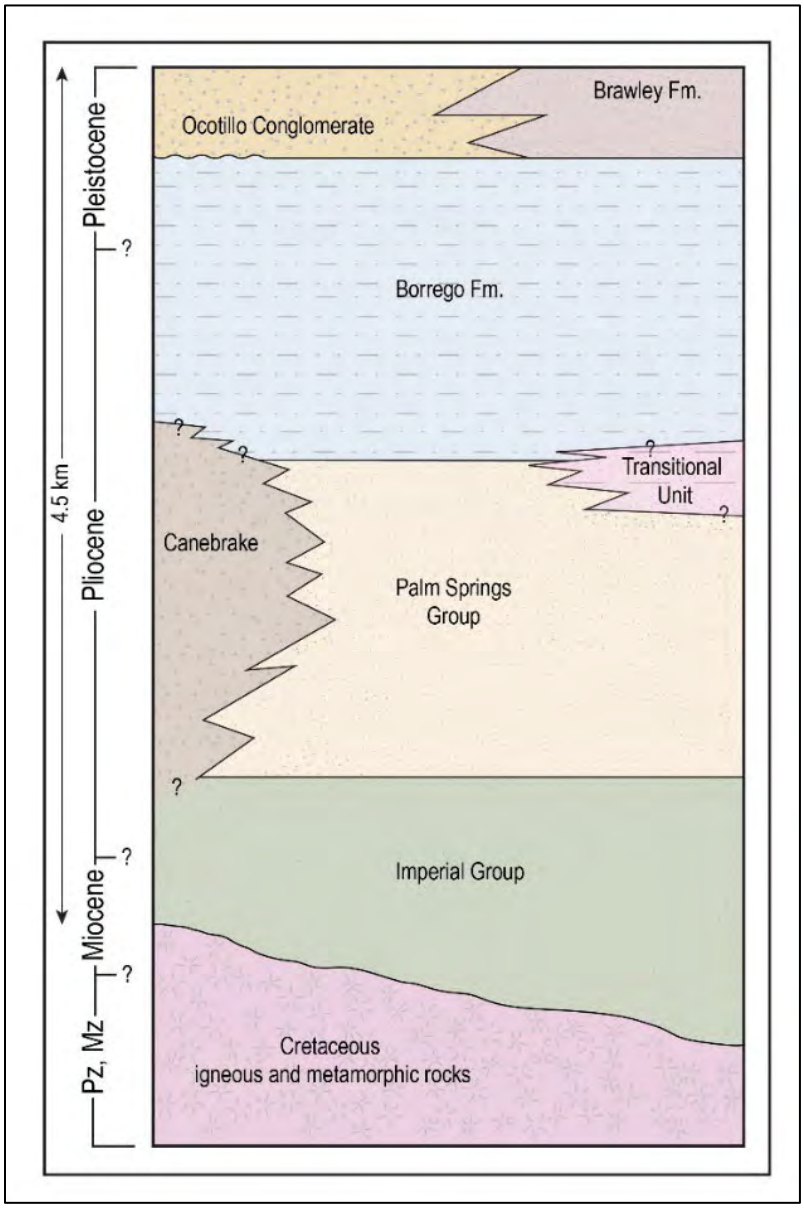

Figure 2: Simplified stratigraphic column of the Salton Trough. Modified from Steely et al., 2009 and Lutz et al., 2006.

The Salton Trough stratigraphy records its tectonic evolution in three main phases: early to late Miocene, Pliocene to early Pleistocene, and early Pleistocene to present (Figure 2). During the Oligocene to Miocene the Farallon Plate began its subduction beneath the North American Plate. The Salton Trough began to rift, and magmatism initiated along the eastern margin (Dorsey,

2006). In the Late Miocene two factors resulted in a marine transgression: a rapid rise in global seal level and accelerated basin subsidence along the western edge of the Salton detachment fault. A thick package of fossiliferous claystone, siltstone, and sandstone sediments of the Imperial Group (Figure 2) were deposited. After sediment deposition, the Colorado River delta developed in the northern portion of the Trough. The delta began to prograde, depositing additional sediment, resulting in the coarsening upward sedimentary sequences in the Imperial Group (Dorsey, 2006). In the Middle Pliocene the Colorado River delta continued to grow until it eventually isolated the Trough from the Gulf of California (McKibben, 1991). The landscape was dominated by a vast delta plain and lush wetlands. Intermittent argillaceous intervals and arkosic sandstone of the Palm Springs Formation were deposited during this period. Eventually a perennial lake basin formed in the northern trough correlating with the lacustrine deposits of claystone, siltstone, and fluvial sandstone of the Borrego Formation (Dorsey, 2006). In the early Pleistocene to Holocene, the Colorado River fluctuated between flowing north or south and as a result, paleolake Chauilla repeatedly flooded and dried (McKibben, 1991). This deposited lacustrine mudstone and evaporitic deposits of the Brawley Formation (Helgeson, 1968). Quaternary age alluvium sediment consisting of unconsolidated gravel, sand, silt, and clay overlies the entire basin (Dutcher et al., 1972).

2.2 Previous conceptual model descriptions

Legacy models of the Salton Sea Geothermal Field (SSGF) have provided insights into the temperature and structural behavior of the reservoir. Hulen et al. (2002 and 2003) highlighted the presence of a still-cooling felsic igneous heat source beneath the geothermal field, estimating it to be 1-10 km^3 in volume and located around 3.6 km below sea level. This source likely fuels the hydrothermal activity observed in the SSGF, which may have started over 100,000 years ago. The permeability of the reservoir is characterized by high vertical permeability through fractures and breccias, as well as sedimentary layers with secondary permeability from calcite dissolution (Hulen, 2002). Although the full extent of the reservoir remains uncertain, the study suggests the presence of deep, permeable zones with significant hydrothermal activity.

Building on the work of Hulen et al. (2002 and 2003), Kaspereit et al. (2016) updated the conceptual model using new geophysical data. Their revised model suggests that the SSGF is compartmentalized by a series of northwest-striking faults, with extensional fractures creating vertical permeability, particularly at the edges of rotated fault blocks. The center of the compartments is interpreted as the thinnest and weakest point for thermal features to form. These interpretations are then correlated with seismic, magnetic, and gravity surveys and with the known rhyolite domes near the Salton Sea, as seen in Figure 3. They serve as the basis for the regional features of this paper's conceptual model.

3. CHM elements and constraining data sets

The CHM proposed in this paper incorporates geoscience data gathered from the HRP1 project to describe this part of the geothermal reservoir (location shown in Figure 3). The key elements of the CHM, defined using geoscience data, include the heat source, permeability structure, temperature model, thermal recharge pathway, characterized reservoir, interactions with shallow hydrology, and a thermochemical description of the salinity distribution of the system. The

geoscience elements are presented individually below and synthesized in Section 5 where the final conceptual model is described.

3.1 Heat source

Estimates of heat flux in the SSGF vary from study to study but converge with a mean of nearly 450 mW/m^2 (Sass, 1988), and with some estimates >500 mW/m^2. Fournier (1990) suggests the heat flow may be greater than 1000 mW/m^2 above the recent intrusives, demonstrating a larger deep conductive zone underneath the Salton Sea and a shallower conductive zone on the periphery to the northwest and southeast.

The shallow heat anomaly was initially generated using data compiled from previous drilling programs in 1982 and 1985 (Newmark et al., 1988). With additional onshore borehole control a revised boundary was compiled in 2002 (Kaspereit, 2016). Both the 1988 and 2002 boundaries were completed using gradient data points only, an analysis of geophysical structure was not included. In 2016 Kaspereit re-contoured the shallow heat anomaly (Figure 3) incorporating the limits of the SSGF extension model. The 2016 northwestern boundary edge was constrained by regional magnetic and gravity data as there are no thermal gradient holes in this area (Kaspereit,2016).

The following geophysical studies further constrained the areal extent of the heat source in the SSGF. In1976 (Meidav et al., 1976) a resistivity survey was conducted by Geonomic, Inc. around the Salton Sea. A zone of high conductance was identified primarily on the known field and ranging along the SE axis of the valley (Araya, 2023). Recently, new marine magnetotelluric technology was applied to provide an integrated approach and discover potential geothermal reservoirs extending beneath the Salton Sea. This 2009 MT survey demonstrated the first combined full field coverage onshore/offshore magnetotelluric survey (Nichols, 2009).

The 2009 Schlumberger onshore/offshore magnetotellurics project provided additional insights for the SSGF (Kaspereit,2016). Four survey profile lines were integrated and interpreted revealing an offshore boundary of the field that is delineated vertically by a deep resistive basement and a thick package of less resistive sediments. These findings are consistent with the assumption that an intrusive basement body would be more resistive than basin sediments. Generally, this boundary aligns with the SSGF extension model, however, towards the northwest there is a slight divergence between the resistivity anomaly and heat anomaly boundary (Kaspereit, 2016).

3.2 Permeability structure

The Salton Trough is situated in a continental rift zone comprised of a series of dextral faults that link the East Pacific Rise to the San Andreas fault system. Recently acquired 2-D seismic at HRPI in 2023 has enabled the identification of fault interactions explaining the vertical permeability and its structural setting on the eastern edge of the reservoir. The seismic interpretation presented here suggests deformation in the reservoir underlying HRP1 consists of a system of almost N-S striking normal faults that steps to the northeast with decreasing displacement. Likely, these faults are not purely dip-slip, and accommodate some kind of oblique motion given the tectonic setting. However, the 2-D seismic does not provide any clear evidence to quantify the oblique or strike-slip, component.

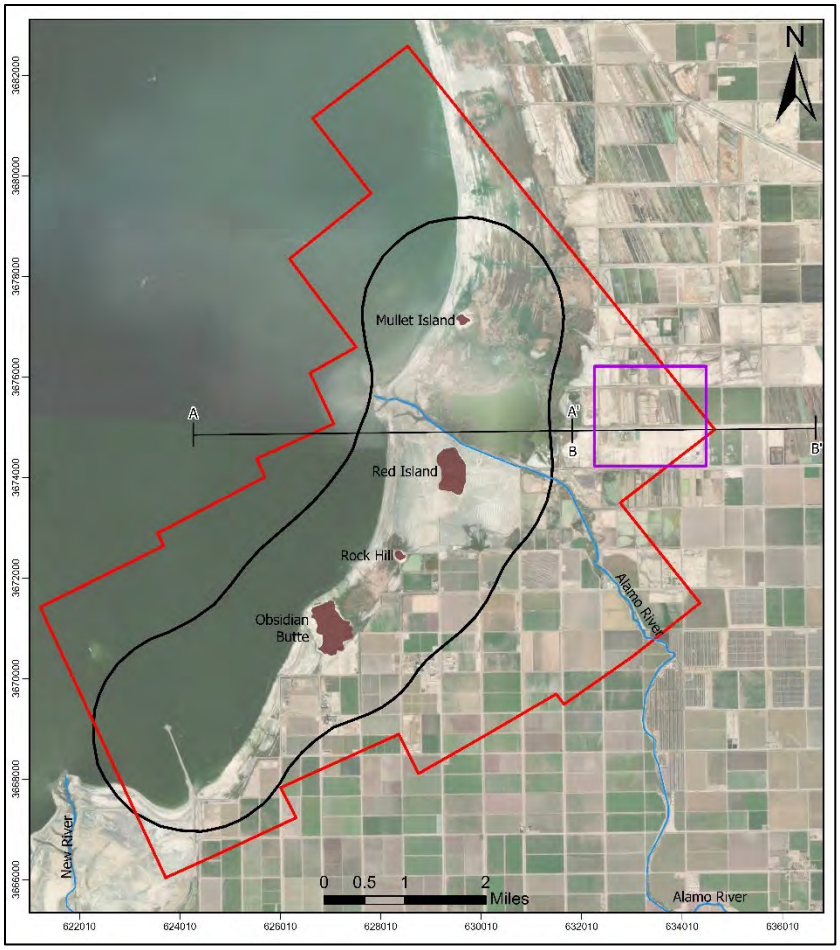

Figure 3: Borehole-controlled reservoir boundaries outlined in red from Kaspereit (2016), with the assumed heat source shape in black, and the Hudson Ranch Wellfield area highlighted in magenta, and conceptual cross section location

The seismic interpretation presented here is an extract from a survey over the HRP1 unit area. Eleven 2D profiles were collected, 6 in the east-west direction and 5 in the north-south direction. The line presented here runs east west, and was acquired along McDonald Road. Six interpreted horizons are presented in our 2D profile (Figure 4). The top white colored horizon marks the based of the youngest, conformable package of reflections which exhibit minor to no evidence of brittle deformation. The next deeper, blue shaded horizon, marks the based of a group of reflections exhibiting regional dip and potential stratigraphic growth or minor extensional folding, suggesting their deposition occurred in the latest stages of deformation along the underlying structures. The next deeper, yellow shaded horizons, marks and important high amplitude reflection that can be regionally correlated, and demonstrates distinct offsets. This horizon marks the top horizon to clearly experience brittle deformation, and is the high confidence seed point for fault tips in our interpretation. The next deeper, orange shaded horizon, was interpreted locally on this line to illustrate growth stratigraphy between it and the deeper green horizon, reflecting a period of significant extensional activity and sedimentary deposition. The green horizon regionally reflects the base of quasi conformable, rotated, high amplitude low frequency reflectors not clearly shown on this line. The package between the orange and green horizon appears to be a depositional package developed before major slip along this fault, that has been rotated down to the east and

south. The final horizon illustrated here is a black dashed line, which marks the last clearly traceable high amplitude reflection in the profile. The fault geometry interpreted here are inferred primarily from offsets visible in the yellow, orange, and green horizons, projected to depth.

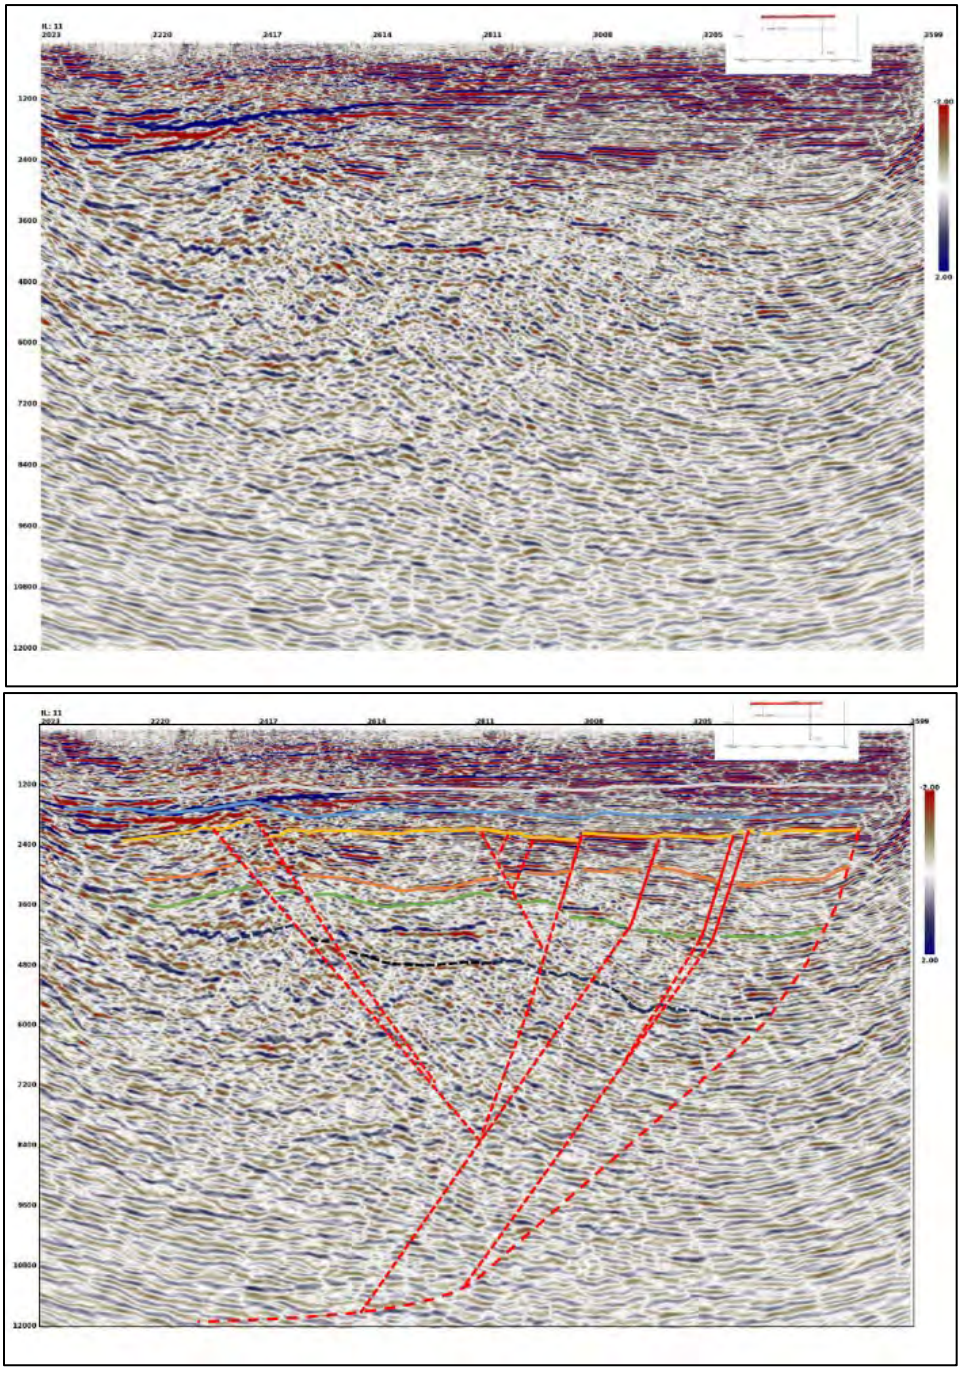

Figure 4: 2-D uninterpreted and interpreted depth migrated seismic survey line taken in the HRP1 wellfield Line orientation shown in inset map at upper right.

Two sources of permeability are probable and may exist either discreetly or simultaneously in the HRP1 reservoir area: a) stratigraphic reservoir permeability that is either primary in shallow units or secondary in deeper units that have undergone metamorphosis and are permeated by brittle

fractures, and b) fault-controlled permeability that allows to a certain degree, some connection between the hot, hypersaline reservoir, and the shallow, low salinity and groundwater reservoir. Shallow drilling losses and some recognized flow zones from temperature and spinner surveys support the presence of permeability in shallow units in HRP1 well 13-1. While core samples and deep production from other wells in the area suggest production from densely fractured meta-sediments, HRP1's wellfield suggest a complex stratigraphic architecture that may challenge the notion of a continuous homogeneous reservoir at depth (Figure 8) but still provides abundant stratigraphic and natural fracture targets in hydrologic communication.

Without image logs, it is difficult to determine the exact differentiation between stratigraphic and structural permeability. Generally, geophysical logs can be used to differentiate between sands and shales in the unaltered portion of the stratigraphy, or above the reservoir at depths greater than -4,000 ft ASL. At greater depths correlations become difficult using geophysical logs as hydrothermal alteration and metamorphism changes the geophysical responses. Additionally, major units are not laterally continuous as is consistent with dynamic fluvial-deltaic environments. Nevertheless, well inflow analysis suggests a mixed permeability contribution. Permeability estimates from the wells analyzed in the HRP1 project indicate values as high as 6,000 mD associated with discreet flow zones. The high permeability value and the narrow distribution of the flowing formation (<100 ft) is consistent with fracture permeability (Bear, 1972). Lower permeability wells were also tested, with permeability values estimated at 20 mD. By using the interpreted geology from the mud logs and the feed zone location, this lower permeability can be attributed to well-sorted sands (Bear, 1972).

3.3 Temperature model

The Salton Sea KGRA is classified as a high-enthalpy, high-salinity geothermal system in an extensional magmatic setting. The well temperature dataset used to interpret the temperature distribution in this study is presented in Figure 5 and was selected due to the vicinity to the HRP1 project. Temperatures for production zones range from 550 °F to nearly 650 °F. The majority of active wells exhibit a similar behavior, with conductive-convective profile boundaries occurring at depths of -3,200 to -4,700 ft ASL (Figure 5).

The temperature anomaly deepens to the northeast, southeast, and east. Wells on these eastern margins display conductive temperature profiles at depths from -5,000 to -9,000 ft ASL. In contrast, wells located to the west and southwest show a conductive-convective boundary as shallow as -3,000 ft ASL, with deep temperatures exceeding 600°F (Figure 5 and Figure 6). The northern edge of the temperature anomaly is poorly constrained, so an extension of the temperature anomaly towards the north is not ruled out. The temperature to the southwest is not well constrained either beyond the geophysical surveys, and no well data was available. The isotherms derived in this study from available well data exhibit a broad, flat shape that appears to terminate in the southeast, indicating a possible reservoir boundary. The isotherms extend towards the west, with a slight increase in shallow temperatures near the *'Old Mud Pots'* as shown in Figure 6.

The isotherm shape is similar to that described by Kaspereit (2016). Temperature mapping at -5,000 ASL and -7,000 ft ASL (Figure 6), shows decreasing temperature from the bottom to the top and from the center to the side of the SSGF corresponding to recent intrusive magma and heat source locations. The lateral extension and termination of the isotherms suggest a flow geometry characterized by a combination of primary high-permeability upflow near the heat source and deep

in the reservoir, with an outflow towards the shallow, matrix-permeable sediments allowing for lateral temperature extension of the system (Wallis, 2017). This interpretation supports Kaspereit's identified compartment in the HRP1 wellfield. The eastern side of the SSGF is cooler than the central thermal anomaly, providing hydrologic support such as a constant pressure boundary at a constant fluid density of ±1.0 g/cm³, meeting a condition for double-diffusive convection, later discussed in this paper.

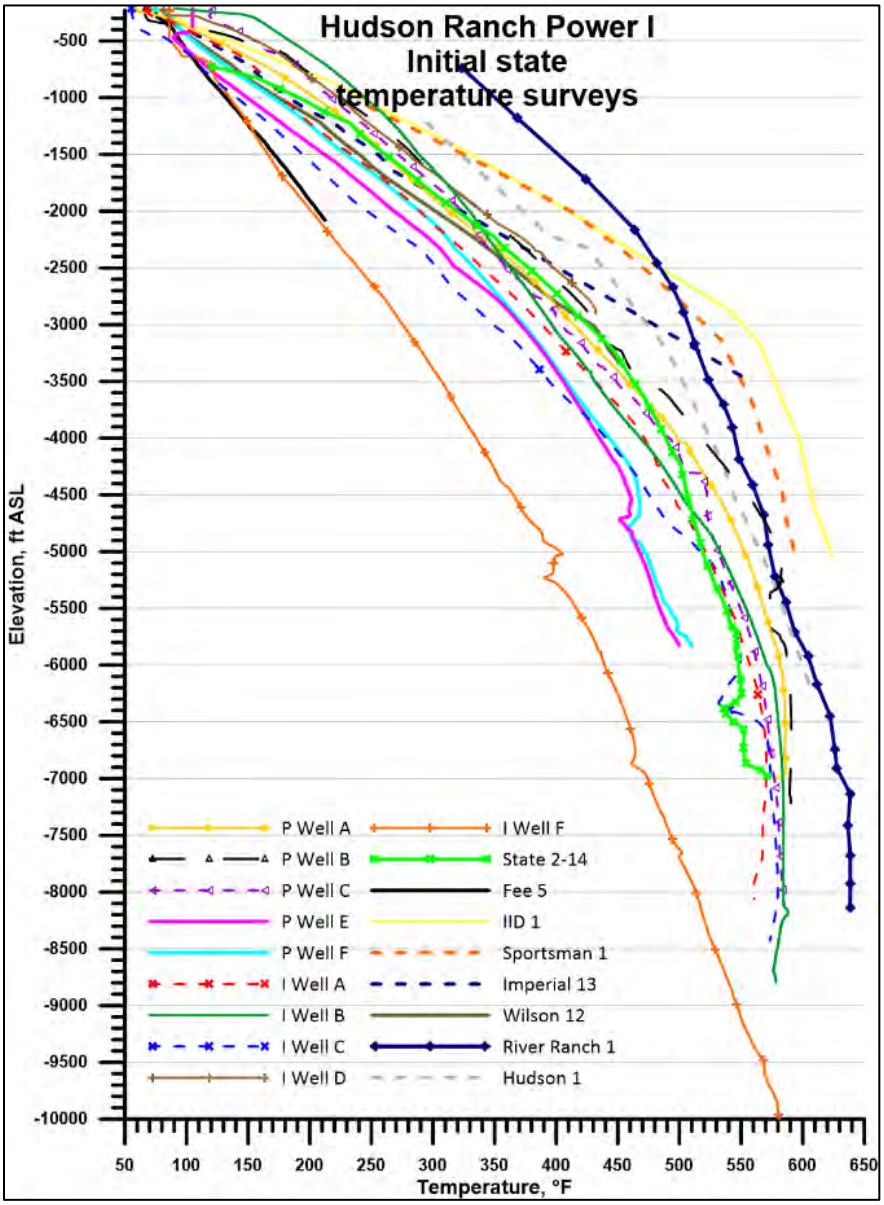

Figure 5: Temperature surveys of some of the wells used in this study. Profiles vary depending on the proximity to the main upflow and/or main heat source. The temperature data used in this study is a combination of legacy surveys conducted before 1990 and more recent surveys conducted after 1990. Most of the surveys in this study were tracked and corrected to better represent the initial state of the reservoir. However, some of the temperature points used in this analysis lacked information on the timing of the surveys, introducing a margin of error in the estimated initial temperatures at depth.

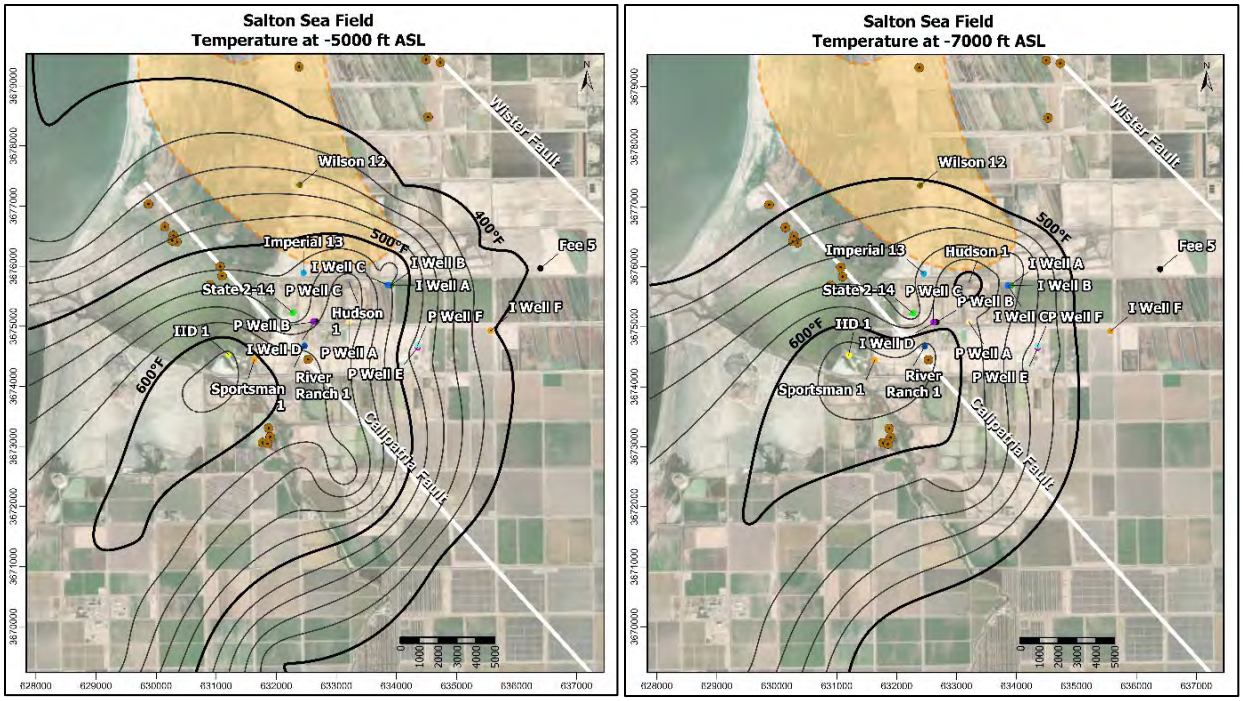

Figure 6: **SSGF temperatures at -5,000 ft and -7,000 ft ASL from thirty-three temperature surveys. Contours are constrained by available data and modified from Faulder (2022). The Imperial carbon dioxide field extent is outlined in orange, production zone from less than 1,000ASL, modified from Hulen and Kaspereit (2002). '*Old Mud Pots*' denoted with brown bullseyes. Calipatria fault originally evidenced by infrared detection (Babcock, 1971) and mud pot fields. Wister fault interpretation by Lynch and Hudnut (2008). Reservoir characterization**

3.4 Recharge pathways

A shallow aquifer system and a deeper hypersaline confined body make up the two aquifers systems for the Imperial Valley (Araya, 2023). The shallow aquifer is relatively stable and recharges primarily from the infiltration of the Colorado, New, and Alamo Rivers, as well as from irrigation seepage and canal leakage. A marginal degree of meteoric discharge is expected given the arid climate. It is theorized that the deeper (<-4,000 ft ASL) aquifer originates from ancient seawater that became isolated when the Colorado River Delta formed (Tompson, et al., 2008). This seawater then began to percolate into the subsurface, forming the deep hypersaline system. The two aquifer systems are generally separated by a lower permeability shale formation (Araya, 2023) and/or due to density differentials between the low and high saline reservoirs interaction that evolve into a stable interface (Oldenburg and Pruess, 2000).

In the HRP1 wellfield, permeable extensional structures (fractures and faults) correlate with the identified upflow, connecting the deep hypersaline reservoir with the known productive zones. The significant downward deflection of isotherms near the footwall of the imaged structure at HRP1 (Figure 6 and Figure 8) suggest the master fault of this structure may be a permeability barrier, with geologic units on its east side being dominated hydrologically by cold downflows from recharge of the shallow hydrology, or simply marginal permeability preventing the incursion of hot geothermal brine. Similar behavior may be achieved within the different compartments of the Salton Sea, where the temperature upflow is closely associated with the rhyolite domes and deep intrusion. The flanks of the reservoir recharge, providing a constant pressure boundary.

Well testing, PTS surveys, and production data. including salinity contribution estimates from production data (Siddique et al., 2024) were used for reservoir characterization of the HRP1 wellfield. The data suggests permeable zones as shallow as -3,200 ft ASL and as deep as -7,700 ft ASL. The average productivity and injectivity indices are 13 and 15 kph/psi, respectively, indicating very permeable wells. There is a significant spread in the estimated indices, ranging from as high as 37 kph/psi to as low as 2 kph/psi, an order of magnitude. This variation in addition to the permeability distribution described earlier suggests that the nature of the permeable productive zones can vary significantly from well to well. This can be explained by the presence of zones with fractured as well and some with matrix permeability.

The top of the high-salinity, high-temperature reservoir can be identified around -4,000 ft ASL, where the temperature profiles switch from conductive to convective. This change also corresponds with the first appearance of epidote in mudlogs. The nature of this boundary is not fully understood, but it can be explained by the double-diffusive effect (discussed later in this paper), where increased density contrast at the top of the plume—resulting from the advance of the brine front—impedes the upward movement of fluid, forming an effective barrier for the thermal and brine plumes (Oldenburg et al., 2000).

Estimating the reservoir bottom is challenging, as many of the wells had convective profiles close to their total depth, suggesting productive zones can also be found at deeper intervals. Well State 2-14 encountered major loss zones at depths as great as -10,000 ft ASL (Paillet, 1986). The only non-productive wells studied (P Well E and P Well F), which were drilled deeper than -9,000 ft ASL, displayed very conductive profiles and over-pressured zones on the last few hundred feet, indicating the possible limit of productive, commercial zones. For this study, the high enthalpy, high salinity commercial reservoir is bounded between -4,000 and -9,000 ft ASL.

Evidence from geochemical sampling and production salinity from Mass Energy Balance (MEB) estimates (Siddique et al, 2024) suggests that production salinity varies from 20-32% with depth in the hypersaline reservoir. The salinity content in each productive zone increases from the shallow to the deep parts of the reservoir and from the core proximal to the heat source toward the flanks where temperature decreases.

3.5 Imperial CO2 field and mud pots as outflow zones

Carbon dioxide was commercially produced in the Imperial Carbon Dioxide Gas Field from 1934 to 1954 (Muffler and White, 1969). Though this CO_2 field has since been abandoned, greater than 54 wells exploited gas reservoirs at depths of -500 to -700 ft ASL and static pressures up to 178psi (Muffler and White, 1968). The legacy Imperial CO_2 field is located north of the current HRP1 geothermal field as shown in Figure 6.

Elevated carbon dioxide levels are likely attributed to volcanic activity and metamorphic reactions at depth. Rook and Williams (1943) conclude that carbon dioxide gas is closely related to volcanic activity. Shallow faulting offers a means of gas migration. Muffler and White (1968) conclude that two hydrothermal metamorphic reactions also affect sediments at depth, destroying original carbonates and liberating additional CO_2. The hydrothermal processes frequently coincide with hydrothermal epidote as the carbonate replacement phases include epidote and other calc-silicate minerals (Norton and Hulen, 2006).Carbon dioxide is released through carbonate dissolution by the hot acid brine at depth and the alteration of calcareous siliciclastic rocks (Norton and Hulen

2006). These processes charged the shallow sandstone/alluvial reservoirs that were exploited in the Imperial carbon dioxide field.

The CO2 field and mudpots are indicative of the natural, low-pressure point where hydrothermal fluid can naturally flow out from the deep hypersaline reservoir. By incorporating the proposed temperature model, surface expressions in the area, seismic data, and the known higher CO_2 content in the legacy Imperial CO_2 field, this zone can be interpreted as a leakage pathway from the deep, hot hypersaline reservoir into the shallow hydrological system, with the fluid migrating northward in response to shallow hydrological forces.

3.6 Salinity distribution

Siddique et al. (2024) proposed a salinity model for the SSGF using data from production wells in the HRP1 project, where a clear thermochemical boundary can be found at -4,000 ft ASL. This model suggests a salinity gradient of 5% per 1,000 ft of total dissolved solids (TDS) in the reservoir brine for the first -4,000 ft ASL in the conductive, low-salinity reservoir. In the convective, highly saline reservoir from -4,000 ft to -8,500 ft ASL, the gradient is reduced to nearly 2.5% per 1,000 ft of TDS in the brine. While the exact salinity of a feedzone can be influenced by a highly permeable zone, the overall behavior of the system is expected to stabilize as a salinity-stratified reservoir, consistent with Fournier (1990).

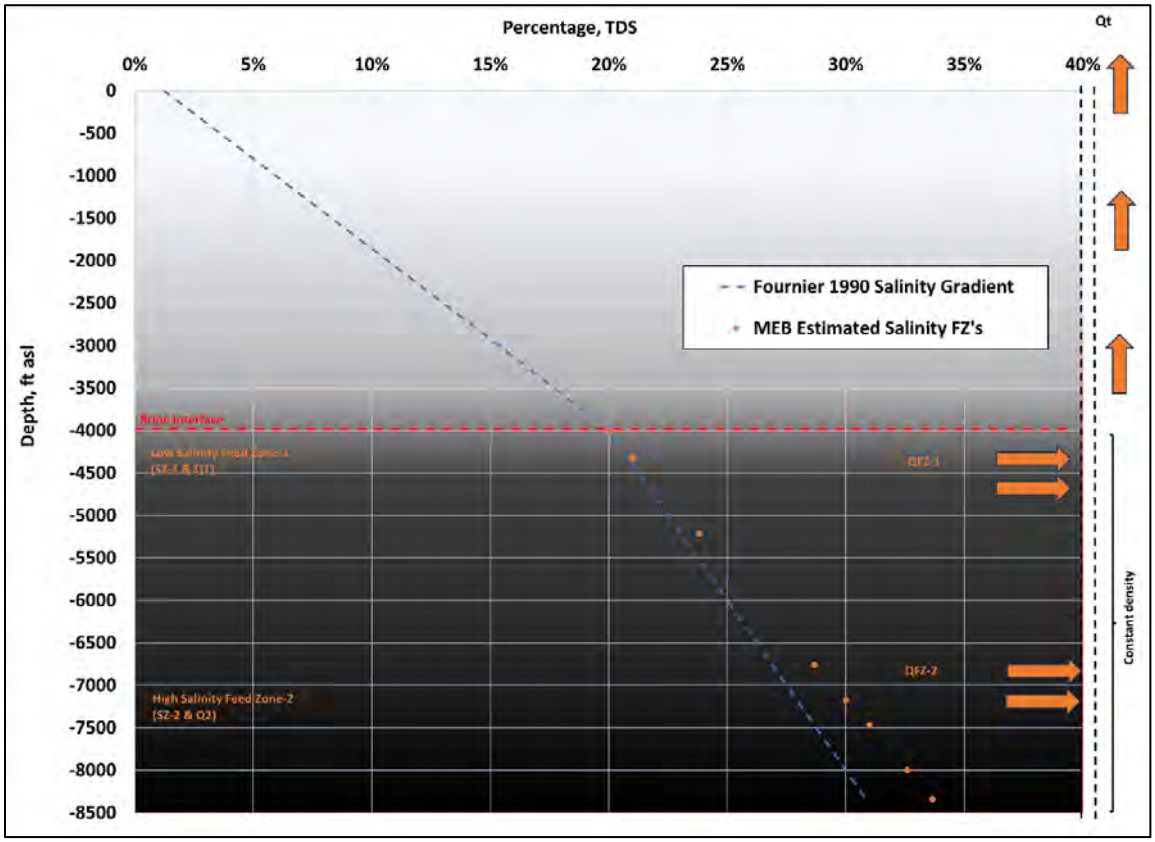

Figure 7: Salinity gradient plot for Salton Sea based on literature and double-diffusive convection model. Feed Zones (FZ) salinity estimated using MEB in orange, compared to Fournier's (1990) salinity gradient in blue. Differences between datasets can be attributed to the distance from the FZ data and the proposed heat source for the SSGF. Modified from Siddique et al. (2024).

The salinity distribution in the SSGF has been theorized and numerically studied using a Double-Diffusive Convective System (DDCS) by Fournier et al. (1990) and Oldenburg et al. (1995 and 2000). Understanding the nature of this salinity distribution is essential for the future development of the SSGF, not only for brine mining but also to effectively prevent scaling in production wells. This is crucial because the SSGF brine tends to precipitate scale based on its composition (Rocha et al., 2023), with significant economic and developmental implications, particularly the potential extraction of metals such as lithium from the brine. Consequently, a separate section is dedicated to describing the DDCS and its application in the proposed conceptual model.

4. Nature of a Double-Diffusive Convective System (DDCS)

Fournier (1990) proposed the possibility of the Salton Sea reservoir behaving as a Double-Diffusive Convective System (DDCS). This concept requires two conditions: the fluid must contain multiple components with different molecular diffusivities, and these components must have offsetting contributions to the fluid density. This leads to a low-salinity and high-salinity brine interface with a density contrast between brines.

Fournier (1990) describes this process as an initially gravity-stable system with heating from below and the sides. Cooler dilute brine lies above hotter, more concentrated brine, both undergoing convection. As the basal heat flow warms the underlying brine, it rises buoyantly into the overlying dilute brine, forming an intermediate layer of gravitationally stable brine with intermediate salinity and temperature. This process continues through the advecting column. The higher density at the top of the plume, caused by the faster movement of the brine front, hinders the upward flow of fluid and creates an effective barrier for the thermal and brine plumes (Oldenburg et al., 1995). Additionally, the medium's porosity and permeability directly affect the transport of mass and heat. Lower velocity systems will produce smaller convective velocities, thereby slowing the flow in a given layer. This process continues through the vertical column, achieving a quasi-steady state temperature, salinity profile, and fluid density (Siddique et al., 2024).

The Salton Sea reservoir high-salinity fluid approaches saturation as temperature increases with depth. This behavior aligns with the double-diffusive convection model, as described by Fournier (1990) and Oldenburg (2000), who identified three key characteristics of the reservoir after performing numerical model simulations of the DDCS:

1. Temperature and salinity decrease from the bottom to the top and from the center to the side of the anomaly.
2. A very high basal heat flow in the center of the thermal anomaly, sometimes exceeding 1000 mW/m^2, enabling significant convective heat flow in a chemically stratified reservoir.
3. A relatively uniform vertical fluid density throughout the hypersaline reservoir under all pressure, temperature, and salinity conditions.
4. A brine interface with a density contrast differentiates the cool, shallow, low salinity reservoir from the hot, deep hypersaline reservoir.

Despite increasing temperature with depth, the fluid density remains constant at approximately 1.0 g/cm^3, a phenomenon first noted by Helgeson (1968). Measurements in the State 2-14 well found the fluid density to be 1.017 ± 0.0023 g/cm^3 with a median of 0.999 g/cm^3. A review of Salton Sea wells by Williams and McKibben (1989) showed that the hypersaline portion of the reservoir, with fluid salinity greater than 20 wt%, had ranging from 0.98 to 1.0 g/cm^3. This requires fluid salinity

to increase with temperature, resulting in a linear increase in salinity with depth, meeting the conceptual requirements of a double-diffusive convective densities system.

Numerical exploration and validation were performed by Oldenburg et al. (1995) supporting this concept by establishing gravity equilibrium in a liquid column with 400°F at the top and 540°F at the bottom, where the heat source was placed, with a constant pressure boundary on the right side of the model. The reservoir parameters were chosen to represent the Salton Sea reservoir. The model equilibrated to a pseudo-steady-state condition over 30 ky, replicating a typical temperature distribution and a uniform brine density of 0.91 to 0.940 g/cm^3, slightly lower than measured. This model exhibits large salinity and temperature gradients in the top -4,700 ft ASL, speculated to result from top no-flow and constant temperature (400°F) boundary conditions, causing vertical convective flow to divert horizontally near the top to the right and the constant pressure boundary, thus forming a convection cell.

5. Proposed Conceptual Hydrothermal Model (CHM)

The model described in this work represents elements similar to those discussed in the literature review, with a particular emphasis on the southeastern section of the SSGF, where the Hudson Ranch Power I project is located. The main differences introduced include the permeability distribution (matrix and fractured permeabilities) in the hypersaline reservoir, a transitional zone, a refined structural framework based on seismic interpretation, the salinity distribution in the system related to the DDCS with a brine interface, and thermal outflow into the shallow reservoir with known surface expressions.

This work conceptualizes the southeastern section of the Salton Sea field, where the Hudson Ranch Power I project is situated, believed to be one of the reservoir's flanks. Lateral temperature extent is lost to the southeast section of the reservoir, while salinity increases due to the stratification described in the DDCS. Non-commercial wells were drilled there in 2013 (Kaspereit, 2016) just outside the commercial reservoir. This conceptual description offers an opportunity to understand the system's behavior on what could be one of the reservoir's flanks.

The following section outlines the main elements of the CHM presented in this work (Figure 8) using a framework for CHM elements described by Faulder (1991).

5.1 Heat Source

The primary heat source for the Salton Sea Geothermal Field in our model is the "still-cooling granitic pluton" located at southern margin of the Salton Sea, as described and invoked in previous works (Hulen, 2002 and Kaspereit et. al, 2016). We adopt the size and locations estimates of previous authors for this body: 2 km in diameter at -3.6 km above sea level providing an estimated heat flux of ~450 mW/m^2.

5.2 Permeable pathways

The permeable pathways in this model are similar to those described by Hulen et. al (2003). High vertical permeability is attributed to fractures, breccias, and veinlets that facilitate the vertical flow of both cooler (recharge) fluid and hot, high-salinity brine heated by the intrusion. These main vertical pathways connect the heat source to the shallow sediments in the basin. The seismic interpretation presented in this paper depicts these high permeable pathways for both, hot and

hypersaline brine, and cool, groundwater hydrology over the HRP1 wellfield. Most of the connection between the two brine systems is conceptualized as flowing from the hot, highly saline reservoir to the cooler, low-salinity reservoir. Although some migration of shallow groundwater into the geothermal system is not ruled out, the stable interface observed on the DDCS suggests only minor percolation of groundwater into the hot, high-salinity reservoir. Nonetheless, groundwater over the sink likely plays a major role for pressure support for the system.

Secondary horizontal permeability is presented by sedimentary and porous (potentially metamorphosed) sandstone layers where calcite is hydrothermally dissolved, creating fluid pathways that explain the lateral extent of the temperature profiles in the Hudson Ranch wellfield. These secondary layers may be difficult to consistently target at depth due to lateral stratigraphic variability, but the permeable heterogeneity of the system can be correlated with sedimentary changes from identified lacustrine and fluvial deposition in the Salton Sink and is expressed in the shallower seismic sections. These productive zones in the Hudson Ranch wells can be identified between -3,400 ft ASL and -7,700 ft ASL, below the low salinity reservoir (brine interface), and is described as the shallow section of the transitional zone, where the rock undergoes metamorphosis and calcite is dissolved from the matrix. Deeper permeability in the transitional zone may be due to brittle fracturing of metamorphosed sedimentary rocks and/or faults and fault associated fractures where present. The combination of these permeable pathways allows for the lateral transport of hot brine away from the intrusion, resulting in the eastern temperature anomaly one mile east of the primary heat source. Inspection of Figure 5 at -5,000 ft ASL shows indications of shallower eastward lateral flow with temperature anomalies to the north and south that may also represent vertical upwelling.

5.3 Thermal recharge

Thermal recharge of the system is facilitated horizontally by the connection between different “compartments” of the reservoir, as described by Kaspereit (2016). Vertical connection between surface water, groundwater and hypersaline water is facilitated by known permeable fractures along the mentioned compartments. Main faults near the heat source facilitate thermal recharge, while faults further away allow cold regional hydrology to recharge the system. Permeable structures west of the primary fault interpreted in the HRP1 seismic appear to be associated with an upflow, linking the deep hypersaline reservoir with the known productive zones and mud-pots at surface. East of the major fault interpreted at HRP1, temperatures quickly fall off, suggesting the fault, which has the highest relative displacement in the area, may be impermeable due to clays or other fine materials generated along the fault during deformation. The porosity east of this boundary, if it exists, is either isolated from the convective system by this permeability barrier and or in stronger communication with the shallow, cooler ground water.

The recharge flow of the system is inferred to be derived from waters following the shallow hydrologic gradient of the basin, reflected by the New and Alamo Rivers, which flow from the Mexicali Valley, towards the Salton Sea. Lateral permeability in the transitional or brine interface layer allows interaction between cold and hot fluids, forming a convective cell. Shallow waters may flow laterally towards the center of the field where they descend, are heated, and are transported laterally and vertically in a convective cell (Figure 8).

5.4 Characterized reservoir

Defining the extent of the reservoir using geophysical data has been challenging because most of the available seismic data is not public. This paper uses Kaspereit's (2016) description, which states that the commercial Salton Sea reservoir is bounded by the NNW Calipatria fault (Figure 6) on the northeast and extends southwest to an unnamed fault parallel to the Calipatria fault along the New River mouth. Perpendicular faults define the southern and northern limits, with rhyolite domes assumed to be compartment centers (see Figure 3).

Commercial reservoir top depths vary around -4,000 ft ASL, where the high and low salinity interface is believed to be located. The reservoir bottom cannot be clearly identified, as there is evidence of producible fluid at greater depths (Paillet, 1986). However, current commercial wells do not exceed -9,000 ft ASL, where over-pressured zones have been found to the southeast. This is the reservoir bottom depth used for this conceptual model.

The salinity of the reservoir varies depending on its proximity to the main heat source and with depth. According to the double-diffusive convection system (DDCS) concept, salinity decreases from the bottom to the top and from the sides to the center of the anomaly. Empirically, the salinity of the system increases gradually at a rate of 2.5% per 1,000 ft over the characterized reservoir from -3,800 ft to -9,000 ft ASL, with slight increases with horizontal distance from the temperature anomaly.

5.5 Outflow into surrounding hydrology

Previous conceptual models describe the deep, highly saline reservoir but often neglect its interaction with the basin's shallow hydrology. Evidence of CO_2 presence is found at both shallow (less than -4,000 ft ASL) and deep (greater than -4,000 ft ASL) levels, evidenced from the HRP1 production brine chemistry. The legacy Imperial CO_2 field indicates the migration direction of CO_2 from the deeper to shallow hydrology, north of the Hudson Ranch Power I (HRP1) wellfield. Surface steam expressions, known as *'Old Mud Pots'*, near the HRP1 project and the legacy Imperial CO_2 field are interpreted to represent the system's outflow, extending north and possibly to the eastern edge of the Salton Sea shoreline. Connectivity of the deep system to the shallow is inferred along the east dipping faults imaged near HRP1, where projections of the fault traces to the surface intersect the mud puts (Figure 8).

6. Conclusions

The proposed conceptual hydrothermal model for the southeastern part of the Salton Sea Geothermal Field, particularly the Hudson Ranch Power I project area, emphasizes the heterogeneous nature of both vertical and horizontal permeability within the hypersaline reservoir. The model provides crucial insights into fluid flow and heat transfer dynamics by distinguishing between matrix and fractured permeabilities. These permeable features described using geoscience data, downhole logs, drilling data, and production history from the HRP1 wells, explains the temperature anomaly on the reservoir's edge and suggests a horizontal extension of the system, even one mile east of the described heat source.

Main permeable structures also highlight the interaction between groundwater recharge and the reservoir's edge, essential for maintaining the reservoir's thermal balance and influencing the overall dynamics of the geothermal system. Additionally, the model describes the potential

outflow of geothermal fluids into the shallow system, explaining the location of the legacy Imperial CO_2 Field and the surface expression of the ‘Old Mud Pots’.

The model addresses salinity distribution within the reservoir as being closely related to the double-diffusive convection system (DDCS). The salinity stratification affects the behavior of the brine and its interaction with surrounding geological formations, with a distinct brine interface between the shallow and deep reservoirs. Understanding brine composition and its distribution is vital for future geothermal development, not only to predict scale precipitation behavior in the wells but also to assess the potential for lithium extraction from the geothermal brine. This aspect underscores the economic viability of geothermal energy projects in the region and its potential for future development.

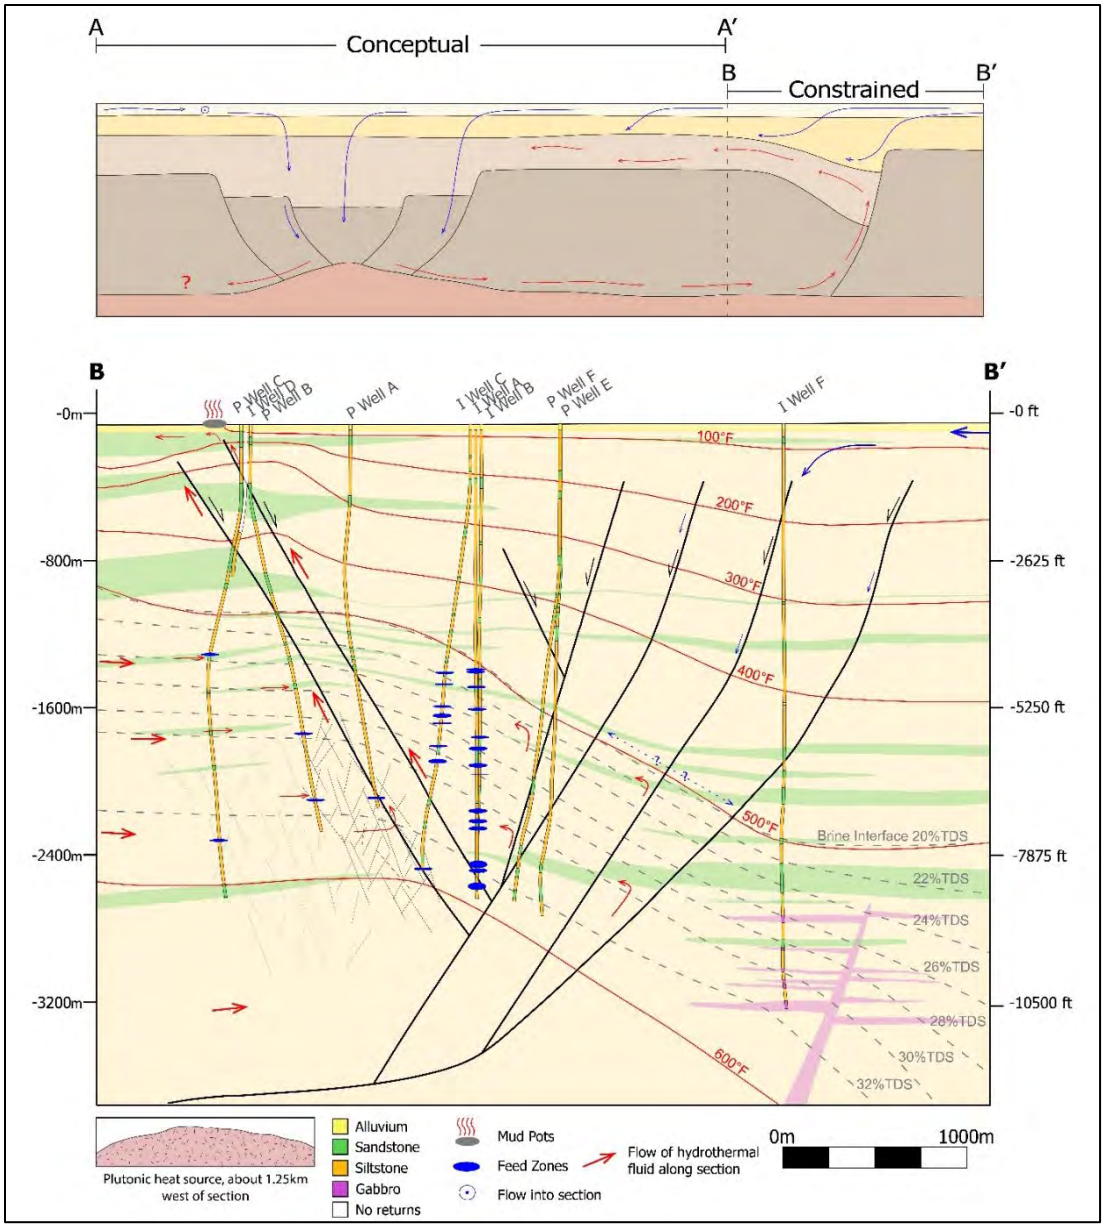

Figure 8: Preliminary conceptual model for the Hudson Ranch Wellfield and location within the Salton Sea Geothermal Field. The following well traces are projected onto the section: I Wells A-C (~2,300 ft due north), and P Wells F and E (~1,300 ft due south). Not depicted, Calipatria fault to the west and Weister fault to the east bounding the HR wellfield. Hot geothermal brine flows from the west into the section, flowing through permeable stratigraphic features, upwelling through faults and fracture dominated damage zones, charging shallow stratigraphic reservoirs in the subsurface. Numerous mud pot surface expressions may indicate outflow of the system. Recharge of the system follows the hydrologic gradient of the basin and flows towards the Salton Sea. Shallow waters descend, are heated, and are transported in a convective cell. The brine interface marks the boundary between the convecting system and the base of the shallow hydrologic system. Salinity contours depict the variation with depth and proximity to the heat source.

Thermoelectric generators, Field test, Geothermal power generation, Cost.

ABSTRACT

There have been many experimental studies on thermoelectric generators (TEG) for generating electricity using geothermal energy and waste heat from various industries in recent years. TEG power output has been measured at different flow rates of water, different temperatures, and other different conditions. However, there have been few large-scale field tests at geothermal wells and industry sited.

Considering these experimental measurements and field test results, some questions arise. Are there any relationships among the TEG power outputs measured in laboratory and pilot test sites at different temperatures? Can we predict the power output at the field tests (larger scale) using the experimental results with a single TEG module? Does TEG have any advantages in terms of cost compared to solar PV (photovoltaic) panels?

To answer the above questions, we have collected and analyzed the experimental and field test data of the TEG power output at different temperatures and temperature differential (TD). The power output data include those of single TEG module, TEG devices with 6, 10 and 20 layers (the highest number of layers reported) respectively. The 10- and 20-layer TEG devices were tested for power generation using the industrial waste heat from a gas power plant at a temperature of about 80 °C. The field test of the 6-layer TEG device was conducted at a geothermal field with higher temperatures up to 170 °C.

The data analysis demonstrates that the TEG power outputs measured in laboratory and pilot test sites at different temperatures are closely consistent. An equation coupling TEG power outputs and TD has been established. We may predict the power output for large-scale field applications using the experimental results with a single TEG chip at different TD. The cost of TEG is lower than solar PV (photovoltaic) panels when TD is greater than 90o C.

1. Introduction

In recent decades, thermoelectric generators (TEGs) have obtained considerable attention as a sustainable technology for generating electricity from low-grade heat sources. These include geothermal energy and industrial waste heat. As the global demand for renewable energy solutions intensifies, TEGs offer a promising avenue to convert thermal energy directly into electrical energy, using heat to produce power under temperature differentials (TD). This direct conversion process circumvents the need for complex mechanical systems, making TEGs an attractive option for various applications, from remote power generation to enhancing the efficiency of energy utilization during industrial processes.

The principle of thermoelectric generation is based on the Seebeck effect, where a temperature difference across a thermoelectric material induces a voltage, generating an electric current. TEGs have been utilized in various applications, including space missions, remote sensing, and waste heat recovery. The efficiency of TEGs is primarily determined by the material's figure of merit (ZT), which is a function of the Seebeck coefficient, electrical conductivity, and thermal conductivity. Recent advancements in materials science have led to the development of high-performance thermoelectric materials, enhancing the practical applicability of TEGs (Snyder & Toberer, 2008).

Numerous experimental studies have explored the performance of TEGs under different conditions. For instance, Rowe and Min (1998) investigated the effect of temperature gradients on the power output of TEG modules, finding a direct correlation between TD and generated power. Other studies, such as those by Snyder and Ursell (2003), have focused on optimizing the material properties and chip design to maximize efficiency. These laboratory experiments provide a foundational understanding of TEG behavior, but they often lack the complexity of real-world conditions.

Chen et al. (2017) focused on enhancing the efficiency of TEGs through mechanical and electrical structure optimization. Their study in Energies explored how modifications in the mechanical and electrical configurations of TEGs can improve overall performance. By optimizing these aspects, Chen et al. demonstrated enhanced efficiency in converting waste heat to electricity, contributing to advancements in TEG technology.

Li et al. (2020) conducted experimental studies on an expandable thermoelectric power generator, focusing on the power output under different conditions. Their work demonstrated the scalability of TEG systems and provided a foundation for further field tests. Additionally, Li et al. (2021a) provided a comprehensive cost estimation of TEG systems, comparing them to other renewable energy technologies.

Li et al. (2021b) conducted a significant field test of TEGs at the Bottle Rock geothermal power plant. Their study provided critical insights into the challenges and opportunities of deploying TEG

technology in real-world conditions, highlighting the potential for large-scale applications and the need for system optimization to achieve consistent performance.

Field tests of TEGs are less common, but they are crucial for assessing the technology's scalability and practical performance. A notable study by Champier et al. (2010) conducted field tests using TEGs to recover waste heat from biomass boilers, demonstrating the feasibility of TEGs for industrial applications.

Despite the potential of TEGs, much of the research to date has focused on laboratory-scale experiments, investigating the power output of TEG modules under controlled conditions. These studies have provided valuable insights into the performance characteristics of TEGs, examining variables such as temperature gradients, flow rates, and material properties. However, there remains a gap in understanding how these laboratory findings translate to real-world, large-scale applications. Field tests at geothermal wells and industrial sites are limited, leaving critical questions unanswered about the scalability and economic viability of TEG technology.

This research aims to bridge this gap by analyzing experimental and field test data to establish relationships between TEG power outputs measured in laboratory settings and those obtained from larger-scale pilot tests. Specifically, the study seeks to determine whether it is possible to predict the power output of large-scale TEG applications based on single-chip experimental results and to evaluate the cost-effectiveness of TEGs compared to solar photovoltaic (PV) panels under varying temperature conditions.

2. Power output data of TEG from the field tests and the experiments in laboratory

The field test of the 6-layer TEG device, as shown in Figure 1, was conducted at Bottle Rock geothermal field with a temperature of steam up to 170 °C (Li, et al., 2021).

Figure 1: The 6-layer TEG apparatus installed for field test at Bottle Rock geothermal field (Li, et al., 2021).

The total power of the six-layer TEG apparatus measured at Bottle Rock geothermal field is depicted in Figure 2. According the field test results, each layer had 24 TEG chips and each chip could generate a maximum power of around 3.9 W with a temperature difference of 152 °C between the cold and hot fluid manifolds.

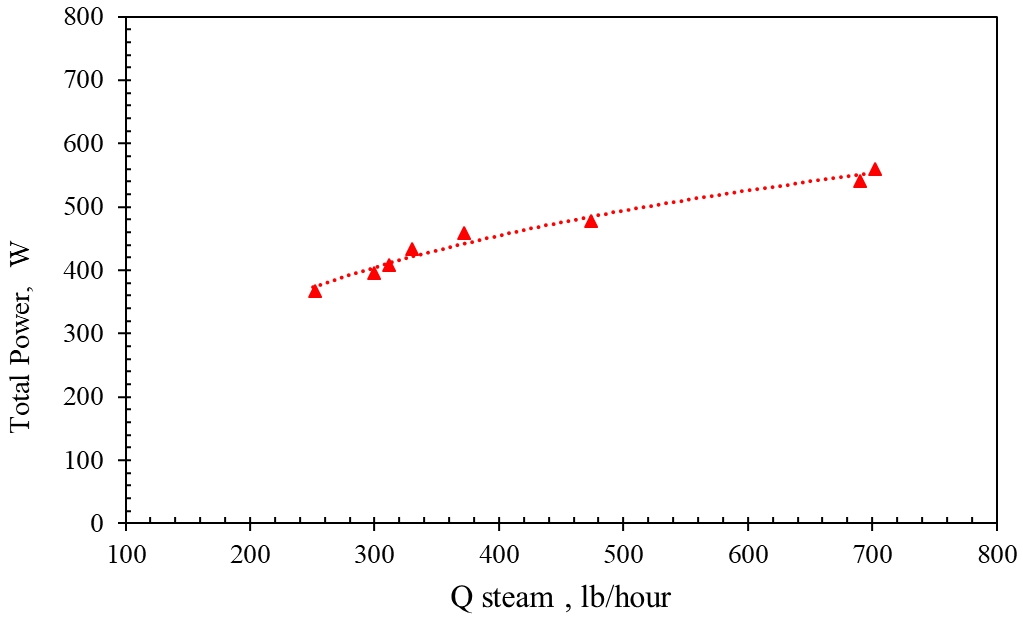

Figure 2: The total power estimated for the six-layer TEG apparatus in field tests at Bottle Rock geothermal field (Li, et al., 2021).

The 10- and 20-layer TEG devices were pilot tested for power generation using the industrial waste heat from a gas (coal bed methane) power plant at a temperature of about 80 °C.

The gas power plant is located at a coal mining area with abundant coal-bed methane resources in Shanxi Province, China. The gas power plant had three gas generators of 1.8 MW with a total installed capacity of 5.4 MW. The waste heat mainly exists in the exhaust gas emissions and the engine cooling closed-loop. The overview of the gas power plant is shown in Figure 3.

Figure 3: Photos of the gas power plant.

As shown in Figure 4, one of the TEG devices (20 layers) was installed nearby the windows. The hot flow channel of TEG was connected to the pipelines via two heat insulated tubes. The valves allowed to control the pressure and flow rate of hot water in the tubes. The cold flow channel was connected to a water tank. Another TEG (10 layers) was connected in the same way in the field tests. The 10-layer TEG contains 24 modules per layer and the 20-layer TEG contains 18 thermoelectric modules per layer.

Figure 4: One of the TEG devices (20 layers) installed for field tests.

The power output of the TEG device at different hot and cold flow rates are depicted in Figs. 5 and 6, respectively. Two times of the power output by the 10-layer TEG matches well with the power of the 20-layer TEG device. This observation implies that the power of the expanded 20-layer TEG device from the 10-layer TEG device was not decreased, which is very important at large-scale industry applications.

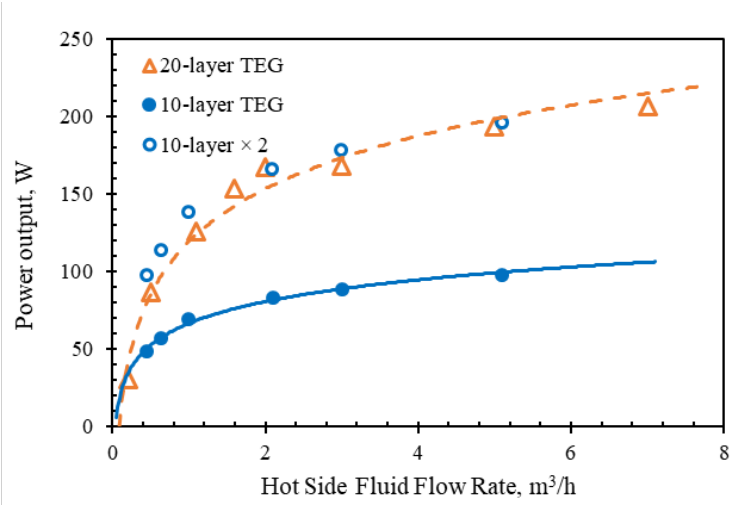

Figure 5: The total power output of the TEG devices at different flow rates on the hot side (water flow rate on the cold side was 3 m^3/h and the temperature difference was 60 °C (Zhu et al., 2024).

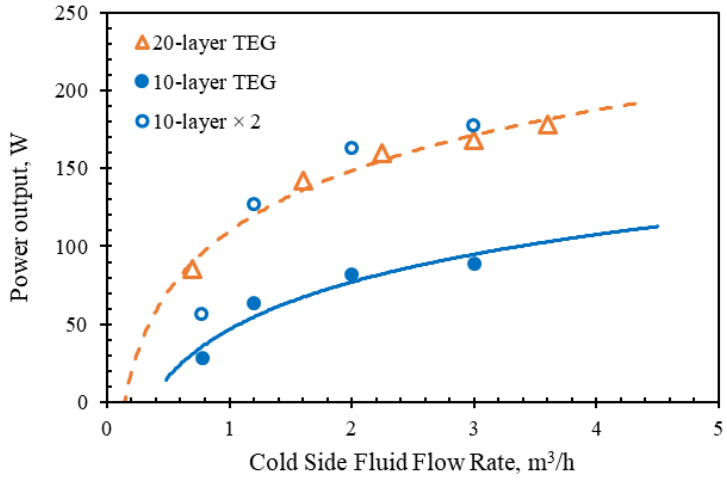

Figure 6: The total power output of the TEG devices at different flow rates on the cold side (water flow rate on the hot side was 3 m^3/h and the temperature difference was 60 °C（Zhu et al., 2024）.

The details of the TEG pilot tests at low temperatures could be found in the paper by Zhu et al., 2024.

Li et al. (2020) conducted the laboratory experiments using a 5-layer TEG apparatus to measure the power output and efficiency at different flow rates of water, different temperature, and different temperature differences between hot and cold sides. The five-layer TEG device could generate about 45.7 W electricity with a temperature difference of 72.2°C between the cold and hot sides. The power of each chip was about 0.51 W at this temperature difference (see Figure 7). Other experimental data could be found in the paper by Li, et al. (2020).

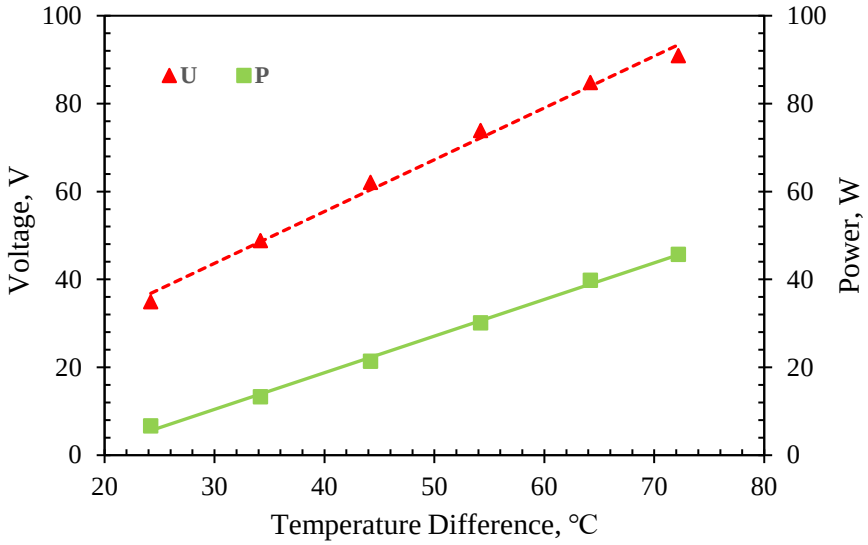

Figure 7: Voltage (U, dashed line) and power output (P, solid line) of the five-layer TEG apparatus at different temperature differences (water flow rates on the cold and hot sides were 654.55 and 1028.57 L/hour, respectively).

Zhu et al. (2023) measured the power output of a single TEG chip in the laboratory at temperatures lower than 100 ºC and the results are depicted in Figure 8. One can see that the power output of a single TEG chip increases with TD almost linearly.

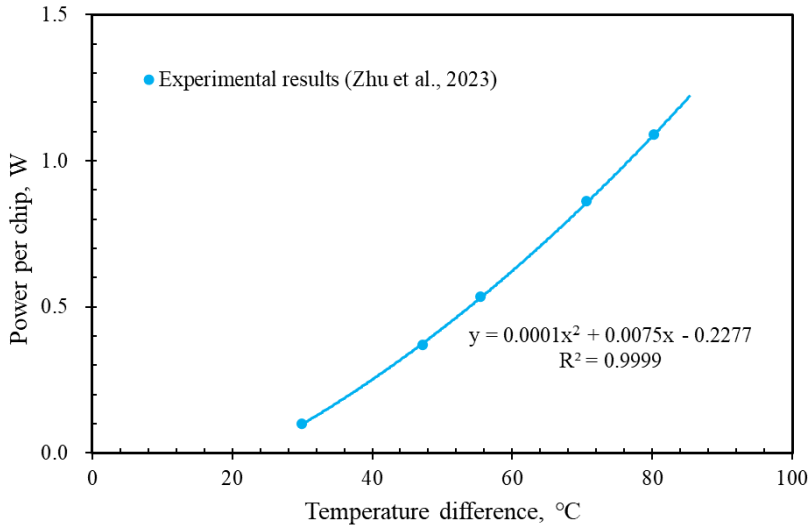

Figure 8: the power output of a single TEG chip in the laboratory vs. TD at temperatures lower than 100 ºC (Zhu et al., 2023).

Zhu et al. (2024) reported that the power output of TEG devices measured at the pilot field test sites increases with TD but not linearly. The reason is discussed in the next section.

3. Results and Discussions

It is useful to predict the power output of large-scale TEG applications based on single-chip experimental results. In order to check such a possibility, we collected all of our previous data of the power output at different TD and converted these data to the power output per TEG chip vs. TD. The results are shown in Figure 9. The red square symbol represents the power data from the geothermal field test reported by Li, et al. (2021). The red triangle symbols represent the power data from the field test reported by Zhu, et al. (2024). The blue circle symbols represent the power data from the lab test reported by Li, et al. (2020). The power output per TEG chip in the above data sets was derived from TEG devices with more than five layers. The green solid circle symbols represent the power data of a single TEG chip from the lab test reported by Zhu, et al. (2023). One can see that all of the data points sit well on a curve characteristic of an exponential function. The matching equation is listed in Figure 9. Note that the value of fitting goodness is over 0.99. This demonstrates that it is possible to predict the power output of large-scale TEG applications based on single-chip experimental results.

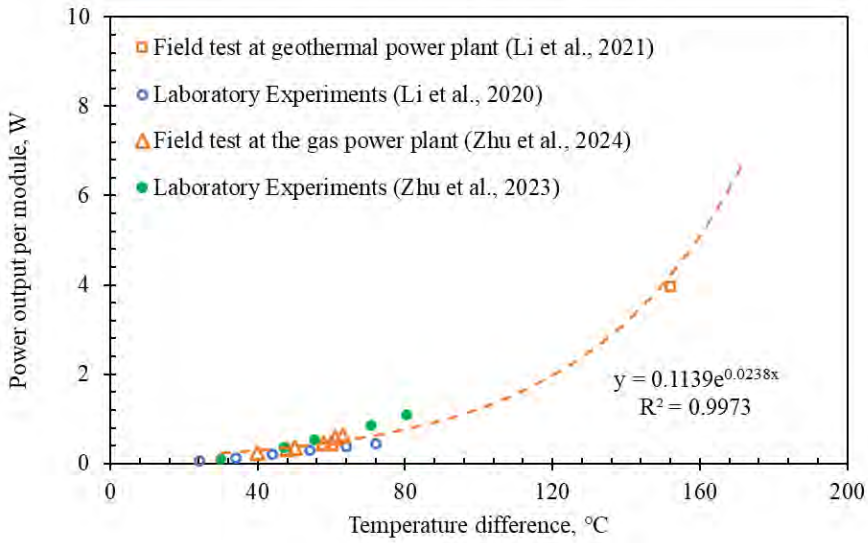

Figure 9: The power output per chip vs. temperature differences.

The power output data of the TEG device with both 10- and 20 layers at different hot and cold flow rates are depicted in Figure. 10. The power output increases with the flow rates on both hot and cold sides and follows the same trend, that is, an exponential function. Note that the power output of the 10-layer TEG device in Figure 10 is multiplied by two in order to compare with the same number of layers.

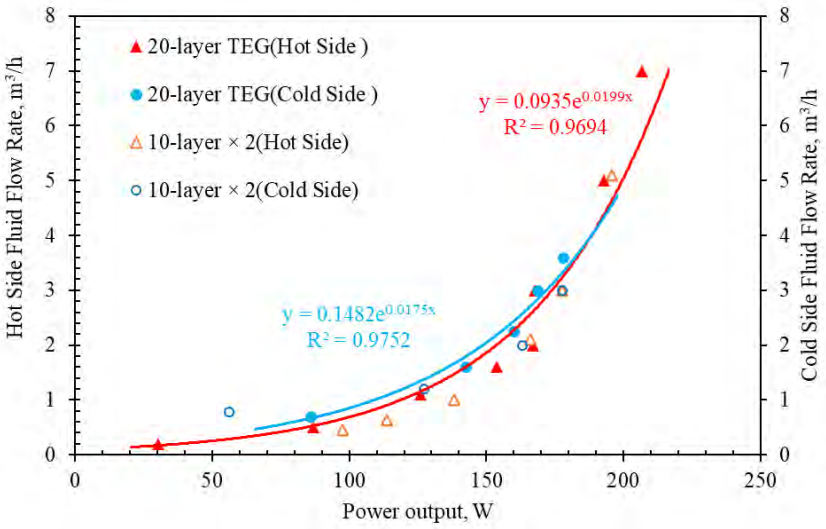

Figure 10: The total power output of the TEG devices at different flow rates on the hot/cold side (water flow rate on the cold/hot side was 3 m^3/h and the temperature difference was 60 °C (± 1 °C)).

Figure 11 shows the efficiency of the TEG devices at different temperature differences and different flow rates. The efficiency of the power generation from heat to electricity increases with temperature difference and decreases with the increase in flow rates at the hot side. The last observation is interesting and the mechanism behind it is not clear yet.

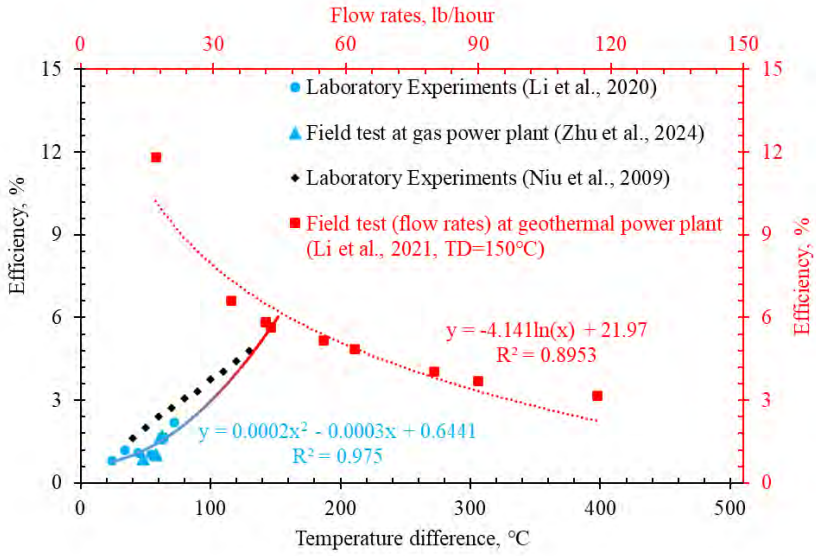

Figure 2: The efficiency of the TEG devices at different temperature differences and different flow rates.

The data of the power per unit area of TEG chips and the power per unit thermoelectric particle area of TEG chips at different temperature differences are shown in Figure 12. Also listed is the power per unit area of PV panels, which is in the range of 150 – 250 W/m^2. The power per unit

area of TEG chips will exceed that of PV panels at temperature differences above 80°C. Interestingly, Lee and Lee (2018) reported a TEG with a very high power density of 233.1 kW/m^2 at a temperature difference of 155 °C.

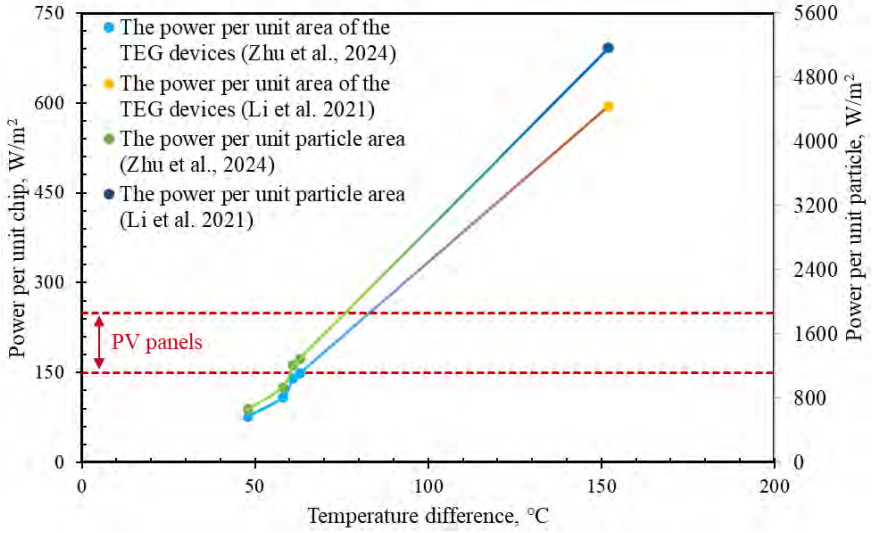

Figure 3: The power per unit area of the TEG devices and per unit particle at different temperature difference.

Figure 13 shows the estimated cost of the TEG devices based on the results of the field tests conducted by Zhu et al.(2024) and the geothermal field tests by Li et al. (2021). The installation cost ($/kW) and the Levelized Cost of Electricity (LCOE) of TEG at different temperature differences were calculated with reference to the cost data of geothermal power generation (from International Renewable Energy Agency). One can see that the relationship between the cost and TD is linear on a single-log coordination plot. As reported by Li et al. (2021), the cost of TEG is also attractive compared with PV panels if the capacity factor were considered.

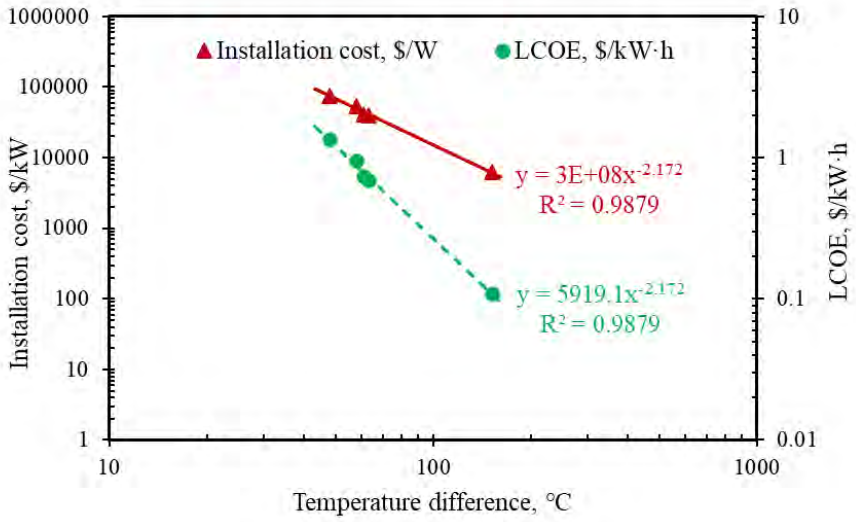

Figure 13: The installation cost and LCOE of TEG at different temperature differences.

4. Conclusions

Thermoelectric generators hold significant potential for sustainable energy generation from low-grade heat sources. Despite the extensive research conducted on TEGs, there remains a critical need to bridge the gap between laboratory-scale experiments and large-scale field applications. According to the field test results, the following conclusions may be drawn:

(1) The TEG power outputs measured in laboratory and pilot test sites at different temperatures are closely consistent. An equation coupling TEG power outputs and TD has been established.

(2) We may predict the power output for large-scale field applications using the experimental results with a single TEG chip at different TD.

(3) The cost of TEG is lower than solar PV (photovoltaic) panels when TD is greater than 90 ℃.

Dynamic Fracture Modeling, Reservoir Modeling, Discrete Fracture Networks, Hydro-shearing, Hydraulic Fracturing

ABSTRACT

Fully coupled high-resolution dynamic modeling of the subsurface is required to optimize geothermal field producibility while ensuring planned operations do not give rise to geohazards. In geothermal settings, understanding the thermo-hydro-mechanical behavior of natural and induced fracture networks is essential to assess the enhancement capacity of target reservoirs. The associated simulation of microseismic locations, magnitudes, and mechanisms is critical for evaluating stimulation success and the risk of induced seismicity.

A Discrete Fracture Network (DFN) hydrostructural approach that incorporates the geometry and properties of discrete features is dynamically calibrated against available reservoir hydrological tests to provide the central component controlling flow and transport through the reservoir. Enhancing the geothermal system through hydro-shearing/hydraulic fracturing is simulated by Dynamic Fracture Modeling (DFM) through the natural fracture network. The DFM was carried out using the numerical software *XSite*, which uses the lattice approach to implement the synthetic rock mass (SRM) method to simulate hydraulic fracturing in naturally fractured rock masses. Fully coupled hydro-mechanical simulation is conducted in the model that explicitly represents pre-existing fractures, and reservoir stimulation is a combination of hydraulic fracture propagation and opening or shear of pre-existing joints (i.e., hydro-shearing). The DFN and DFM-derived fracture permeability distribution was then used in dynamic fluid modeling to explore well-engineering scenarios for optimal production.

This study presents the full link between subsurface characterization and dynamic modeling of natural and induced fracture networks for a geothermal exploration site in Zambia to provide a high-resolution base for reservoir dynamic flow modeling. The results of this full-physics approach reveal the main drivers toward project success.

1. Introduction

Kalahari Geo Energy is undertaking the development of a geothermal power generation project with a minimum of 10 MW and aims for up to 20MW, in the Bweengwa River area at the southern boundary of the Kafue Rift basin. The geothermal resource is represented at the surface as a suite of hot springs clustered along the basin-bounding faults but developed in the subsurface as a deep circulating geothermal system associated with the Karoo age basin-bounding faults.

The resource has been explored in detail over the last 11 years through a combination of geophysics, surface mapping, geochemical sampling and data from twenty-one shallow boreholes (Figure 1).

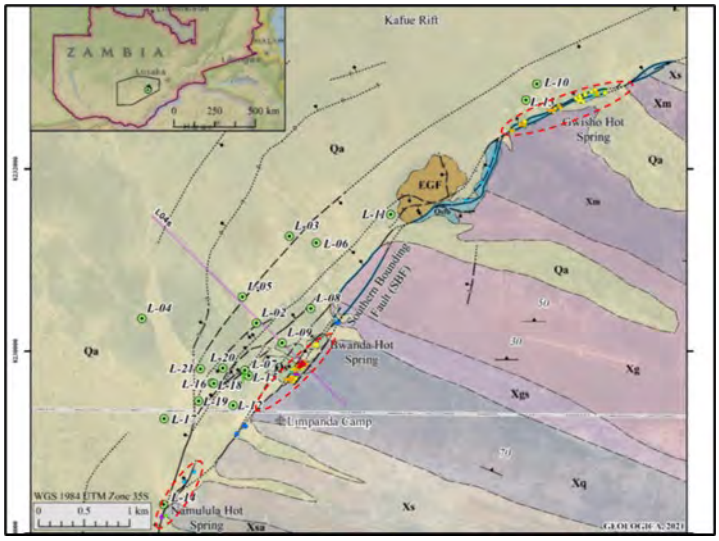

Figure 1. Summary surface geology map showing the Namulula, Bwanda and Gwisho hot springs plus the exploratory LOCH (L) wells focused on the Bweengwa resource (from Geologia Geothermal Group, 2021).

In a recent study (Salter et al., 2024) the productivity hosting fracture system present within the deeper basement was modeled using a discrete fracture network (DFN) with input derived from core review and the faults contained within a newly derived fault framework. Deterministic faults and stochastically generated fracture sets of the DFN were utilized to perform an integrated modeling workflow and deliver 3D models with predictive resource capability. The DFN fracture model was conditioned to well-test transmissivities and calibrated to the thermal model and reservoir rock type. The resulting parameters include directional hydraulic conductivity tensor and fracture porosity, which were upscaled to provide input to dynamic reservoir fluid flow simulation.

In this study, we simulate hydraulic stimulation of the preexisting fracture network by coupling Dynamic Fracture Modeling (Damjanac and Cundall (2016) and Fu et al. (2016, 2019) with Dynamic Reservoir Modeling (Salter et al., 2024) to explore the enhanced permeability and enthalpy achieved through the application of EGS techniques to this field.

2. Base DFN Model

2.1 DFN Fracture Network Model

The fracture conceptual model and the numerical approach used to develop the base DFN model for this study are detailed in Salter et al., 2024. The finite element software used, ConnectFlow™, employs the hydrostructural approach of DFN model generation. This approach involves analysis and modeling which explicitly incorporates the geometry and properties of discrete features as a central component controlling flow and transport. In these DFN models, a stochastic 'pipe' network type algorithm is used to calculate the flow and transport through the fracture network.

Unoriented cores from 17 wells were used to identify fractures' dip magnitude, intensity, and spatial occurrence. The distributions of fracture orientations were divided into five (5) sets (Figure 2b-f) consistent with nine (9) major fault trends (Figure 2a) of the structural model. Fracture set orientations are constrained both by the major faults trends and fracture dips measured from core (Figure 3).

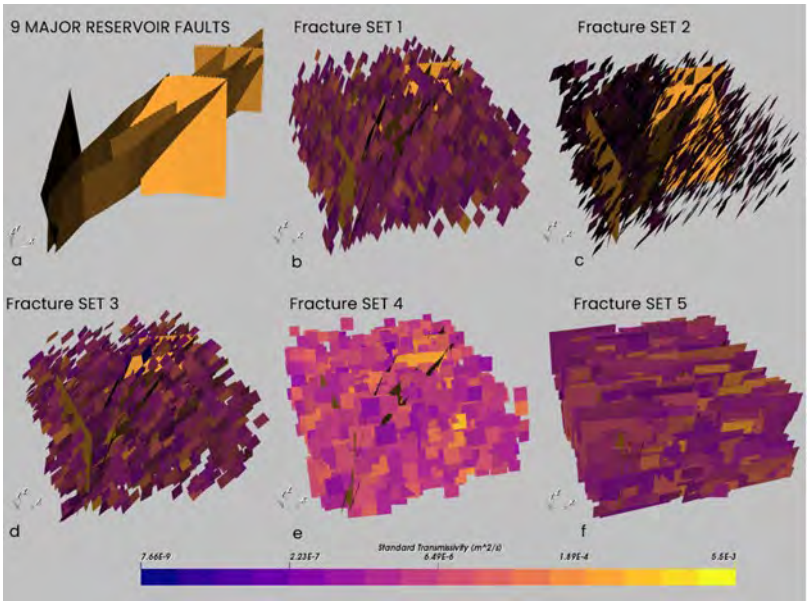

Figure 2. Deterministic faults and stochastically generated fracture sets of the DFN.

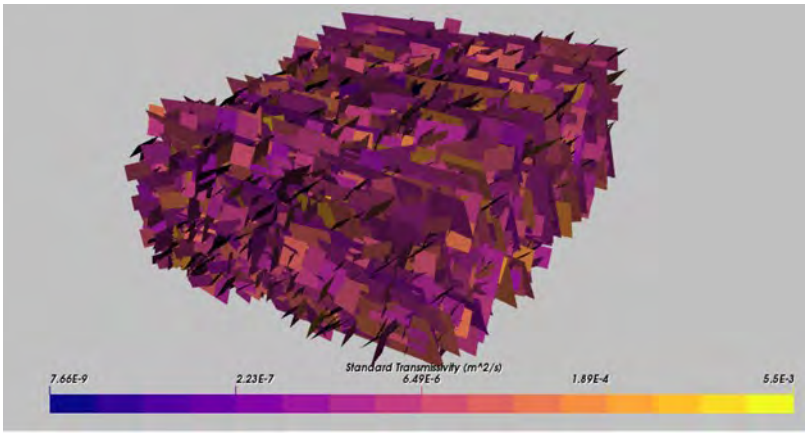

Figure 3. Final DFN realization utilized to calculate the contribution to reservoir permeability of the natural fracture and large-scale faults.

The distribution of fracture intensity was derived by the superposition of reservoir rock type and reservoir temperature-based fracture intensities. An observed characteristic of the Bweengwa fracture system is that although fractures are widespread in the basement rock (in the 17 cored wells, more than one fracture per meter was recorded on average), flow, as evidenced by production or anomalies in PT surveys and drilling information, is dominated by a small number of structures per well. This implies that flow is restricted to a subset of fractures within deformation zones that have sufficient intensity to form extensive interconnected networks.

The DFN was calibrated by matching well-based measurements to the deterministic and stochastically generated fractures intersecting field wells. Matrix permeability was assumed to be negligible for DFN modeling.

2.2 DFN Upscaling

To model flow and transport on the regional scale or over a long time, it is necessary to consider larger-scale bulk properties in the context of an equivalent continuous porous medium (ECPM) continuum concept. Converting the properties of a network of discrete fractures of lengths less than the continuum grid blocks into ECPM grid properties requires upscaling**.** A flux-based upscaling method is used that requires several flow calculations through a DFN model in different directions. In 3D, six directional components characterize the symmetric hydraulic conductivity tensor. Using the DFN flow simulations, the fluxes through each face of each grid cell are calculated for each head gradient direction. The hydraulic conductivity tensor is then derived by a least-squares fit to these flux responses for the fixed head gradients. Figure 4 captures the derived Kx, Ky, and Kz permeabilities within the volume by filtering permeability below 3×10^{-13} m^2.

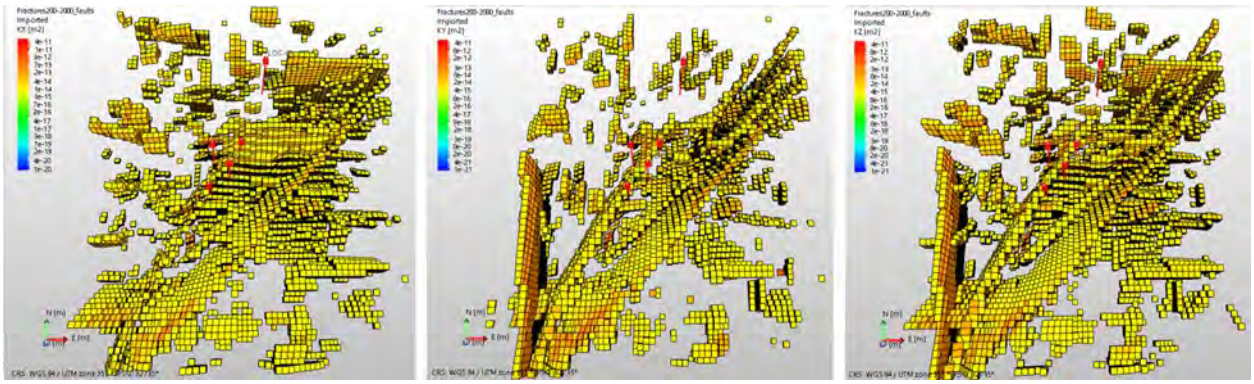

Figure 4. Derived Kx, Ky, and Kz permeabilities within the volume filtered below 3×10^{-13} m^2.

3. Previous Dynamic Reservoir Modeling

In the previous study, the integration of static parameters with dynamic transmissivity enabled a confident initialization of the static model for simulation. Thermal equilibration runs showed stability of the thermal plume, maintaining a suitable balance of conductive and convective heat transfer processes dominating in the Karoo-age sedimentary cap-rock and the resource-hosting metamorphic basement, respectively.

Simulation of prediction cases with existing well doublets highlighted the risk of injection water breakthrough related to permeability anisotropy. Geothermal power output was maximized by injecting into the shallower basement layers whilst producing from the deeper, hotter basement layers. An optimized development scenario of 3 producers plus 3 injectors, with production targeting the deep, hot up-flow and using well rate constraints consistent with the well-test-derived flow rates of up to 2,218 m^3/d, proved to deliver a stable thermal output of 22 MW over a 20-year span.

The dynamic modeling provided optimized well design (insulated tubulars, length of tubing and casing, casing thickness, cement thickness, etc.) to achieve maximized temperature and enthalpy output. Artificial lift assessment was considered for low- and medium-productivity wells using a conceptual ESP design. Although results of this assessment show ESP can allow wells to produce with higher WHFP, the question of achieving higher production rates (or, equivalently, higher injectivity) with stimulation remained unanswered.

In this study, we use the base DFN previously developed for the study area to simulate the creation of an SRV by EGS hydraulic stimulation to enhance permeability and injectivity. The resulting DFN/DFM-derived fracture permeability distribution was then used in dynamic reservoir modeling to explore well-engineering scenarios for optimal EGS production.

4. Reservoir Stimulation Model

4.1 Numerical Model Description

XSite, a Discrete Element Method (DEM) code developed by Itasca Consulting Group (Itasca, 2023), was utilized for simulating fluid injection, hydraulic fracturing of rock masses, and hydro-shearing of natural fractures. Through the implementation of the synthetic rock mass (SRM) method using a lattice numerical approach, *XSite* accurately models deformation, hydraulic fracture (HF) propagation, and related microseismicity in naturally fractured reservoirs. Its capabilities have been extensively verified for both viscosity-dominated and toughness-dominated hydraulic fracturing regimes, as well as for the unrestricted interactions of hydraulic fractures with existing fractures and joints, as demonstrated by Damjanac and Cundall (2016) and Fu et al. (2016, 2019).

4.2 Model Setup

The model consists of a 1 km³ cube, with the top representing a depth of 600 m. At a depth of 1100 m, a horizontal wellbore is placed in the center of the simulation domain, aligned with the horizontal principal stress orientation. The focus of this study is not on accurately representing near-wellbore fracture initiation or the influence of well perforations and casing, so these details are not explicitly included, as in Fu et al. (2024).

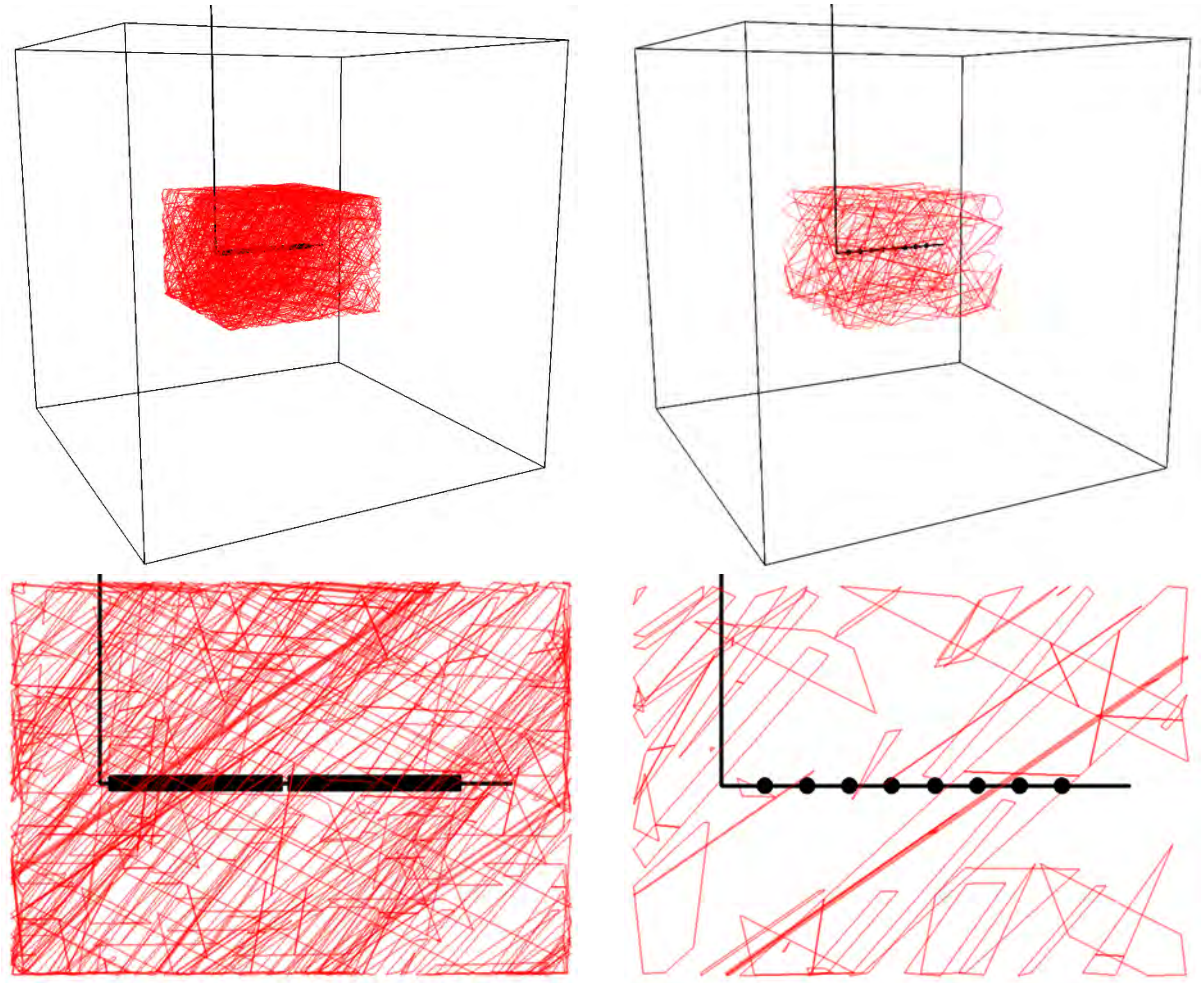
The Discrete Fracture Network (DFN) generated for the Kalahari project is explicitly represented, with numerous fractures ranging in length from 200 m to 2000 m intersecting the horizontal wellbore. Two stimulation designs were evaluated: one with the injection well in a dense DFN area (Scenario 1) and another in a sparse DFN area, five times less dense than the dense DFN (Scenario 2).

Scenario 1: Dense DFN (Figure 5a)

In the first scenario, an openhole completion is employed with two stages of reservoir stimulation achieved by injecting fluid directly into natural fractures intersecting the openhole. The objective of the injection strategy for the dense DFN is to stimulate fractures by inducing hydro-shearing. Each stage involves stimulating a section of the openhole with a length of 125 m. The code resolves the partition of the injected rate between the pre-existing fractures intersecting the active segment of the openhole well while maintaining the same pressure within the stage (no pressure drop). The pumping rate is 7.5 bpm (0.02 m³/s) for 1.5 hours per stage.

Scenario 2: Sparse DFN (Figure 5b)

The second scenario uses a cased-hole completion with eight stages of reservoir stimulation. During each stage, fluid is injected at a constant rate of 30 bpm (0.08 m³/s) for 25 minutes into a single spherical perforation. Perforation clusters are spaced at 30 m. The stimulation strategy for the sparse DFN is to propagate hydraulic fractures to connect with the DFN and induce hydro-shearing of the pre-existing fractures. The stages include a single perforation cluster to achieve the best uniformity of stimulation along the well.



(a) Openhole - Dense DFN (scenario 1) (b) Cased borehole - Sparse DFN (scenario 2)

Figure 1: Stimulation modeling. Top: a) openhole and b) cased borehole simulation domains. Bottom: Zoomed in and trimmed views of the intersection between the DFN and the injection clusters.

The rock mass properties (Schistose Quartzite of the Raduwa Formation as reported by Panthee et al. (2016)), fluid properties, and in-situ stress magnitudes and directions are summarized in Table 1. The properties of the pre-existing fractures are provided in Table 2. The strength properties were determined to ensure that the natural fractures are not in the state of limiting equilibrium under in-situ conditions. Both scenarios assume the in-situ DFN to be permeable initially with a uniform aperture, which is higher in the dense DFN due to the expected greater permeability.

Table 1: Rock properties and initial conditions

Parameter	Schistose Quartzite
Young's modulus, GPa	5
Poisson's ratio	0.25
Fracture toughness, MPa.m$^{1/2}$	1.5
Fluid viscosity, cP	2
Pore pressure, MPa/m	0.00981
Minimum horizontal stress, MPa	0.013 – Dip Direction 135˚
Maximum horizontal stress, MPa	0.018 - Dip Direction 45˚
Vertical stress, MPa	0.025

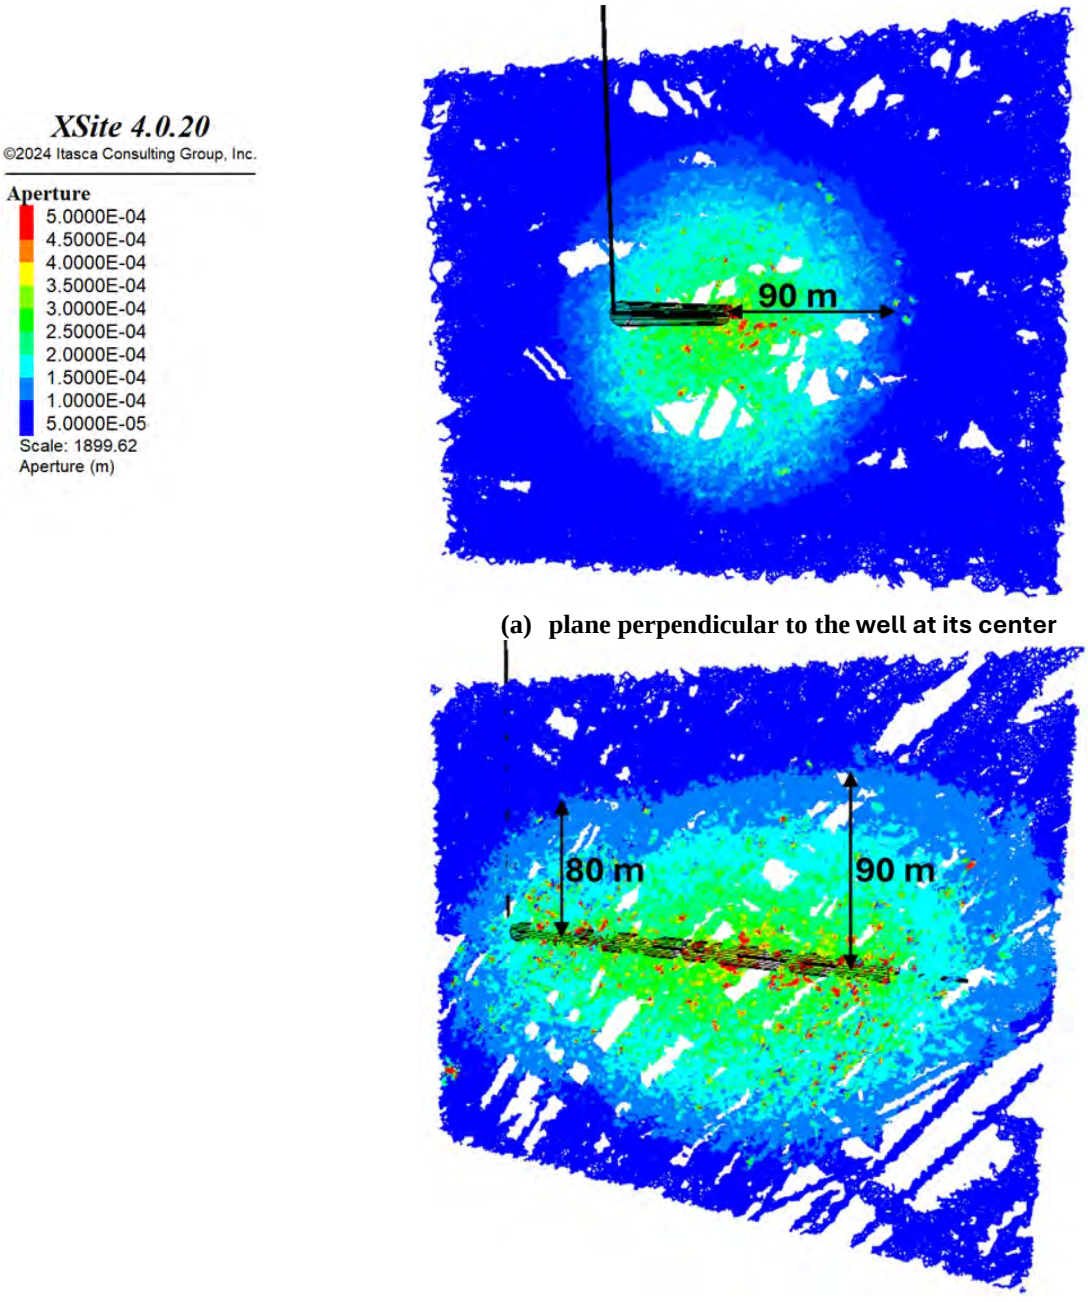
Table 2: Fracture properties

Parameter	Dense DFN	Sparse DFN
Average aperture, mm	0.05	0.01
Cohesion, MPa	10	
Friction angle, ˚	45	
Tensile strength, MPa	5	

5. Stimulation Results

5.1 Dense DFN

The aperture contours at the end of the two stages of hydro-shearing are shown in Figure 6 in two planes: one perpendicular to the well at its center and the other parallel to the well. As can be seen, this scenario resulted in shear stimulation of existing fractures in a nearly cylindrical domain with an average radius of 90 m centered around the well, contrary to hydraulic fractures that preferentially grow in an upward direction. An aperture increase of four to five times was predicted in the sheared fractures within a 70 m radius from the well. Given the low injection rate occurring directly in the permeable fractures intersecting the well, the resulting pressure increase is minimal, less than 1.2 MPa, as shown in Figure 7.



(a) plane perpendicular to the well at its center

(b) plane parallel to the well

Figure 6: Simulated distribution of fracture aperture at the end of the second stimulation stage in Scenario 1 in two planes.

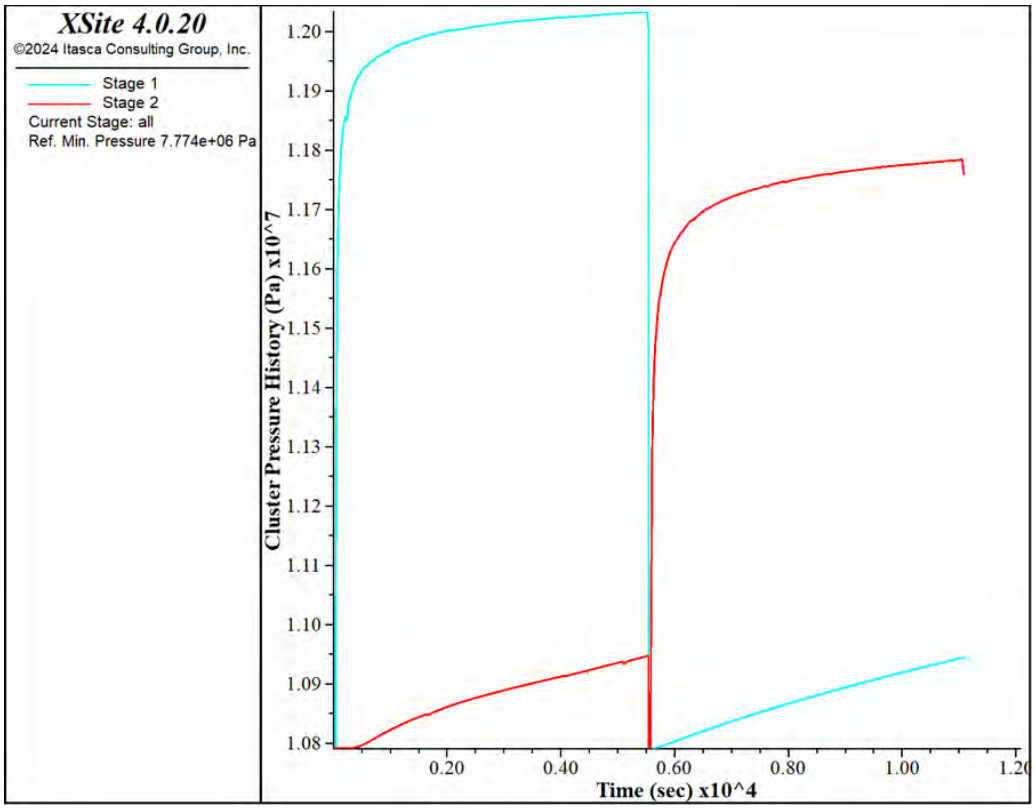


Figure 7: History of pressure in the two stages in Scenario 1.

5.2 Sparse DFN

The fracture geometry and the aperture contours at the end of stimulation of the eight stages are shown in Figure 8. No natural fractures intersect the first cluster. The hydraulic fracture propagates in a planar, penny-shaped manner perpendicular to the well until it intersects one of the natural fractures. At this point, the flow becomes controlled by the sparse network of natural fractures. This same process occurs in Stages 6 and 8, where the natural fractures do not intersect well near the cluster. Otherwise, there is no fracture propagation, and the injection pressure monotonically increases. As expected, Figure 9 shows that high cluster pressures are observed when the perforation cluster does not intersect a natural fracture. As the hydraulic fractures propagate unbounded or when they intersect with the permeable pre-existing fractures of sparse DFN, the pressure drops or stops increasing. Note that cluster pressure here accounts for pressure losses due to the presence of perforations.

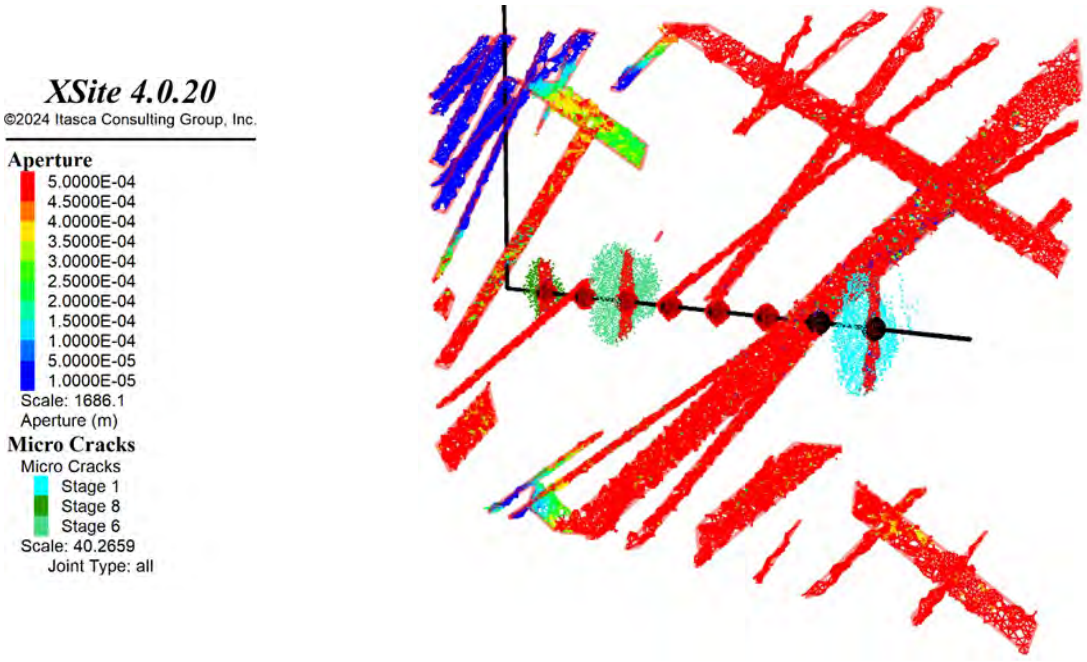

Figure 8: Simulated distribution of microcracks and fracture aperture at the end of Stage 8 in Scenario 2. Sparse DFN is trimmed in the Y direction.

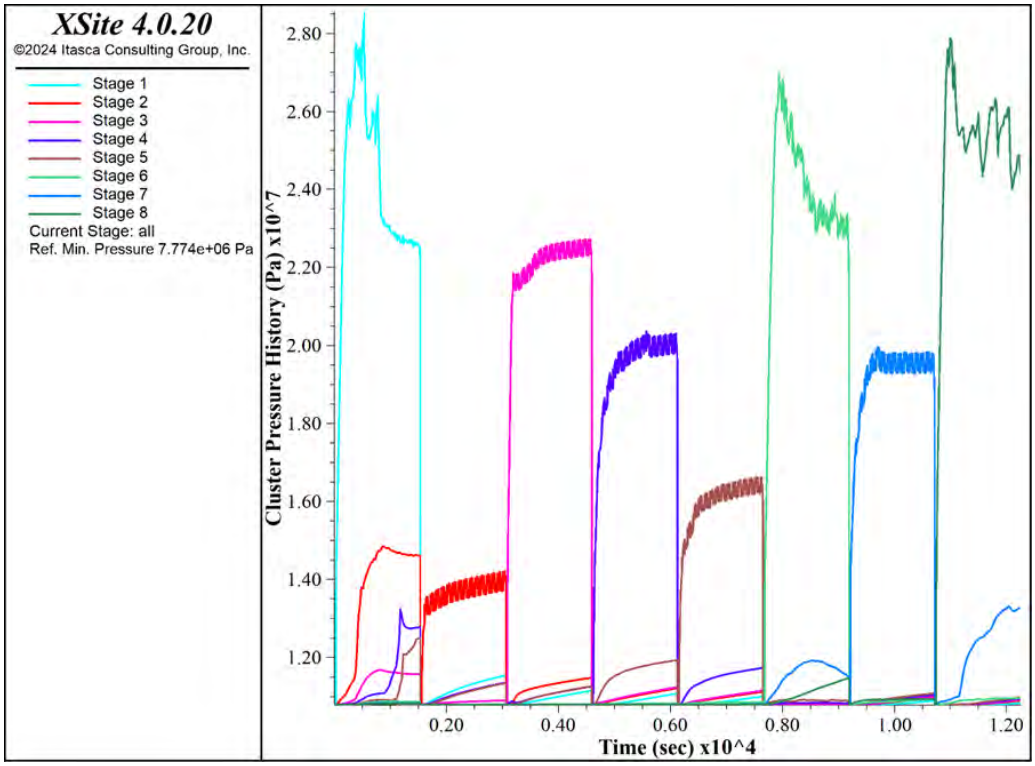

Figure 9: Histories of cluster pressures in the eight stages of hydraulic fracturing in Scenario 2.

6. Dynamic Flow Modeling Results

The 3D static geomodel grid of the stimulated area with the upscaled permeability tensor was exported and incorporated into the base dynamic simulation model. The grid was initially quality checked to optimize dynamic modeling runs. The cell count in IJK (comparable to X, Y and Z) directions was 59 × 66 × 116, respectively. The total number of active grid cells was 188179 after setting cutoffs for cell thickness and volume to avoid numerical instabilities in simulations. Full details of the base equilibrated dynamic model are provided by Salter et. al, 2024.

Multiple forecast scenarios were simulated for SRVs in dense and sparse DFNs, varying well trajectories, well position, well spacing, well stimulation, and injection rates. These parameters and subsequent results are only to highlight the workflow. Additional field data are required to assess the best subsurface characterization for field operations. Well configurations modeled included lateral producers 100 m and 200 m above and below a stimulated lateral injector and a stimulated lateral producer with a vertical injector. The minimum flow rate simulated was 2,218 m^3/d based on the previous study, and a maximum flow rate increase of 3.3 times was assumed based on the average permeability enhancement between the base and stimulation cases along the wellbore. The maximum drawdown was assumed to be 3000 kPa for injectors and producers. The injection temperature was set to 60°C. Forecasts were run for 20 years. Injection enthalpy (enthalpy at 60°C) was subtracted to calculate the net enthalpy gain in kJ/kg. The objective of scenario testing was to determine the optimal injector/producer configuration for sustained heat production at the lowest CAPEX.

Simulation of prediction cases with new well doublets constrained the nominal well spacing for all scenarios to greater than 200 m, again highlighting the risk of injection water breakthrough related to permeability anisotropy. Based on simulations, as anticipated, higher injection rate cases outperformed low-rate cases in maximum heat output and sustainability. Simulated dense DFN cases produce, on average, a higher heat output than sparse DFN simulation cases at equivalent injection rates (Figures 10 and 11). Both sparse and dense DFN cases of a lateral stimulated injector and lower producer do not sustain thermal output over time.

The optimal configuration for both dense and sparse DFN cases is of a stimulated lateral production well (Figure 12 upper) coupled with a vertical injection well at a distance of approximately 500 m perforated above the SRV (Figure 12, lower) injecting at a rate of 7,388 m^3/d. Post-stimulation flow rate testing must be performed to verify the actual maximum injectivity/productivity for this hypothetical configuration.

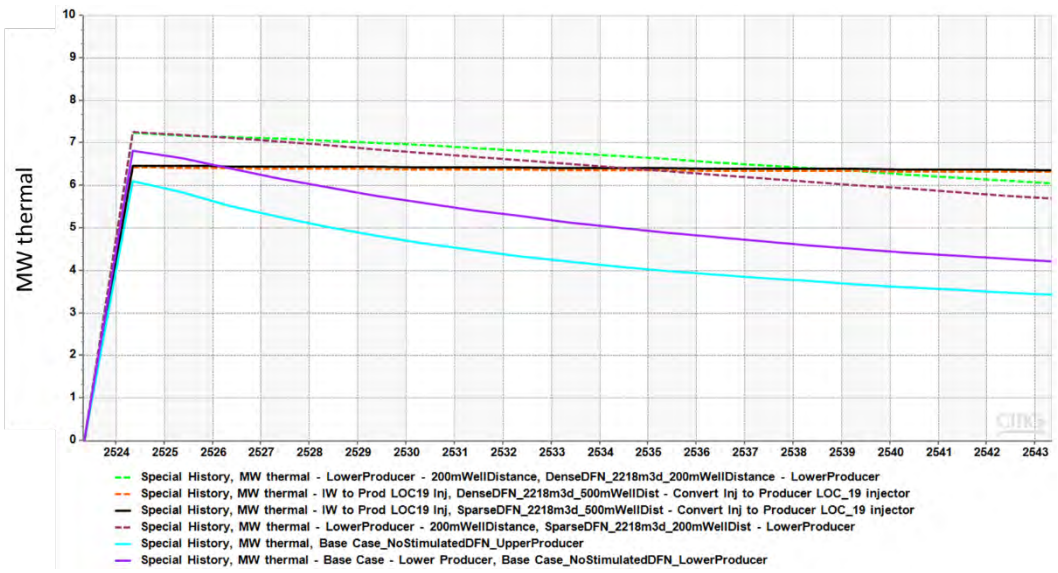

Figure 10. Lower injection rate simulation scenarios compared with the base case of an unstimulated DFN.

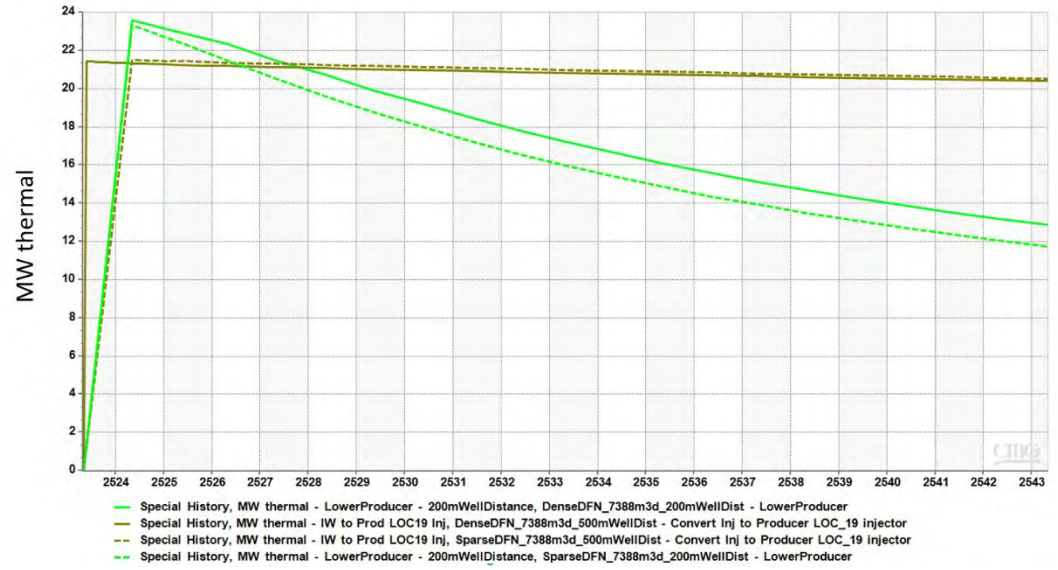

Figure 11. Higher injection rate simulation scenarios comparing vertical unstimulated injector and stimulated lateral producer with stimulated lateral injector and unstimulated lateral producer.

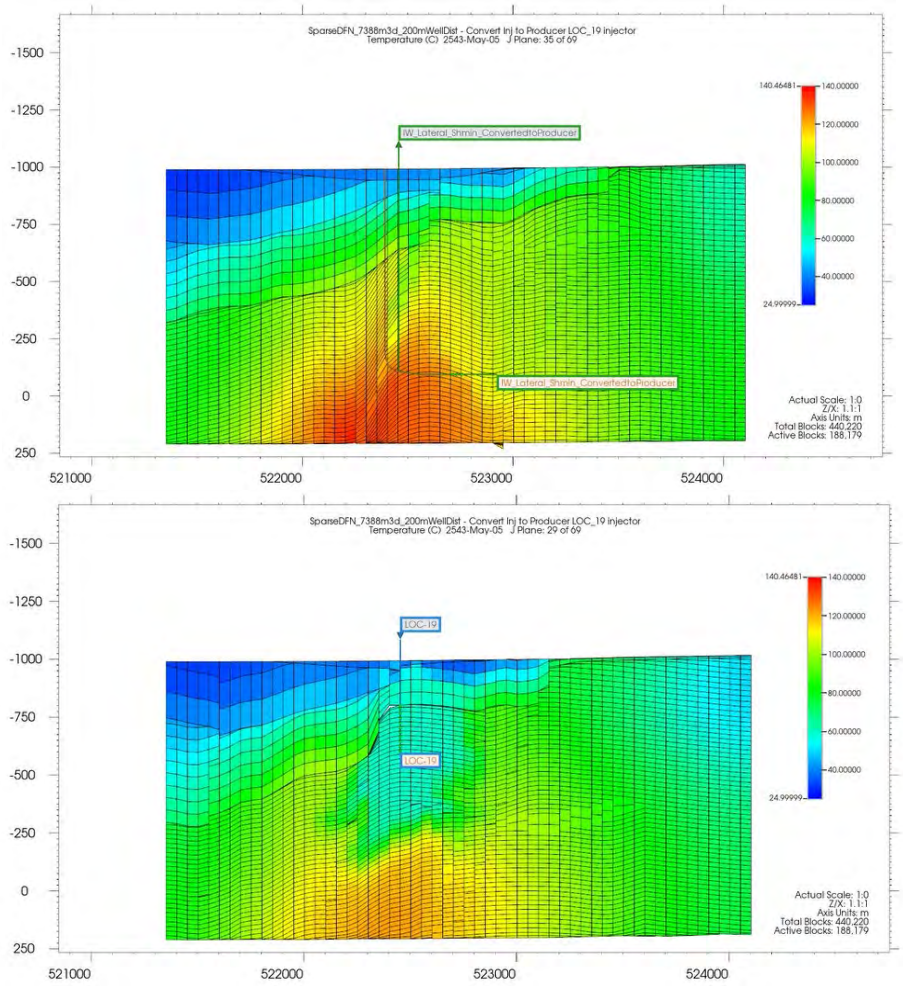

Figure 12. Optimal configuration for a single vertical injector/lateral producer pair. Temperature contours are shown in two vertical cross-sections through the volume (the upper is an E-W section at the location of the lateral producer, and the lower is an E-W section at the location of the vertical injector) at the end of 20 years of injection.

Conclusions

In this paper, we provide a case study example of a full physics-integrated modeling workflow to deliver 3D models with predictive resource capability. Through extensive scenario testing, we conclude for this case study:

- Optimum well spacing depends on the additional fracture permeability created by stimulation.
- Placement of a lateral producer above a lateral injector is not a valid strategy in the presence of a well-connected fracture network due to early breakthrough.
- Placement of a vertical producer above the SRV will limit breakthrough while maintaining reservoir pressure.
- Stimulating lateral producers will maximize contact with DFN, where multiple subsets of fractures at different orientations provide the hydrostructural fracture network.

- The sparse or dense nature of the fracture network can have a significant impact in cases of a stimulated lateral injector and unstimulated lateral producer.

Multi-segment wellbore modeling, heat transfer, geothermal

ABSTRACT

Harnessing geothermal energy for power generation in sedimentary basins has traditionally faced significant challenges, primarily due to the lack of prevalent natural fracture network, and the narrow margin of thermodynamically favorable conditions. However, recent technological advancements, particularly those adapted from the oil and gas industry, have made it possible to extract heat from deep sedimentary formations at lower temperatures than previously considered feasible. The Deep Earth Energy Production Corp. (DEEP) geothermal project, located in the Williston Basin of southeastern Saskatchewan, Canada, exemplifies these advancements. To support the development of a 5-MW-gross pilot geothermal project, DEEP has conducted surface exploration and subsurface interrogation activities to characterize the geothermal resource and its ability to support the development of geothermal power. This paper presents an integrated multi-segment wellbore model coupled with a thermal simulation framework in INTERSECT* to assess the geothermal resource performance for the DEEP project.

This approach offers several improvements, including more accurate calculations of wellbore pressure gradients, enhanced crossflow modeling, and improved wellbore storage representation. Importantly, it allows for a precise depiction of heat transfer with surrounding formations and thermal interference between the cased sections of horizontal production and injection doublets. These advancements are critical for validating the feasibility of low-temperature geothermal resources, as even small variations in the pressure and temperature of geothermal brine can significantly impact the long-term viability of the project. The model accurately captures the thermal effects of cold water reinjection and wellbore heat loss on production fluid temperature, enabling the exploration of various production rates, injection temperatures, reservoir permeabilities, wellbore trajectories, and conductive heat transfer rates within the cased sections of the wells. This allows for a detailed quantification of their respective impacts on the thermodynamics of the production fluid.

1. Introduction

DEEP has conducted surface and subsurface resource exploration and characterization activities to understand the geothermal resource in the Williston sedimentary basin of southeastern Saskatchewan, Canada (the Project area) to support the development of a geothermal power project. DEEP's geothermal project is situated about 34 kilometers southwest of Estevan, Saskatchewan, Canada, and 2.4 kilometers north of the border of North Dakota in the United States (**Figure 1**). Prior analyses of this deep basin heat source has led to a strong interest in harnessing geothermal energy to meet the region's green energy needs. DEEP is planning a geothermal power generation project using binary-cycle generation technology, starting with a pilot phase of 5-MW gross, and a project plan to ramp up to 200 MW of power to the grid. This project is targeted to be Canada's first clean, renewable baseload electricity project. The initial pilot development will feature 2 production wells and 2 injection wells (intended to flow at 60 liter/second each), interconnected by a production and injection pipeline system.

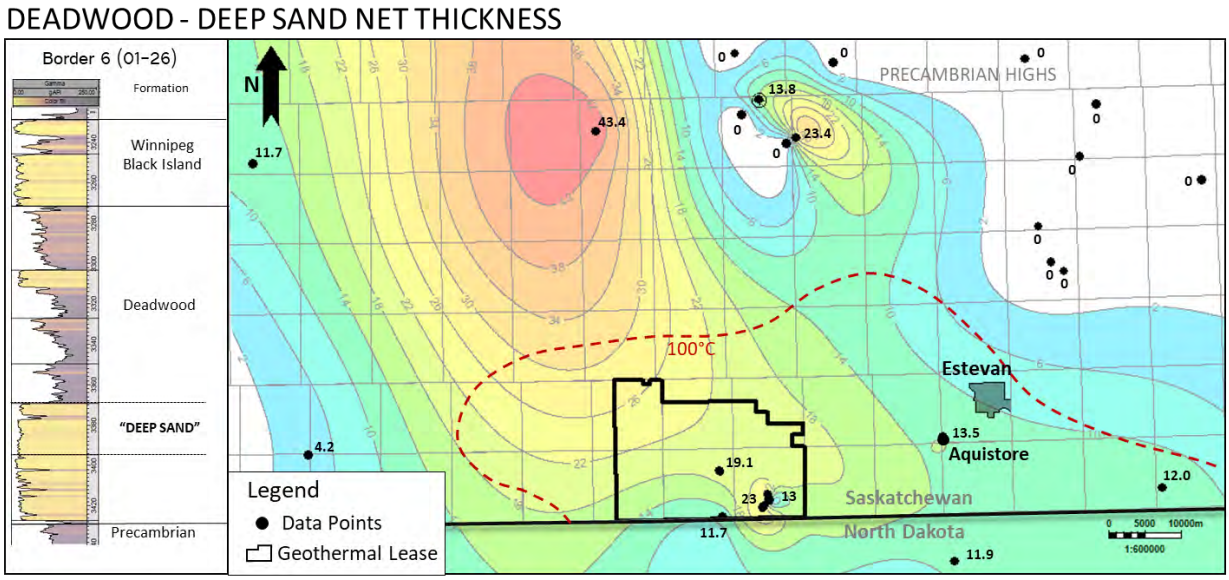

Figure 1: Location of the DEEP Saskatchewan project. The contour of the net sand sand thickness of the Deadwood Formation (porosity greater than 9%) is shown. Solid black boundary is extent of DEEP geothermal license. Dotted red line is 100°C temperature contour.

Cutting-edge horizontal drilling techniques in hot sedimentary geothermal aquifers allow for precise drilling through specific stratigraphic layers (Marcia *et al.*, 2021). Combined with improved cementing and open-hole packer technology for ensuring isolation integrity, these drilling techniques have facilitated access to larger reservoir surface areas for energy extraction. Rock-fluid interaction and heat transfer between the geofluid and wellbore mechanical components (*i.e.*, casing, tubing, etc.) require accurate modeling of heat loss and gain during the circulation of geofluid across the wellbore length and within the reservoir. This paper discusses the application of multi-segment wellbore modeling to improve the characterization of heat transfer of geothermal fluid to inform future decisions on efficient geothermal energy extraction.

2. Resource Characterization

By reviewing publicly available subsurface databases and academic studies, DEEP identified a target area in the Canadian side of the Williston Basin comprised of two geologic units that host with high-temperature brines: the Deadwood and Winnipeg Formations. These two formations are deep in the basin and therefore have the highest temperatures. The development plan focuses on a higher porosity interval within the lower Deadwood Formation to access the hot brine reservoir, named the DEEP Sand (**Figure 1**). The sandstone unit targeted for developing the for geothermal reservoir (the DEEP Sand) is 21.8 to 25.3m thick with an average porosity of 12% and permeability (as measured from core) of 18mD. For these intervals, DEEP's reservoir calculations were developed using a 9% porosity cut-off for the productive intervals, an average thickness of 18.8m, an average porosity of 13%, and an average permeability of 24mD. Stratigraphic correlation and mapping of the basal Deadwood clastics showed a continuous sandstone depositional and temperature fairway capable of supporting multiple arrays of horizontal wells to supply the geofluid to binary-cycle power units.

The successful Border-01 exploration well (which is the deepest well ever drilled in Saskatchewan) reached a depth of 3,530m (**Figure 2**). Recognizing the importance of enhancing fractures in the target lithology, the wellbore was strategically located near the intersection of two significant structural features of the Williston Basin: the Brockton Froid fault zone and the Nesson anticline (Groenewoud and Marcia, 2020). Logging operations recorded temperatures greater than 125°C; the measured temperature gradient within the DEEP Sand is approximately 2°C/100m.

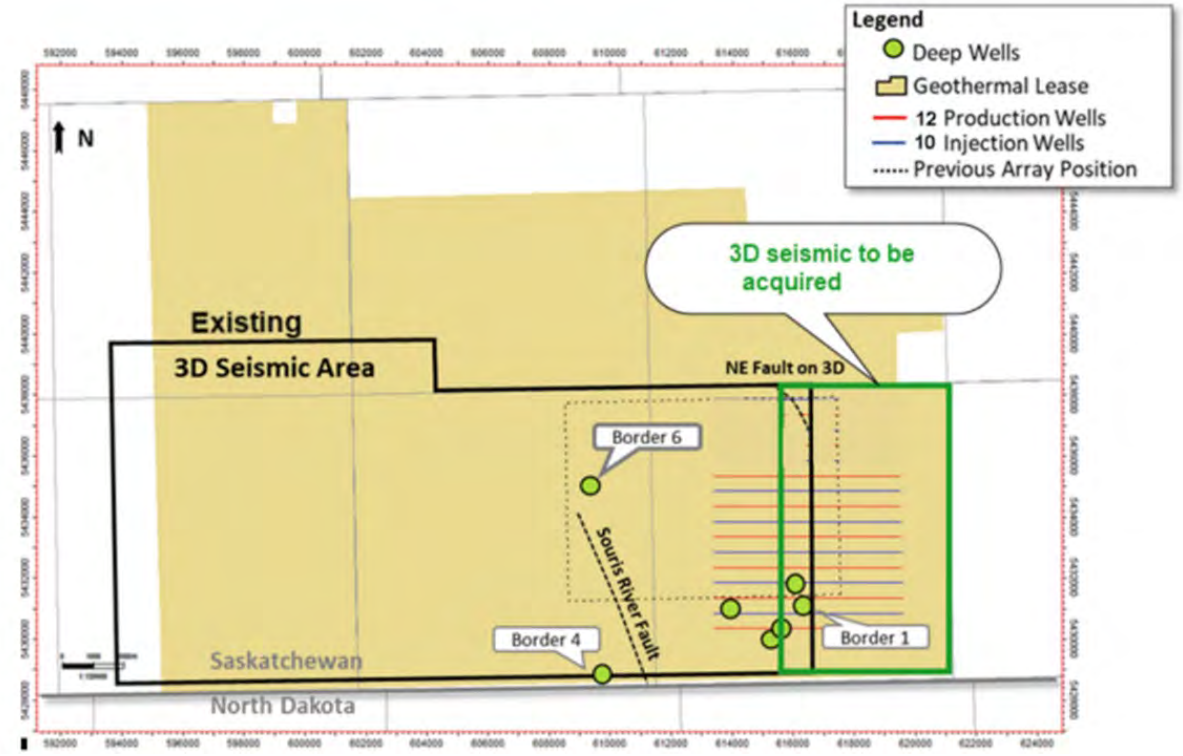

Figure 2: Extent of existing 3D seismic data for the DEEP Saskatchewan Project. Existing Border wells are shown together with the planned development well array.

Between 2018 and 2021, DEEP drilled six vertical and deviated wells in the project area. Data from these wells showed that while the DEEP target sand was productive, it did not have enough thickness to produce hot brine at the required rates using vertical wellbores. The horizontal well Border-5Hz was completed in 2020 as a proof-of-concept test to demonstrate that horizontal wells could achieve the necessary flow rates for a commercial geothermal power project. The Border-5Hz well targeted the main porosity unit of the Cambrian basal clastic (the Deadwood Formation), reaching a total measured depth of 5,672m (3,450m total vertical depth. TVD) with a 2,000m horizontal section. This well proved the viability of horizontal drilling, supported geophysical analyses, and confirmed reservoir continuity, leading to DEEP's geothermal project development plan to focus on drilling horizontal wells within the laterally continuous DEEP Sand for production and injection.

A hydraulic well stimulation was performed at well Border-5Hz to address the reservoir laminations and compartmentalization identified from core samples, which improved overall well productivity. This horizontal well was tested for 53 days in January to March 2021, flowing at an average volume of 1,800 m^3/day (about 330 gal/min or 20.8 L/s) using an Electrical Submersible Pump (ESP), at a production temperature of approximately 114°C. This test provided the necessary data to finalize the development array's design parameters, including lateral length, well spacing, and completion design. The spacing between producers and injectors was optimized to maintain reservoir pressure and minimize thermal breakthrough times. The results of a tracer test confirmed that there was no tracer breakthrough from the injection wells during the production testing period, significantly reducing the risk of early thermal breakthrough during power generation.

3. Coupled Multi-Segment Wellbore Modeling (MSW)

A detailed description of the fluid flow conditions within the well is achieved by dividing the wellbore (and any lateral branches) into several one-dimensional segments (**Figure 3**). Each segment is characterized by its own set of independent variables, such as fluid pressure, total molar flow rate, and flowing molar densities, which describe the local fluid conditions. These variables are evaluated by solving material balance equations for each phase or component, along with a pressure drop equation that considers local hydrostatic, friction, and acceleration pressure gradients. The multi-segment well model offers improved functionalities and greater flexibility, including: enhanced handling of multilateral well topology; more realistic modeling of crossflow; and the capability to simulate complex crossflow regimes in multilateral wells, including branch-to-branch crossflow and crossflow within individual branches.

Each segment includes a node and a flow path to the node of its parent segment. Segments are characterized by specified attributes such as length, diameter, roughness, area, and volume. The volume is used to make wellbore storage calculations, while the other attributes relate to the flow path and are used in friction and acceleration pressure loss calculations. Additionally, the flow rates of water associated with each segment's flow path are determined by the well model calculation. Each segment node is located at a specific depth and has a nodal pressure determined by the well model calculations. Flow from the formation through grid-block-to-well connections also occur at these segment nodes. Heat transfer along the wells was modeled explicitly in INTERSECT using the MSW well modeling tool, which accounts for the pressure and temperature changes along each well in operation (**Figure 4**). This functionality also allows the model to

account for the thermal interaction between injection wells and production wells heating and cooling the formations next to one another above the producing reservoir.

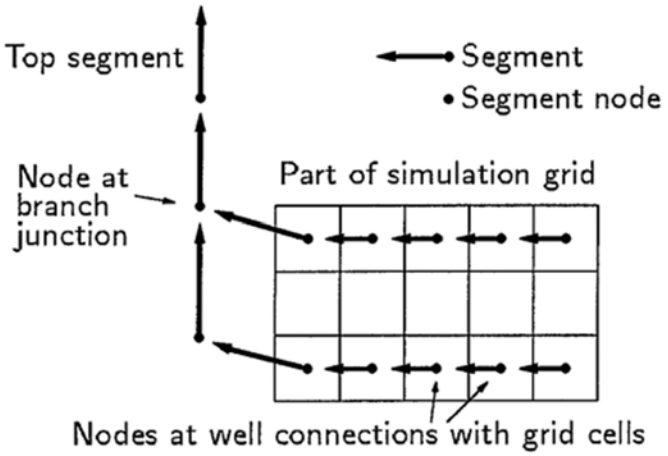

Figure 3: Schematic diagram illustrating the segment structure for an example multilateral well (Holmes *et al.*, 1988).

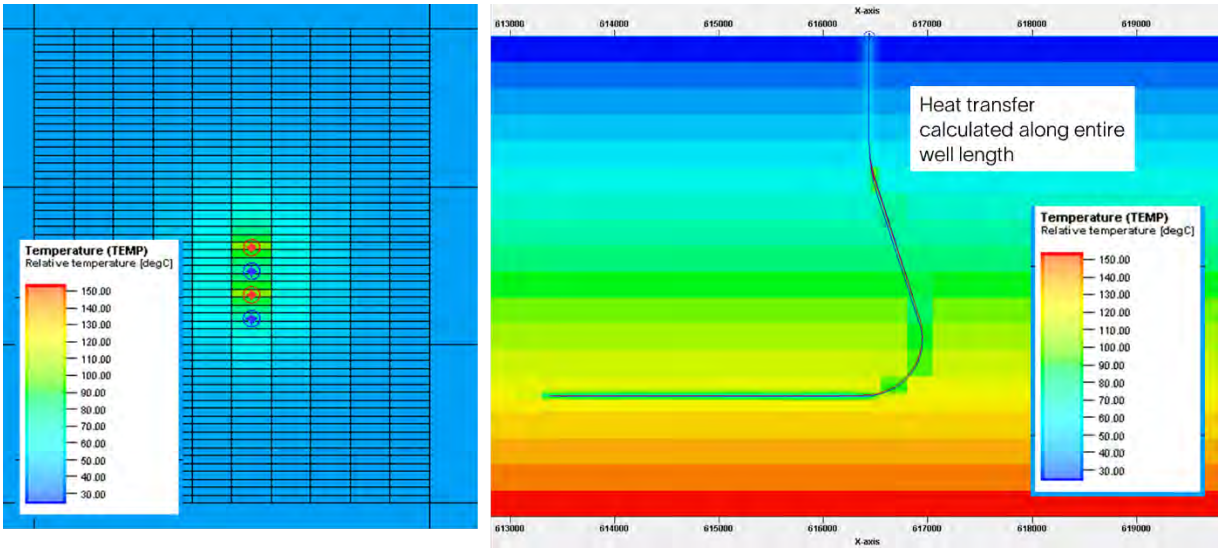

Figure 4: Multi-segment wellbore modeling in the DEEP project. A refined grid was created around the vertical well section to capture the thermal interference between the wells.

4. Numerical Model

To assess the resource's ability to support the project development plan, we utilized a full-field thermal reservoir model to quantify the impact that various uncertainties may have on the long-term sustainability of production from the resource. The numerical model was created in the Petrel* E&P Platform and utilized INTERSECT to perform the numerical flow simulation calculations.

* Mark of SLB

The project has a large set of petrophysical data that has been used to develop, constrain, and calibrate the numerical reservoir model. The petrophysical properties and structure of the reservoir model were created using the structural surfaces identified from completed wells, combined with depth-converted seismic interpretations. The petrophysical properties assigned in the reservoir model were obtained from core data analysis, petrophysical log analysis, and well test analysis.

The final base case design consists of 12 production wells and 10 injection wells to achieve the target flow rate, minimize capital costs, and maintain a reasonable pressure balance. The preliminary subsurface design optimizes well spacing at 500m and enables the configuration to generate ~20 MW of power after the pilot project. Each well will be drilled to a depth of 3.5km with a horizontal length of ~3km (**Figure 5**). The reservoir model was constructed to contain the development's full well array of 22 wells and the surrounding reservoir formation.

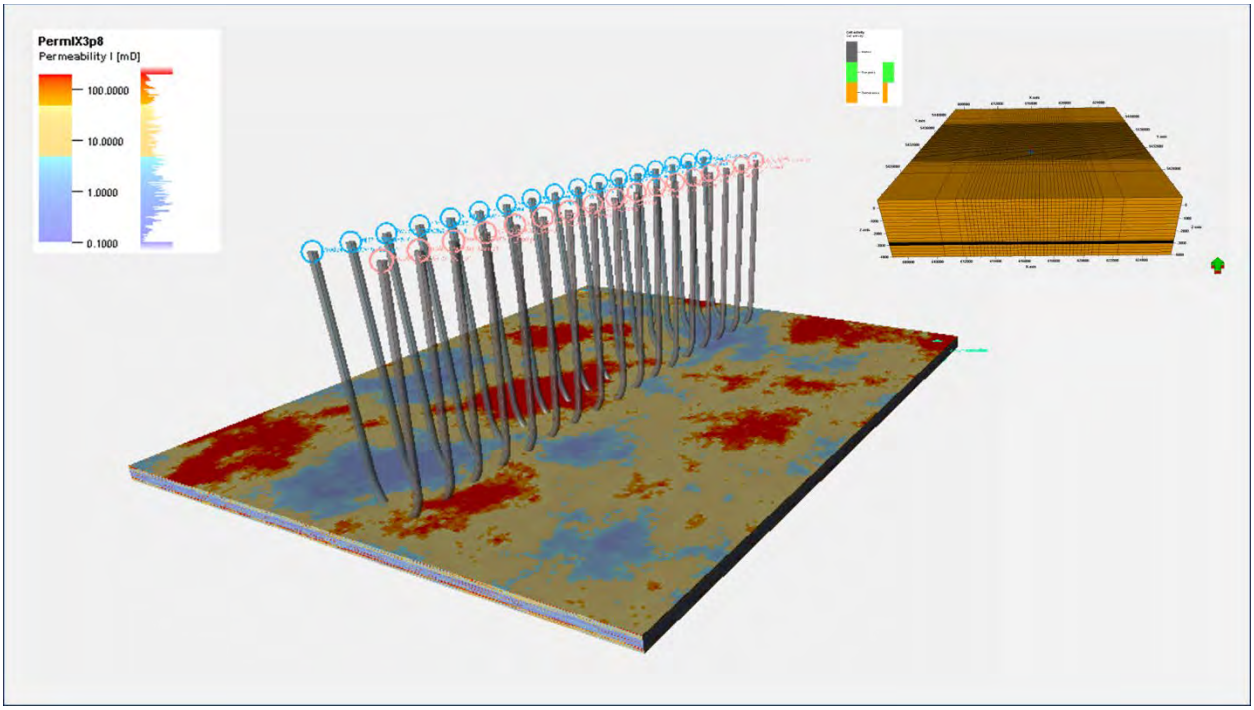

Figure 5: Proposed production and injection well array for the DEEP Saskatchewan project, with extent of reservoir model shown.

4.1 Initial and Boundary Conditions

The model is a single-porosity, single permeability reservoir model, which has been set up to be self-contained, without any thermal or pressure boundary conditions for fluid or heat flow to enter or exit the model (other than through the operating well field). This approach was used so that all fluid and heat content are contained within the grid cells for the forecast; this eliminates any potential influence of boundary condition assumptions on the model forecast. To model the sustainability of the resource during exploitation, the reservoir model was extended 5 km beyond the planned field development to capture the pressure support coming from the region surrounding the reservoir. The formations above and below the target reservoir were also explicitly included in the model to capture the thermal energy available to conductively heat the formation fluids

during project operations. The model was extended to the ground surface to allow it to account for the conductive heat transfer between the cased section of the wells and the overburden formation surrounding them (**Figure 5**). **Figure 6** presents the full-development layout, including the 4 pilot wells.

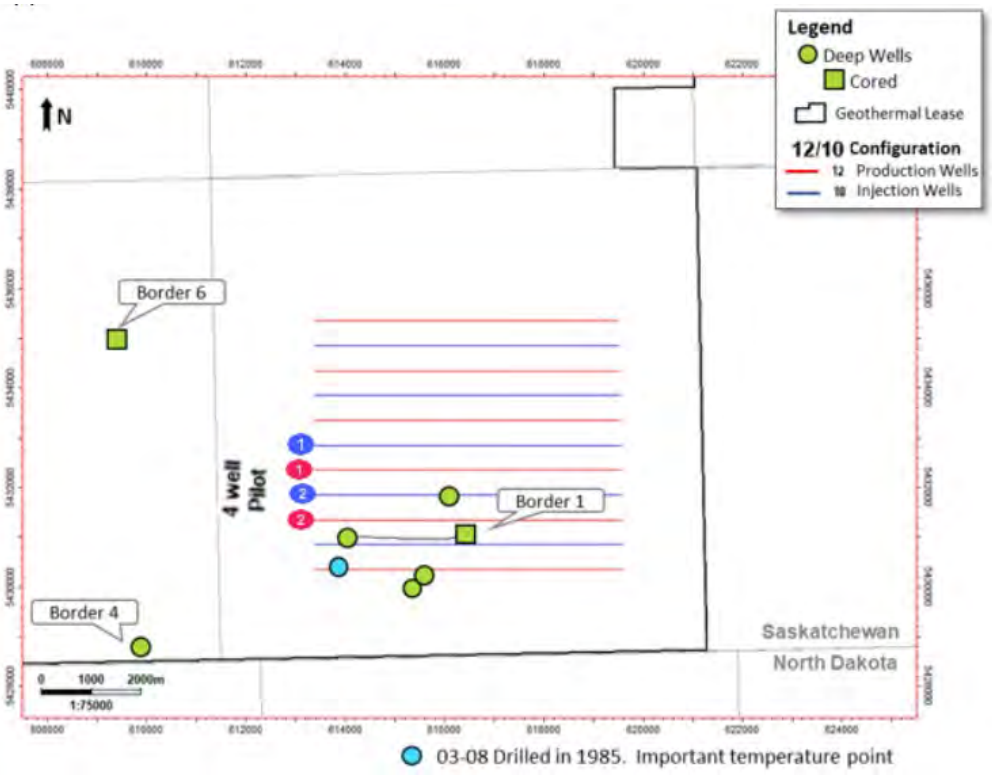

Figure 6: Location map for DEEPs proposed production and injection well array for the full 20 MW project, with 2 production and 2 injection wells identified that would support the 5 MW pilot project.

4.2 Property Assignment

Reservoir permeability was assigned based on well testing and core testing data. The DEEP well 1-26 build-up and fall-off test analysis indicated a formation permeability of 125mD, which is consistent with core data from well 1-26. The arithmetic average permeability of cores collected across the reservoir section was calculated to be 30mD. Appreciating that well testing evaluates the larger-scale permeability structures, while core data sample small-scale permeability, we created a heterogeneous model with permeability ranging from 10mD to 200mD and an average of 65mD. This heterogeneous geologic model was created to capture the expected variability in permeability within the reservoir by accounting for the depositional environment and measured permeability variation in core data. In the modeling study, this heterogeneous permeability model was assessed against a homogeneous permeability model to assess the impact that heterogeneity could have on project operation. **Figure 5** shows the heterogenous permeability of a layer in the DEEP sand unit at the approximate level of the proposed production and injection wells.

4.3 Pilot Development

The base case plan for the 5-MW pilot project is to operate with 4 wells, including 2 injectors (I4 and I6) and 2 producers (P6 and P8), producing 60 L/s and returning the fluid to the reservoir at 60°C (**Figure 6**). The forecast shows that production temperatures will increase over the first year as the near-well region is heated and thermal energy losses diminish. When production starts, hot geofluid flows up the wellbore passing through shallower and cooler surrounding layers and resulting in observable conductive heat loss (**Figure 7**). Gradually, within the first 5 years before the thermal impact of injection becomes significant, hot production fluid heats up the localized region adjacent to the production wellbore. This localized heat up around the production wells diminishes the conductive heat loss, thereby raising the production temperature. The production temperature of the base case reaches ~125°C at its peak after 5 years of production, which is comparable to the reservoir temperature. This is explained by the fact that heat loss due to wellbore friction and conductive heat transfer is balanced by the slight increase in production fluid temperature due to de-pressurization. The reservoir (liquid water) experiences a decompression from ~350 bars at the producing layers to ~40 bars at the production pump. If no conductive heat loss occurred in the adiabatic (constant fluid enthalpy) upward flow, that decompression can yield a 5°C increase in production fluid temperature. Integration of MSW into the modeling workflow helps capture this fine details to ensure proper planning for the project economics.

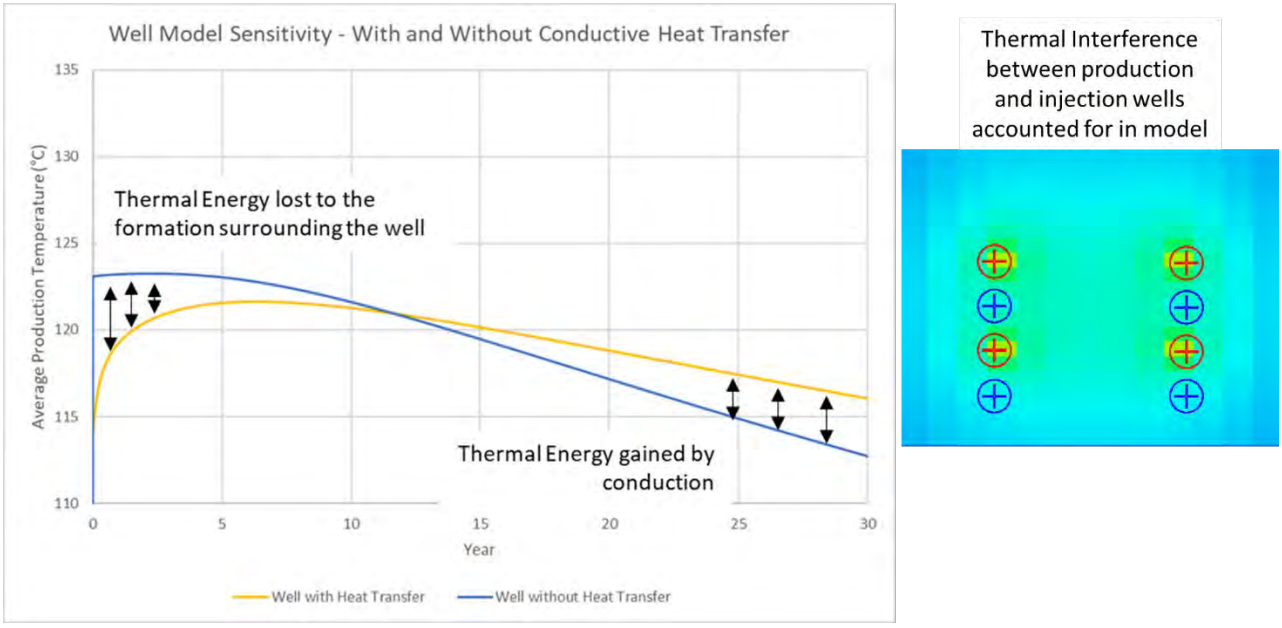

Figure 7: 4-well pilot project forecast – wells with and without heat transfer. Analysis showing the impact of including conductive heat transfer along the well during production. During the initial production period heat is lost to the formation as it heats the upper formation sections, later time heat is recovered by conduction along the well, reducing temperature decline.

The production pressure at the pump intake depth of 650 m-TVD remains above 35 bar (absolute), indicating that the pumps maintain positive suction pressure throughout the life of the project. Similarly, the injection well shows the equivalent of a negative wellhead pressure, indicating that the liquid level is predicted to remain below surface for the forecast period. This indicates that injection pumps will not be required to return the produced fluid to the reservoir given the permeability-thickness achieved by the lateral well completions. Overall, the lower density of the

heated production fluid increases the production intake pressure due to its reduced density, while the cooler fluid sent to the injection wells aids injection because of its greater density. The fluid density changes are advantageous for the project because they reduce injection and production power requirements.

4.3.1 Trajectory Sensitivity

DEEP has proposed several well trajectory configurations to optimize drilling cost and schedule. Two different well configurations are shown in **Figure** 8, where the horizontal separation between the two deviated legs of the new configuration is smaller, contributing to decreased heat loss for this early phase. Because of this trajectory-associated reduction in conductive heat loss, the peak production temperature of the new pilot well trajectories is about 2.5°C higher than for the original trajectories. The shorter length of the lateral results in less conductive heat loss for the production wells and less conductive heat gain for the injection wells (**Figure** 8).

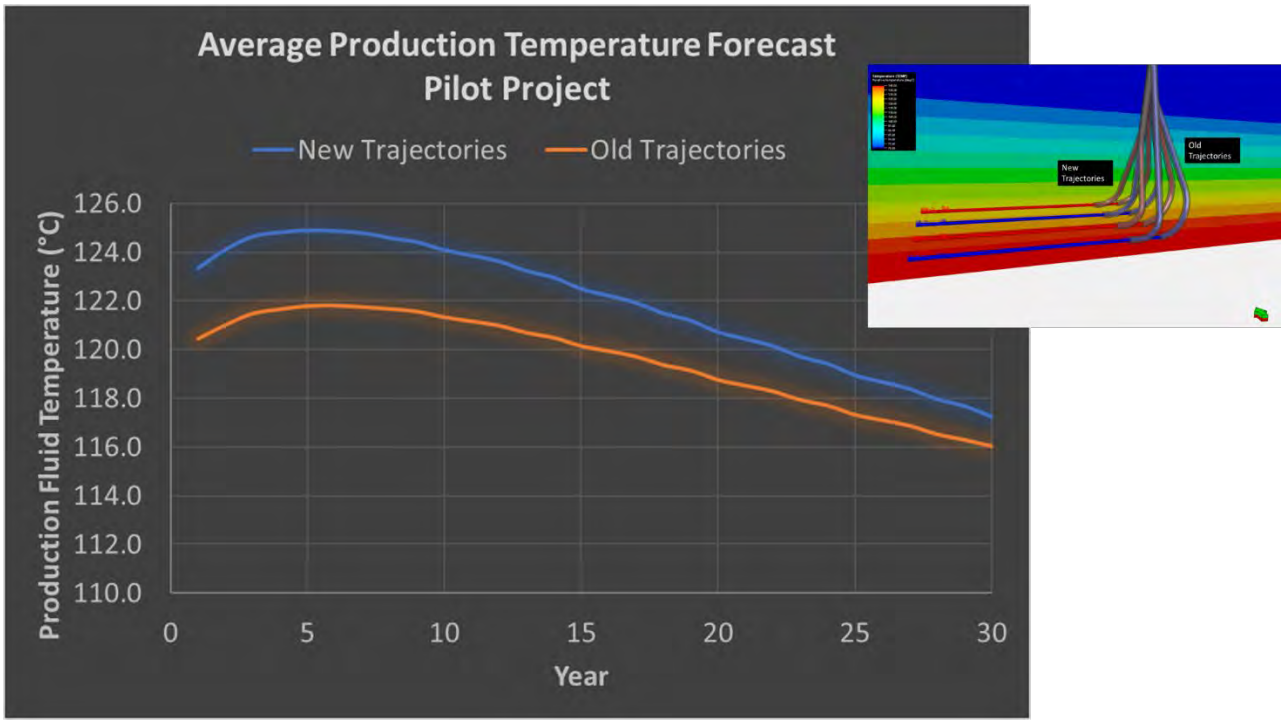

Figure 8: Production temperature at pump depth of different trajectories.

4.3.2 Rate Sensitivity

To evaluate the project's sensitivity to operating flow rates, two additional forecasts were made at average rates of 55 L/s and 65 L/s. **Figure 9** presents the results of this analysis, which show an impact of less than 2°C on production fluid temperatures at the end of a forecast period of 30 years. Production pressures remain adequate to support pumped production at 650 m-TVD, and injection wellhead pressures remain below zero. This indicates that the production and injection can be adjusted without creating a severe impact on the operational sustainability. Higher injection rates produce higher production temperature at first, then lower production temperature is observed toward the end of the forecast (**Figure 9**). Higher injection rate also results in lower average pressure intake at the pump and at higher negative injection pressures.

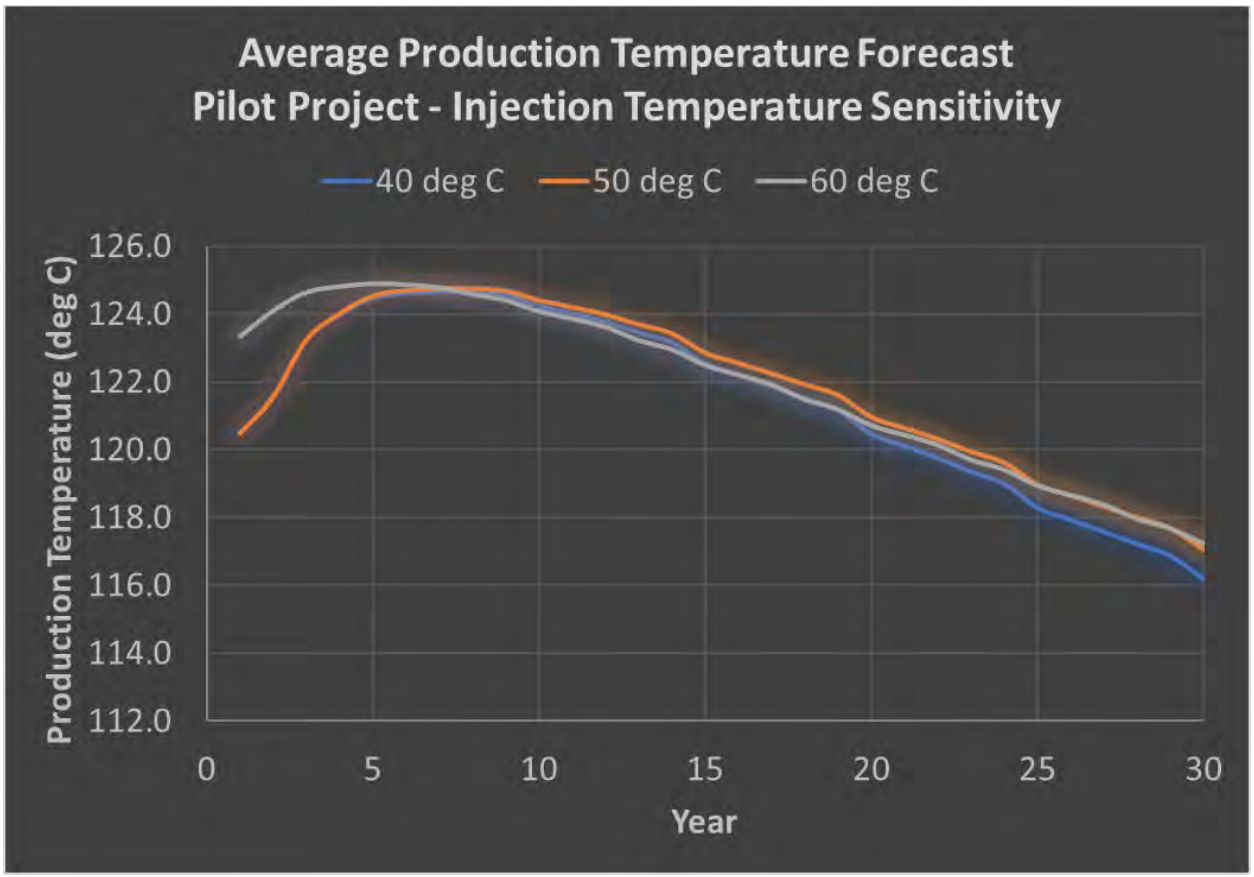

Figure 9: Sensitivity of injection temperature on production temperature at pump depth.

4.3.3 Injection Temperature Sensitivity

To assess the impact of reducing the injection fluid temperature on the production fluid temperature, a sensitivity analysis was performed in which the injection fluid temperature was modeled at 40°C, 50°C, and 60°C. The results show that reducing injection fluid temperature has a minimal impact on the production fluid temperature (**Figure 10**). With a 20°C reduction in injection temperature, the model forecast shows the maximum impact on production fluid temperature is 2°C after 30 years. The injection fluid temperature has a minimal impact on the production temperature because of the advantageous geometry and properties of the DEEP reservoir. The relatively thin DEEP Sand (22 m thick on average) allows conductive reheating from above and below the formation to heat injected fluids. Additionally, the dominance of matrix permeability in the reservoir reduces the fluid velocity, providing sufficient time for the injected fluid to reheat conductively.

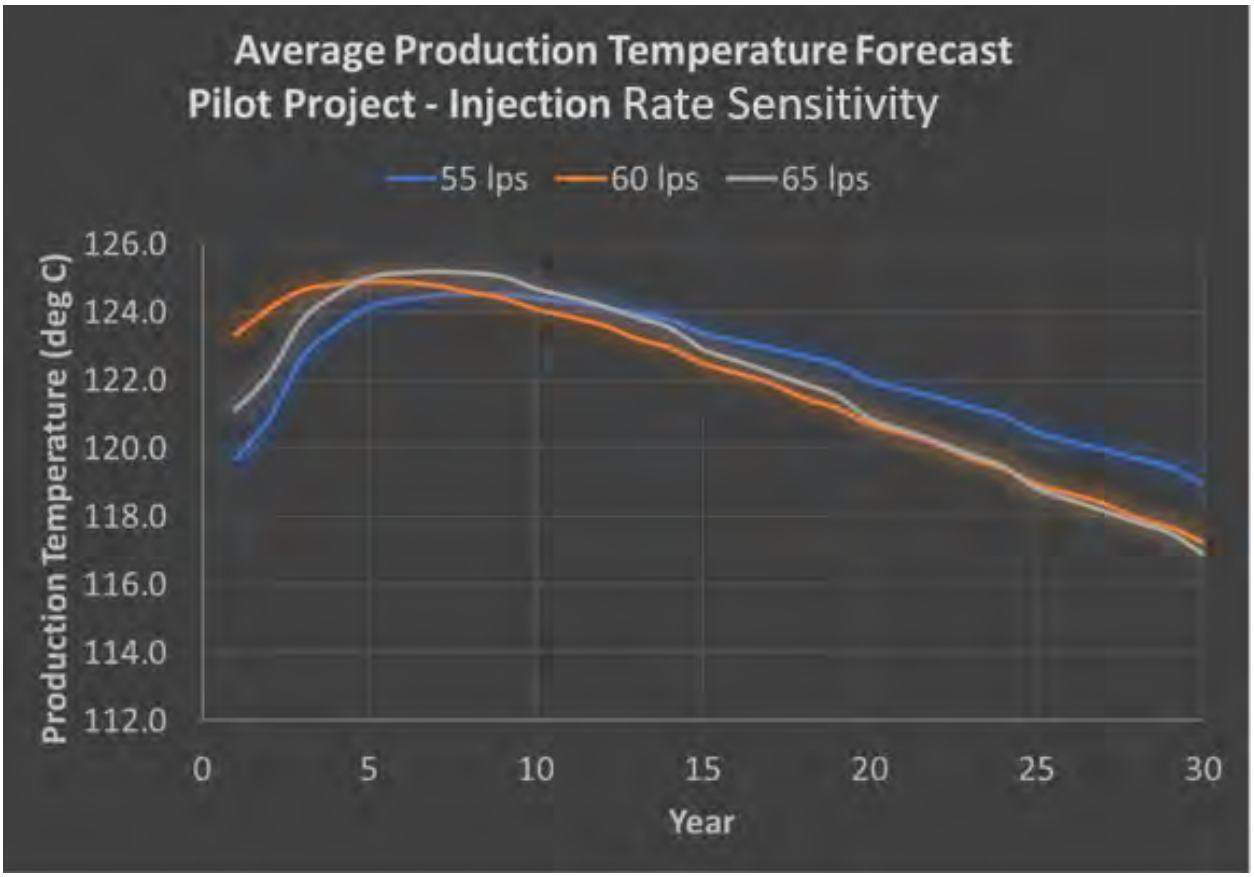

Figure 10: Sensitivity of injection rate on production temperature at pump depth.

5. Conclusion

The project design and well layout enable exploitation of conductive heating from above and below the targeted DEEP Sand to sustain thermal energy production. Employing the latest multi-segment wellbore modeling techniques, the reservoir modeling study has shown that this conductive heating from above and below significantly reduces the impact that heterogeneity could have on sustained thermal energy production. The Project plan targets distributed flow through the formation between the production and injection wells to maintain the production temperature and maximize the thermal energy sweep between the wells. If distributed flow can be maintained, the numerical model predicts that the production temperature will decline by approximately 6-8°C after 30 years. Additionally, the modeling results have shown that the project design takes advantage of changing fluid density gradients to reduce power consumption for pumping. The forecasts indicate that the project can sustain injection with zero wellhead pressure, because the cooled fluid has a higher density gradient, which aids injection. Conversely, the higher-temperature production fluid aids the production pumps by increasing the intake pressure and reducing the pumping power requirements.

Thermal rock properties, petrophysical properties, mineralogy, reservoir simulation.

ABSTRACT

Understanding sedimentary rocks' mineralogy, petrophysical properties, and thermal behavior is crucial for the effective characterization of geothermal reservoirs. In this study, we investigate the relationship between textural properties, mineralogy, petrophysical properties, and thermal behavior of 30 core samples of sedimentary rocks using scanning electron microscopy (SEM).

The study reveals that well-sorted rocks exhibit superior porosity, permeability, thermal conductivity, diffusivity, and higher quartz content among the samples analyzed. Improved grain sorting enhances the interconnected pore network, facilitating fluid flow and heat transfer within the geothermal reservoir. Moreover, the higher quartz content in well-sorted rocks enhances thermal conductivity and diffusivity. The results provide valuable insights for reservoir characterization and geothermal resource assessment, emphasizing the significance of grain sorting as a controlling factor in the porosity, permeability, and thermal properties of reservoir rocks. Incorporating textural analysis into geothermal reservoir models can improve resource assessments and aid in site selection for geothermal projects.

This study contributes to geothermal energy exploration by highlighting the importance of textural analysis in understanding the geothermal behavior of sedimentary rocks. The findings offer practical implications for enhancing the accuracy of geothermal reservoir models, optimizing resource utilization, and promoting the development of sustainable geothermal energy.

1. Introduction

Geothermal reservoir characterization in sedimentary basins involves understanding the subsurface rock and fluid properties to assess the potential for geothermal energy production. This process is crucial for determining the economic viability of geothermal projects in these environments.

Sedimentary basins offer several advantages for geothermal development, including existing subsurface data from oil and gas exploration, lower drilling costs, and favorable porosity and

permeability conditions compared to traditional geothermal reservoirs (Khankishiyev et al., 2023; Mohamed et al., 2022; Ortiz-Sanguino et al., 2022; Salehi et al., 2022; Vivas et al., 2023a, 2023b). However, identifying suitable reservoirs and their characteristics remains a significant challenge.

Traditional geothermal reservoirs for power generation are typically found in metamorphic or volcanic rock formations. These reservoirs are considered ideal when they possess a network of highly conductive fractures, which facilitate the movement of fluids at high flow rates commonly observed in geothermal fields. In contrast, sedimentary reservoirs exhibit distinct characteristics. In sedimentary porous media, the intrinsic permeability of the reservoir rock plays a crucial role in determining its ability to allow fluid flow. This intrinsic permeability is an inherent property of the material itself. In conventional sedimentary basins, where convective heat transfer is typically dominant, higher temperatures are achieved by drilling deeper wells to access regions with steeper geothermal gradients. As the well depth increases, the temperature also rises. However, it is important to note that deeper reservoirs tend to exhibit lower porosity and permeability. This decrease in permeability becomes particularly significant for power generation projects, as high flow rates are essential for the economic viability of a geothermal power development.

Sedimentary rocks are highly complex, exhibiting both anisotropy and heterogeneity at various scales. Anisotropy arises from the ordered heterogeneities smaller than the seismic wavelength, such as aligned fractures, bedding planes, or preferred mineral orientations (Lynn, 2004). The natural heterogeneity of sedimentary rocks is given by the spatial variations in the porosity, permeability, and lithology within the rock formation. In geothermal systems, these characteristics have significant implications. Anisotropy can lead to preferential fluid flow paths along fractures or bedding planes, influencing heat extraction and reservoir productivity (Panja et al., 2021). Heterogeneities can create localized zones of high or low permeability, affecting the distribution of geothermal fluids and heat transfer efficiency (Goupil et al., 2022). Additionally, anisotropic and heterogeneous rock properties can impact the state of stress and deformation behavior, which is crucial for understanding reservoir stability and potential induced seismicity (Ijeje et al., 2019).

Heterogeneity as well have implication in the rock thermal properties. Sedimentary rocks exhibit significant heterogeneity in their thermal properties due to variations in mineralogy and texture. The thermal conductivity, which governs heat transfer, is strongly influenced by the mineral composition and porosity of the rock (Schön, 2015). Quartz-rich sandstones and siliceous shales tend to have higher thermal conductivities compared to clay-rich mudstones or organic-rich shales (Fuchs et al., 2021; Robertson, 1988). Similarly, the presence of evaporite minerals like halite or anhydrite can substantially increase the thermal conductivity (Jorand et al., 2013). The thermal diffusivity, which determines the rate of heat propagation, is also affected by the rock's mineralogical makeup. Sedimentary rocks with higher quartz and feldspar content generally exhibit higher thermal diffusivities, while clay-rich rocks have lower values (Carmichael & Klein, 2024). Additionally, the anisotropy in sedimentary rocks, arising from features like bedding planes and aligned minerals, can lead to directional variations in thermal properties (Schön, 2015).

In this study, information extracted from experimental research is used to understand the implication of the natural heterogeneity of sandstones, and their petrophysical properties, thermal properties and mineralogy in geothermal reservoir simulations.

2. Materials and Methods

The approach involves examining 30 core samples that exhibit diverse thermal properties. These samples are prepared for scanning electron microscope (SEM) analysis, and detailed SEM images are obtained at a high resolution. Advanced image processing and analysis techniques are utilized to identify and measure various microstructural attributes, including grain size, pore size, and connectivity. Any significant correlations can be determined by comparing the known thermal properties of the core samples with the observed characteristics in the SEM images.

The rock samples used in this study consist of different types of sandstones obtained from formations such as Berea Sandstone, Boise Sandstone, and Kentucky Sandstone. Figure 1 illustrates the workflow and equipment employed for measuring the petrophysical properties, thermal properties, and mineralogy of the samples.

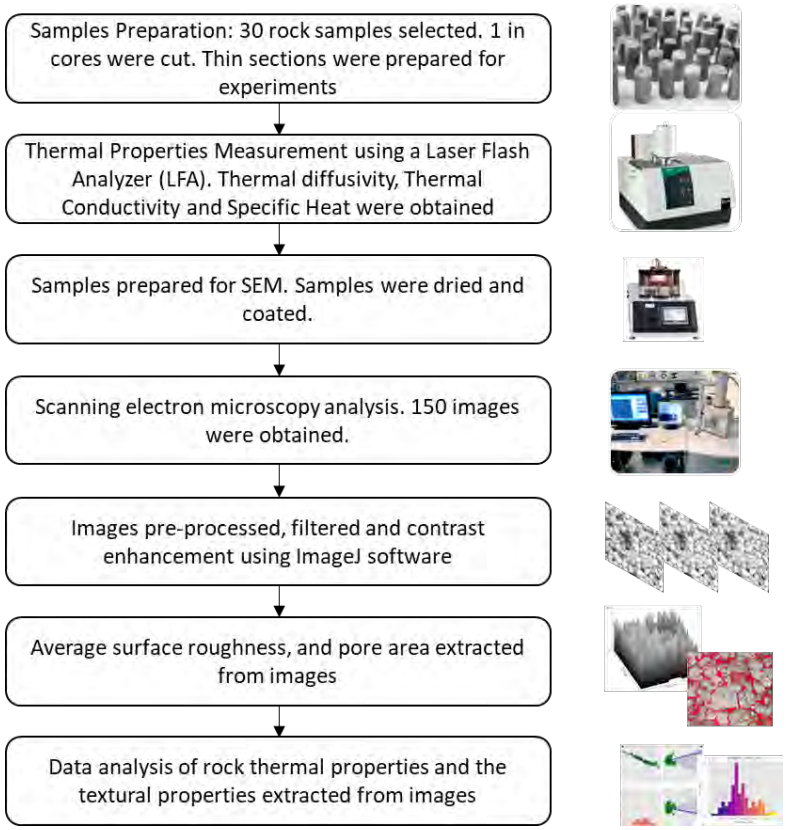

Figure 1: Experimental workflow of this study

2.1 Samples Thermal Properties

The thermal properties of the 30 sandstone samples were obtained experimentally. The thermal properties were measured using the LFA (light flash apparatus) Netzsch LFA 467. The equipment uses a short pulse of energy light to heat up the front surface of a flat sample, which is parallel to a plane. An infrared detector measures the temperature change of the back surface caused by the heat pulse. This measurement allows for the determination of thermal diffusivity and specific heat. When combined with the density of the sample, these thermophysical properties can be used to calculate thermal conductivity.

The variation of equation 3 is used to calculate the thermal conductivity:

$$\lambda = \kappa * \rho * C_P \quad (1)$$

Where λ represents thermal conductivity, κ represents thermal diffusivity, C_P represents specific heat capacity, and ρ represents the density of the samples collected in the laboratory.

2.2 Samples preparation

The 1-inch core samples were cut to expose the surfaces that are going to be analyzed by SEM. This is done to obtain more insight about sample texture. Once the samples were cut to the appropriate size, they were coated with a conductive metal layer to improve conductivity. For this study a carbon coating was applied, to prevent the buildup of electrical charges during SEM analysis. Before performing every experiment, the samples were stored in an oven at 65°C for 24 hours. The objective of this was to have the samples completely dry, prevent moisture from affecting the measurements, and have comparable results.

2.3 SEM Experimental equipment and experiment description

To quantitatively assess the morphological features of the rocks, the samples were prepared and examined using an FEI Quanta 200 Scanning Electron Microscope. A total of 150 SEM images were captured and the magnification considered was 300 times. Micrographs with magnifications of 500, 1000, and 2000, were evaluated, however, the mentioned sizes were discarded since they did not allow to capture textural details that are lost for the higher resolution.

The SEM instrument was then used to scan the surface of the cut section, producing high-resolution images of the rock's texture and structure. To extract the information required to understand how textural features affect the thermal properties of the rocks, the images were analyzed with the Fiji version of the software ImageJ. ImageJ is a widely used open-source image processing software that provides a range of tools and plugins for analyzing and quantifying various properties from SEM images. Image J has been used to analyze SEM rock images for analyzing morphological features, particle size evaluation, or porosity (Bai et al., 2013; Kelly et al., 2016; Nole et al., 2016; Tao et al., 2020; Voutilainen et al., 2019). In this study, the surface roughness and porosity were analyzed.

2.4 Image preparation

Once the SEM images were obtained, a pre-processing process helped to enhance the image features extraction process. Firstly, the images were filtered using the "Median" filter in ImageJ software. This is a type of spatial filter used to reduce noise in digital images. It works by replacing each pixel in the image with the median value of the neighboring pixels within a given radius. For this study, the radius of 2 pixels was sufficient to enhance the images. After the filter, the enhance contrast option in ImageJ software was used to automatically adjust the brightness and contrast of SEM images to improve their visibility. Initially, the color scale of the image is normalized, which scales the pixel values in the image so that the minimum value becomes 0 and the maximum value becomes 255. This ensures that the full range of values is used in the image. Then, the pixels of the images were saturated, which refers to the percentage of pixels in the image that should be saturated (set to either 0 or 255). For this study, this was set to 0.5%, which means that the brightest

and darkest 0.5% of pixels in the image were set to 255 and 0, respectively. An example of SEM preparation result is presented in **Fig. 2**.

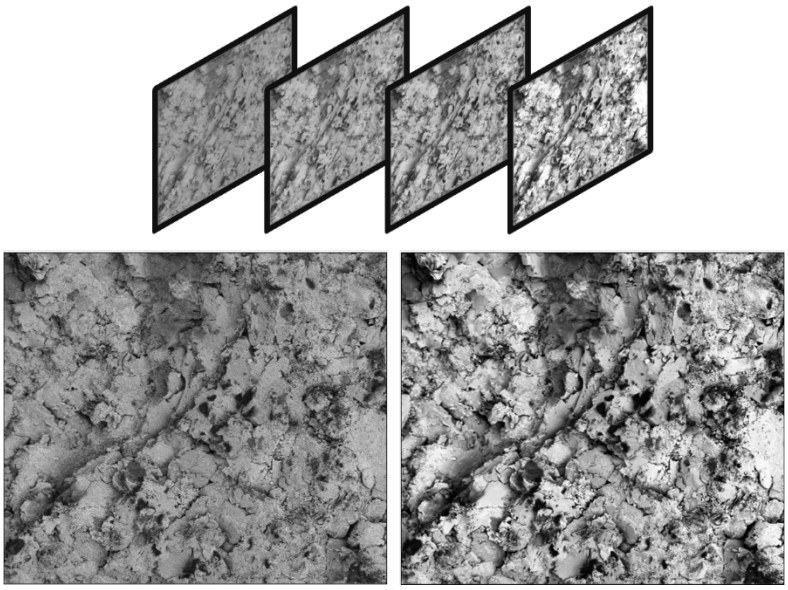

Figure 2: SEM Images, before [left], and after [rigth] pre-processing enhancement.

3. SEM Rock Images Analysis

SEM images were examined to evaluate the feasibility of using them to assess their thermal properties based on textural features. **Fig. 3** shows SEM images of 3 rock samples; they represent samples that have, from left to right, low, medium, and high values of thermal properties from the analyzed dataset.

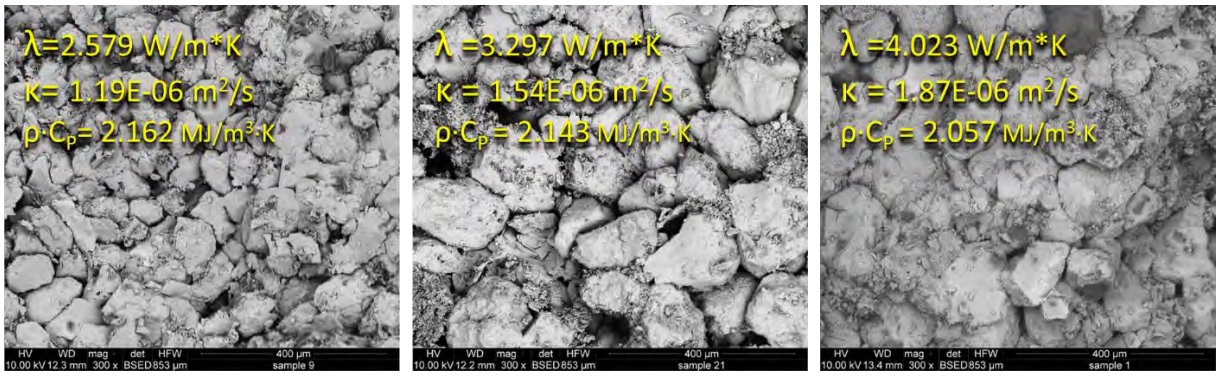

Figure 3: SEM images magnified 300X for samples with high [left] and low [right] thermal properties in the present dataset.

The SEM images showed how different grain sizes, pores and voids, and grains separation affect the rocks' thermal properties. More spaces between grains allow air pockets to form, trapping air that acts as a thermal insulator. The samples with higher porosity, and thus more air pockets, show higher thermal resistance as represented by their higher thermal properties. The software ImageJ was used to extract the morphological characteristics of the rocks.

3.1 Surface Roughness

Surface roughness analysis involves quantifying and characterizing roughness features of a surface profile using various variables obtained from SEM images. These variables play a crucial role in understanding the topographic characteristics of the surface.

In **Fig 3** it is depicted the analysis performed in all images. The average surface roughness is a measure of the height variations in the surface of a material. It is calculated by averaging the absolute values of the deviations of the surface from its mean plane. The average surface roughness is calculated by first subtracting the mean plane from the surface height data. This produces a residual height map that represents the surface roughness.

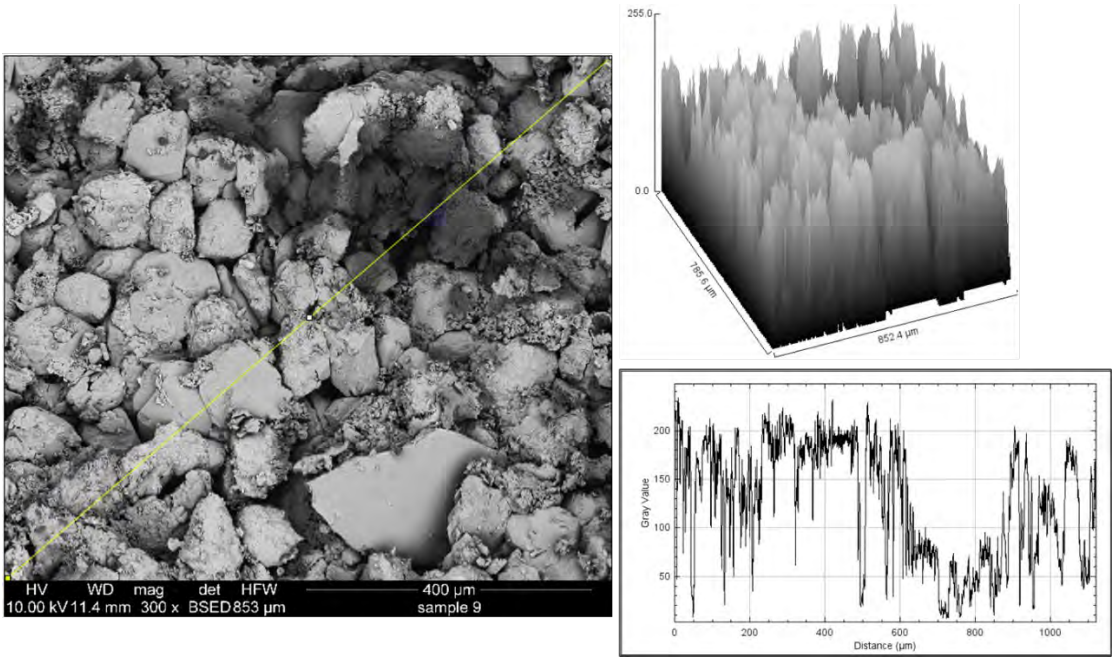

Figure 4: Surface roughness analysis of SEM rock images.

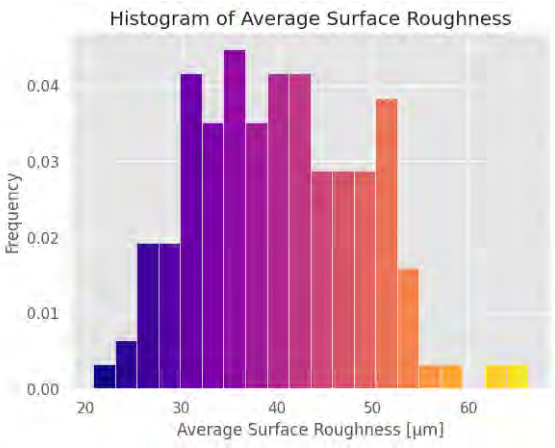

Figure 5: Histogram of the average surface roughness [Ra] values obtained.

3.2 Pore, Voids, and Cracks Area

SEM images of rocks contain complex textures and structures that make it difficult to identify and measure the areas of interest manually. By using the threshold function in ImageJ, the pores and voids in every image were identified and segmented **Fig. 6**. The threshold function in ImageJ was the tool that was used to segment the SEM image into foreground and background based on pixel intensity values. The tool was useful for separating the pores, voids, and cracks of the rock SEM images from the background. The threshold function applies the threshold to the image and generates a binary mask that separates the foreground and background pixels. The mask can then be used for measuring the area of objects in the image that represents the pores, voids, and cracks. **Fig. 7** shows the histogram of the calculated pore in μm^2.

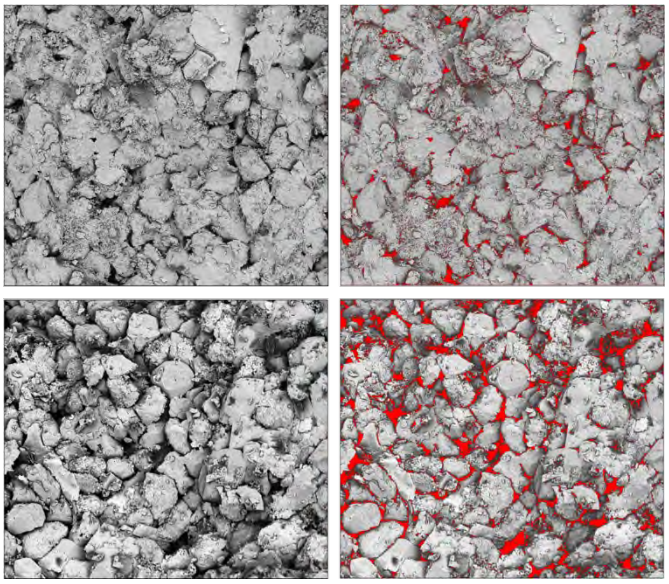

Figure 6: Pore, cracks and voids area analysis of SEM rock images.

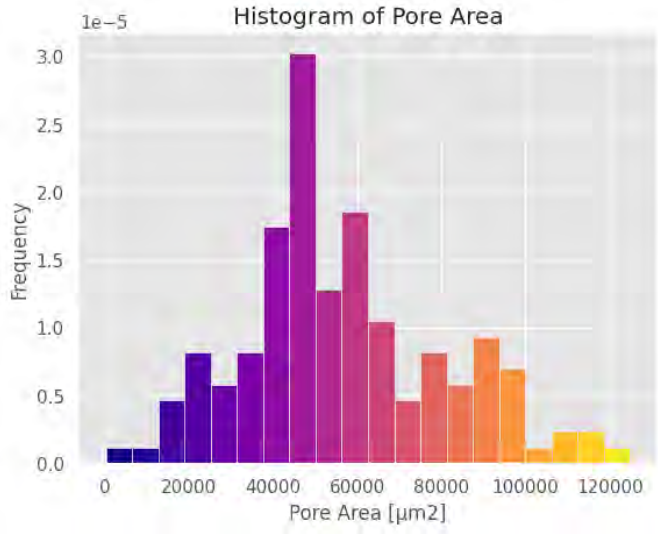

Figure 7: Histogram of pores, cracks, and voids surface area obtained.

4. Results Analysis

The analysis of textural properties in SEM images helps to understand the relationship between the morphologic characteristics of rock samples and the rock's thermal properties. In this section, the average surface roughness and the pores, cracks, and voids surface area extracted from the SEM images are compared with the thermal properties of the rock samples obtained experimentally.

4.1 Surface Roughness Analysis

Fig. 8 presents the relationship between surface roughness (Ra) and thermal properties, specifically thermal diffusivity, thermal conductivity, and volumetric heat capacity for the 150 images. The plot of thermal diffusivity against Ra exposed a trend, indicating that as the Ra values increased, the thermal diffusivity consistently decreased. This suggests that higher surface roughness impedes the efficient conduction of heat, resulting in reduced thermal diffusivity. Similarly, in the plot of thermal conductivity against Ra, as the Ra values increased, indicating greater surface roughness, the thermal conductivity showed a corresponding decrease. When examining the relationship between volumetric heat capacity and Ra, no clear correlation was observed. The plot of volumetric heat capacity against Ra displayed scattered data points, indicating that volumetric heat capacity and Ra are uncorrelated.

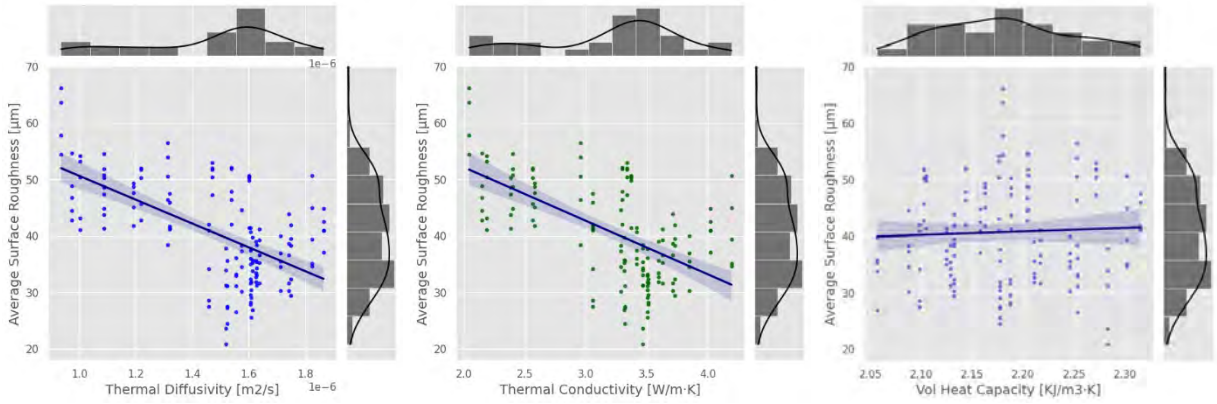

Figure 8: Arithmetic average roughness influence in thermal diffusivity [left], thermal conductivity [middle], and volumetric heat capacity [right].

The surface roughness of the rock is influenced by the grain size and distribution. A smoother surface is indicative of smaller grains that are well-sorted, possessing similar grain shapes. Smaller grains can pack tightly together, while similar grain shapes fit more harmoniously. Consequently, the result is a smoother surface. On the other hand, a rough and irregular surface indicates larger grains that are poorly sorted, with varying grain shapes. The larger grains cannot pack as tightly, and the differing shapes do not align perfectly, leading to a rough and uneven surface.

Additionally, the scale or wavelength of roughness features can provide clues about the grain size. Larger grains produce roughness features on a larger scale, while smaller grains result in smaller-scale roughness. The presence of isotropic or uniform roughness in all directions indicates well-sorted grains with similar sizes and shapes. Conversely, anisotropic roughness, where smoother and rougher areas align in different directions, signifies poorly sorted grains with variable sizes and shapes. Lastly, the texture of roughness features, ranging from smooth to jagged, can offer

insights into the interlocking of grains. Jagged and angular features indicate grains that are not well-interlocked, while smoother undulations suggest grains that are more interfit, demonstrating their interlocking nature. These observations enable a deeper understanding of the geological properties and composition of rocks based on their surface roughness characteristics.

These findings highlight the impact of surface roughness on thermal properties. Higher Ra values lead to decreased thermal diffusivity and thermal conductivity, indicating a hindered ability to conduct and transfer heat. In contrast, the volumetric heat capacity does not exhibit a significant dependence on surface roughness, as indicated by the lack of correlation between volumetric heat capacity and Ra. These findings contribute to our understanding of the intricate relationship between surface roughness and thermal properties, aiding in the design and optimization of materials for efficient heat transfer applications.

4.2 Pore Area Analysis

Fig. 9 shows the relationships between the pore area and the thermal diffusivity, thermal conductivity, and volumetric heat capacity. The plot of pore area versus thermal diffusivity indicates an inverse relationship between the two variables. This means that as the pore area increases, the thermal diffusivity of rocks decreases. Thermal diffusivity is a measure of how quickly heat is conducted through a material, and a lower thermal diffusivity means that heat takes longer to travel through the material. This relationship makes intuitive sense since pores and cracks in rocks are essentially empty spaces that do not conduct heat as well as the solid material. Therefore, as the pore area increases, the proportion of non-conductive material in the rock increases, leading to a decrease in thermal diffusivity.

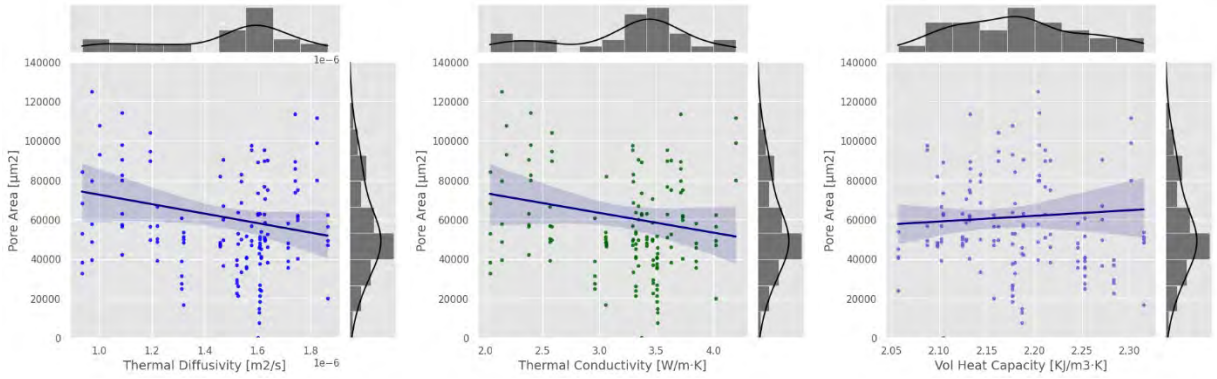

Figure 9: Pores, voids, and cracks area influence in the thermal diffusivity [left], thermal conductivity [middle], and volumetric heat capacity [right].

Similarly, the plot of pore area versus thermal conductivity also shows an inverse relationship between the two variables. This means that as the pore area increases, the thermal conductivity of rocks decreases. Thermal conductivity is a measure of how well a material conducts heat and a lower thermal conductivity means that the material is a poorer conductor of heat. This relationship is also understandable since pores and cracks in rocks act as thermal insulators, reducing the overall thermal conductivity of the rock.

The plot of pore area versus volumetric heat capacity, however, indicates that there is no correlation between the two variables. Volumetric heat capacity is a measure of how much heat a material can absorb before its temperature increases, and in this case, it seems that the presence of

pores and cracks in rocks does not have a significant effect on their volumetric heat capacity. This may be because the amount of solid material in the rock is still the primary determinant of its volumetric heat capacity.

5. SEM Results Discussion

The experimental study surface roughness of rocks can be correlated with their thermal properties. Rocks with rougher surfaces generally exhibit larger, more poorly sorted grain sizes. This leads to a reduced number of grain boundaries per unit volume and inefficient packing, ultimately decreasing the connectivity of the grain network. As a result, heat transfer through the rock becomes more challenging, resulting in lower thermal conductivity and diffusivity.

In contrast, rocks with smoother surfaces tend to have smaller, well-sorted grain sizes. The smaller grain size increases the number of grain boundaries per unit volume, and efficient sorting enables effective packing. This results in a well-connected grain network that facilitates heat transfer. Consequently, rocks with smoother surfaces exhibit higher thermal conductivity and diffusivity.

The presence of grain boundaries can scatter or impede heat transfer. Rocks with smaller, well-sorted grains have a higher density of grain boundaries, providing more opportunities for heat transfer between grains. On the other hand, rocks with fewer, larger grains possess fewer grain boundary sites, limiting heat transfer. Additionally, better packing and grain sorting in rocks minimize the presence of air spaces or pores. This reduces scattering or impedance of heat transfer since air does not conduct heat as efficiently as mineral grains. In contrast, poorer sorting and packing result in more air spaces, creating barriers to heat flow. Smooth grain shapes allow for increased surface contact between grains, enhancing heat transfer. In contrast, angular and irregular grain shapes lack sufficient surface contact, impeding the flow of heat. These insights highlight the significant influence of surface roughness and grain characteristics on the thermal properties of rocks, shedding light on their heat transfer behavior and conductivity.

Fig. 10 displays the correlation between the textural features analyzed, average surface roughness, and the pore, cracks, and voids area extracted from the SEM images, with experimentally obtained thermal properties. Average surface roughness has a strong negative correlation, -0.59 and -0.6 with thermal conductivity and thermal diffusivity respectively. In contrast, the volumetric heat capacity and the average surface roughness are uncorrelated, confirming the results presented in the previous section. The pore, cracks, and void surface area have a less apparent negative correlation, -0.18 and -0.17, related to the thermal conductivity and thermal diffusivity. The reason that the pore, cracks, and voids area values have a less apparent negative correlation with thermal conductivity and thermal diffusivity compared to the average surface roughness could be that these properties affect heat transfer differently. The negative correlation between average surface roughness and thermal conductivity/diffusivity is stronger, as the surface roughness directly affects the connectivity of the grain network and packing efficiency, which are important factors in determining thermal conductivity and diffusivity. On the other hand, the effect of voids on heat transfer is dependent on various factors, and the correlation between pore, cracks, and voids area and thermal conductivity and diffusivity may be weaker due to the complexity of the effect of voids on heat transfer. Factors such as the size, shape, and distribution of the voids affect heat transfer. If the voids are interconnected, they can provide networks for heat to flow through, which can increase the thermal conductivity and thermal diffusivity of the sandstone. Additionally, the

size and shape of the voids can affect the rate at which heat is transferred. Smaller voids, for example, can trap heat more effectively than larger voids.

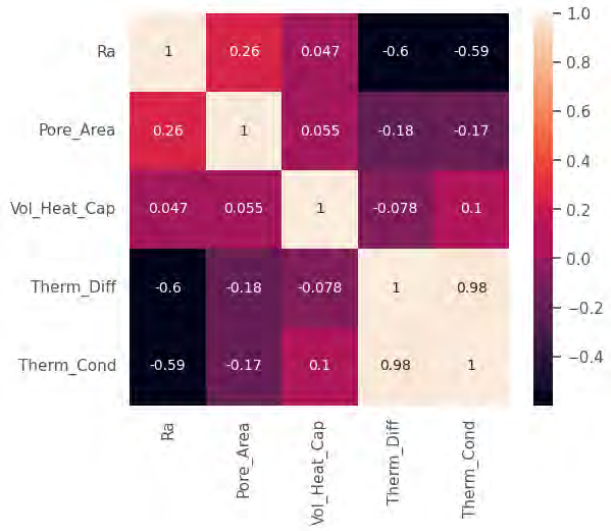

Figure 10: Heat map with the Pearson correlation between thermal properties and textural features where 'Ra' refers to average surface roughness [µm2], 'Pore_Area' refers to the pore area [µm2], 'Vol_Heat_Cap' refers to volumetric heat capacity [KJ/m3·K], 'Therm_Diff' refers to thermal diffusivity [m2/s], and 'Therm_Cond' refers to thermal conductivity [W/m·K].

The thermal properties of rocks are influenced by several factors, including their texture, mineralogy, and porosity. These characteristics can be difficult to discern through visual inspection alone, especially when looking at a two-dimensional image. SEM provides high-resolution, detailed images of the rock's surface, allowing for a more accurate analysis of its texture and other characteristics that can impact its thermal properties.

6. Conclusions

The study aimed to analyze the porosity, permeability, density, and thermal properties of core samples and their correlation with mineral content. In this study, we present the results of the analysis of SEM images obtained from rock samples to investigate various surface roughness properties. The objective was to quantitatively evaluate and characterize the roughness features of the rock surfaces. By utilizing these parameters, we aimed to gain insights into the micro-structural defects, crack types, and other surface characteristics that impact the thermal properties of sedimentary rocks. The analysis of these properties provides valuable information for optimizing the selection of rocks for geothermal energy systems and thermal energy storage applications.

The thermal properties of rocks are affected by their texture, mineralogy, and porosity, which can be difficult to discern through visual inspection alone. The use of SEM images allows for a more accurate analysis of these characteristics, providing insights into the micro-structural defects, crack types, and other surface characteristics that impact the thermal properties of sedimentary rocks. The study found that surface roughness plays a significant role in determining the thermal conductivity and diffusivity of rocks, with smoother surfaces exhibiting higher thermal conductivity and diffusivity. The correlation between pore, cracks, and voids area and thermal conductivity, and diffusivity was found to be weaker than that of surface roughness, likely due to

the complexity of the effect of voids on heat transfer. The findings of this study provide valuable information for optimizing the selection of rocks for geothermal energy systems and thermal energy storage applications. parallel maximum stress to minimize short circuiting in the reservoir

Unlocking the Full Production Potential of Geothermal Wells in Indonesia using a Novel In-situ Generated Acid Fluid Technology

Ahmed S. Zakaria, Baker Hughes

Keywords

Geothermal, Non-Corrosive Acid, Stimulation, HSE

ABSTRACT

Global demand continues to grow for a clean and renewable energy source for electricity generation. Geothermal power has the potential to contribute significantly to the global energy mix. However, most of geothermal wells produce below their potential because of the scales deposited around wellbore tubulars or the formation damage that occurs because of drilling fluid invasion, silica plugging, scales deposition in the natural fractures, and fines migration. To restore productivity from geothermal wells, it is often necessary to perform matrix acid stimulation. However, acid treatment fluids under the extremely high temperature environment of geothermal wells are very corrosive to the wellbore tubulars/downhole equipment and spends near-wellbore. This paper presents the next generation acid system that utilizes environmentally friendly non-corrosive fluids to generate acid in situ in the formation for geothermal matrix stimulation.

The non-corrosive deep-penetrating acid is a neutral, non-reactive treatment fluid at the surface and only when it is injected in the formation, it generates acid at a controlled rate in situ under temperature and time. The in-situ generation of acid at a controlled rate allows for safe transport of the acid from the surface to the formation without exposing wellbore tubulars to an acidic fluid and also allows for deep penetration to dissolve deposited materials or scales in the porous formation or along the fractures. A series of solubility testing in HPHT reactor at temperatures above 450°F was first conducted to understand the chemical reactions that generate the acid as a function of temperature, concentration of acid generating components, and time, and to identify the optimum composition that maximize the dissolving of silica and calcite minerals. Coreflow testing was then conducted at 300°F and 475°F using 1.5” in diameter and 6” in diameter Berea sandstone cores to evaluate the penetration of the acid and its capability to provide remarkable permeability improvement.

This paper discusses the laboratory testing results, guidelines for the design of the treatment fluid, and its application in the field to restore the productivity of geothermal wells. The present study explains how the use of the new fluid technology will help to eliminate the need for acid tanks on site, reduce transportation difficulties and logistics, and eliminates HSE concerns associated with acids handling on geothermal sites.

1. Introduction

The potential of many geothermal wells is limited by scales deposition and/or formation damage incurred due to drilling fluid invasion, fines migration, silica plugging, and scaling. To restore productivity from geothermal wells, conventional matrix acid treatments are needed. However, matrix acid treatments for geothermal wells impose many challenges.

Matrix stimulation would involve injecting acid into the formation to remove damaged regions near the wellbore resulting from hydrothermal minerals deposited in fractures and/or the creation of larger aperture fractures via the dissolution of rock forming minerals instead of shear dilation (Portier et al., 2009). At the very high temperature conditions of geothermal wells, acidic fluid would be very corrosive to wellbore tubulars and downhole equipment's. Corrosion can result in a series of undesirable reaction products, which can cause plugging in the formation as iron sulfides, etc. It is very difficult to inhibit acid corrosion as it adds a prohibitive cost of corrosion package to the treatment. Another alternative is to use large water cooldown pads in order to reduce temperature, preferably to the 200 ^{o}F range, where corrosion inhibition can easily last for the duration of the acid treatment. However, this alternative requires sourcing large volumes of water and adds costs related to transposition and logistics.

Another challenge with the matrix acid treatments under high temperature conditions is the rapid reactions of the acid with the rock forming minerals that lead to significant secondary and tertiary precipitations. Furthermore, the acid wouldn't be able to penetrate deep enough to dissolve minerals over long distances or scales along the fractures. The acid reacts with the rock forming minerals throughout three-stage reactions to produce some insoluble precipitates as shown in the following reaction equations.

$$\text{The primary reaction} \qquad \text{aluminosilicates} + HF \rightarrow H_2SiF_6 + 2H_2O$$

Then the produced fluosilicic acid reacts with different aluminosilicates such as potassium feldspars throughout a secondary reaction as follows

$$\text{the secondary reaction}$$
$$SiF_6^{2-} + 6KAlSi_8O_8 + 20H^+ + 10H_2O \rightarrow 6K^+ + 6AlF^{2+} + 18H_2SiO_3 + H_4SiO_4$$

After that, the ratio of fluorine (F)/aluminum (Al) continues to decrease in the aluminum fluoride compounds because of their reaction with aluminosilicate compounds in the presence of HCl. This reaction chelates the aluminum ions from the aluminosilicates leaving silica gel as a precipitate as following

$$\text{The tertiary reaction} \qquad AlF_2^+ + KAlSi_3O_8 + 4H^+ + 4H_2O \rightarrow K^+ + 2AlF^{2+} + 3H_4SiO_4$$

To improve geothermal well stimulation and overcome issues related to corrosion, precipitations, and deep stimulation, a new fluid system has been developed. The new fluid system is neutral (pH around 7) at the surface conditions and only when it is pumped in the formation and under temperature, the fluid system self-generates an acid to dissolve the scales or for formation stimulation. Use of this new fluid system would allow pumping a safe and non-corrosive fluid to the wellbore tubulars, save the prohibitive cost of the corrosion inhibitors needed to inhibit the acid at the very high temperature conditions, and save thousands of gallons of water volumes needed for geothermal wells cooling. The new fluid system is also non-reactive when it is injected

into the formation which would allow for deep stimulation or dissolving scales at long distances before it self-generates acid. In the subsequent sections, the capability of the new fluid system to dissolve different minerals and its stimulation performance at different temperature conditions will be discussed.

2. Experimental Studies

2.1 Solubility Testing

The capability of the new fluid system to dissolve different minerals was assessed in a HPHT reactor cell. Different rock/scales forming minerals were placed in the HPHT reactor cell and heated to a predetermined temperature of 450°F under a pressure exerted by nitrogen gas of 800 psi. The new acid system was also preheated to the same temperature and then transferred to the HPHT reactor to allow for the reaction between the rock and the acid. After the test is completed, the mineral was collected, dried and weighed to identify the dissolution ratio. Fluid samples were also collected from the reactor at specific time intervals and analyzed using ICP-spectroscopy to measure different ions concentration.

2.2 pH Measurements

The new fluid system is neutral (pH is around 7) at the surface conditions and only when it is pumped and under temperature, it self-generates acid for stimulation and scale dissolution. pH measurements were conducted on the fluid system at 75°F at specific time intervals up to 48 hrs to ensure that no acid is being generated at the surface conditions. The fluid system was then heated in a HPHT cell to 450°F and pH measurements were conducted at specific time intervals for up to 4 hours to monitor the acid generation with time.

2.2 Coreflow Experiments

Coreflow experiments were conducted using a high-pressure/high-temperature coreflow setup shown in **Figure 1**. A backpressure of 1,200 psi was set to keep most of the carbon dioxide in solution. An overburden pressure at least 300 psi higher than the inlet pressure was kept while running the experiments to prevent the fluid from bypassing the core. Berea Sandstone plug samples of 1.5” in diameter and 6” in length were used in the coreflow experiments. The plug samples mineralogy is presented in **Table 1**. Berea plug samples were selected since the core samples contain different mineralogies including silica, clays, and calcite. The brine permeability of the plug samples was measured using 5 wt% NH_4Cl and ranged from 10 md to 300 md. In each test, the brine permeability of the plug sample was first measured, followed by predetermined pore volumes of an acid preflush. Then a predetermined pore volumes of main acid treatment was then injected at 2 ml/min. A stage of postflush acid was lastly injected before the regain permeability measurements were conducted using 5 wt% NH_4Cl to assess the stimulation or if any damage is occurred.

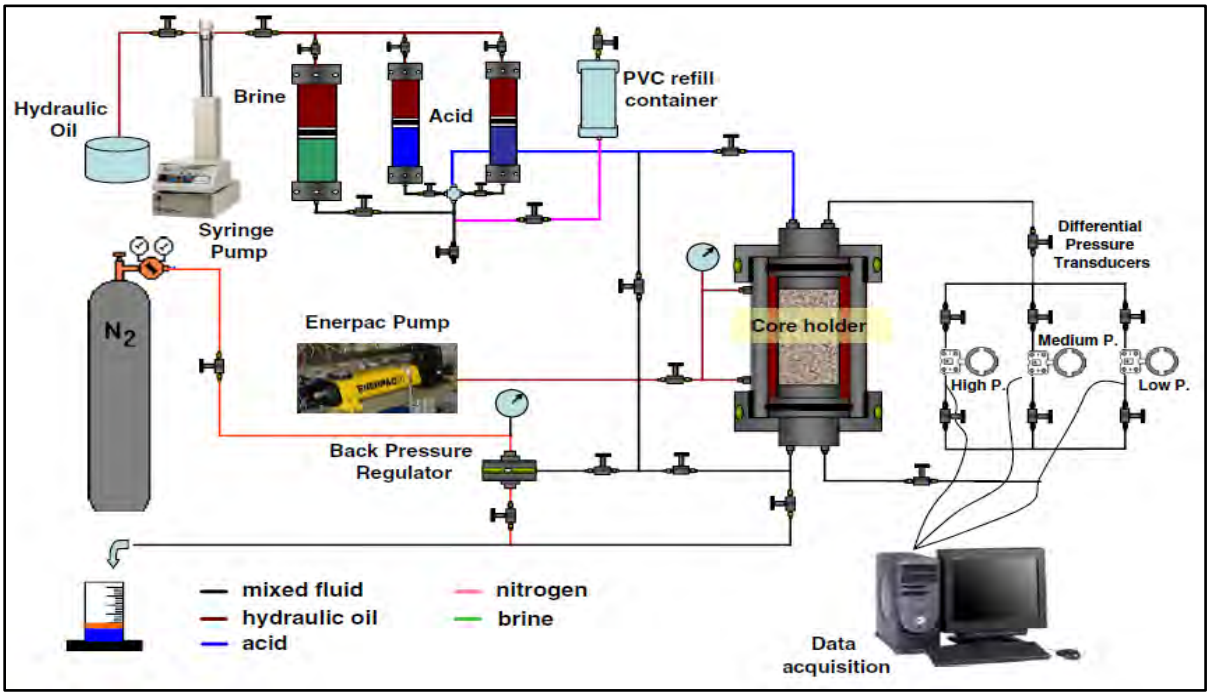

Figure 1: A Schematic of high-pressure/high-temperature coreflow setup

Table 1. Mineralogy of Berea sandstone plug samples.

Mineral	Content (wt%)
Quartz	87
Kaolinite	6
Potassium Feldspar	2
Chlorite	1
Illite	1
Calcite	2
Dolomite	1

3. Results and Discussion

3.1 Solubility Testing

To assess the capability of the new acid to dissolve calcite, a known weight of calcite mineral was allowed to react with 100 mls of the new acid in the HPHT reactor at 450°F for 3 hours. The calcite mineral was collected, dried, and post-reaction weight was measured to identify the calcite dissolution in the new acid. The composition of the new acid was adjusted to generate 5 wt% HCl. The new acid dissolved 51.23% that was similar to the dissolution of calcite in 5 wt% HCl (54.2%)

under same conditions. Increasing the concentration of the components of the new acid by 1.5 increased the generated acid strength to 7.5 wt%.

The composition of the new acid could also be adjusted to generate mud acid of any HF acid strength. Silica particles were placed in the HPHT reactor and allowed to react with the new acid at 450°F to assess the capability of the system to dissolve quartz. After 5 hours of reaction, fluid sample was collected and analyzed by ICP-Spectroscopy to measure Si+ ion concentration. The Si+ ion concentration was 5310 mg/l which is equal to the measured Si+ ion concentration for 1.5 wt% HF mud acid (5010 mg/l). Increasing the concentration of the components of the new acid by 2 dissolved 10,945 mg/l which was very similar to the one measured for 3 wt% HF mud acid (10,221 mg/l). The results showed that the new fluid system can generate HF acid at 1.5 wt% and 3 wt% acid strengths with similar dissolving power.

3.2 Corrosion and pH Measurements

The corrosivity of the fluid is determined primarily by its pH. Fluids with pH from 6.5 to 7.5 is generally considered non-corrosive. Fluids with pH less than 6.5 are considered acidic and corrosive while fluids with pH more than 7.5 are considered alkaline and corrosive. The new acid composition that is designed to generate 5 wt% HCl, was tested for pH changes at different temperatures with time. As shown in **Table 2**, the new acid system was neutral (pH around 7) for the tested time period of 48 hours at surface temperature. This would eliminate the need for acid tanks and all HSE concerns when handling acids on site and allow for easier and safer operations. As shown in **Figure 2**, at a temperature of 450°F, the new fluid system was neutral (pH around 7) for 3 hours and after 3 hours, the fluid system self-generated 5 wt% HCl acid and pH dropped to zero. Pumping the new fluid system in a neutral state would provide a non-corrosive and safe fluid to the wellbore tubulars and downhole equipment's as ESP, etc. and save the prohibitive cost of the corrosion inhibitors needed to inhibit the acid at those very high temperature conditions and for geothermal applications. Only when the fluid system is placed in the formation and under the effect of temperature and time, the fluid system self-generates acid to dissolves calcite and silica scales or for formation stimulation. It is worthy to mention that the triggering time could be controlled to allow for enough pumping time and placement of the new acid system into the formation before an in-situ acid is generated.

Table 2. pH measurements of the new fluid system at surface conditions (75°F).

Time	**4 hrs**	**8 hrs**	**16 hrs**	**20 hrs**	**32 hrs**	**48 hrs**
pH	6.82	7.02	7.15	6.80	6.92	7.05

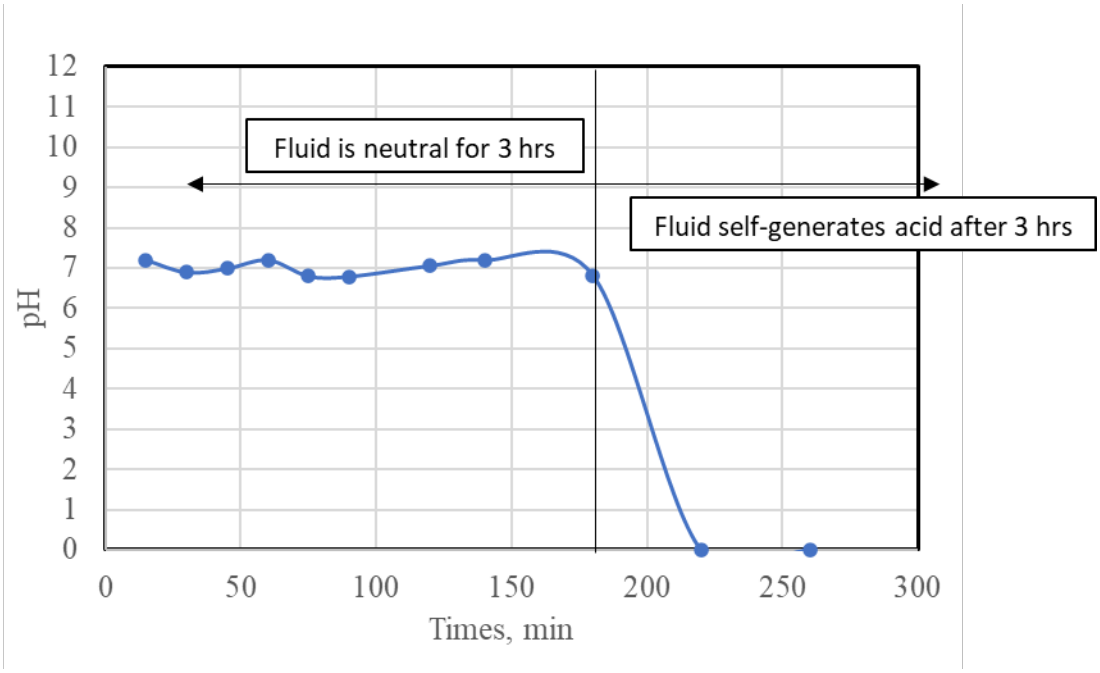

Figure 2: pH measurements of the fluid system during 4 hrs time period at a temperature of 450°F. Fluid system was neutral during the first 3 hrs. Under temperature and time, fluid system self-generated acid after 3 hrs and pH dropped to zero.

3.3 Stimulation Assessment

One coreflow test was first conducted to create a control test to assess the dissolving of silica, clays, and calcites in Berea cores using regular mud acid at very high temperature of 475°F **(Figure 3)**. A 5 wt% NH_4Cl was first injected through the core sample at different flow rates and the corresponding pressure drops were measured. Those pressure drops were used to determine the initial brine permeability. The initial brine permeability was 18 md. A preflush of 4 pore volumes of 10 wt% HCl was then injected followed by 12 pore volumes of 1.5 wt% HF regular mud acid. Then, a postflush stage of 4 pore volumes of 10 wt% HCl was injected before final brine permeability measurements were conducted. All acid stages were injected at 2 ml/min. The final brine permeability after acid treatment was 4.7 md with a regain permeability of 26%. The damage resulted from acid treatment is contributed to the rapid reaction of the regular mud acid with the clays and the precipitations occurred during the secondary/tertiary reactions at these very high temperature conditions.

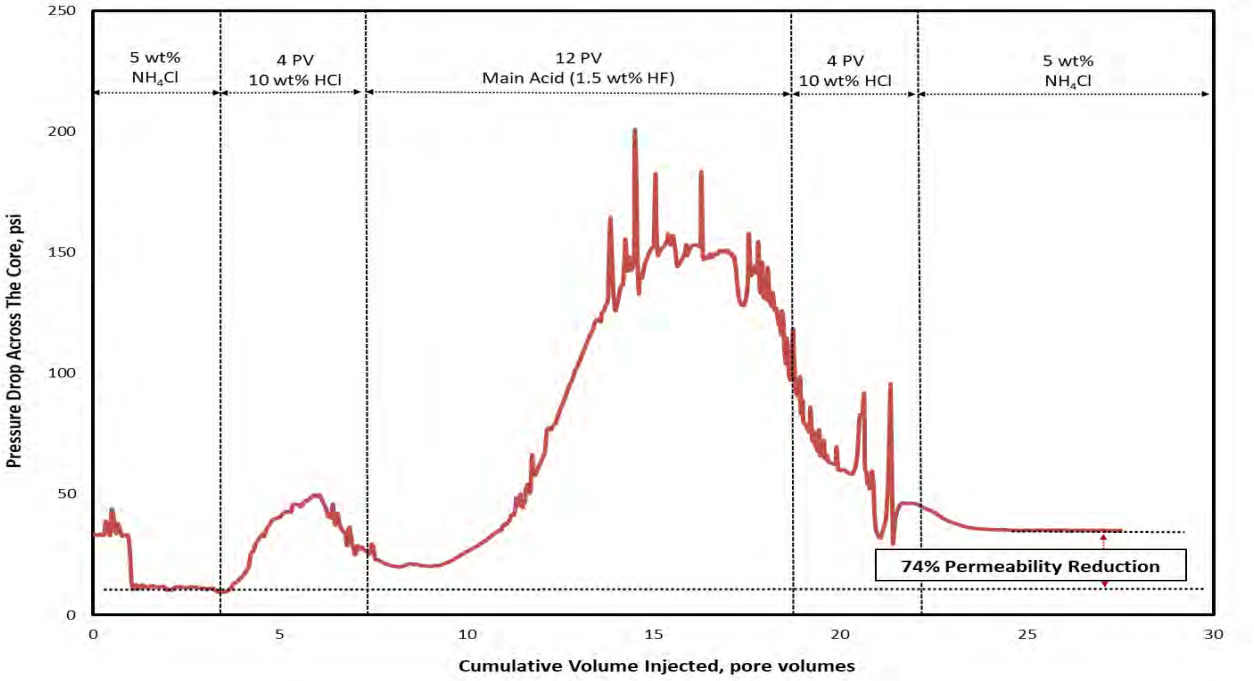

Figure 3: Pressure drop across the plug sample as a function of cumulative pore volume injected. The plug sample was treated with 10 wt% HCl + regular 1.5 wt% HF mud acid + 10 wt% HCl. The test was performed at 475°F and a flow rate of 2 ml/min.

In the second coreflow test **(Figure 4)**, the new non-corrosive deep-penetrating acid was evaluated to stimulate Berea sandstone cores and dissolve different minerals content (calcite, silica, and clays) in those cores at the very high temperature conditions of 475°F. The new acid is a neutral, non-reactive fluid at the surface temperature and when it is injected into the core, the high temperature triggers the in-situ generation of the acid. After the initial brine permeability measurements, a preflush of the new acid of 6 pore volumes was first injected to dissolve calcite content of Berea core. 10 pore volumes of the new acid for the main stage was then injected followed by 6 pore volumes of postflush of the new acid. The new acid composition was designed to generate 10 wt% HCl acid for preflush and postflush stages, and 1.5 wt% HF mud acid for the main stage. Final brine permeability measurements showed 166.7% regain permeability which indicates a remarkable permeability improvement at 475°F and the ability of the new in-situ generated acid to dissolve calcite, clays, and silica. Flow of the new fluid system in a neutral state in the formation before the temperature triggers the in-situ generation of the acid allowed for deeper penetration, uniform dissolution across the penetration depth, and significantly less precipitations from acid/rock reactions. In traditional mud acid, rapid reactions with the various rock mineralogical components, because of the high temperature, leads to significant secondary and tertiary precipitations.

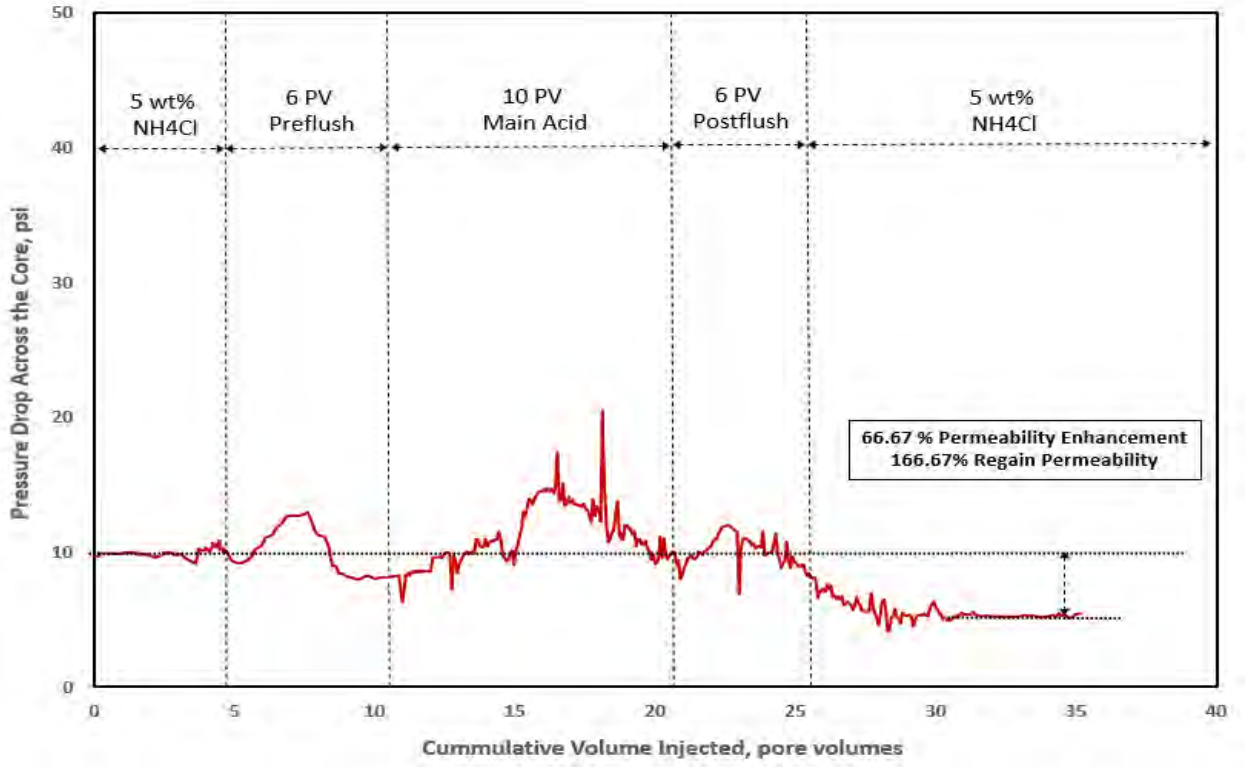

Figure 4: Pressure drop across the plug sample as a function of cumulative pore volume injected. The plug sample was treated with in-situ generated acid. The test was performed at 475°F and a flow rate of 2 ml/min.

In geothermal applications, large stage of water may be injected before acid treatment for cooling. A third coreflow test **(Figure 5)** was then conducted to assess the stimulation efficiency of the new acid at lower temperatures since the in-situ generation of the acid is triggered by temperature. The coreflow test was conducted at a temperature of 300°F. The initial brine permeability is 225 md. After the acid treatment, the permeability increased to 346 md with a regain permeability of 152%. The results showed that the acid was able to significantly improve the permeability which indicates the dissolution of carbonates, clays, and silica.

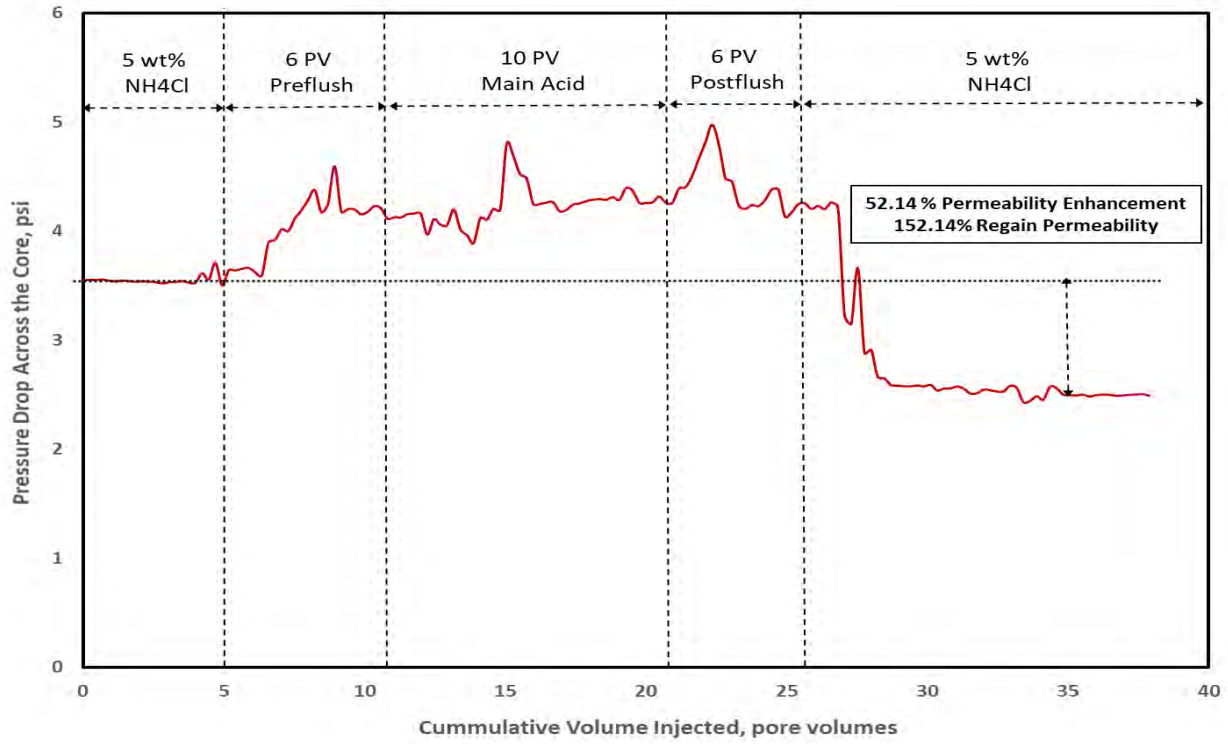

Figure 5: Pressure drop across the plug sample as a function of cumulative pore volume injected. The plug sample was treated with in-situ generated acid. The test was performed at 300°F and a flow rate of 2 ml/min.

4. Conclusions

1. A new non-corrosive, in-situ generated, and deep penetrating acid system has been developed to improve the matrix stimulation for geothermal wells.

2. The solubility testing showed that the new fluid system can self-generate in-situ HCl acid for calcite dissolution and HF acid at any strength for silica dissolution

3. pH measurements showed that the new fluid system is neutral (pH around 7) at the surface conditions and under temperature and with time, it self-generates in-situ HCl or HF acids.

4. The new fluid system was able to significantly improve the permeability and stimulate Berea cores at very high temperature of 475°F as indicated by the coreflow testing.

5. The use of the new fluid system would eliminate the need for acid tanks, and all HSE concerns related to handling acids on site. It also provides safe and non-corrosive fluid for the wellbore tubulars and downhole equipment's

Super-Hot Geothermal

An Integrated Asset Management Model for Superhot Rock Enhanced Geothermal Systems

Greg Asher and Sriram Vasantharajan

Mazama Energy, Inc., Seattle, WA

Keywords

Superhot Rock (SHR), Enhanced Geothermal Systems (EGS), Engineered Rock Volume (ERV), Supercritical Water, Thermal Lattice, Newberry Volcano, Injection, Production, Power Plant

ABSTRACT

The vision is to build a new clean energy industry to catalyze energy transition globally by creating Enhanced Geothermal Systems (EGS) to harvest heat from Super-Hot Rock (SHR) resources (rocks above 375 °C). The goal is to generate terawatt-scale, carbon-free power from such unconventional resources that will be globally accessible, secure, and cost less than $45 per MWh. Two critical technology areas of focus to achieve sustained power generation from SHR-EGS developments are:

- High integrity well construction: design of reliable, long-life injection and production wells for hostile SHR environments.
- Creation of a thermal lattice: a novel stimulation process to create high-rate pathways that maximize contacted rock volume in SHR. Flow from injection well to production well will be primarily through this Engineered Rock Volume (ERV).

Our internal discussions on how to guide our development of the wells and the thermal lattice led to adopting the use of models. Commercial geothermal models were judged to be not fully applicable for the conditions of the planned implementation. Through an evolutionary process we internally developed an Integrated Asset Management (IAM) model for the full system cycle of injection wells, heat harvesting from the ERV, production wells, and electrical generation. This model, coupled with economic evaluation, has advanced the project well design, stimulation treatment, and operational strategy. It has given greater understanding to unconventional heat harvesting, and it is an enabler towards the goal of cost effective power generation.

The model is based on fundamental physics of heat and mass transfer that includes conduction, convection, and advection for heat harvesting from SHR geothermal wells. It is a transient pressure and enthalpy balance solved as a finite element model with dynamic cells. Water transports through the cells a) down injection wells, b) through the thermal lattice, c) up production

wells, d) through steam turbines for electrical generation, and e) finally, recycled back to the injection wells. The integrated framework solves the entire system to best meet a specified, electrical power target.

A SHR-EGS model must address the operational challenge above 375 °C when water becomes supercritical and its thermophysical properties change dramatically. These supercritical changes affect the production well pressure-temperature characteristics differently compared to conventional geothermal wells. These changes also affect the flow in the wells and in the thermal lattice and guide the needs of the wells and the stimulation treatments to create the reservoir. Finally, an important benefit is that supercritical water has a much higher enthalpy capacity than at conventional temperatures. Therefore, SHR-EGS considerably reduces water requirements while yielding well power capacities substantially beyond conventional EGS.

The goal is reliably assessing and resolving the challenges of SHR-EGS, and it is about addressing the issues need that to be addressed, and that haven't been addressed, in unconventional heat harvesting. A model must be living and learning that will evolve based on data and findings from the field.

1. Introduction

Super-Hot Rock (SHR) is a unique challenge, well beyond conventional geothermal. Our mission is to make the technological and engineering advances to make SHR-EGS reliable and economic, and, as a guide to make these advances, developed an Integrated Asset Management (IAM) model. The model combines an injection well, engineering pathways in the rock, production wells, and a power plant. The goal for this model is to guide business decisions that define a successful economic path forward.

Key requirements for representing the SHR-EGS characteristics are:

1. SHR needs rigorous supercritical water handling because rules-of-thumb from conventional geothermal can lead to erroneous results. Thermophysical properties of water are calculated using the National Institute of Standards and Technology (NIST) Steam (US National Institute of Standards and Technology, 2022) which is built on work of the Internation Association for Properties of Water and Steam (IAPWS).
2. SHR heat harvesting requires an Engineered Rock Volume (ERV) that is economic. Assumptions of negligible decline over decades of harvest are incorrect with an economic ERV. Heat recovery, from this volume via engineered high-rate pathways, is unconventional and will decline significantly faster than conventional geothermal.
3. The injection and production wells influence overall efficiency. The injection well profile will be conventional whereas the production well profile will have water flow as liquid, steam, and/or supercritical that has declining heat recovery and water quality.
4. Power generation should have constant electrical power delivery rather than constant heat delivery. Produced water quality will decline over time, and this will cause a decline in turbine efficiency. This will require managing the water injection rate to have constant power generation.

We reviewed the available literature on geothermal models, and, while we found representations that matched our objectives in part, no model matched our goals in whole.

1.1 Significance of Supercritical Water

SHR heat harvesting occurs at temperatures above the supercritical point of water. Assumptions valid for conventional geothermal can be incorrect for superhot rock. For example, in conventional geothermal, researchers assume that water temperature at the producer wellhead is the rock temperature. It is wrong to extend this assumption and thereby claim that 400 °C rock will produce 400 °C water at the wellhead. Figure 1 shows the pressure temperature response of an ideal production well (fully insulated, adiabatic, and no frictional pressure losses) from bottomhole conditions at Newberry for reservoirs at 200 °C and 400 °C (calculated using NIST STEAM). Note that at 200 °C the temperature at the surface can be the temperature of the rock, but at 400 °C the temperature at surface is 338 °C. For SHR, the temperature at the surface will be less than the rock temperature, because, as the water rises in the production well, the pressure falls causing the temperature to fall per the thermophysical properties of water.

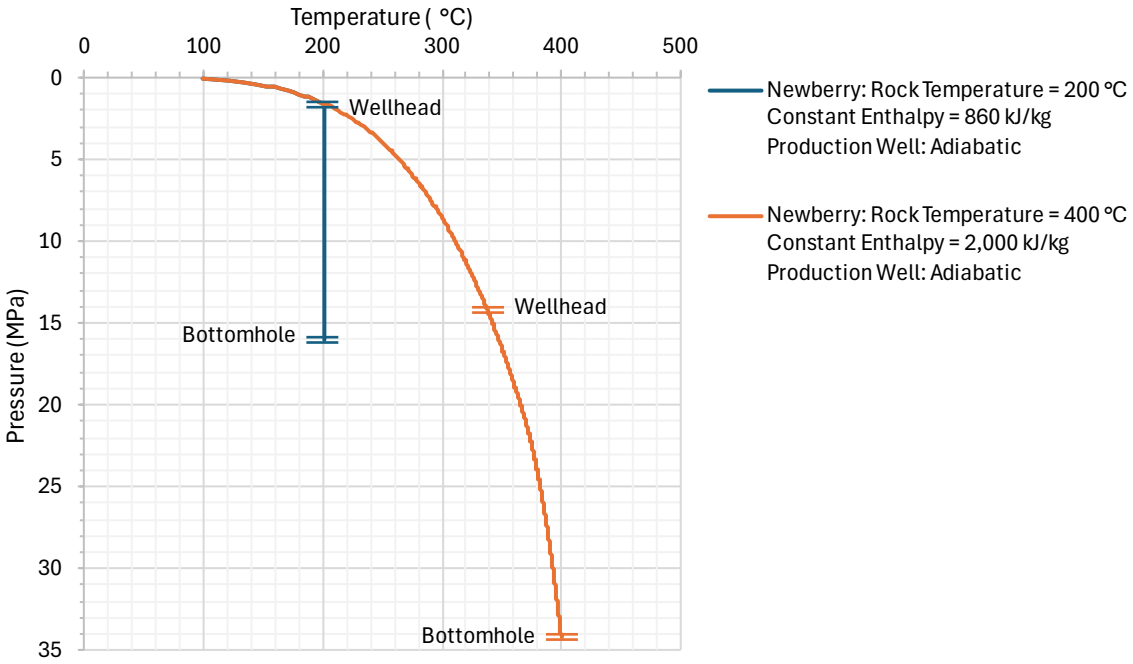

Figure 1: Isenthalpic Expansion of Water by NIST STEAM at Newberry Production Well Conditions

The behavior of water properties at SHR temperatures and pressures is critical. Figure 2 shows the calculated water relative enthalpy, thermal conductivity, product of density and heat capacity, and kinematic viscosity at bottomhole temperatures and pressures for Newberry. This figure shows:

- Water enthalpy at 400 °C is about twice that at 200 °C. Superhot water can carry more heat. But there is no discontinuity in the enthalpy that can occur at constant pressure, because, as the rock temperatures increase with depth, so does the harvest pressure increase with depth.
- Water thermal conductivity at 400 °C is about half that at 200 °C. This is not an issue for harvesting because it is still more than two orders of magnitude greater than the thermal conductivity of rock.

- At conventional temperatures, the product of density and specific heat capacity, ρCp, is constant but not at SHR temperatures. SHR requires variable water thermophysical property modeling.
- The kinematic viscosity, μ/ρ, declines up to supercritical temperatures and then increases. Reynolds number is inversely proportional to kinematic viscosity, and thus, important to maintaining laminar flow in the fractures. Turbulent flow in the fractures yields excessive frictional pressure losses that cause excessive injection pressure requirements causing a parasitic loss of the power generated.

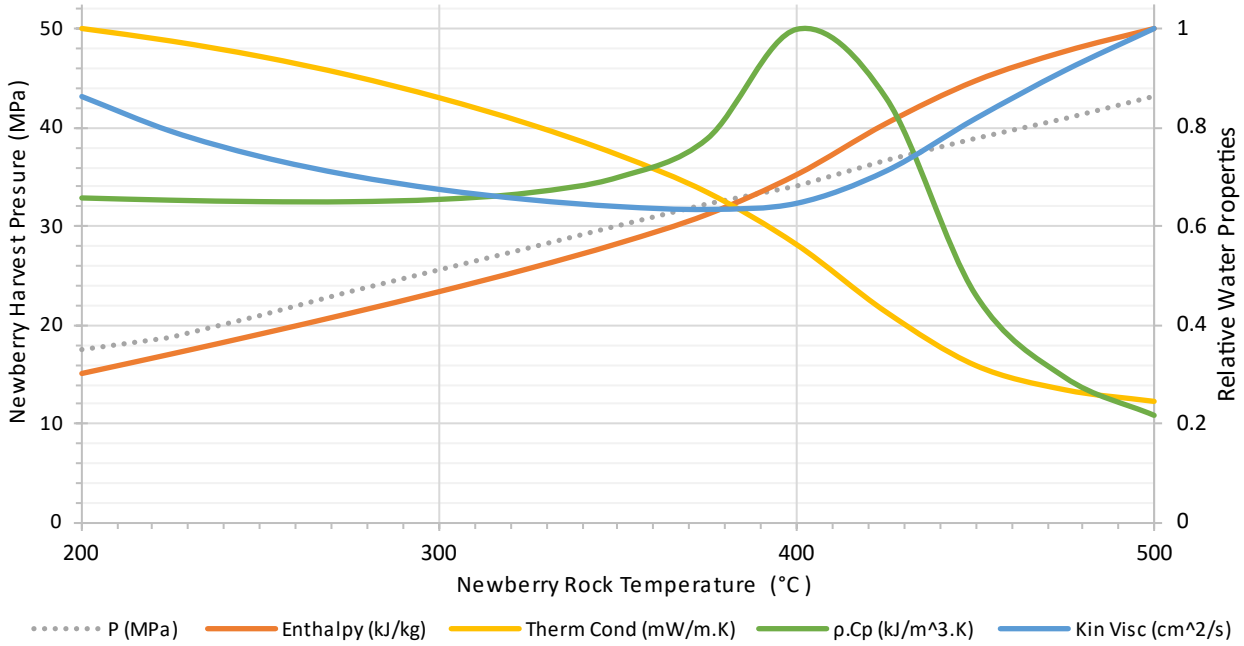

Figure 2: Water Property Behavior at Harvest Conditions for Newberry

1.2 Significance of Engineered Rock Volume (ERV)

Our SHR-EGS pilot targets igneous rock created by the Newberry Volcano in Oregon. In general, there is no heat harvest in SHR without an ERV, and the challenge is how to create an economic volume. Recently, the EGS industry has made significant advances. Fervo's pilot (Norbeck, 2023) produced approximately 50 kg/s at 160 °C, and Forge's pilot (Jacobs, 23 May 2024) produced approximately 40 kg/s at 140 °C. EGS is in progress at lower temperatures, while the challenge of superhot rock remains.

Our pilot plan is ~400 °C. Tensile and shear fracturing will form a thermal lattice of to-be-determined architecture. The heat will be harvested via this reservoir that connects from the injector to the producer. Without a connection, natural fractures activated by the shear fracturing are dead ends that will not contribute to the harvest.

Our ERV, currently, represents the thermal lattice as a tensile planer fracture with multiple, natural, planer fractures. The fractures can be of varying height, length, width, and conductivity, and these fractures are separated by homogeneous and isotropic, impermeable rock. This model is akin to

the concept presented by (Gringarten, 1975) which was an analytical model for an infinite series of identical fractures. The Gringarten representation was a pressure temperature model, with constant volume flow, pressure high enough to hold liquid state, constant product of density and heat capacity, and infinite conductivity fractures. Significant was the statement:

> *"Develop an adequate fracture surface to be used for heat transfer purposes. Because of the low thermal conductivity of rock, a very large heat transfer area must be provided; otherwise, meaningful amounts of energy cannot be extracted at practical rates."* (Gringarten, 1975)

The question becomes how large is large enough? Figure 3 shows "Fig. 6" from Gringarten where 10 fractures have a quite stable heat recovery for rock at 300 °C. Note that this was for 1-km2 fractures for a total fracture face area of 10 * 1000 * 1000 = 10,000,000 m2. Assuming a fracture this size could be pumped and propped, a 3 mm fracture width at a proppant density of 2 g/cc requires 60,000 metric tonnes of proppant. A SHR capable proppant could be ~$600 per metric tonne costing ~$36,000,000. The total upfront SHR fracture treatment costs would be significantly greater, and it would be economically prohibitive to create an ERV that declines a minimal percent per year for decades. An economic ERV is smaller to avoid excessive up-front capital, and this will lead to more rapidly declining thermal recovery.

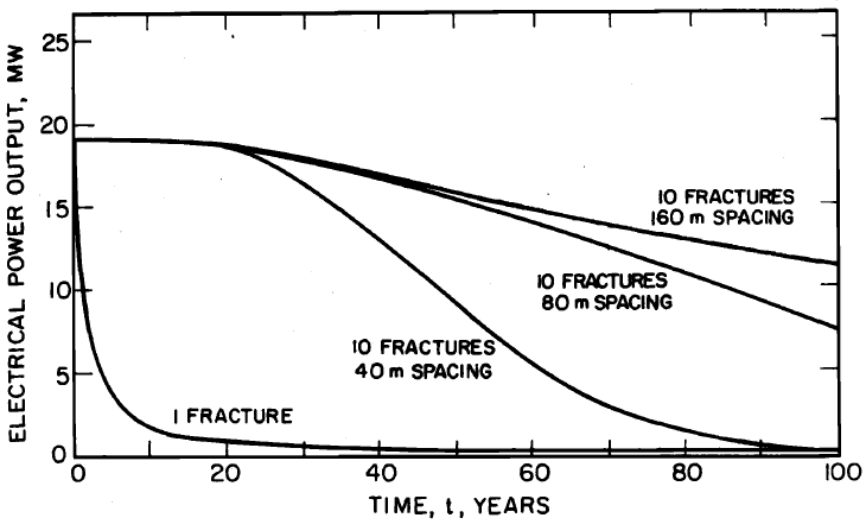

Fig. 6. Electrical power output from 1-km² fractures.

Figure 3: Gringarten Fig. 6. Electrical Power Output from Rock at 300 °C with 1-km2 Fractures

1.3 Significance of Well Models

A SHR asset will have water injection wells and production wells, and the flow regime within each type of well can be different. A single injection well can have a production well for each wing of the fracture. Injection well profiles vary with injection rates but will not experience supercritical conditions during injection. Production well profiles will initially have supercritical flow that diminishes in time as the ERV cools. Details for these well types are:

- Injection well: The control factors for heat recovery are the wellhead injection mass rate, pressure, and temperature. The temperature entering the fractures will be higher than the temperature at the wellhead, and the higher bottomhole temperature will reduce the overall heat recovery compared to the lower wellhead temperature. The injection pressure is set to make sure the water flows to the production wellhead at the minimum pressure required by the steam turbines.
- Production well: Superhot rock flows supercritical water into the production well and the water quality will degrade over time as heat recovery degrades. Depending on well construction and rates, heat harvested from the ERV can be lost in flowing to the surface. Modeling the quality of the water at the production wellhead is critical as that quality controls the efficiency of the power plant. It's more than taking the product of MW harvested from the ERV and multiplying by an efficiency factor to get MWe.

1.4 Significance of Power Plant

Fixed power delivery rates, rather than a fixed heat recovery rate, are essential to the IAM model since a contract is for electricity rather than heat. This presents a challenge given the declining water heat quality over time, caused by economically-size ERV's, that will cause declining efficiency of the stream turbines. Modeling the asset harvest thus requires integrating a power model into the framework.

2 Integrated Asset Management (IAM) Model

The goal of an IAM model is to make business decisions to define a successful economic path forward akin to the use of integrated asset management, or integrated production management, in the petroleum industry. It is a step before rigorous simulations can become possible with data from the pilot projects. It is an evolving model, and it will progress as work toward and beyond the pilot progresses. Figure 4 shows the flow path of the water as down the injection well, through the ERV, up the production well(s), and to the power plant where the heat is converted to electricity.

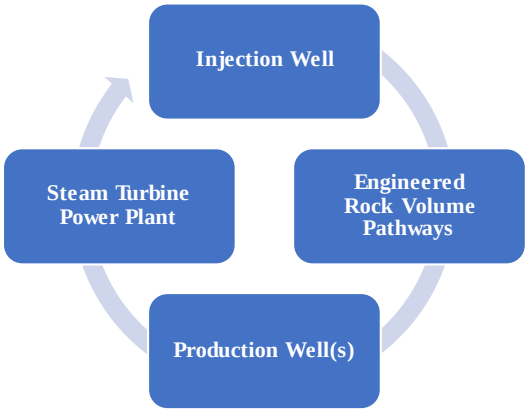

Figure 4: Integrated Asset Management Model Components

The asset model targets SHR bearing supercritical water via a pressure-enthalpy balance model. Pressure balances manage the fluid flow, and enthalpy balances manage the heat flow. The algorithm targets the production life of the asset to enable production decisions through a transient-on-production-scale algorithm built with a pseudo-steady-state finite-element scheme (a general concept used by IPM software in the petroleum industry). The algorithm includes:

- Heat harvesting through ERV pathways built with pressure-enthalpy modeling that includes fluid transfer with conduction, convection, and advection heat transfer. The model begins with an effective set of pathways that will evolve from the learnings of the pilot.
- The injection and production wells use pressure-enthalpy modeling coupled with correlations built on geothermal industry recommendations for flow correlations originally created by the petroleum industry.
- Electrical generation by a SHR power plant uses a multi-stage steam turbine model built on the methods and logic presented by the US Department of Energy (DOE) Energy Efficiency and Renewable Energy (EERE) Steam System Modeling Tool (SSMT) (US Department of Energy EERE, n.d.).

2.1 IAM: Engineered Rock Volume (ERV) Modeling

The integrated model represents the ERV as an effective array of parallel fractures connecting the injector to the producer. This is akin to the Gringarten model with added complexity of flowing supercritical water within fractures that can be of varying height, length, width, and conductivity. Also, the fractures are separated by varying distances of impermeable rock and have a finite fracture face area. The model is for all EGS with pilot SHR application to be at the original Newberry Demonstration Project site and in collaboration with the US DOE (US Department of Energy, 2024).

Davenport Newberry (Waibel, 31 May 2012), in conjunction with DOE Innovative Exploration (IET) Grant 109 program, drilled two deep exploration wells on the western flank of the Newberry Volcano where they found isolated fractures yet no indication of hydrothermal activity. AltaRock Energy assumed operating control of the lease and used hydroshearing to activate the existing fractures (Cladouhos, September 2016). Models of these fractures showed no likely flow from an injector to a producer. Mazama Energy, born from AltaRock Energy and Blade Energy, assumed operating control of the lease and plans to create a thermal lattice by tensile and shear fracturing to connect an injector to a producer.

Table 1 shows the path to formation for the ERV modeling. Column A shows the formation with natural fractures from injector to producer yet without connections amongst the natural fractures to flow from injector to producer. Column B shows the thermal where it is to-be-determined how the natural fractures can be energized to connect the injector to the producer. Column C shows the modeling approach in planning for the demonstration. It represents the thermal lattice as a tensile planer fracture with multiple, natural, planer fractures.

Table 1: Formation of ERV Modeling for the Thermal Lattice

A. Formation w/ Natural Fractures	**B. Formation w/ Thermal Lattice**	**C. Formation Modeled**
Production Well  Injection Well	Production Well  Injection Well	Production Well  Injection Well
• **No flow** as fractures not open and connected from well to well	• Single tensile fracture from well to well	• Linear pathways to harvest heat from same volume as plausible pathways
	• Multiple pathways through energized natural fractures connecting well to well	• Linear pathways with added pressure loss of longer plausible pathways
	• Mapping actual pathways implausible so consider what is plausible	• Pressure managed by injection pressure—greater pressure drop in pathways requires greater injection pressure
	• Natural fracture pathways of unknown architecture	• Linear pathways used currently from stimulation analysis

Figure 5 shows a planer view of the fracture and surrounding rock volume at points in time.

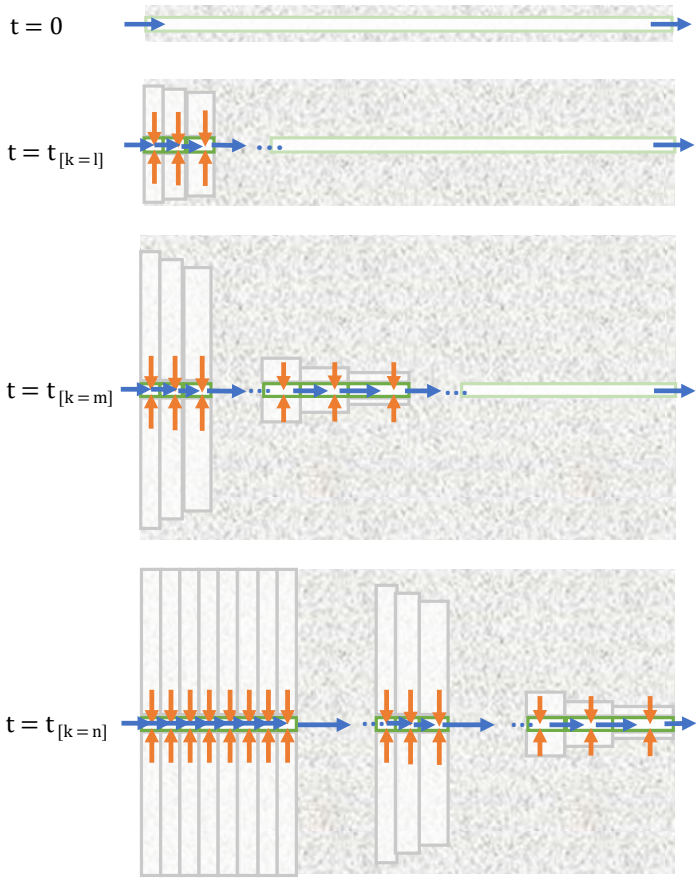

Figure 5: Planer View of Fracture and Rock Volume Elements

1. Initial time, t = 0, where the fracture and the rock are assumed to be in temperature equilibrium with fluid in the fracture remaining from the stimulation treatment.
2. Early time, t = t[k = l], where the water first enters the fracture and quickly comes into equilibrium temperature with the rock. The remaining length of the fracture is near adiabatic, but, at supercritical temperatures as the pressure drops in the fracture from frictional pressure losses due to finite conductivity, the temperature drops that then enables heat flow from the rock. It is important to manage the fracture conductivity and mass rate per fracture to keep the pressure drop minimal and the water not in vapor state.
3. Middle time, t = t[k = m], where the fracture length contributing to heat transfer from the rock continues to lengthen. The elements at the fracture entrance grow until reaching interference with a neighboring fracture. The fluid still exists at maximum enthalpy as there is fresh fracture face to contribute heat to the fluid.
4. Later time, t = t[k = n], the entire fracture length will contribute, and the heat harvested will decline as there is no rock at initial state. Eventually, along the entire fracture length, the thermal penetration distance reaches maximum distance due to neighboring fractures. Decline in the heat harvested is inevitable and becomes a matter of managing the decline.

2.2 IAM: Injection/Production Well Modeling

Well modeling is important to the integrated asset management for the two well types.

- The injection well model takes wellhead injection temperature, pressure, and mass rate and calculates the pressure, enthalpy, and mass rate to each fracture. Through the well model, the wellhead injection conditions translate to the fracture injection conditions. The water gains pressure based on the depth of the ERV, loses pressure due to friction, and gains enthalpy from the surrounding rock before reaching the fractures.
- The production well takes the pressure, enthalpy and mass rate from each fracture to ensure a pressure mass balance from injector to producer. This balance combines injector modeling, fracture flow modeling, and producer modeling. The producer then models the recombined fluid from the last fracture flowing into the well back to the surface. The water loses pressure based on depth of the ERV, loses pressure due to friction, and loses enthalpy to the surrounding rock. This is important to model as the production wellhead water stream is the feed for the power plant.

Flow in the injector well is single phase flow up to the point of entry for each fracture, flow in the fracture is best as single phase liquid or supercritical, flow in the producer changes continuously in time and is single to multi-phase flow.

From the petroleum industry, there are many correlations for water flow in wells. Geothermal researchers have reported the correlations that work for geothermal wells. Although, there are no correlations validated for the flow of supercritical water (outside of the nuclear industry and those are not for well flow). This work built well flow models using correlations validated by geothermal researchers at conventional temperatures using thermophysical properties at supercritical temperatures. The well model employs a finite element well model using a pressure enthalpy balance. The well model works as follows:

- Define the flow regime for Liquid-Bubble-Slug-Transition-Mist-Vapor flow regime map presented by (Ortiz-Ramirez, 1983)
- For single phase flow, the model uses the Fanning liquid and gas correlation as presented by IHS for Harmony (IHS, 2020) and validated using the Petroleum Experts software PROSPER correlation Petroleum Experts 2.
- For two phase flow, the model uses the Ortiz-Ramirez implementation Orkiszewski correlation (Ortiz-Ramirez, 1983), which was based on work presented by (Orkiszewski, Jun 1967) and (Ramey, 1962).

All flow models are pressure enthalpy balances with pseudo-steady-state heat transfer coefficient. Future work will extend the heat transfer to transient conditions.

2.3 IAM: Power Plant Modeling

The plant modeling goal is to study how the changing efficiency of the generator in time affects asset operations to produce fixed electricity rates. At early production life, before the full fracture face contributes to the heat harvest, the harvest is stable, but as the full face contributes the harvest declines in water enthalpy leaving the fracture. And, as the adjacent fractures begin to interfere with each other, the enthalpy declines further. The continual enthalpy decline means, at a constant

mass rate, there is less enthalpy available to generate electricity, and it leads to a declining overall efficiency of the power plant. The power plant in IAM model addresses the changing efficiency effects on asset operations by managing the injector mass rate.

Power plants for geothermal can be steam or binary turbines, and the modeling addresses this by:

- For temperatures above 200 °C, the model use power conversions with a multi-stage steam turbine model built on the thermodynamic methods and logic presented by the US Department of Energy (DOE) Energy Efficiency and Renewable Energy (EERE) Steam System Modeling Tool (SSMT) (US Department of Energy EERE, n.d.).
- For temperatures below 200 °C, the model uses other power plants suitable for lower temperatures based on binary turbine correlations presented by (Moon, 19-21 November 2012). These plants are used for comparison purposes to superhot rock.

3 Integrated Asset Management (IAM) Forecasts

3.1 IAM: Pilot Forecasting

The IAM model guides us in reliably assessing and solving the challenges of SHR-EGS. We began considering vertical and deviated wells, but found the economic answer, regardless of temperature, is that EGS needs long horizontal wells with large numbers of tensile fractures, and that the well spacings be as large as possible to maximize the ERV. The IAM model showed SHR can capture more enthalpy per kg/s of water and therefore make better use of limited water. SHR also yields temperatures where steam turbines are more efficient yielding an even greater MWe per MW of heat harvested. Economic studies showed to have no heat decline for decade upon decade failed to recover upfront capital costs. It showed the harvesting is economically best if accelerated for a given ERV, and this leads to a declining harvest.

A pilot is in development to implement new technologies to drill, complete, and produce SHR successfully at 400 °C. The model forecasts possibilities for the pilot to set reasonable expectations (the actual pilot is currently under review the following is for example purposes only).

- Rock at 400 °C
- Rock thermal conductivity 2.2 W/m.K, density 2,700 kg/m3, and heat capacity 1,000 J/kg.K
- Single injector and single producer with well lengths of 1,000 m and well spacing of 100 m
- Production well not insulated
- Fracture count of 60, height 100 m, width 3 mm, and conductivity of 10 mD.m
- Maximum mass rate = 80 kg/s
- Power harvested = 8, 10, 12, 14, 16, 18, 20 MWe
- Four-stage steam turbine

Figure 6 shows forecasts for the investigative pilot case. The constant power generated is maintained by mass-rate control, shown in Figure 7, and drops in power generated occur when a turbine stage input conditions are no longer met, and a stage is shut down (steam turbine stage design not optimized for this forecast). Figure 8 shows the injection wellhead pressure necessary

to inject the required mass rate. Maintaining the higher injection rates for the high power targets quickly requires excessive injection pressures that are a parasitic pressure loss and could damage the thermal lattice. The wellhead injection pressure must overcome:

- The ERV frictional pressure loss. The tensile/shear fracture treatment design is for a large enough fracture conductivity to control this loss.
- The pressure to lift the fluid in the production well to the surface. As the ERV cools, the production well contains a higher and higher percentage of water thus needing more and more pressure to reach the surface. The production well design must account for time changes of the produced fluid.

For 400 °C, Figure 6, Figure 7, and Figure 8 show that a high power rate is possible, but that rate cannot be sustained given the investigative pilot ERV size. Power targets are set by temperature and the ERV that can be economically put in place.

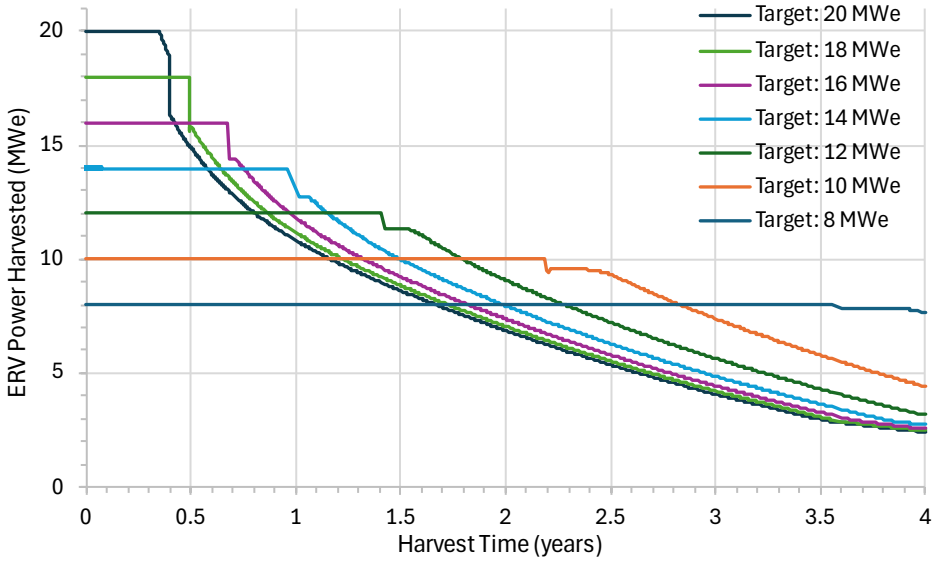

Figure 6: Investigative Pilot Case: Forecast for Power Harvested

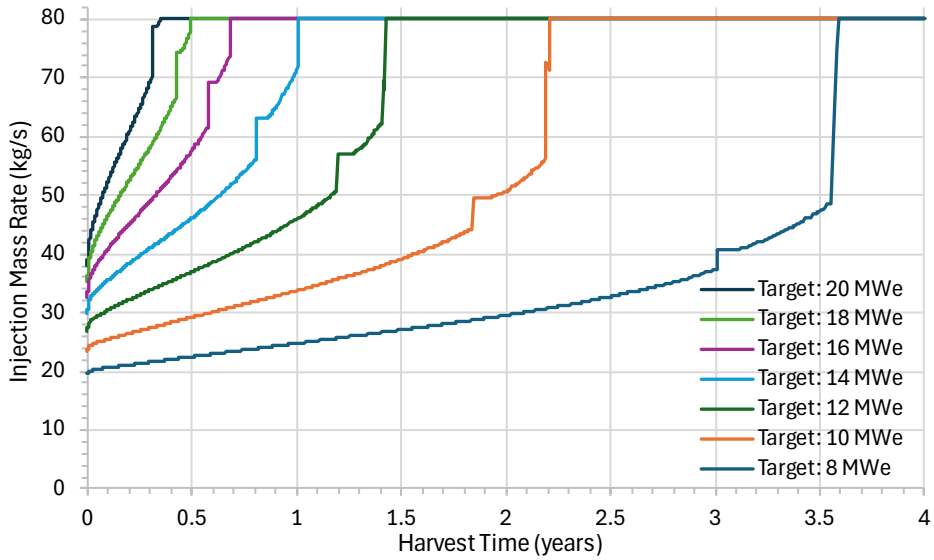

Figure 7: Investigative Pilot Case: Forecast for Injection Mass Rate

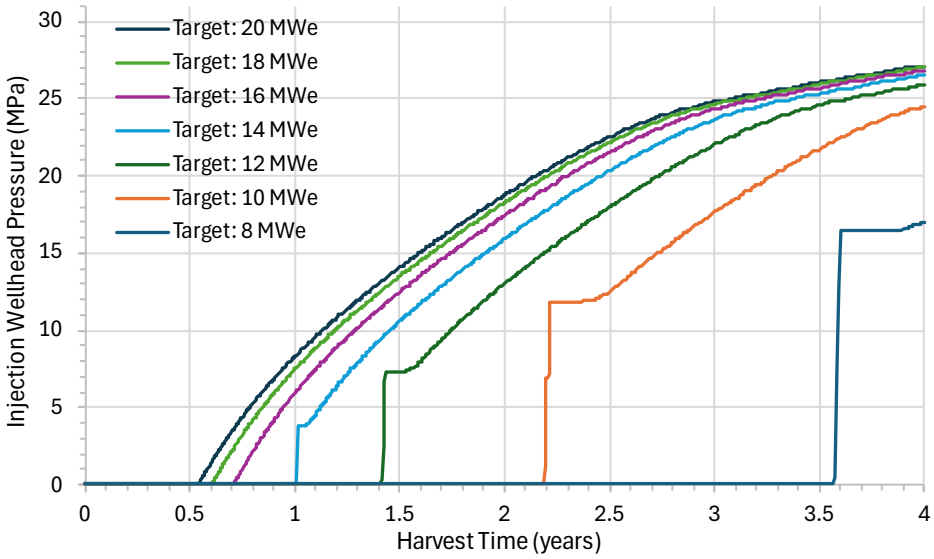

Figure 8: Investigative Pilot Case: Forecast for Injection Wellhead Pressure

Figure 9 shows the fracture pressure for the last fracture on the injection well at various times for the 10 MWe target case. This figure shows two succinct groupings of pressures.

1. Early time. The wellhead injection pump is off and the pressure at the fracture entrance is essentially constant. The fracture outlet pressure as the fracture face cools and the friction pressure increases.

2. Late time. The wellhead injection pressure began to achieve the minimum production wellhead pressure necessary for steam turbine operations. As the ERV continues to cool, the overall density of the fluid in the production well increases and hence the pressure required to lift to surface increases. The continued increase of the injection pressure may cause an issue as the fracture gradient bottomhole pressure is 53 to 61 MPa. For a bottomhole pressure limit of 50 MPa, the pressure is reached at 1008 days, and safe operations would dictate that the injection rate be reduced from 80 kg/s.

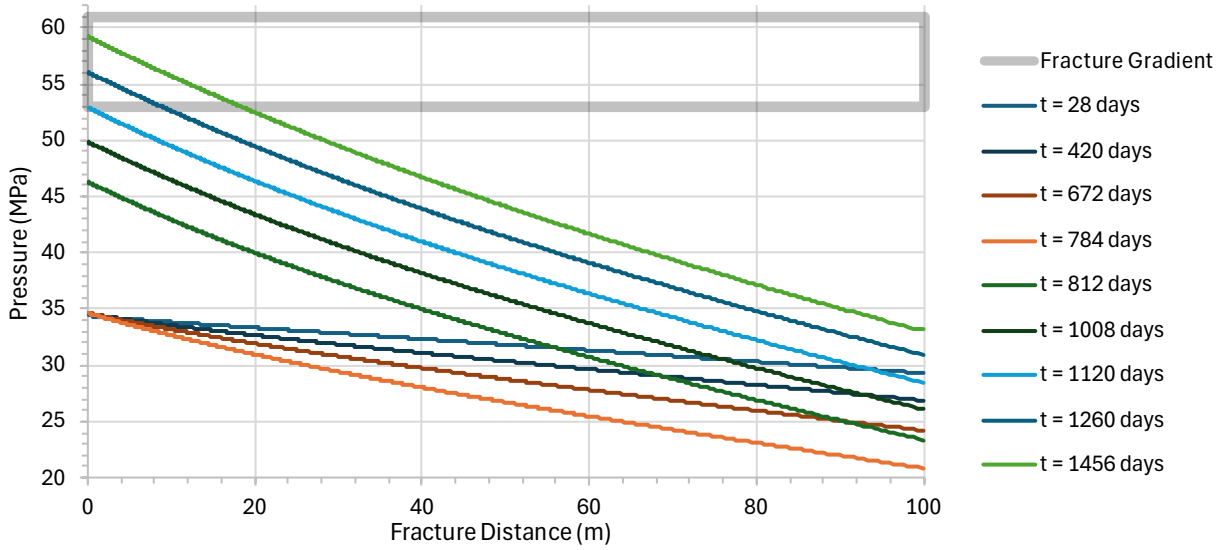

Figure 9: Investigative Pilot Case: Target: 10 MWe Fracture Pressure

Figure 10 shows the bulk enthalpy gradient for the last fracture on the injection well at various times for the 10 MWe target case. At early time most of the enthalpy harvested by the water comes from the fracture as the water enters in fracture. As time progresses the entrance to the fracture contributes a lesser and lesser percentage of the heat harvested. The end of the fracture always has hotter water than the entrance of the fracture, and so the end of the fracture will never be drawn down as far in temperature and hence will always have a lower efficiency. We've considered reversing flow, but unfortunately the injection and production well design differ, and this causes issues in reversing flow. The injection well is always water in liquid state and the producer begins with water in supercritical state. The model, as an IAM model, guides integrated decisions with the wells and fractures combined.

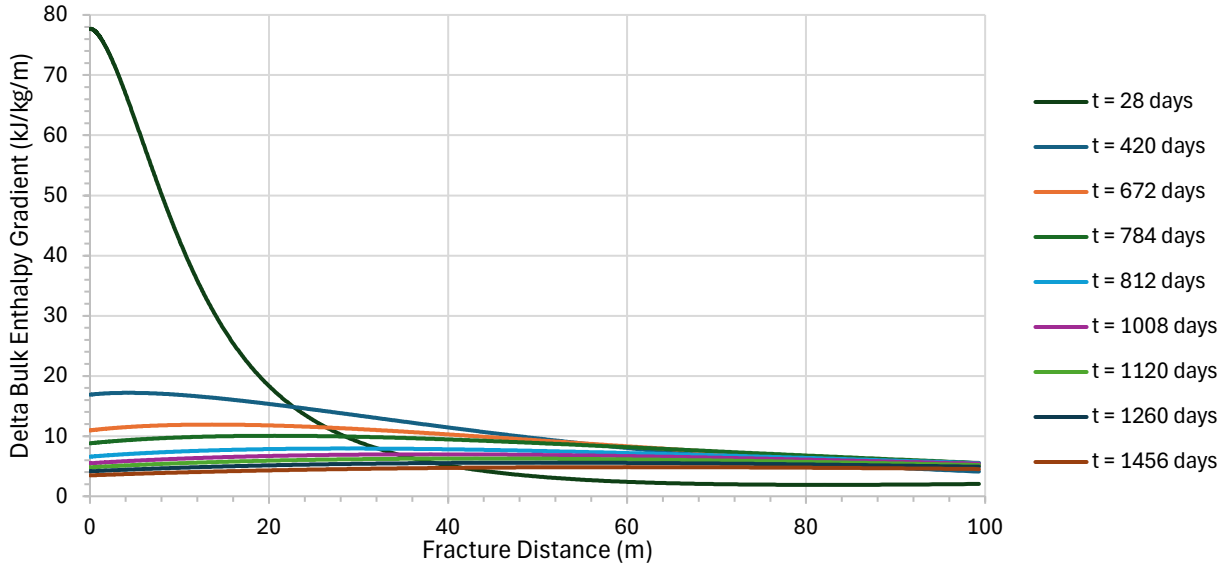

Figure 10: Investigative Pilot Case: Target: 10 MWe Bulk Enthalpy Gradient

There are many conditions to investigate. For example, what are the fracture conductivities that are possible and the range that should be targeted. This work ran multiple fracture conductivity sensitivities and found that a fracture conductivity lower than 10 mD.m significantly reduced the fracture mass rate capacity. These lower mass rates led to a greater residence time in the production well which led to an unacceptable heat loss in the production well per unit of water mass. This set a design goal for the stimulation team to place fractures with a minimum conductivity. Note the fracture conductivity is a function of the ERV, and 10 mD.m for this case may not be the answer for other conditions. Studies of the design and development of an ERV will determine the guidance, and that is the purpose of this modeling work.

3.2 IAM: Post Pilot Constant Mass Rate Forecasting

The following illustrates a case with an identical ERV at depths in the Newberry field corresponding to different temperatures:

- Rock at 200, 350, 400, 425, 450, and 500 °C
- Rock thermal conductivity 2.2 W/m.K, density 2,700 kg/m3, and heat capacity 1,000 J/kg.K
- Single injector and single producer with well lengths of 3,000 m and well spacing of 200 m
- Production well insulated
- Fracture count of 150 equally spaced, height 100 m, width 3 mm, and conductivity of 100 mD.m (approaches infinite conductivity)
- Mass rate = 80 kg/s
- Binary turbine at 200 °C, and a four-stage steam turbine at higher temperatures

The trajectory of the injector and producer at each temperature differs by the depth required for the temperature.

A comparison of this case to Gringarten's Fig. 6 case shown in Figure 3 is:

- Gringarten rock at 300 °C
- Fracture spacing = 20 m—Gringarten 40 m and greater
- Fracture face area = 6 km2—Gringarten = 20 km2
- Mass rate = 80 kg/s—Gringarten = 115 kg/s
- Mass rate / Fracture area = 13.33 kg/s/km2—Gringarten = 5.75 kg/s/km2

Figure 11 shows the model predictions for this case with the power ratio r = {initial power harvested at the given temperature} / {initial power harvested at 200 °C}. The first case where water is supercritical is at rock = 400 °C with r = 4.4, which is a minimal increase from 350 °C with r = 3.5. The first case where water is supercritical at the production wellhead is for rock = 425 °C with r = 6.5, where an additional 25 °C yield a 50% increase in the initial power ratio. Going supercritical is beneficial but it is not an order of magnitude improvement simply being supercritical. To get a tenfold increase in initial power from being supercritical requires rock temperatures above 600 °C, and that is higher than likely with today's technology.

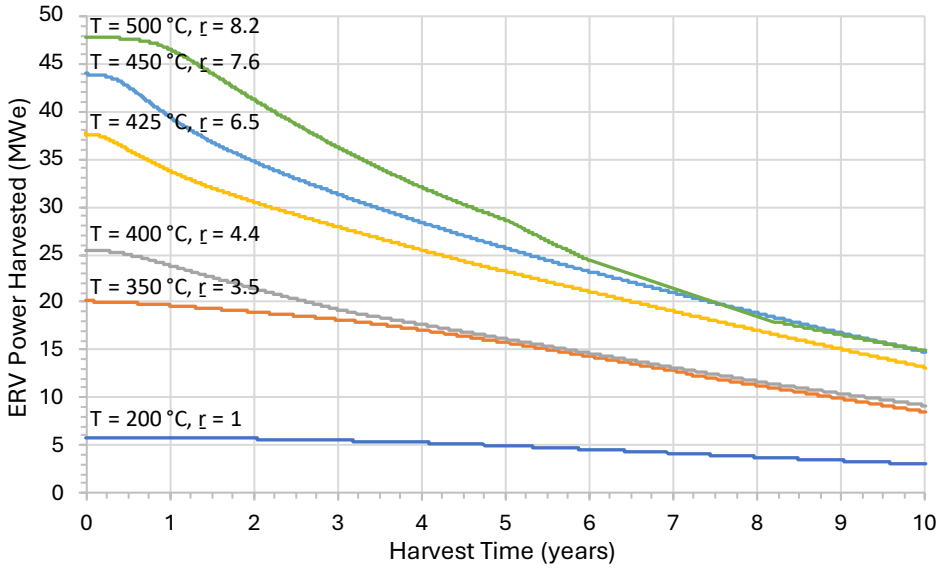

Figure 11: Constant Mass Rate Forecasting: Forecast for Power Harvested

Figure 11 shows that the 200 °C case declines minimally in the first four years while the higher the temperature the greater the decline. This is because all cases are the same mass rate, and the enthalpy of the water increases with temperature to carry more heat per unit mass of water. A simple estimate of the initial power generated is the product of the water mass rate, water enthalpy at the rock temperature, and an efficiency factor. But water is the carrying fluid, not the heat source, and it's the rock's limiting thermal conductivity that determines how the rate of heat

harvesting continues. The higher enthalpy of water at higher temperatures leads to a higher heat harvest rate that the rock cannot maintain, and thus this leads to declining power. To stabilize heat and power recovery, the mass rate should be reduced at higher temperatures to not outpace the rock. This reduces the reduces the power multiplier. This means that the simple estimate to power recovery is not a meaningful estimate for the life of the project.

3.3 IAM: Post Pilot Constant Power Rate Forecasting

The following demonstrates the benefits of constant power rates forecast with managed rates at rock temperature = 425 °C. The model was:

- Rock at 425 °C
- Rock thermal conductivity 2.2 W/m.K, density 2,700 kg/m3, and heat capacity 1,000 J/kg.K
- Single injector and two producers with well lengths of 3,000 m and well spacing of 200 m
- Fracture count of 90 equally spaced, height 100 m, width 3 mm, and conductivity of 100 mD.m (approaches infinite conductivity)
- Production wells not insulated
- Maximum mass rate per producer = 80 kg/s
- Mass rate per producer determined by power target
- Four-stage steam turbine
- Power targets = 25, 33 1/3, and 50 MWe

Figure 12 shows the stable power generation while Figure 13 shows the managed mass rate for a 20 year forecast. Note that the mass rate is held back in time until later achieving the maximum target rate of 80 kg/s. The mass rate is held back to limit the heat recovery (akin to how an oil or gas well is choked control the wellhead pressure and hold production rate at a constant fluid rate). The mass rate increased as the heat recovery potential decreased. Mass rate control is essential to manage a constant power output

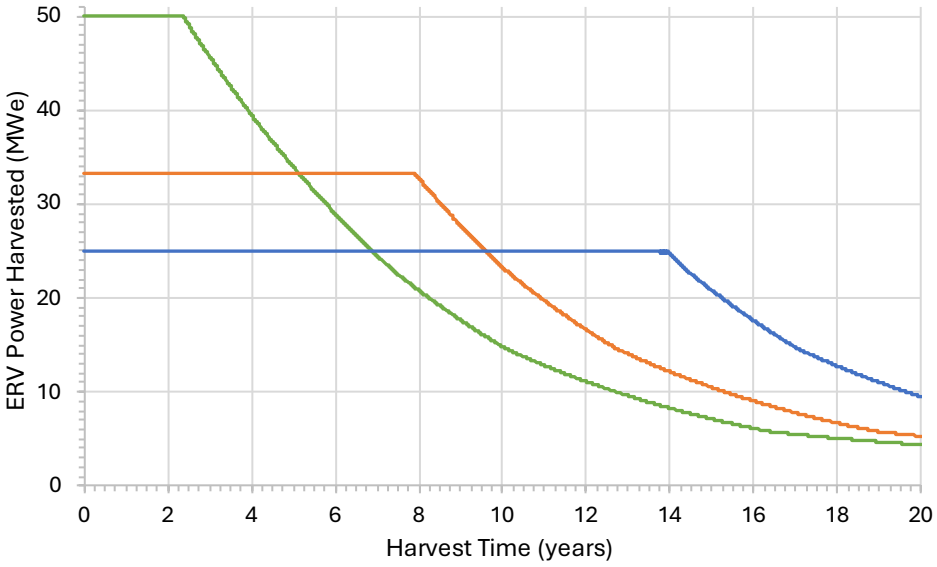

Figure 12: Constant Power Rate Forecasting: Forecast for Power Harvested

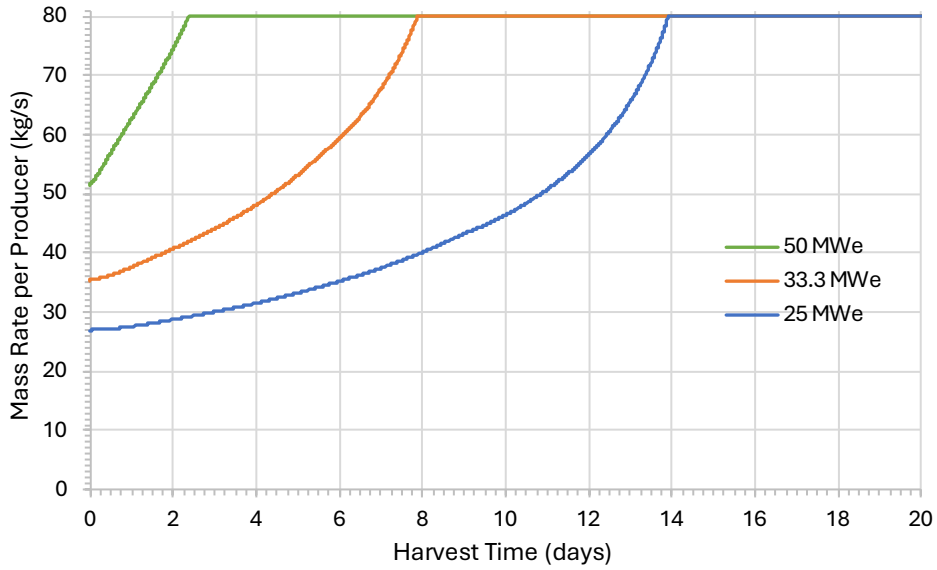

Figure 13: Constant Power Rate Forecasting: Forecast for Mass Per Producer

4 Conclusions

Conventional geothermal models are not applicable for the conditions of SHR-EGS. An Integrated Asset Model which represents the full system cycle of injection wells, heat harvesting from an Engineered Rock Volume (ERV), production wells, and electrical generation is essential to accurately capture the unique characteristics of SHR EGS. Coupled with economics, a model can advance project well design, stimulation treatment, and operational strategy to deliver cost effective power generation outcomes.

Important conclusions for the current work are:

- Heat harvesting potential in time will decline because it is not economically feasible to create an ERV the size required for minimal decline over decades. Studying how to create the optimum ERV is essential.
- Constant power generation requires a managed mass rate and not a constant mass rate to manage the declining heat potential. Studying how to manage the mass rate provides guidance in designing surface facilities.
- Supercritical water temperatures in the ERV does not mean supercritical water temperatures at the production wellhead. In fact, the water temperature will be lower than superhot rock temperature. Supercritical water properties behavior differs from conventional temperatures where that assumption is valid.
- It is a fallacy that supercritical yields tenfold improvement in electricity generated. At initial condition, the fold of improvement comes from the higher enthalpy of super critical water and higher efficiency of the turbines. But water is the enthalpy carrier and not the enthalpy provider. Heat flow by conduction in the low thermal conductivity rock is the bottleneck to heat harvesting, and a higher enthalpy working carrier fluid cannot remove the rock thermal conductivity bottleneck.

SHR-EGS is *unconventional* production when compared to conventional geothermal (hydrothermal) systems. It is akin to unconventional shale gas development, where established assumptions can lead to mismanagement of the asset. This IAM model guides the understanding and management of SHR-EGS.

Superhot, super-critical, New Zealand, Geothermal: The Next Generation, inventory, economics

ABSTRACT

Superhot geothermal appears an attractive opportunity for New Zealand (NZ), from 2037 through to at least 2050. It provides a potentially zero-emissions, reliable, and cost-competitive energy source for electricity generation or high-enthalpy direct-use industrial applications. Superhot geothermal, and even conventional geothermal, has been under-represented in the deliberations and consideration of renewable energy sources by energy planners that NZ might utilise in the future. Policy discussed in several planning documents has focused on solar and wind deployment and has under-appreciated the full potential of geothermal in plans for official endorsement.

The NZ research program, "Geothermal - the Next Generation", has been investigating the potential of supercritical geothermal, and has completed two important assessments for NZ. These challenge the current under-representation of geothermal potential by building electricity scenario models to include utilisation of superhot geothermal resources.

The first assessment is a preliminary resource inventory assessed over a depth range of 3.5 to 6 km, and at temperatures between about 375 ^{o}C and 500 ^{o}C. These inferred resources are located in the Taupō Volcanic Zone (Waikato and Bay of Plenty Regions) and at Ngawha (Northland). The cumulative resource potential is determined to be 4.6 GWe (38 TWh/yr at 95% operating capacity factor). If the resource volumes within current regulatory protected geothermal systems are excluded, the assessed total becomes 3.5 GWe (29 TWh/yr).

The second assessment uses electricity market modelling to provide an estimate of the likely commercialisation process for superhot geothermal power plants. The analysis, adopting the grid system operator's assumptions, forecasts that superhot geothermal power plants could contribute an additional 1.4 or 2.1 GWe capacity (depending on whether or not some gas-fired electricity generation is permitted for peak loads) to the NZ grid between 2037 and 2050. Using economically optimised scenarios, the modelling shows that the addition of superhot geothermal power plants

effectively doubles the expected contribution from conventional geothermal power plants, and would still be economical to construct, even if superhot projects prove to be twice the cost of conventional geothermal projects.

1. Introduction

Geothermal has been under-represented in the plans for future renewable energy sources that NZ consumers might utilise. Policy discussed in several recent planning documents has focused on solar and wind deployment and has under-appreciated the full potential of geothermal in policies for official consideration and endorsement. These documents include: a proposed update (currently underway) of the National Policy Statement on renewable electricity generation (MoE, 2011), the NZ government's future energy strategy (MBIE, 2023), and the NZ Climate Change Commission's energy sector modelling (Climate Commission, 2024).

The benefits of geothermal relative to other renewable power generation options are well known. They include sustainability, reliability, efficiency, allowable multiple land uses, security of indigenous energy supply, small surface footprint, and base-load generation, independent of the weather. Superhot developments will have similar advantages and will likely use even less land for well pads, etc., than conventional developments because of expected higher average well productivity, and the more compact and efficient turbines and the reduced cooling system requirements. Newly developed technologies will also enable full reinjection of the non-condensable gas discharges along with the cooled discharge fluids (McLean 2023). Hence CO_2 gas emissions to the atmosphere from NZ geothermal power plants (currently decreasing but still averaging 64 gCO_{2e}/KWh) are not anticipated to be an issue in future superhot geothermal projects. NZ has also benefited from international collaboration through the IEA-Geothermal Technology Collaboration Program in "Deep Roots" (super-critical and superhot) geothermal research and demonstration projects. A summary of these learnings can be found in Bromley & Carey (2023).

As part of five years of effort undertaken through the Geothermal - The Next Generation (GNG) research project, GNS Science has constructed a preliminary inventory of NZ's superhot - supercritical geothermal resources (Bromley et al., 2024; www.geothermalnextgeneration.com). The principal purpose was to assess potential resource availability to inform a costing analysis and economic assessment. The resource inventory uses geophysical data and interpretations, primarily from magneto-telluric 3D models, to assess NZ's superhot geothermal potential. The inventory applies the project-based United Nations Framework Classification for Resources 2019 update (UNFC, 2022) incorporating the Supplementary Specifications for the application of the classification framework to geothermal energy resources (UNECE, 2019). The UNFC methodology categorises projects listed in the inventory; it reflects the level of uncertainty prior to drilling at potential project locations.

An economic assessment of superhot projects using electricity market modelling was undertaken by Castalia Ltd (2023) on behalf of GNS Science. The results are summarised in Section 3 below. The challenge now for NZ is how to attract the needed capital and operational expertise, identify opportunities for landowners to collaborate, and align policies for this significant—and, until now, mostly overlooked opportunity. We consider the challenge to be analogous to that faced by NZ engineers, scientists, regulators, and politicians, during the early decades of NZ's conventional geothermal resource exploration efforts during the 1950's and 1960's. Although the uncertainties

and commercial risks are high at present for superhot geothermal projects, in essence, history points us towards bold action and "if nothing is risked, nothing will be gained".

2. Superhot Inventory for New Zealand

A preliminary quantification (inventory) of New Zealand's supercritical (>374 °C, >220 bar_a) or superhot (>374 °C, <220 bar_a) geothermal resources has been completed (Bromley et al., 2024). These deep resources are predicted to occur at potentially drillable depths of less than 6 km and at temperatures of up to 500°C. The inventory focusses on the Taupō Volcanic Zone (TVZ), and the Northland Region (Ngawha). The assessment has targeted the 'deep roots' of known geothermal systems, combined with possible 'hidden' superhot resources. The resource assessments utilise the 2019 updated UNFC-2009 and its application to geothermal resources using the UNECE-2022 categorisation approach. By way of comparison, a recent application of this assessment methodology has been applied to conventional depth geothermal resources in the Waikato Region of the TVZ (Ussher et al., 2023). The superhot geothermal assessment is based on deep geophysics data and interpretation, and follows the volumetric approach to quantification of the extraction of heat over a project lifetime (Garg & Combs, 2011), rather than the assumed MW_e/km^2 approach in Ussher et al. (2023). The outcome is a preliminary inventory of potential superhot resources for the purposes of long-term energy planning. The identified resources are subdivided according to locations with respect to their current categorisation status under regional geothermal planning regulations (see Table 1 for unprotected systems and Table 2 for protected systems). Figure 1 shows the locations of nine superhot resources that have been identified at the time of writing this paper from 3D geophysical magnetotelluric (MT) models.

The assumptions noted in Table 1 are further explained in Bromley et al. (2024) and informed by: Garg & Combs (2011), Zarrouk & Moon (2014), and Grant (2015). The MT resistivity anomalies are described in Bertrand et al. (2015, 2022). A challenge in constructing this superhot inventory was estimating the unknown parameter of superhot reservoir permeability (both for natural state conditions and for development-modified or stimulated conditions). Permeability will govern the potential economic energy deliverability, and extraction sustainability of such resources (Watanabe et al., 2020). It is also challenging to predict the mineral compositions, and gas contents, of fluid discharges and how these might influence longer term sustainability (Heřmanská et al., 2020, Chambefort and Stefánsson, 2021, Lamy-Chappuis et al., 2022). Analogous fluid properties are inferred from the observed physical and chemical conditions of superhot geothermal fluids that have been encountered in other countries.

Large scale mathematical models (Kissling et al., 2024) and simulations of natural state mass and heat flow through the TVZ using supercritical capable codes (O'Sullivan et al., 2020), provide constraints on likely rock and reservoir properties at the depths of interest. These properties influence the likely productivity and sustainability of superhot fluid resources. Consequently, although currently there are insufficient data to construct robust simulations of individual prospective resources, representative development scenarios of a typical superhot geothermal prospect can be simulated through economically viable extraction lifetimes, informing the preliminary inventory assessment. The scenarios assume lifetimes may vary between 35 and 100 years.

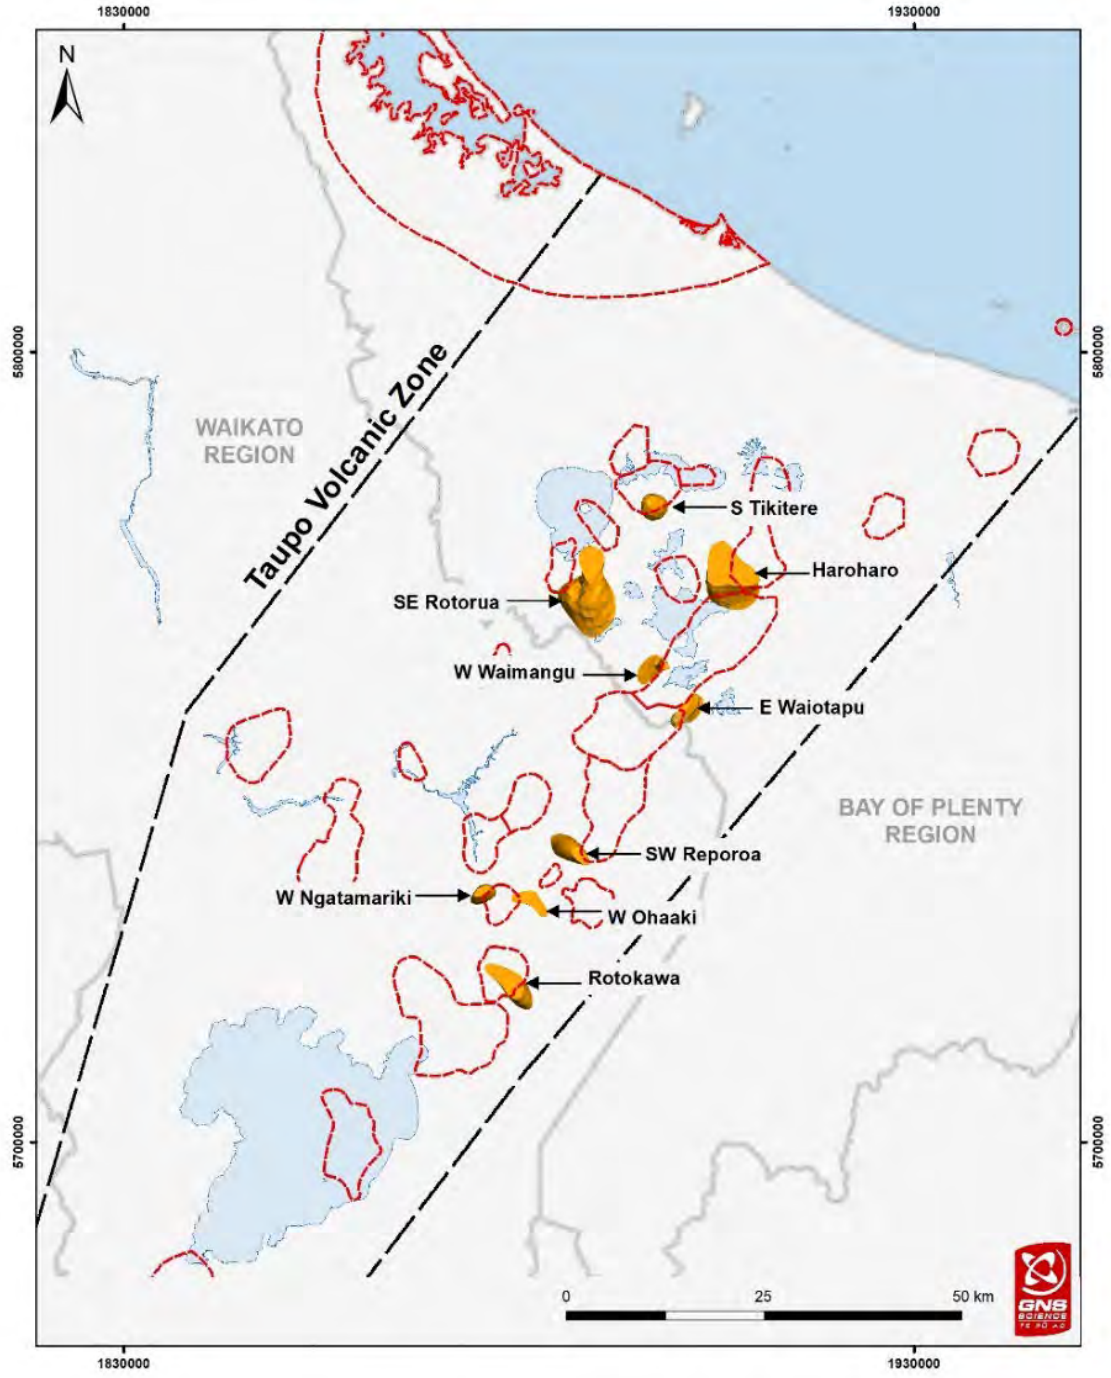

Figure 1: Taupō Volcanic Zone superhot geothermal resources - location and extent of deep, low-resistivity anomalies (shaded relief in orange), 3.5 to 6 km depth, using 3D MT models. Location names are from Tables 1 and 2. Shallow geothermal system boundaries are shown in dashed red contours.

The assessment for a depth range of 3.5 to 6 km identifies that the potential superhot geothermal energy resources suitable for power generation are the equivalent of about 4.6 GWe. The future utilisation is predicated on the assumption that technical challenges are overcome. If systems currently protected under existing regulatory planning regimes are excluded, the assessed resource reduces to ~3.5 GWe of installed capacity capable of generating 29 TWh/yr of baseload power. This may be compared with the current geothermal generation capacity from conventional depth reservoirs of ~1.1 GWe (8 TWh/yr, or 18% of total NZ generation), rising to an anticipated 1.4 GWe of installed capacity by 2030 and possibly 1.7 GWe (12 TWh/yr) by 2040 to 2050.

The geophysical data set of the Taupō Volcanic Zone and Northland is not yet complete. Consequently, the assessment is not fully comprehensive in terms of areal coverage and on that basis is conservative. The UNFC methodology uses a matrix categorisation of potential projects (Figure 2). All these prospects in the New Zealand superhot inventory are at a low confidence level (G_4 on the matrix degree of confidence axis) reflecting the current high level of uncertainty, prior to any drilling being undertaken to access superhot geothermal conditions in the 3.5 to 6 km depth interval. As data coverage is extended, models refined, and drilling depths increased, the assessed potential can be updated. The UNFC-2019 classifications (currently E3.2, F4.2, G4.1) will be revised over time, as exploratory drilling and pilot studies are undertaken, enlarging the knowledgebase of specific superhot geothermal projects.

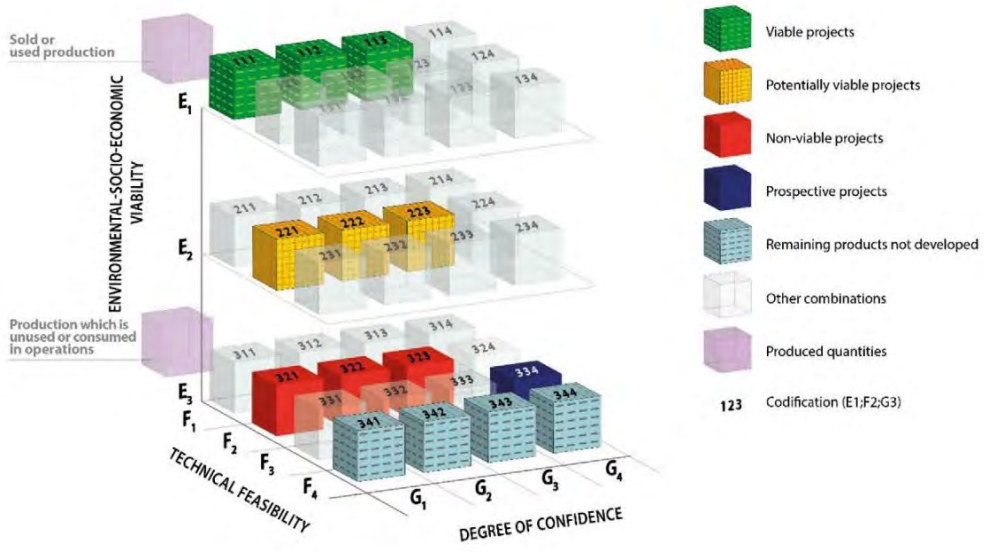

Figure 2: UNFC-2019 Categories and Examples of Classes (Diagram from UNFC-2019). Prior to any deep exploration drilling, NZ superhot projects will remain, for now, categorised as E3.2, F4.2, G4.1.

3. Economic Modelling for the Future NZ Electricity Market

To determine the economic value and potential role of superhot geothermal developments in meeting NZ's future power demand, Castalia (2023) first undertook an economic forecast of the NZ electricity market, considering the NZ Government's climate change commitments regarding use of renewable rather than fossil fuel energy sources. Electricity demand is expected to increase to a value about 19% higher by 2037 and 50% higher by 2050 (based on the NZ Climate Change

Commission's 'demonstration path', (Climate Commission, 2023)). The main drivers for growth are electrification of transport and industry alongside population and economic expansion. The North Island of NZ is forecast to dominate growth in demand (two thirds of the total) like the current split between the North and South Islands (which are linked by a capacity-constrained, DC submarine cable). The seasonal and daily load duration demand curves are expected to retain the same approximate shape in 2050 as in 2023. This affects the relative needs and pricing for baseload and peak generation capacity. The model iteratively calculates the increase in demand distributed across the peak to base load curve for each subsequent year. Wind and solar renewable electricity supplies are de-rated relative to geothermal when calculating a North Island winter-capacity margin to meet demand peaks (that is, variable supplies would require 'over-building' of capacity). The economic model adopts estimates from the grid operator (Transpower) for the peaking role of 'Variable Renewable Energy' to determine the cheapest option, whilst always providing for sufficient capacity.

3.1 Cost analysis

Comparative costs, from the model, for different renewable sources of new generation, and battery storage, as a function of capacity factor, are shown in Figure 3. The costs take into account the need for surplus installed capacity or storage to provide back-up for periods of low supply but high demand (in particular from variable energy sources such as wind and solar). These curves illustrate the cost competitiveness of battery storage and gas-fuelled generation for satisfying short-period peak demand at 10% to 25% capacity factor, but also the cost benefit of building baseload superhot geothermal power plants relative to 'over-built' solar or wind generation for accommodating the full range of capacity factors required to operate the NZ grid. Note that the more expensive battery electric storage capacity would likely substitute for gas peaking if the latter was banned by 2050.

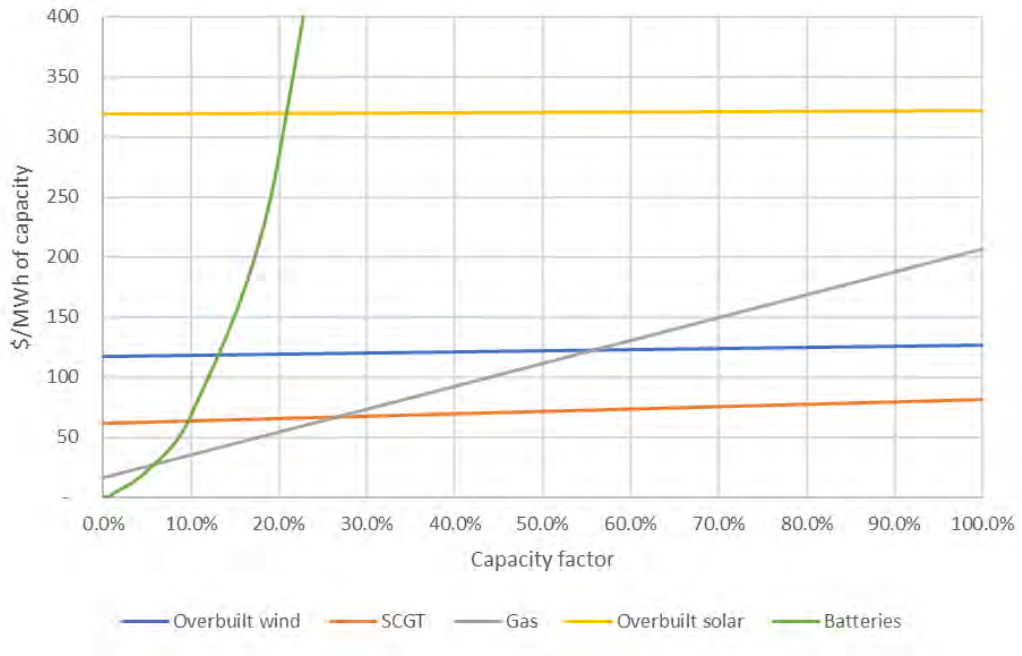

Figure 3: Comparative cost curves ($/MWh) as a function of capacity factor (Peaking 0-20%, Intermediate 20-90%, Baseload 90-100%) for different new-build electricity supply or storage options. (SCGT=superhot geothermal; 'overbuilt' implies some un-used capacity exists during periods of low demand.)

Consequently, the conclusion from the grid capacity modelling is that between 2037 and 2050, about 2 GWe of superhot geothermal capacity would become economic to build (for a 100% renewable scenario, as mandated by the Climate Commission (2023)). A reduced amount of 1.4 GWe would still be economic to build for the alternative scenario where some fossil-fuel (gas) generation is allowed for demand peaks. The 2 GWe scenario would provide about 16 TWh/yr, approximately 55% of the estimated available superhot resource potential from Table 2.2 of 29 TWh/yr. This potential amount is in addition to Transpower's prediction of conventional geothermal capacity by 2035 and beyond, which they expect to plateau at 1.7 GWe (12.5 TWh/yr), based on planned and proposed projects (Transpower New Zealand, 2023). That is, conventional geothermal is expected to grow by about 50% by 2035 compared to the 2023 operating capacity of 1.1 GWe (8 TWhr/yr), then remain stable until at least 2050.

A sensitivity test on varying the cost of superhot geothermal projects (mostly the capital cost of drilling and surface plant) relative to conventional projects, showed that 2.1 GWe of superhot capacity is economic to build if the cost premium is 0%, 2.0 GWe if the cost premium is +20% (the base case scenario), while 1.9 GWe is still economic even if the cost premium is 100% (i.e., costs double). Similarly, if some gas-fired peaking generation is permitted, the economic capacity drops from 1.4 to 1.3 GWe if the relative cost premium for superhot geothermal increases from 0% to 100%.

3.2 Timelines for deployment

Castalia (2023) prepared an ambitious 14-year timeline estimate for NZ superhot projects to reach maturity and become operational. The timeline was informed by the history of previous energy research timelines and learning rates (Our World in Data, 2022), and assumes all conditions will align and barriers will be overcome. The first 10 years (2023-2033) involves continuing geoscientific and engineering research efforts. This is followed by 4 years for design and construction of the first power plant and grid synchronisation (2037). Parallel to these activities, exploratory drilling consents and approvals are predicted to take 1 year, followed by 5 years of drilling. Once technical issues are resolved, the process of site selection, land acquisition, financial and operational approvals are predicted to take another 2 years, prior to commencing the formal design stage for the first power plant and steam gathering system.

Between 2037 and 2050, for deployment to achieve 2 GWe (16 TWh/yr) of new installed superhot capacity (as determined by the economic model), approximately six parallel projects, at about 300 to 400 MWe each, would need to be developed (see Table 1 for the top priority locations). Assuming an average productivity of 40 MWe per well (Rivera & Carey, 2023), one reinjection well per four production wells, and four months to drill each well, this level of new power plant development would require a deep drilling campaign over 10 years (2037 to 2047) using at least two large-capacity drilling rigs.

3.3 Potential value for off-grid and direct industrial energy needs

Off-grid energy needs for industry, in the form of power and/or heat at high enthalpy, could also be met in the future by superhot geothermal resources. Direct use for milk processing, timber drying, wood pellet and paper manufacturing in NZ is already an established and economical

option for conventional geothermal heat. These plants typically use steam or two-phase heat exchangers and are often co-located with electricity generation plants. The opportunity to displace some of the 90 PJ/year of industrial energy still sourced from fossil fuels in NZ is attractive from a carbon emission reduction perspective. A typical application might be a central North Island dairy processing factory which could require about 15 PJ/year of energy. Note that dairy factory demand is inversely correlated with electricity prices because dairy milk supply dries up in winter when power demand is high. In terms of revenue generated, the economics of a co-generation project (dairy factory heat and power), using superhot resources, is comparable to that of an electricity-only plant (see Castalia Ltd, 2023, for more detail).

4. The Next Generation Challenge

The assessment of superhot potential for NZ also identifies the engineering and geoscientific challenges and gaps in technology that require attention and investment to facilitate a smooth transition towards the anticipated renewable energy target by 2050. The challenges include:

- Refine well drilling and completion methods for depths of 3.5 to 6 km, and at superhot temperatures, so that commercial wells can be achieved, and flows maintained.
- Manage scale formation, corrosion, and thermal stress issues so that superhot fluids can be reliably produced from depth.
- Design and construct efficient and cost-effective turbines and related surface infrastructure adequate for the superhot fluids.
- Remove regulatory barriers to help fast-track robust superhot projects.
- Communicate the research findings to key public sector stakeholders, Māori interests, landowners, government agencies, regional councils, potential funding partners and infrastructure investors.
- Coordination among government and private sector parties to mobilise the necessary investment required for exploratory wells and associated scientific and technical research and development.

5. Conclusions

New Zealand's conventional (sub-critical) installed geothermal capacity is currently ~1.1 GW_e generating ~8 TWh/yr (New Zealand Geothermal Association, 2023). This is 18% of the total generation of 43 TWh/yr (2023 data), obtained from a total installed capacity of ~10 GW_e.

Transpower (the NZ grid operator) estimates that about 16 GWe of total capacity will be required by 2037 as NZ decarbonises its energy use. Castalia Ltd (2023) estimates a 50% increase in demand will occur by 2050. Approximately 1.7 GW_e is anticipated by Transpower to be provided by conventional baseload geothermal generation (about 12.5 TWh/yr, or 18% of total demand of 70 TWh/yr, like the current proportion).

The superhot geothermal resource inventory provides, for the first time, additional potential geothermal capacity for the planners to consider. It identifies:

- A total additional capacity of about 4.6 GW_e, or 39 TWh/yr for New Zealand.
- After removing the areas that have protected regulatory planning provisions, this reduces the superhot capacity to ~3.5 GW_e, or 29 TWh/yr of electricity.

Economic assessment shows that 2 GW_e of capacity (15 TWh/yr of generation) would be cost effective to construct between 2037 and 2050 in a fully renewable electricity generation scenario. Alternatively, 1.4 GW_e would be cost competitive if some gas peaking electricity generation is allowed.

The next challenge is how to attract the needed capital, resource the investigative work, identify opportunities for landowners to collaborate, and align policies for this significant renewable energy opportunity for New Zealand to be realised.

Ideal Thermal-Hydraulic Performance of Geothermal Power Systems Above 300 °C

Daniel W. Dichter

Quaise Energy

Keywords

High-temperature, flash, binary, dry steam, cycle, working fluid, exergy, efficiency, supercritical, superhot rock, SHR, utilization

ABSTRACT

Current geothermal power plants are characterized by geofluid production temperatures ranging from about 100-250 °C, with research underway to enable much higher temperatures. The range of 300 °C and above is considered herein, encompassing the region of “superhot rock”, or SHR, defined as exceeding 375-400 °C. To quantify the potential of these systems, the exergetic power of a production well is assessed at its maximum flow capacity, as determined empirically by the onset of erosion. This indicates that at a given temperature, the power output potential is maximized where the geofluid production is most dense. Performance plateaus around the critical point, beyond which higher exergy is approximately offset by reduced mass flow rate. Three types of power cycles were considered: dry steam, flash, and binary, with each cycle corresponding to specific production conditions. Dry steam cycles were found to confer superior exergetic efficiency, but relatively low gross power output because of the characteristically low production density. Flash and binary cycles were found to be a significant improvement on an equal-temperature basis, with the lower exergetic efficiency compensated by a much higher mass flow rate. Single-, double-, and triple-stage cycles were considered for both flash and binary plants, and optimized for exergetic efficiency using gradient ascent algorithms. This yielded heuristics for the optimal design of both cycle types. For binary cycles specifically, pure water was selected as the working fluid of choice on the basis of its superior performance at high temperatures, as compared to the hydrocarbons characteristic of organic Rankine cycles (ORCs). The performances of flash and binary plants were found to be highly similar in the sense of thermal and exergetic efficiency. Diminishing returns were observed in both cycles, with a significant improvement from adding a second stage, and smaller, more localized improvements from a third. The choice between flash and binary may depend more on practical considerations such as geochemistry, reinjection requirements, and capital costs. Altogether, the plants considered herein have the potential to produce about 30 MWe gross per production well with an 8.5 inch minimum inner diameter, up to an order of magnitude more than is typical of current geothermal systems.

1. Introduction

A wide variety of methods have been used to generate electrical power from geothermal heat. Common to all such methods is the drilling of at least one well to produce hot geofluid from a subsurface reservoir, which may be either liquid, vapor, or a two-phase mixture. These wells typically have a minimum inner diameter of $D = 8.5$ inches (IFC/GeothermEx, 2013, p. 22; API 5CT, 2005, p. 185), and are drilled into hydrothermal reservoirs with depths of about 1-3 km (IFC/GeothermEx, 2013, p. 15). Recent global meta-analysis studied the distribution of gross capacity per production well, finding a mode of 3.0 ± 0.5 MWe, with more than 50% of wells between 4.0 ± 2.5 MWe (IFC/GeothermEx, 2013, p. 14).

Research is also underway to enable artificial reservoirs in subsurface rock with minimal pre-existing permeability or fluid content, referred to as enhanced or engineered geothermal systems, or EGS. For generality, this paper considers a geothermal reservoir of arbitrary origin, into which a single production and reinjection well are drilled. The reservoir is assumed to have sufficient pressure to achieve the maximum flow capacity of the production well, as described in the following section.

2. Production Hydraulics

The hydraulic aspect ratio of a production well, as its depth to diameter, is typically on the order of about 10,000, per the figures from the previous section. Drilling to greater depths and temperatures is expected to entail even higher aspect ratios. This extreme slenderness introduces a significant frictional pressure drop between the reservoir and surface. This can be seen from the Darcy-Weisbach equation (Çengel et al., 2012, p. 545):

$$\Delta P = \frac{1}{2} f \frac{L}{D} \rho v^2 \tag{1}$$

Where ΔP is the pressure drop, f is the friction factor, L is the pipe length, D is the pipe diameter, ρ is the fluid density, and v is the average, or superficial, flow velocity. The factor L/D expresses the pipe's aspect ratio, so $\Delta P \propto L/D$, and $\Delta P \to \infty$ as $L/D \to \infty$, all else equal.

Geofluid production can also be expressed in terms of internal flow:

$$\dot{m} = \rho A v \tag{2}$$

Where $\dot{m}$ is the mass flow rate, and A is the cross-sectional flow area. Substituting the expression for v in Eq. (2) into Eq. (1) equation and solving for $\dot{m}$ yields:

$$\dot{m} = \sqrt{\frac{\pi^2 \Delta P D^5 \rho}{8 f L}} \tag{3}$$

For a well with a certain D and L, subject to a certain ΔP between the reservoir and surface:

$$\dot{m} \propto \sqrt{\rho} \tag{4}$$

Neglecting the small dependence of f on the fluid conditions for the sake of approximation. Experiments suggest that the production of high-temperature geothermal systems may be limited

by erosion rather than pressure, even at conventional depths (Ingason et al., 2014). In other words, the production well may be sufficiently pressurized downhole to incur erosion in an open flow scenario. Thereby, safe operation requires controlling the wellhead pressure to limit the production mass flow rate.

The onset and acceptable rate limit of erosion in systems with internal flow are best determined by direct measurement under representative conditions. Without such information, a common empirical standard for two-phase flow states that:

$$v_e = \frac{c}{\sqrt{\rho}} \tag{5}$$

Where v_e is the erosional velocity, and c is an empirical constant, with suggested values of $c =$ 100-250 (ft/s)(lb/ft^3)$^{1/2}$ depending on the duty cycle, presence of solids, and the degree of corrosivity; $c = 100$ (ft/s)(lb/ft^3)$^{1/2}$ is used herein, with appropriate unit conversions (API, 1991, p. 23). The same empirical standard specifies a constant maximum flow velocity of 4.57 m/s [15 ft/sec] for liquid, which is essentially a special case of the two-phase correlation with $x = 0$, where x denotes quality, or dryness fraction. This arises because the density of saturated liquid water is approximately constant with respect to temperature. Vapor flows are more commonly pressure-limited rather than erosion-limited, but the two-phase correlation with $x = 1$ nonetheless provides guidance as to the maximum vapor flow conditions. Supercritical flows are likewise assumed to be limited by the same empirical proportionality, noting that material properties at these higher temperatures require special consideration.

Substituting the expression for v_e in Eq. (5) into Eq. (2) such that $v = v_e$ yields an expression for the maximum mass flow rate of an erosion-limited internal flow:

$$\dot{m} = c\, A \sqrt{\rho} = \frac{\pi}{4}\, c\, D^2 \sqrt{\rho} \tag{6}$$

With respect to fluid properties, this is a restatement of the Darcy-Weisbach equation; namely:

$$\dot{m} \propto \sqrt{\rho} \tag{7}$$

Supposing geofluid production is erosion-limited, with a production pressure no higher than 300 bar per the approximate limitations of current boilers (Çengel et al., 2012, p. 387), the maximum mass flow rate is shown in Figure 1 below.

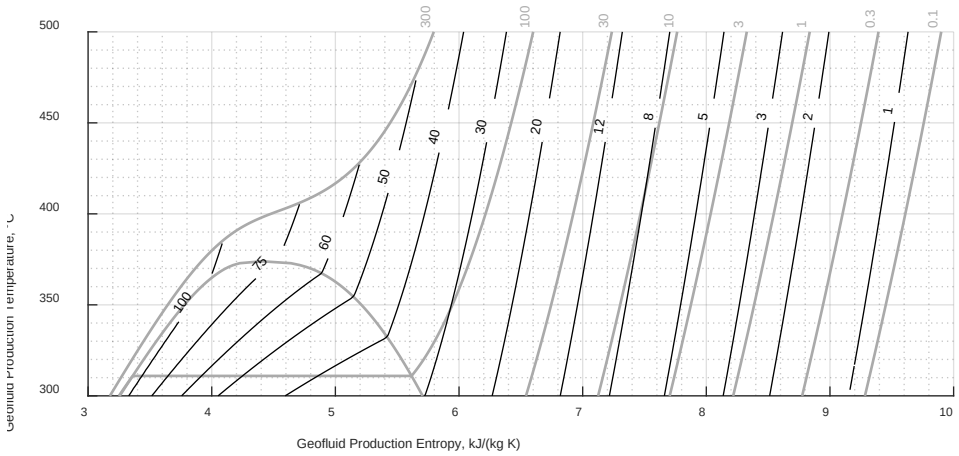

Figure 1: Contours of constant mass flow rate $\dot{m}$ in kg/s (black) for an erosion-limited well with D = 8.5". Overlaid in gray are the phase boundary of water, and a set of isobars labeled in units of bar.

This shows that in the subcritical region, $\dot{m}$ is substantially higher in the liquid phase than the vapor phase, with more than a 3:1 ratio at 300 °C. This disparity decreases to zero as $T \rightarrow T_{crit}$, i.e. as T approaches the critical temperature. In the supercritical region where $T > T_{crit}$, $\dot{m}$ decreases with T on an isobaric basis, because isobaric heat additions strictly decrease density.

3. Exergetic Power

Exergy expresses the maximum amount of work that can be obtained from a substance as it is brought into equilibrium with its surroundings, and can be used to calculate the potential power output of a geofluid flow. Its standard definition in the field of geothermal power is:

$$e = (h - h_o) - T_o\,(s - s_o) \tag{8}$$

Where e is exergy, h is enthalpy, and s is entropy, all of which are specific, or per unit mass; the subscript o refers to the dead state, and T_o is specified in consistent absolute units, e.g. Kelvin (DiPippo, 2016, pp. 295-296). The dead state is commonly taken as saturated liquid, and can thereby be defined by a temperature. The value of $T_o = 50$ °C [323.2 K] is used herein, assuming that heat rejection requires a temperature difference of at least $\Delta T = 10$ °C with respect to a maximum ambient temperature of 40 °C [104 °F] (DiPippo, 2016, p. 128). This represents the anticipated condenser temperature, below which no work can be obtained. Exergetic power, denoted $\dot{E}$, is then given by:

$$\dot{E} = e\,\dot{m} \tag{9}$$

This quantity expresses the maximum power output, e.g. in MWe gross, associated with a geofluid flow, and is shown in Figure 2 below.

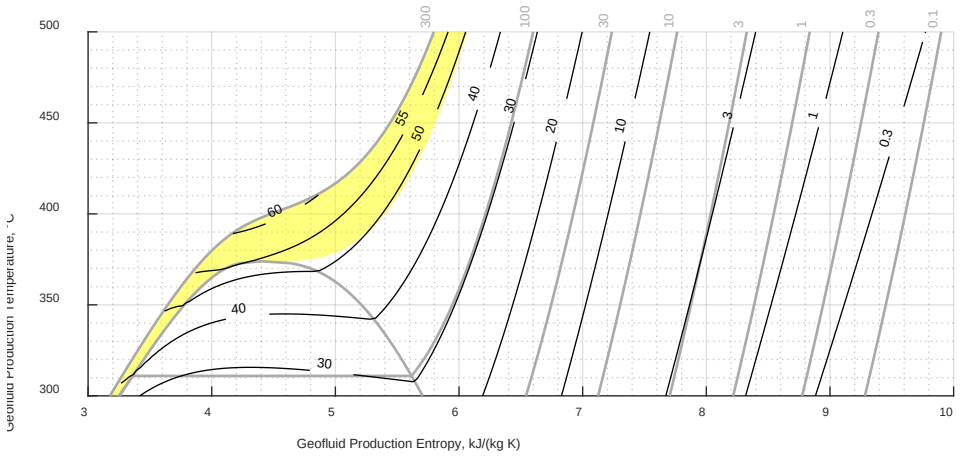

Figure 2: Contours of constant exergetic power $\dot{E}$ in MWe (black) for an erosion-limited well with D = 8.5". Overlaid in gray are the phase boundary of water, and a set of isobars labeled in units of bar. Highlighted in yellow is the region where exergetic power $\dot{E}$ is maximized for a certain production temperature, bounded by $x = 0$ where $T < T_{crit}$, $P = P_{crit}$ where $T > T_{crit}$, and P = 300 bar.

Similar to the earlier plot of $\dot{m}$, this shows in the subcritical region that liquid conveys substantially more exergetic power than vapor. This ratio is about 4:3 at 300 °C, again decreasing to zero at the critical point. In the dry steam and supercritical regions, $\dot{E}$ is approximately constant with respect to T on an isobaric basis, indicating that increases in h and e are offset by decreases in ρ and $\dot{m}$. For a given production temperature, exergetic power $\dot{E}$ is maximized where the production pressure is itself maximized, corresponding to a region spanning both compressed liquid and supercritical fluid. This region is characterized by production pressures of $P >$ 85.9 bar in the subcritical region, and $P >$ 220.6 bar in the supercritical region, per the saturation pressures at 300 °C and the critical pressure, respectively.

Typically, geothermal power plants attain around 25-65% of exergetic power, depending on the type and sophistication of the thermodynamic cycle, which itself is influenced by the geofluid production conditions (DiPippo, 2016, p. 243). This fraction is referred to as exergetic efficiency, or utilization, and is denoted by η_{II}, with the subscript II referring to the Second Law of Thermodynamics on which exergy is based. This is given by:

$$\eta_{II} = \frac{\dot{Q}}{\dot{E}} \tag{10}$$

Where $\dot{Q}$ denotes the gross power output of the plant, itself given by:

$$\dot{Q} = \dot{m}\, w_{net} = \dot{m}\, (q_{in} - q_{out}) \tag{11}$$

Where w_{net} is the net work, q_{in} is the heat input, and q_{out} is the heat rejection. The expression for η_{II} can be simplified to:

$$\eta_{II} = \frac{w_{net}}{e} \tag{12}$$

Note that this neglects parasitic loads from fans, pumps, lights, etc. for simplicity and generality, which are briefly discussed later. This is not to be confused with the more common thermal (or First Law) efficiency η_I, given by:

$$\eta_I = \frac{w_{net}}{q_{in}} = 1 - \frac{q_{out}}{q_{in}} \tag{13}$$

The remainder of this paper seeks to quantify how the value of η_{II} depends on the geofluid production conditions, the type of power cycle, and the cycle's relative sophistication. Thereby, the competing tradeoffs between $\dot{m}$, e, and η_{II} can be balanced, so that local and global optima for $\dot{Q}$ can be found.

4. Cycle Regions

The simplest method of generating power from a geofluid flow is a dry steam power cycle. This entails producing geofluid as a saturated or superheated vapor, then expanding it in a steam turbine, producing work. The basic constraint of this cycle is that the turbine must not have excessive condensation; herein, it is assumed that $x \geq 85\%$ throughout the turbine, based on typical manufacturers' specifications. These cycles also lack reheating, a common feature of non-geothermal plants, because it is not practical to re-flow the geofluid through the reservoir at an intermediate pressure once produced, unlike e.g. with fossil-fired boilers.

After the steam is expanded in the turbine, the residual waste heat is then rejected to ambient conditions by a condenser, as in a Rankine cycle. This imposes an additional constraint that the turbine outlet pressure cannot be lower than about 0.12 bar, the saturation pressure corresponding to 50 °C, the nominal heat rejection temperature.

The performance of the turbine can be described primarily by its dry isentropic, or nominal, efficiency η_{td}, which expresses the ratio of the actual enthalpy change of the steam between the inlet and the outlet, to this same quantity under isentropic conditions without the presence of condensation (Çengel et al., 2012, p. 383). This is taken as 85% herein (DiPippo, 2016, p. 122). Secondarily, the Baumann rule states that turbine efficiency decreases about 1% for each 1% of condensation, in the sense of quality x, according to empirical observations (DiPippo, 2016, p. 122).

Using numerical methods, a turbine process curve can be calculated, representing the set of inlet conditions corresponding to the turbine and condenser specifications described earlier. This curve intersects $x = 1$ at approximately $T = 190$ °C, the approximate maximum saturated vapor temperature for a dry steam power cycle, closely matching actual plants of this type (Calpine Corporation, 2023).

The region in T-s, or temperature-entropy, coordinates to the right of this curve represents the set of acceptable turbine inlet conditions, all of which is superheated vapor. To the left of this curve are regions of superheated vapor (generally, at lower enthalpy), supercritical fluid, saturated vapor, saturated liquid, compressed liquid, and two-phase mixtures. These two regions are denoted as A and B, as shown in Figure 3 below. The boundary between these regions can be approximated by the isentropic curve of $s = 6.236$ kJ/(kg K) over 300-500 °C.

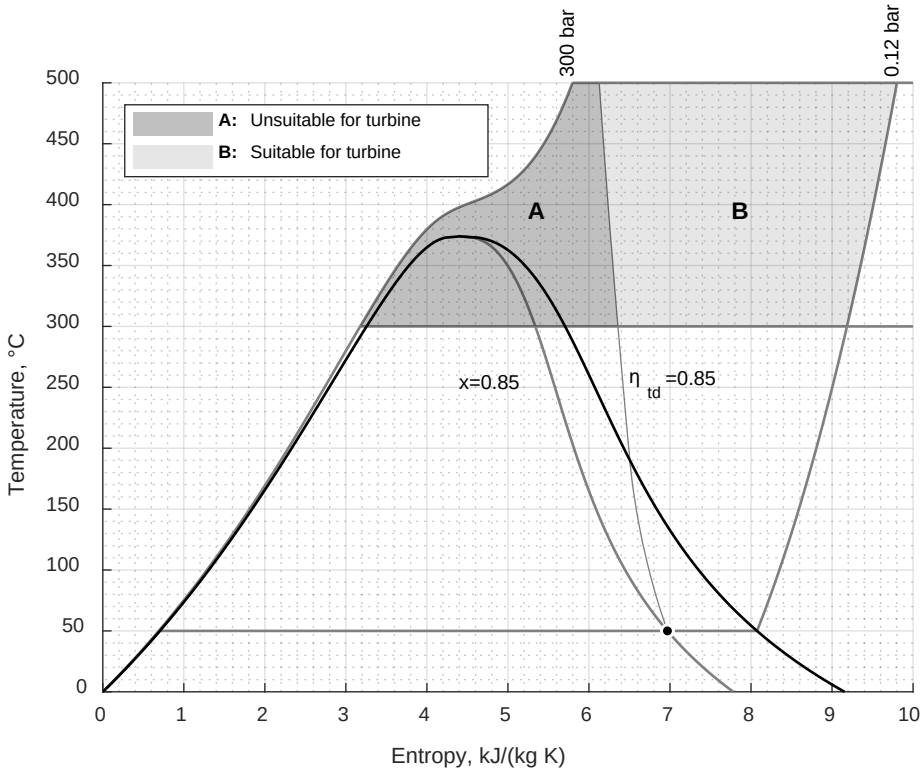

Figure 3: A T-s diagram of water divided into two regions, A and B, based on suitability for supplying typical non-reheat steam turbines.

As will be shown, η_{II} is maximized in dry steam power cycles, because no processing of the geofluid is required to yield vapor suitable for a turbine, which is inherently destructive of exergy. Therefore, this is considered as the most suitable cycle in Region B. In Region A, this type of cycle is not possible, so flash and binary cycles are considered instead. The following three sections describe each of these power cycles in greater detail.

5. Dry Steam Cycles

A dry steam power cycle is essentially a non-reheat Rankine cycle (Çengel et al., 2012, pp. 379-393). The cycle is assumed to be closed by an isobaric heat addition (2-3) for the sake of analysis, so that q_{in}, q_{out}, and w_{net} can be determined. Otherwise, this entails an isobaric rejection of residual heat in a condenser, and an isentropic pumping process. A plant schematic and representative T-s diagram are shown in Figures 4 and 5 below.

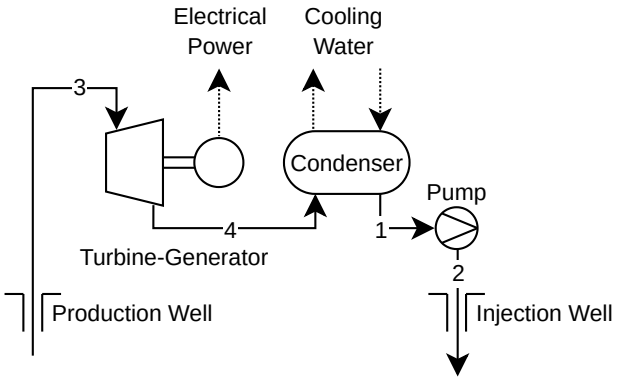

Figure 4: Schematic of a dry steam plant, not to scale.

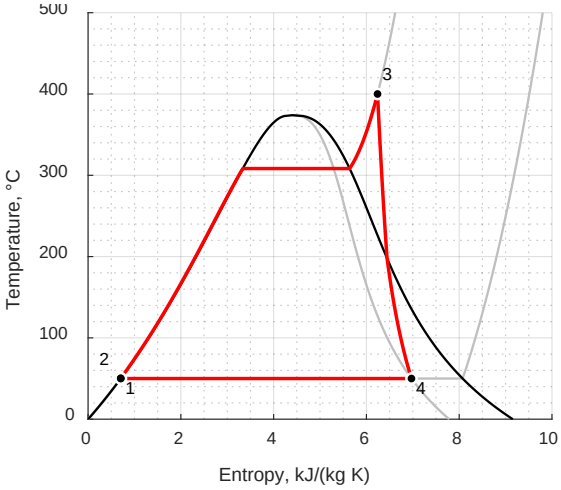

Dry Steam (Non-Reheat Rankine) Cycle

3	400.0	96.45	3105.3	6.24	NaN
4	50.0	0.12	2235.0	6.97	0.850

Figure 5: T-s diagram of a representative dry steam power cycle with $T = 400$ °C at the turbine inlet, and $x = 0.85$ at the turbine outlet.

Evaluating all cycles in the region of interest, Region B, together with the hydraulic constraints for $\dot{m}$ described earlier, yields the plot shown in Figure 6 below.

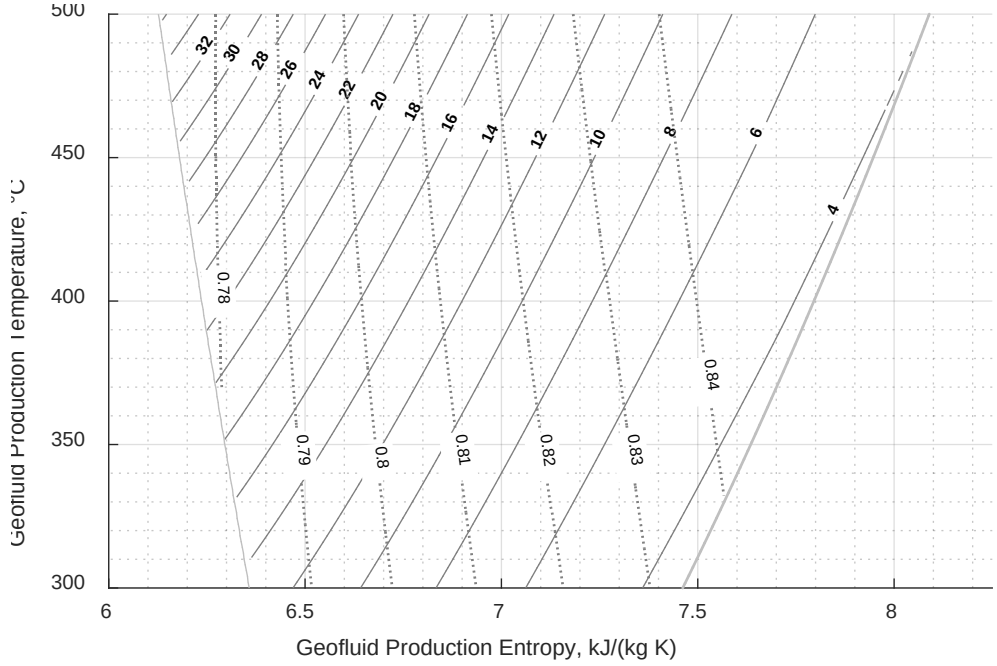

Figure 6: Gross power output in MWe (solid) and exergetic efficiency (dotted) for ideal dry steam cycles. The region of interest is bounded by $\eta_{td} = 0.85$, and $P = 5$ bar.

Although this region shows relatively high exergetic efficiency, this quantity is maximized where ρ and $\dot{m}$ are minimized. The maximum power output $\dot{Q}$ of about 32-34 MWe occurs around 475-500 °C and 150-200 bar, i.e. where the geofluid density ρ is maximized. Per Figure 2, it is anticipated that production in Region A should attain comparable power outputs at significantly lower temperatures, even accounting for the higher exergy in Region B. Thereby, wells producing in Region A could be significantly shallower than in Region B for the same $\dot{Q}$, entailing less capital cost associated with drilling. A further difficulty of producing steam at these extreme conditions is its relatively high compressibility, which typically results in a large frictional pressure drop ΔP between the reservoir and surface. Thereby, sufficiently deep reservoirs may not practically be able to produce at these conditions, because of the characteristic slenderness of the production well.

6. Flash Cycles

Flash cycles work by expanding a liquid-dominated geofluid, separating the resulting saturated vapor, and supplying it to a steam turbine. This is possible because isenthalpic expansion of saturated liquid or two-phase mixtures strictly increases quality x, though it also decreases exergy e. More sophisticated arrangements introduce a second, or less commonly, a third, flash-separation process, yielding higher exergetic efficiency.

Ideal flash cycles are characterized by isenthalpic flash processes, and isobaric separation processes (DiPippo, 2016, pp. 107-163). The separators are assumed to yield separate streams of saturated liquid and saturated vapor. Mixing of fluid streams is assumed to be isobaric, and is governed by conservation of mass and energy. Likewise, the condenser is assumed to be isobaric, and to yield saturated liquid. After leaving the condenser, the geofluid is pumped to the pressure of the final separator and mixed with the residual un-flashed liquid. This yields the final outlet conditions of moderately compressed liquid at an intermediate temperature between that of the condenser and the final separator. A schematic is shown in Figure 7 below.

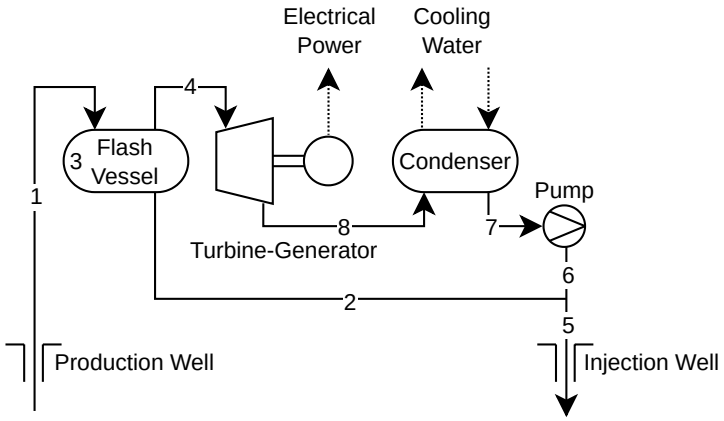

Figure 7: Schematic of a single-flash plant, not to scale.

Conventional geofluid production conditions for flash plants range from about 100-200 °C and $0.1 < x < 0.9$ (Zarrouk and Moon, 2014, pp. 147-148). Because this is generally less than the maximum saturated vapor temperature at the turbine inlet of 190 °C, as derived earlier, geofluid is conventionally separated rather than flashed once produced (DiPippo, 2016, p. 115). However, at the higher temperatures considered herein, the produced geofluid must instead be flashed before it can be separated, to achieve sufficient turbine dryness.

Only a subset of Region A is suitable for flash cycles. Of particular significance is the maximum enthalpy of saturated vapor: where $h >$ 2,800 kJ/kg, isenthalpic expansion generally yields superheated vapor, not a two-phase mixture, as shown in Figure 8 below.

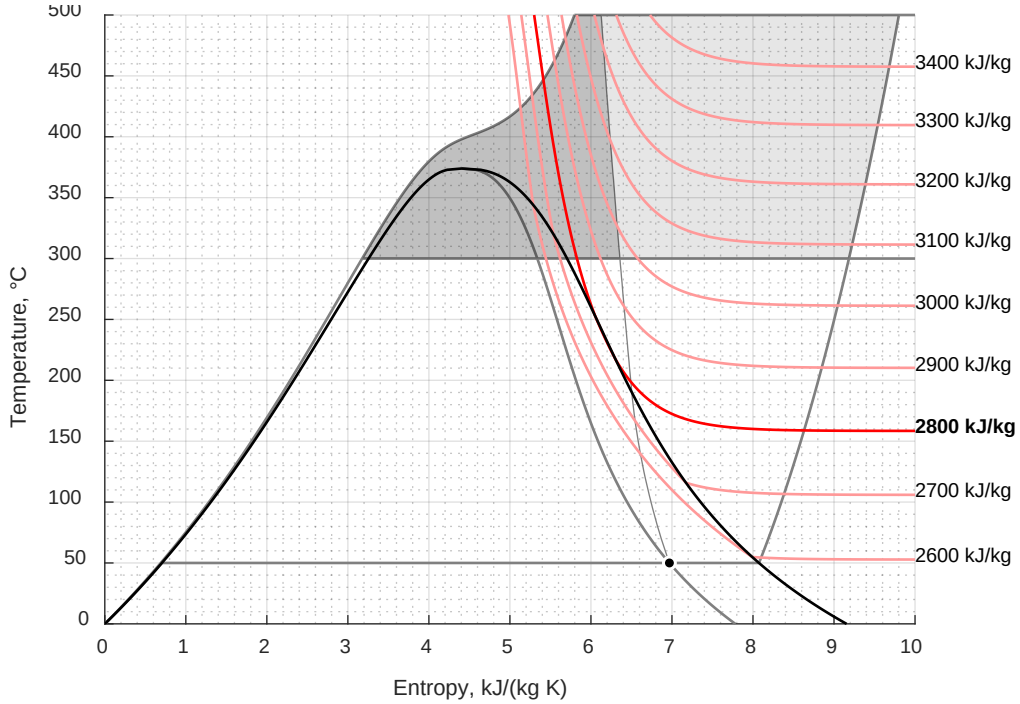

Figure 8: Cycle regions from Figure 3 overlaid with isenthalpic contours in the superheated vapor region. Highlighted is h = 2,800 kJ/kg, the approximate maximum enthalpy of saturated vapor, i.e. $x = 1$.

In the subset of Region A where $h >$ 2,800 kJ/kg, unconventional cycles could nonetheless be developed, for example by expanding the produced geofluid until intersecting the turbine process curve with $\eta_{td} = 0.85$, or by expanding the geofluid in the turbine and separating out the liquid condensate at least once to maintain sufficient dryness, incorporating elements of both dry steam and flash cycles. However, comparing Figures 2 and 8 indicates that the exergetic power $\dot{E}$ in this subset of Region A is relatively low, as compared to where $h <$ 2,800 kJ/kg, on an equal-temperature basis. For this reason, only the subset of Region A where $h <$ 2,800 kJ/kg is considered further in this section.

Given the turbine and condenser specifications described earlier, the main parameters required to define the flash cycle are the quantity of flashes, and the associated separator temperature(s). Conventionally, the optimal separator temperature(s) are well-approximated by the "equal-temperature-split" rule, or ETS, which states that the temperature differences between the inlet, any/all separator(s), and the condenser, are all mutually equal, regardless of the number of flashes (DiPippo, 2016, p. 132).

However, ETS has only limited applicability to high-temperature flash cycles, for two reasons. First, ETS assumes that saturated liquid water has a constant specific heat capacity C_p with respect to temperature. This is accurate to within ±3.6% over 0-200 °C, i.e. over the conventional temperature range for flash plants, but rapidly deteriorates at higher temperatures approaching the critical point, as shown in Figure 9 below. Specific heat at the critical point is effectively undefined, in the sense that $C_p \to \infty$, and $\partial T / \partial h \to 0$, as $T \to T_{crit}$, i.e. heat addition produces no

sensible temperature change, as with vaporization or condensation. Second, it can be shown that ETS generally yields deficient turbine outlet qualities for inlet conditions in Region A.

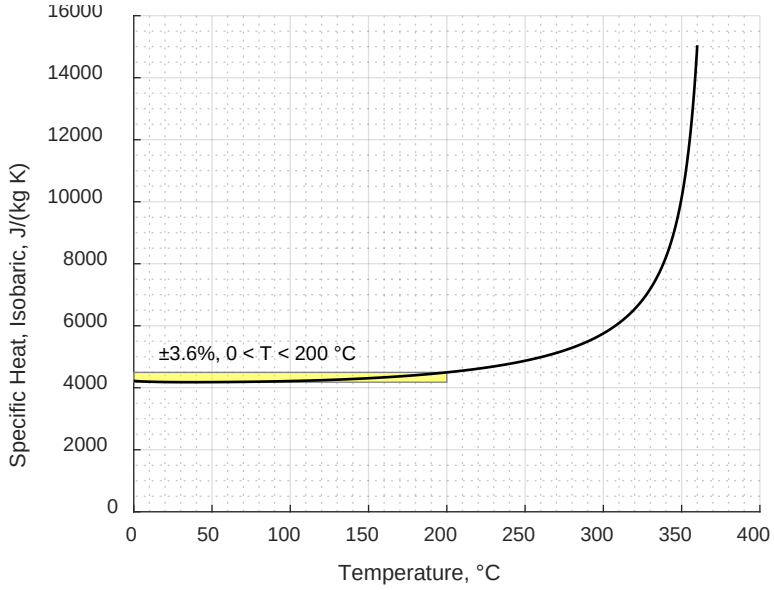

Figure 9: Specific heat capacity of saturated liquid water, showing that relative constancy (highlighted, yellow) breaks down above about 200 °C, as $T \rightarrow T_{crit}$.

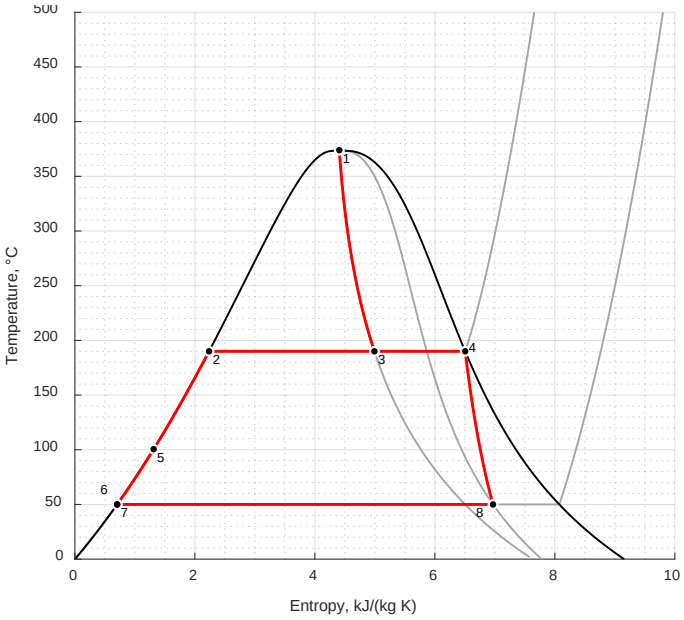
Instead, a gradient ascent algorithm is used to determine the optimal separator temperature(s), in the sense of η_{II}, or equivalently w_{net}, with a step size of 1 °C. Although this method is not guaranteed to find global optima because of possible local maxima in w_{net}, its results compared favorably against exhaustive evaluation for select cases. Optimization is constrained such that no separator operates under vacuum, which is generally considered impractical (DiPippo, 2016, p. 155), and sufficient quality is maintained throughout any/all turbine stages.

Figures 10, 11, and 12 on the following pages show single-, double-, and triple-flash cycles, optimized for representative geofluid production at the critical point, where the gross power output is approximately maximized, per Figure 2. The quantity m is introduced to account for the branching and mixing of geofluid flows, expressing the mass flow rate fraction at each state point.



Direct-Use Single-Flash Cycle

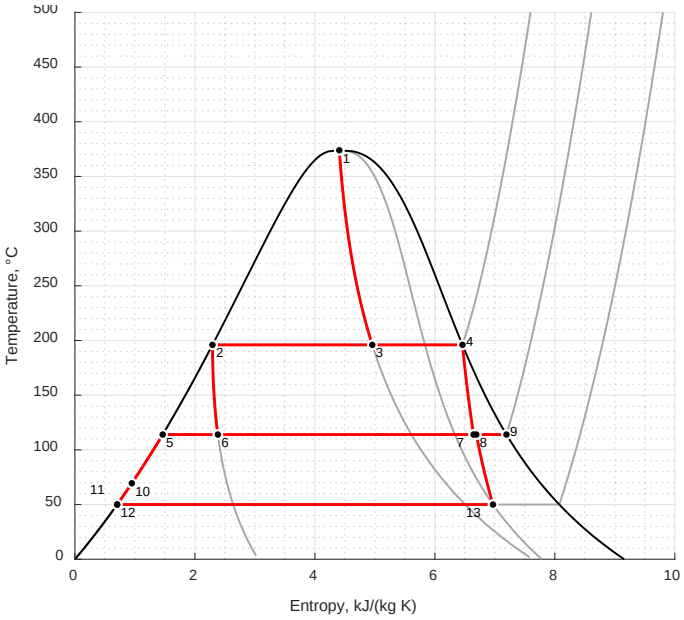
Figure 10: Single-flash cycle for geofluid production at the critical point.

For a single-flash cycle, optimization generally entails maximizing the turbine inlet temperature, which is limited herein to about 190 °C according to the specifications of the turbine and condenser. Thereby, there is generally no dependence between the geofluid production conditions and the corresponding optimal flash cycle. The geofluid outlet temperature is typically high, at least 100 °C, indicating incomplete utilization of the geofluid.



Direct-Use Double-Flash Cycle

Figure 11: Double-flash cycle for geofluid production at the critical point.

Adding a second flash-separation process significantly reduces the geofluid outlet temperature, increasing the exergetic efficiency η_{II}. The small amount of vapor produced in the lower-pressure separator allows the temperature of the first separator to increase slightly, while maintaining the same turbine outlet conditions. The thermal efficiency η_I is essentially unchanged.

Figure 12: Triple-flash cycle for geofluid production at the critical point.

By contrast, adding a third flash-separation process yields less than a 1% improvement in η_{II}, and only about a 5 °C reduction in the geofluid outlet temperature. Likewise, there is no improvement in the thermal efficiency η_I. Unlike a more conventional flash cycle, e.g. at 150 °C, introducing a third flash does not significantly increase the vapor fraction at the turbine outlet, which is relatively high because of the large ΔT, ΔP, and Δx of the first flash alone.

Generally, the result of the gradient ascent optimization can be described as a variant of ETS, applied only between the first separator and the condenser, rather than between the inlet and the condenser, such that the first separator temperature is maximized, subject to the constraints of the turbine and condenser. This heuristic method yields a w_{net} that closely approximates the result via gradient ascent.

Figures 13, 14, and 15 on the following pages show the gross power outputs and exergetic efficiencies of single-, double-, and triple-flash plants, for geofluid produced in the subset of Region A where $h < 2{,}800$ kJ/kg.

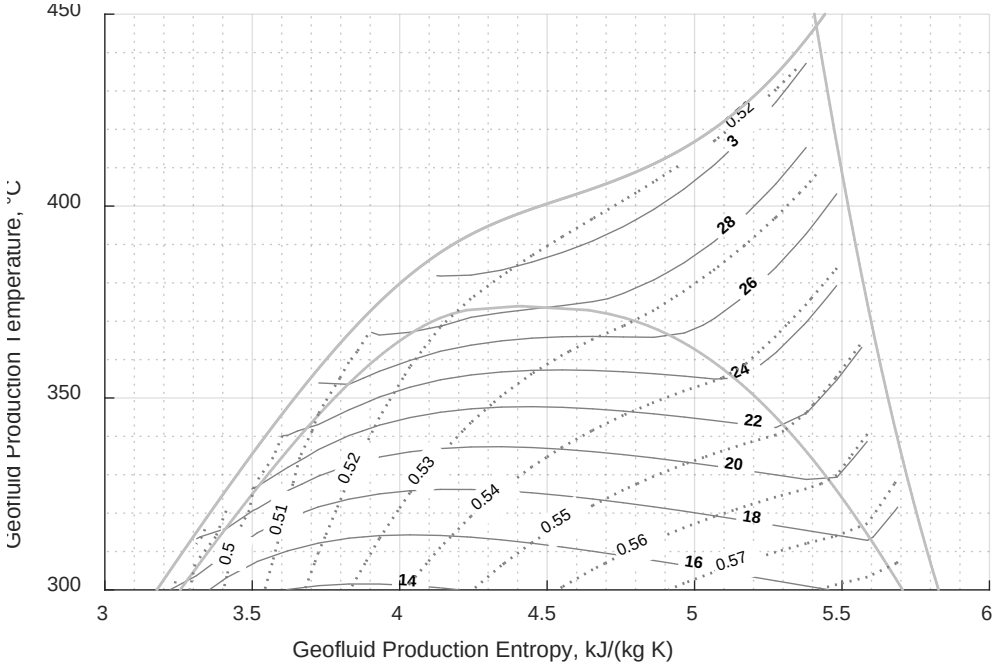

Figure 13: Gross power output in MWe (solid) and exergetic efficiency (dotted) for ideal single-flash cycles.

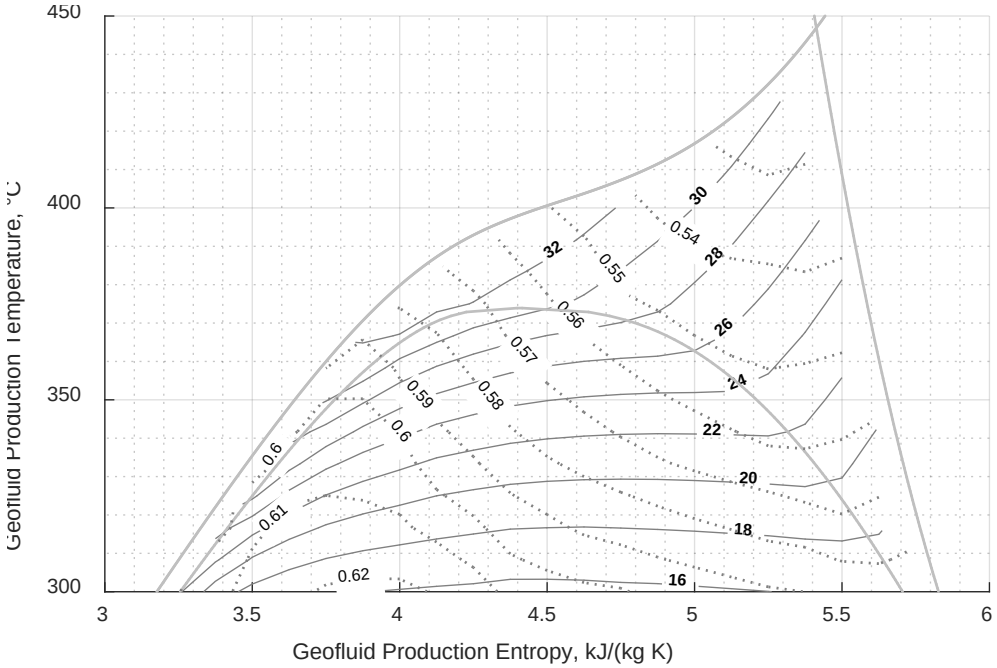

Figure 14: Gross power output in MWe (solid) and exergetic efficiency (dotted) for ideal double-flash cycles.

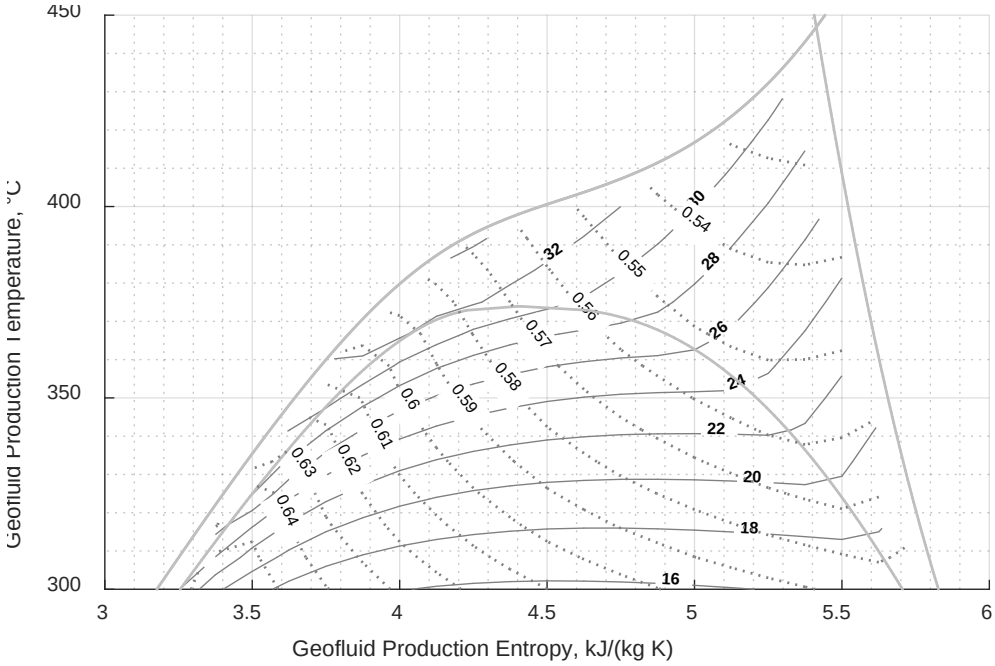

Figure 15: Gross power output in MWe (solid) and exergetic efficiency (dotted) for ideal triple-flash cycles.

These figures show ideal gross power outputs of up to about 30-32 MWe per well. In the subcritical region where $T < T_{crit}$, gross power output $\dot{Q}$ is generally maximized for a given temperature T in the compressed liquid region, confirming the earlier finding on the basis of exergetic power $\dot{E}$. Likewise, in the supercritical region where $T > T_{crit}$, gross power output $\dot{Q}$ increases with pressure P. In the subcritical region, as the quality of the produced geofluid x increases, there is less benefit to incorporating additional flashes, because the first flash alone yields a relatively high fraction of vapor m. The improvement to η_{II} associated with adding a second or third flash depends sensitively on the geofluid production conditions, with generally more improvement towards the liquid-dominated and supercritical regions. Notably, the maximum power attainable is approximately equal between the subcritical and the supercritical regions, indicating that attaining supercriticality is not necessary to maximize the gross power output. Further, the temperature required for maximum power output is significantly lower in the subcritical region.

The main drawbacks associated with flash cycles are their susceptibility to geofluid impurities, and their relatively large pump loads. The flash-separation process concentrates any solid impurities in the residual liquid of the flash vessel(s), which can cause scaling and fouling (DiPippo, 2016, p. 156), while permitting non-condensible gases (NCGs) such as carbon dioxide, methane, and hydrogen sulfide to enter the turbine and condenser, which reduces performance, increases corrosion, and can require specialized treatment (DiPippo, 2016, pp. 660-661). Particularly for subsurface systems requiring high-pressure reinjection, the large amount of geofluid pressure dissipated by the flash cycle increases the plant's parasitic pump load: for example, pressurizing 100 kg/s of water by 100 bar requires at least 1 MWe. Both drawbacks are mitigated by binary cycles, as described in the following section.

7. Binary Cycles

Whereas flash cycles use the produced geofluid directly, binary cycles instead transfer the geofluid's heat to a secondary working fluid in a series of counterflow heat exchangers, producing vapor suitable for a turbine. The main benefit of this approach is that the plant is less exposed to any contaminants that may be present in the produced geofluid, because the geofluid and working fluid do not mix (DiPippo, 2016, pp. 193-234). Because the heat transfer from the geofluid to the working fluid is ideally isobaric, the geofluid may require less pressurization before reinjection as compared to a flash plant, and thereby may incur less parasitic pump load. A schematic is shown in Figure 16 below.

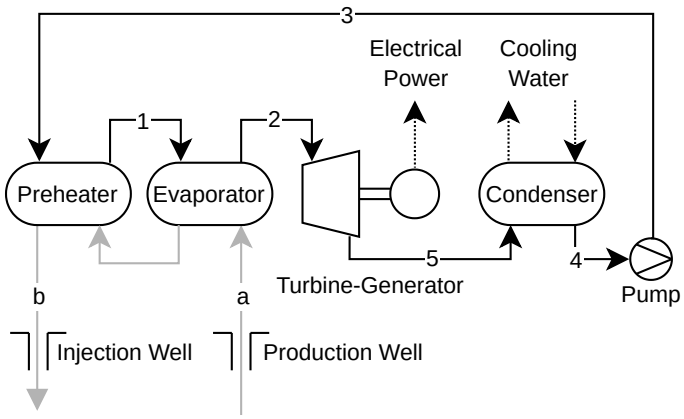

Figure 16: Schematic of a single-pressure binary plant, not to scale. Black arrows denote working fluid, and gray arrows denote geofluid.

The main irreversibility inherent to binary cycles is the heat transfer in the heat exchangers. Because heat can only transfer spontaneously in the direction of decreasing temperature, the working fluid can only approach, but cannot attain, the geofluid's production temperature. Thereby, vaporizing the working fluid inherently destroys some of the geofluid's initial exergy. This loss can be compared to the flash process of flash cycles, which is similarly irreversible and destructive of exergy.

This irreversibility can be mitigated in several ways, the most significant of which is the choice of working fluid. Ideally, the working fluid maintains a constant, small temperature difference ΔT at all points throughout the heat exchanger, as heat is transferred from the geofluid. The degree to which an actual heat transfer approaches this ideal "matched" condition is commonly evaluated using temperature-heat transfer, or T-q, diagrams.

Organic Rankine cycles, or ORCs, are a type of binary cycle that use a hydrocarbon working fluid, most commonly isobutane, butane, isopentane, or pentane, in order of increasing critical temperature. These are well-suited for typical geofluid production temperatures of 100-250 °C (Zarrouk and Moon, 2014, p. 150). This can be understood in terms of the match between the geofluid production temperature and the working fluid critical temperature, the latter of which ranges from 134.6-196.5 °C for the hydrocarbons cited. An additional benefit of an ORC is a relatively compact, dry turbine, because of the high density and retrograde condensation of hydrocarbon vapor, in both senses unlike steam.

However, it is not practical to superheat a hydrocarbon working fluid much beyond its critical temperature. This tends to increase q_{in} approximately as much as q_{out}, such that there is only marginal benefit to w_{net}, η_I, and η_{II}; that is, any superheat added before the turbine must be rejected in approximately equal magnitude by the condenser, as shown in Figure 17 below. This can be attributed to hydrocarbons' retrograde condensation, which causes superheating of the working fluid in the turbine, rather than partial condensation. Secondarily, fluid density decreases sharply after the critical point, progressively inhibiting heat transfer. For these reasons, ORCs do not typically exceed about 200 °C.

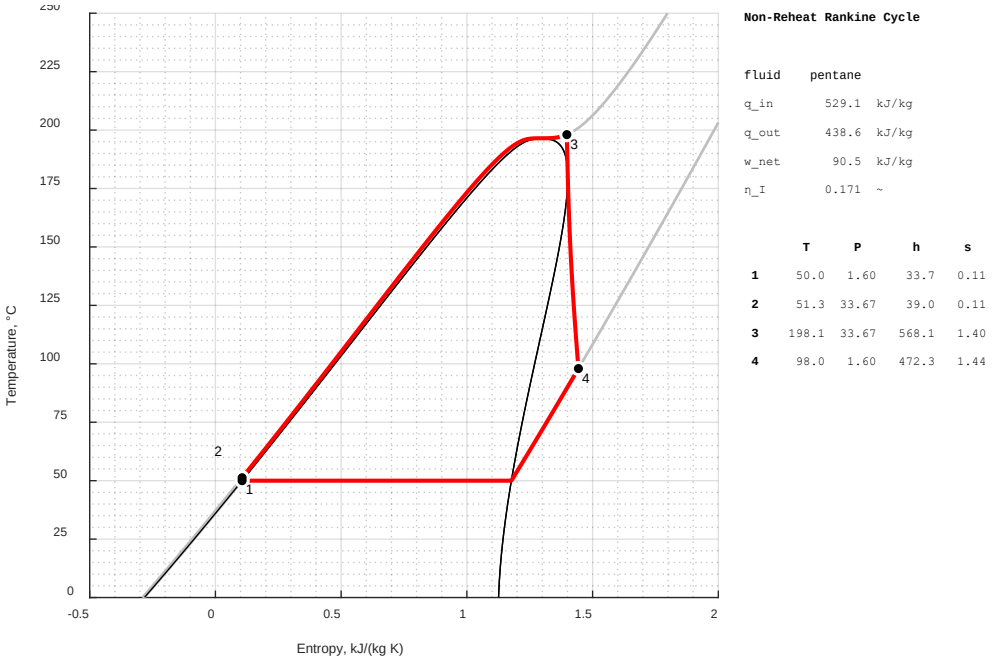

Figure 17: Supercritical pentane cycle, showing that any superheat added before the turbine, 3-4, must be rejected in approximately equal magnitude by the condenser, 4-1.

Because of this limitation, it can be shown using the methods developed later in this section that water outperforms typical ORC hydrocarbons for geofluid production temperatures exceeding about 315 °C, as shown in Figure 18 below. Note that each working fluid's critical temperature T_{crit} correlates to the range of geofluid production temperatures over which it is best suited. It can also be shown that cyclopentane ($T_{crit} = 238.5$ °C) has comparable performance to water over this temperature range, although no such plants are known to exist, and it compares unfavorably in cost, toxicity, and flammability. For these reasons, water is considered as the working fluid of choice for geofluid produced at 300-500 °C.

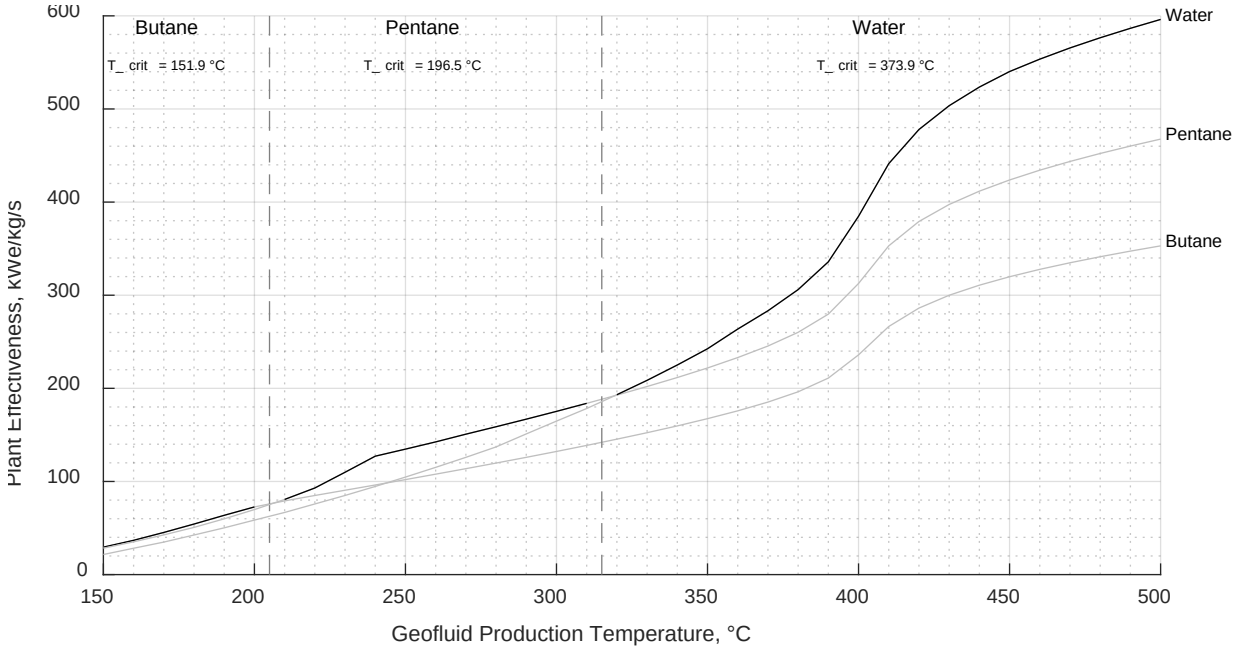

Figure 18: Optimized double-pressure binary plant effectiveness as a function of the working fluid composition and geofluid production temperature, for geofluid produced at 300 bar. Working fluids are emphasized in black over the temperature range for which they are best suited.

The simplest form of a binary cycle consists of two heat exchangers, or sets of heat exchangers, collectively called a preheater, and an evaporator. These produce saturated liquid, then saturated vapor, respectively, which is then supplied to a turbine. This configuration, sometimes referred to as single-pressure, typically has a single pinch point between the preheater and evaporator, where the temperature difference between the two fluids is minimized. The allowable value for this pinch point depends on hardware specifications, but is taken generically as $\Delta T_{pp} = 10$ °C herein. A dual- or double-pressure binary cycle improves on this design by adding an additional pump, preheater, and evaporator at a different pressure, producing vapor at two temperatures simultaneously that eventually mix in the turbine at the appropriate pressure. Typically, two pinch points occur, between both sets of preheaters and evaporators. Triple-pressure cycles are also possible, but are less common because of the diminishing returns associated with additional pressures.

Many of the same assumptions made earlier for ideal flash cycles also apply to ideal binary cycles, specifically: isobaric heat transfers, isentropic pumping, and mixing governed by conservation of mass and energy. Superheating is theoretically possible in binary cycles, but can be shown to confer only marginal benefit, and is less practical because of the decrease in heat transfer efficiency, so is not considered herein. The parameters governing the turbine(s) and condenser are taken as identical to the flash cycles described earlier.

For a given geofluid production scenario and working fluid selection, the remaining parameters required to define a cycle are the quantity of pressure(s), their associated saturation temperature(s), and for multi-pressure cycles specifically, the relative mass flow rate at each pressure. No flow branching occurs in single-pressure cycles, so trivially $m = 1$ throughout these cycles. In double-pressure cycles, m_{HP} implicitly defines m_{LP} by conservation of mass, and likewise with m_{HP}, m_{IP}, and m_{LP} in triple-pressure cycles, where HP, IP, and LP denote the high-, intermediate-, and low-pressure loops. The geofluid's T-q curve, and thereby the q_{out} or Δh of the geofluid, is determined by the bisection method, using the working fluid's T-q curve, and the specified ΔT_{pp}.

Optimization is either one-, three-, or five-dimensional, depending on the choice of a single-, double-, or triple-pressure cycle, respectively. The optimal values of these parameters are again determined using a gradient ascent algorithm, with fixed step sizes of 1 °C for T, and 0.01 (or 1%) for m. The optimization criterion is the exergetic efficiency η_{II} of the coupled geofluid-working fluid system, or equivalently its net work w_{net}. Local minima typically exist in η_{II} for double- and triple-flash cycles, such that converged solutions from the gradient ascent method are not necessarily global optima, but close approximations of it. Optimization is again constrained such that the evaporator(s) do not operate at sub-atmospheric pressure.

The mass flow rate of the working fluid is related to that of the geofluid by conservation of energy; that is, the heat power of the geofluid is ideally equal and opposite to that of the working fluid, neglecting leakage:

$$\dot{m}_g \, \Delta h_g = \dot{m}_w \, \Delta h_w \tag{14}$$

Where the subscripts g and w denote the geofluid and working fluid, respectively. Since $\Delta h_w = q_{in}$, the mass flow rate of the working fluid cycle can be expressed as:

$$\dot{m}_w = \frac{\dot{m}_g \, \Delta h_g}{q_{in}} \tag{15}$$

Figures 19, 20, and 21 on the following pages show T-s and T-q charts for single-, double-, and triple-pressure binary cycles, for representative geofluid production at the critical point.

Figure 19: Single-pressure binary cycle for geofluid production at the critical point.

The optimal single-pressure working fluid cycle is generally independent of the geofluid production conditions. Maximizing η_{II} entails maximizing the turbine's inlet temperature, which is limited herein to about 190 °C per the constraints of the turbine and condenser. A single pinch point occurs between the preheater and evaporator, at State 1. The geofluid outlet temperature is generally high, at more than 100 °C, except where production is vapor-dominated; in these latter cases, the condensation of the geofluid in the evaporator with $\partial T/\partial q = 0$ increases the geofluid's $\partial T/\partial q$ in the preheater, improving the T-q curve match, and decreasing the geofluid outlet temperature.

Figure 20: Double-pressure binary cycle for geofluid production at the critical point.

Adding a second vaporization pressure enables a better T-q curve match and a lower geofluid outlet temperature, conferring a significant improvement in exergetic efficiency η_{II}, and by extension gross power output $\dot{Q}$. Two pinch points occur between both pairs of preheaters (8-4, 3-1) and evaporators (4-7, 1-2). Optimization equalizes the magnitudes of these two pinch points at States 1 and 4. Most of the working fluid flows through the HP loop, with the small remainder flowing through the LP loop, enabling a slightly higher turbine inlet temperature. The thermal efficiency η_I is essentially unchanged.

Figure 21: Triple-pressure binary cycle for geofluid production at the critical point.

By contrast, adding a third vaporization pressure does not confer significant benefit to thermal efficiency η_I or exergetic efficiency η_{II}, and thereby does not appear to be economical. This can be seen heuristically from the optimized T-q curves, which show only two significant pinch points at States 4 and 9, one less than the maximum implied by the quantity of vaporization pressures.

Figures 22, 23, and 24 on the following pages show the gross power outputs and exergetic efficiencies of single-, double-, and triple-pressure binary plants for geofluid produced in Region A.

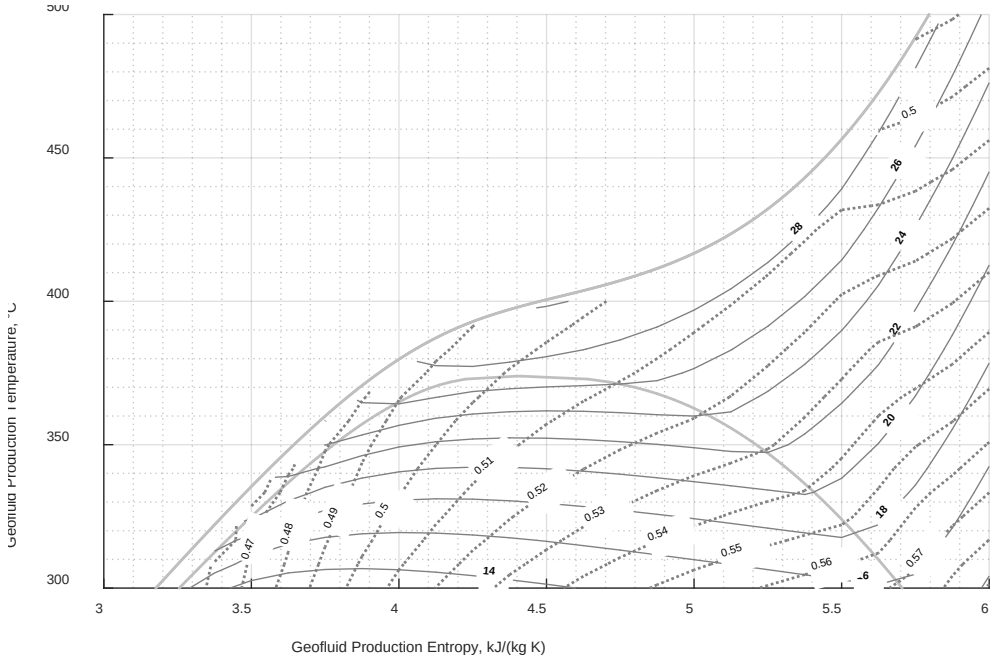

Figure 22: Gross power output in MWe (solid) and exergetic efficiency (dotted) for ideal single-pressure binary cycles.

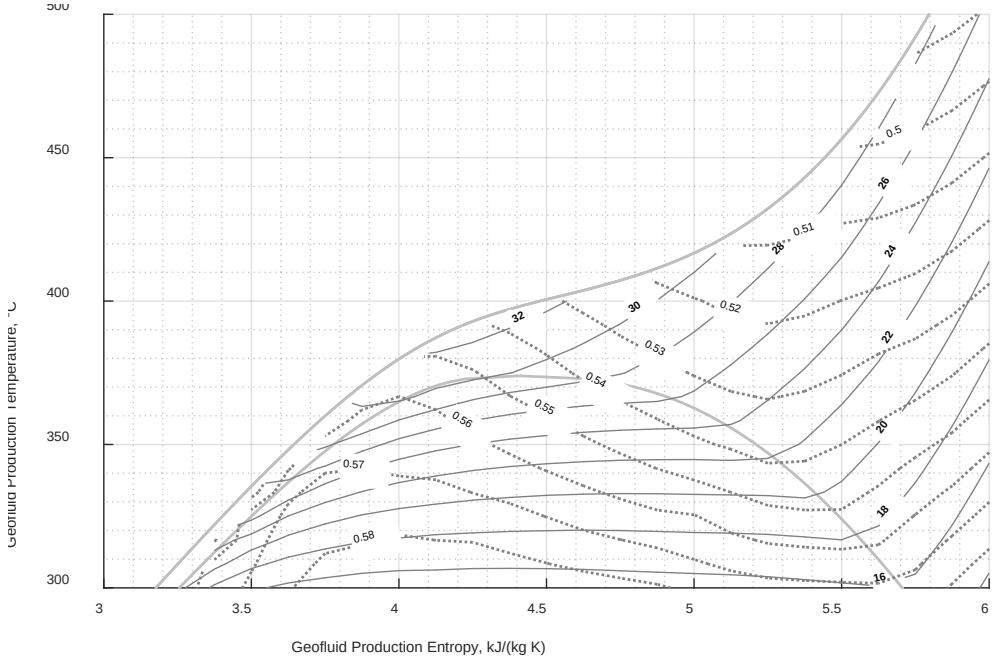

Figure 23: Gross power output in MWe (solid) and exergetic efficiency (dotted) for ideal double-pressure binary cycles.

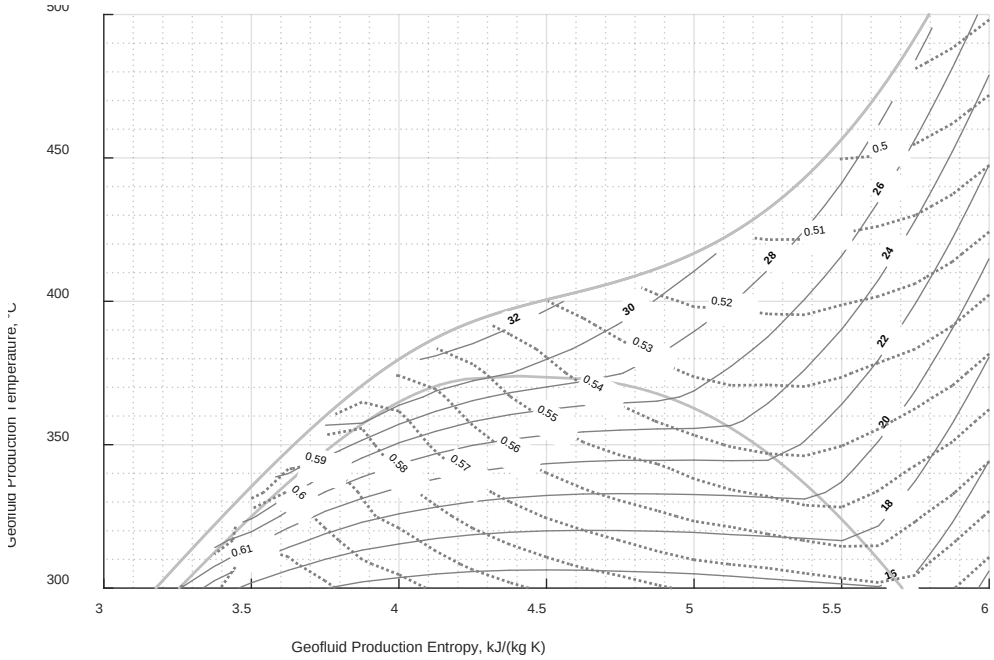

Figure 24: Gross power output in MWe (solid) and exergetic efficiency (dotted) for ideal triple-pressure binary cycles.

These plots show that the characteristics of ideal high-temperature binary plants are highly comparable to those of high-temperature flash plants. The gross power output is increased significantly by introducing a second vaporization pressure, while introducing a third vaporization pressure confers benefit mainly towards the liquid-dominated region. For a given temperature T, the gross power output $\dot{Q}$ is generally maximized where the geofluid production is densest, corresponding to the phase regions of compressed liquid and supercritical fluid. The gross power output increases significantly with temperature in the subcritical region, and less significantly with pressure in the supercritical region.

8. Conclusion

This paper considered the ideal gross output of a generic geothermal power system producing between 300-500 °C. The characteristically high slenderness of the production well imposes significant hydraulic constraints on geofluid production. Accordingly, the maximum mass flow rate of a production well with an 8.5” minimum inner diameter was found to be about 100 kg/s. Combining this hydraulic constraint with the thermodynamic constraint associated with exergy indicated that exergetic power is maximized in the compressed liquid and supercritical regions of water, at about 55-60 MWe, which have characteristic production pressures of $P > 85.9$ bar in the subcritical region, and $P > 220.6$ bar in the supercritical region. Further, it was noted that exergetic power plateaus around the critical point of water, after which gains in exergy are approximately offset by losses in mass flow rate, suggesting that supercriticality is not necessary for maximum performance.

Geofluid production was classified into two regions, A and B, based on suitability for supplying typical non-reheat steam turbines. Region B was defined as being sufficient for a dry steam power cycle, while Region A required a more complex power cycle, i.e. flash or binary, to attain sufficient turbine dryness.

Dry steam power cycles in Region B were found to be superior in terms of exergetic efficiency, ideally around 78-84%, because no processing of the geofluid is required, entailing minimal irreversibility. However, the gross power output is limited by the characteristically low geofluid production density, limiting the production mass flow rate and pressure.

Flash cycles were considered in the subset of Region A where $h < 2{,}800$ kJ/kg, i.e. where isenthalpic expansion generally produces a two-phase mixture. The conventional "equal-temperature-split" (ETS) guideline for flash separator temperatures was shown to break down above about 200 °C, as the temperature approaches the critical point where the specific heat becomes undefined. Instead, a gradient ascent algorithm was used to determine the optimal separator temperatures that maximize the cycle's exergetic efficiency. Single-, double-, and triple-flash cycles were evaluated, showing substantially greater gross power output on an equal-temperature basis, as compared to the earlier dry steam power cycles. Though the exergetic efficiency was lower, at 50-65%, this was more than compensated for by the denser geofluid production, yielding higher mass flow rates. It was noted as a heuristic approximation that ETS applied between the first separator at the highest possible temperature and the condenser yielded a net work that closely matched the result obtained via gradient ascent. Adding a second or third flash was found to be more effective towards the liquid-dominated and supercritical regions. Drawbacks associated with solid and gaseous geofluid impurities, as well as pump loads, were noted.

Binary cycles were also considered in Region A. The choice of working fluid was considered as the primary means of mitigating the irreversibility inherent to this type of cycle. It was shown that the hydrocarbon working fluids characteristic of organic Rankine cycles (ORCs) cannot practically attain temperatures exceeding about 200 °C because of their retrograde condensation. As a result, water was found to outperform these hydrocarbons above a geofluid production temperature of about 315 °C, and was considered as the working fluid of choice. A gradient ascent algorithm was again used to determine the optimal evaporator temperature(s) and mass flow rate fraction(s) to maximize the cycle's exergetic efficiency, accounting for pinch points between the two fluids in T-q coordinates. The thermal efficiencies, exergetic efficiencies, and gross power outputs of these optimized cycles, in single-, double-, and triple-pressure variations, were found to be highly comparable to flash cycles of equal sophistication. This can be attributed to the many properties that are shared between the two cycles, including the working fluid composition, the turbine performance, and the heat rejection scheme. In this sense, binary plants attain performance comparable to flash plants, with significantly less susceptibility to geofluid impurities, and potentially with less parasitic pumping load.

As a whole, this work indicates that geothermal systems may attain their maximum power output with a production temperature as low as 350-375 °C, i.e. near the critical temperature, provided that the production pressure is sufficiently high. For a production well with an 8.5” minimum inner diameter, the ideal power output is about 30-32 MWe gross, using either a double-flash cycle, or a double-pressure binary cycle. This represents the potential of up to an order of magnitude improvement over the typical performance of current geothermal systems.

Nomenclature

The symbols shown in Table 1 below are used throughout this paper. Where applicable, the assumed value is also shown.

Symbol	Definition	Value	Units
C_p	Specific heat capacity, isobaric	-	J/(kg K)
$\dot{E}$	Exergetic power	-	MW, or MWe
$\dot{Q}$	Gross power output	-	MWe
T_{cond}	Condenser temperature	50	°C
T_{crit}	Critical temperature	-	°C
T_o	Temperature, dead state	50	°C
$\dot{m}$	Mass flow rate	-	kg/s
q_{in}	Heat input	-	kJ/kg
q_{out}	Heat output, or rejection	-	kJ/kg
v_e	Erosional velocity	-	m/s
w_{net}	Net work	-	kJ/kg
x_{min}	Turbine minimum quality	0.85	-
η_I	Thermal (First Law) efficiency	-	-
η_{II}	Exergetic (Second Law) efficiency	-	-
η_{td}	Turbine efficiency, dry, isentropic	0.85	-
h	Enthalpy	-	kJ/kg
Δ	Difference, or change	-	-
ΔT_{pp}	Temperature difference at pinch point	10	°C
A	Wellbore minimum cross-sectional flow area	0.0366	m^2
D	Wellbore minimum inner diameter	8.5	in
L	Wellbore length	-	m
P	Pressure	-	bar
T	Temperature	-	°C
c	Erosional constant, empirical, API RP 14E	100	$(ft/s)(lb/ft^3)^{1/2}$
e	Exergy	-	kJ/kg
f	Friction factor	-	-
m	Mass flow rate fraction	-	-
q	Fraction of heat transferred	-	-
s	Entropy	-	kJ/(kg K)
v	Velocity	-	m/s
x	Quality, or dryness fraction	-	-
δ	Partial derivative	-	-
ρ	Density	-	kg/m^3

ABSTRACT

Commercial utilization of superhot rock geothermal energy could significantly contribute to global decarbonization by making high-enthalpy geothermal power available across diverse geographical settings. This paper reviews an assessment of the optimal energy production pathways of superhot rock energy downstream of the geofluid production at the surface. It identifies equipment gaps for dealing with geothermal fluid above 400˚C in a power plant system. The focus is on the need to foster innovation and identify an efficient system that is not currently available off-the-shelf. Setting a benchmark of 500 MW for energy production represents an approach aligned with industry trends in high-temperature, high-pressure, hot dry rock geothermal systems. This benchmark sheds light on critical technological gaps that must be addressed to unlock the full potential of superhot rock energy and facilitate a seamless transition toward sustainable energy sources.

By undertaking this evaluation, the paper provides valuable insights into the current state of superhot rock energy technology and paves the way for future research and demonstration initiatives. Ultimately, the findings of this study are poised to inform strategic decision-making processes, guide investment priorities, and shape the trajectory of superhot rock energy production towards a more sustainable and resilient energy landscape.

1. Introduction

This study assesses the optimal energy production pathway of superhot rock energy after the point of fluid production at the surface. It uses that assessment to define the most efficient production pathway and identify technology gaps that must be tackled for superhot rock energy to enable the energy transition.

The following phases were studied:

Production Pathways and Electricity Demand: Identify and define a high-efficiency electricity production pathway from superhot rock geothermal resources.

Cooling System Analysis: Evaluate various technologies for cooling and/or condensing of the produced fluid.

Component Specifications and Technology Gap Analysis: Further definition of essential characteristics of each significant component based on a final power plant technology.

Cost Estimate: Generate a Class 5 (Association for the Advancement of Cost Engineering, AACE) cost estimate for capital and operating costs.

This study will help to enable policies, further private and public investment, and push continued technological innovation to help commercialize superhot rock geothermal. This study can inform the future research and demonstration needs for the production of superhot rock energy and assess how downstream technologies, such as direct air capture (DAC), hydrolysis, hydrogen production, and more, may be able to benefit from the production of electricity using superhot rock energy.

2. Overview of Relevant Projects (Hill 2022)

Several R&D projects around the world have already drilled into superhot rock and have begun developing methods for operating in these extreme heat and pressure conditions. However, superhot steam has yet to be harnessed for power production.

Iceland Deep Drilling Project: IDDP has been a superhot rock drilling initiative for over a dozen years as a part of the European Union's DEEPEGS program. The first test well, IDDP-1 Krafla, was completed in 2009 after drilling was terminated when it encountered magma. Krafla demonstrated the energy potential of superhot wells with a projected energy flow of 36 MWe. The second IDDP well, IDDP-2 Reykjanes, reached its objective of supercritical (superhot) conditions at 426°C in 2017. IDDP planned to flow test the well in 2021. An inferred casing collapse shortly after completion of the well ultimately rendered it unusable for testing as planned. IDDP is currently planning a third superhot well.

Japan Beyond Brittle Project: The Japan Beyond Brittle project (JBBP) was initiated to investigate the feasibility of creating enhanced geothermal systems in the brittle–ductile transition zone. This study grew out of the initial deep drilling work conducted at the Kakkonda geothermal area in Japan. Anticipated advantages of such a system include a potentially very large geothermal energy resource that could result in economic energy extraction, simpler reservoir design and control, reduced parasitic fluid losses, and reduced induced seismicity.

Hotter and Deeper: The Hotter and Deeper Exploration Science (HADES) project in New Zealand has been exploring superhot resources in the Taupo Volcanic Zone since 2009 and has been planning a scientific drilling project into New Zealand's deep-seated superhot rock. Like JBBP, the project hopes to investigate potential reservoir systems in the superhot plastic brittle-ductile transition zone at about 7 km where geophysics suggests there is little seismic activity. This is another EU supported project.

DESCRAMBLE: Italy's Larderello geothermal field has been a heat resource for over a century, with electric power production since 1913, and was the site of an intensive EU collaborative effort from 2015-18 (known by the acronym DESCRAMBLE) to drill into superhot rock (also as a part of the EU DEEPEGS program). Superhot conditions were initially encountered in the early 1980s in Larderello's San Pompeo-2 well. Larderello's Venelle-2 is the hottest geothermal well on record, registering 514°C at a depth of 2.9 km (1.8 mi).

3. Design Basis

The study site location assumed for this high-level analysis exercise was in the general vicinity of San Luis Obispo, CA, as representative of a location without temperature extremes. The well pads are assumed to be located 500 m from the plant with 5 well pairs per well pad. Each well pair consists of one injection and one supply wellhead as shown in Figure 1.

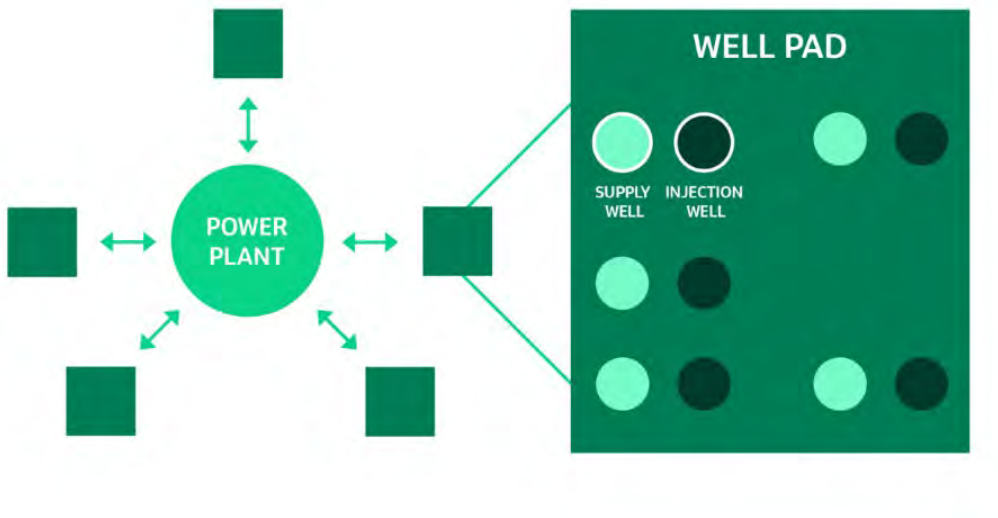

Figure 1: Visual schematic of wells and power plant

The assumptions that form the basis of this study are outlined in Table 1.

Table 1: Design basis assumptions

Parameter	Units	Value
Superheated Steam Supply Pressure (at production wellhead)	bar	140
Superheated Steam Supply Temperature (at production wellhead)	°C	400
Superheated Steam Flow Rate (per production well)	kg/s	33.8
Injection Pressure (at plant boundary)	Bar	155
Injection Flow Rate (at plant boundary)	Kg/s	33.8
Plant Output	MW	500
Water Loss in Downhole Superhot Rock System	%	5
Wet Bulb Temperature	°C	21

Plant inlet conditions were assumed to be 130-135 bar and 390°C to allow for losses in the gathering system. A plant size of 500 MW gross was selected to represent a range for the superhot rock industry to strive for to balance the costs of the wells and the expected revenue generation from electricity production.

For the purpose of evaluating the most efficient energy production pathway, geochemistry of the superhot rock geofluid was considered at a high level. There are considerations in design that would need to be addressed depending on the resource. Traditionally, hydrothermal resources have contaminants that come up with the geofluid, including silica, sodium, chlorides, etc., that, in addition to the fluid pH, can cause a variety of issues, including pipe corrosion and damage to the steam turbine. To remove the contaminants, operators often "wash" the steam with a condensate spray to bring the incoming steam slightly below saturation. The contaminants will become entrained in the condensate that is then separated prior to the steam entering the turbine.

4. Production Pathways for Electricity Demand

Three different plant configurations were evaluated for power production. For evaluating plant output and steam usage, a wet cooling tower was used as a condensing heat sink. With the plant size set to 500 MW gross, the total geofluid required to meet that demand was calculated based on the assumed well capacity. This dictated the number of wells required for the plant and has a significant impact on the overall cost of the facility.

The following plant designs were evaluated:

1. **Dry Steam Plants**
    a. **Direct steam use**. The superheated steam is used directly in the steam turbine as received from the wells.
    b. **Washed steam.** Washing the superheated steam to remove contaminants, resulting in clean but saturated steam fed to the steam turbine.
2. **Binary Cycle Plant:** use the geofluid in a heat exchanger to boil water in a typical closed loop steam cycle.

4.1 Dry Steam Plant Model

Figure 2 displays the dry steam plant model that was developed using a combination of the modeling software packages AspenTech HYSYS and Thermoflow.

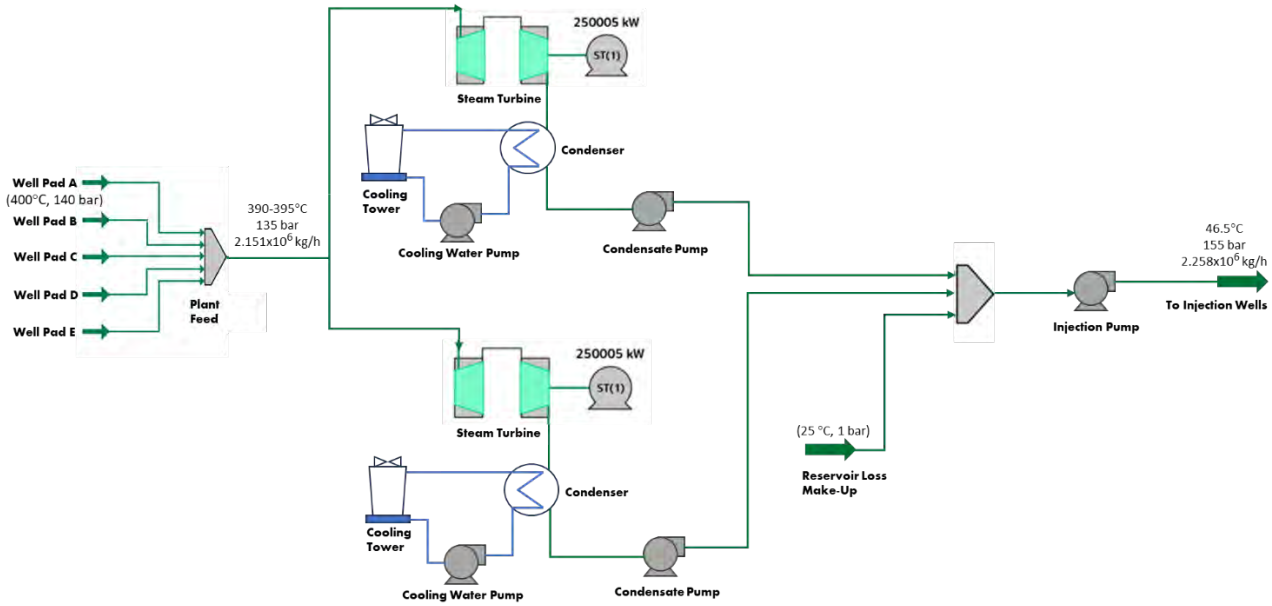

Figure 2: Dry Steam Plant Configuration

The steam is collected from the wellfield and combined into a supply header at the plant boundary. The steam is split into 2 x 250 MW condensing steam turbines to represent the current industry standard for steam turbine sizing. Larger steam turbines are possible but are considered a bespoke product. The cooling tower provides cooling water to condense the turbine exhaust efficiently under vacuum in a surface condenser. The condensate and injection pumps provide the pressure to recirculate the fluid through the downhole superhot rock system. The noncondensable gas (NCG) removal system that would be used to extract the NCGs from the condenser is not shown.

For the washed steam case, water will be sprayed into the incoming steam sufficient to desuperheat and slightly cool the steam. A separator between the wash water spray and the turbine inlet will remove the resulting condensate, which contains a large portion of the steam contaminants that could cause corrosion or deposits in the steam turbine.

4.2 Binary Model

The intent of using a binary cycle to extract energy from a superhot rock resource is to avoid using the potentially contaminated resource directly in a turbine and instead put it through an intermediate heat exchanger. This would eliminate the need for specialized turbine materials, significantly reducing mitigation costs. In Figure 3, the superhot rock resource is used in a heat exchanger where the heat is transferred to a closed water/steam loop. The cooled geofluid is then sent back to injection. Depending on the geofluid process conditions and pressure drops from the wells or in the system,, there may be NCG breakout which would require an NCG removal system (not shown). The closed loop cycle was modeled using water that would be heated and vaporized in the heat exchanger and sent through a similar 2 x 250 MW steam turbine system. A wet cooling tower supplies cooling water to a surface condenser, which condenses the turbine exhaust.

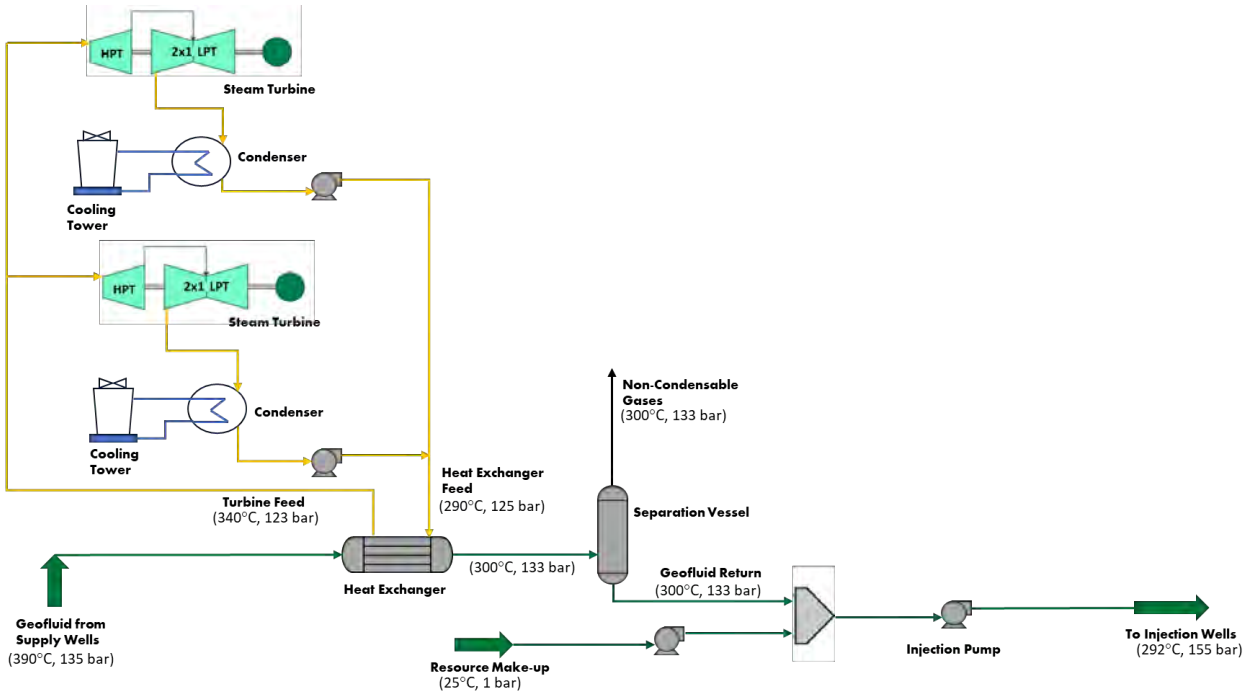

Figure 3: Binary Cycle Plant Configuration

Performance in the binary loop as modeled is limited by temperature approaches in the heat exchanger between the incoming geofluid and the closed water loop. This limits the geofluid exit temperature from the heat exchanger. To improve the efficiency of this type of plant, the geofluid leaving the heat exchanger ("geofluid cold" in the diagram) could become the hot side of a second heat exchanger that generates steam in a closed loop at a lower pressure, which would be fed to the steam turbine at the appropriate pressure location. It is possible that a third (low pressure) steam generation loop could be created, effectively creating a three-pressure steam cycle.

4.3 Results and Conclusions

Table 2 presents a relative comparison of the modelling results and the key performance indicators for the direct use, washed steam, and binary cycle models using the direct use cycle as a basis.

Table 2: Relative Comparison of Values

Relative Comparison	Direct Use	Washed Steam	Binary Cycle
Geofluid Required	1.0	1.16	1.44
Parasitic Load	1.0	1.16	1.39
Geofluid per MW	1.0	1.25	1.51
Production wells	17	20	25

The washed steam and binary cycles require more geofluid, have a higher parasitic load, and require more geofluid per MW of power produced compared to the direct use case. From a performance standpoint, the direct use configuration is the most efficient.

This study focuses on the needs for innovation in a more efficient power plant system that is not yet readily available off-the-shelf. The remainder of this study was based on the direct use configuration for the power plant to address equipment requirements and cost.

5. Water Use Analysis

With the direct use cycle configuration established, different cooling methods were evaluated using the following designs:

- Forced Draft Cooling Tower (CT)
- Natural Draft Cooling Tower (CT)
- Air-Cooled Condenser (ACC)

Table 3 summarizes the water usage for each technology.

Table 3: Water Use Requirements

	Units	Natural Draft CT	Forced Draft CT	ACC
Total Water Required	kg/hr	2,067,840	2,115,216	109,080
Annual Water Use	$x10^6$ kg	18,114	18,529	956
Water Usage	kg/kWh	4.14	4.23	0.22

The total water required for the natural and forced draft cooling towers is similar. There is no water required for air cooling, therefore the only water required for a plant with an ACC system is makeup water due to the loss within the formation. The comparison found that water requirements for a wet cooling system are approximately 20 times that of a plant using dry cooling. Strictly based on water consumption, the ACC would be the best cooling system choice for the plant design. However, there are parasitic power penalties associated with the ACC compared to the wet cooling systems.

Developers may opt to locate plants near large bodies of water and use cooling systems similar to nuclear and Natural Gas Combined Cycle (NGCC) plants as a method to minimize water costs. However, the dry cooling (ACC) option for the final version of the model for this study was selected to represent a plant that could be located anywhere and not limited to sites with access to makeup water.

6. Technology Gap Analysis

The objective of this phase of the study was to develop a major equipment list for the representative power plant model selected: direct use with dry cooling. Ultimately, equipment and material selections will also be dependent on the conditions of the geofluid and the specific site location.

Technology Readiness Levels (TRLs) were originally developed by NASA in the 1970s for space exploration technologies and are used to assess the maturity level of a technology throughout its research, development and deployment phase progression. TRLs are based on a scale from 1 to 9, with 9 being the most mature technology as shown in Table 4.

Table 4: Technology Readiness Level Definitions

TRL Level	Description
1	Basic Principals Observed
2	Technology Concept Formulated
3	Experimental Proof of Concept
4	Technology Validated in Lab
5	Technology Validated in Relevant Environment
6	Technology Demonstrated in Relevant Environment
7	System Prototype demonstrated in Operational Environment
8	System Complete and Qualified
9	Actual System Proven in Operational Environment

The information provided in Table 5 includes potential vendors for each item listed and an assessment of the Technology Readiness Level (TRL) of the various items.

Table 5: Technology Gap List

System	Equipment	TRL
Steam Gathering System	1. Wellhead Unit/Valves (typical geothermal design but rated for 140+ barg) 2. Test Unit 3. Carbon steel piping with large corrosion allowance.	1. TRL 8 2. TRL 9 3. TRL 9
Injection System	316 stainless steel piping	TRL 9
Warm-Up separator/ Atmospheric Flash Tank	Carbon steel with 2205 duplex stainless steel internal cladding and internals	TRL 9
HP Separator	Carbon steel with 3/16" 625 Inconel thermomechanical internal cladding, Inconel 625 internals	TRL 9
Steam Turbine Generator	2x250MW (gross) STG	TRL 5-6
Condenser	Surface condenser: AL2003 Lean Duplex shell & tube	TRL 9

System	Equipment	TRL
Condensate Storage Tank	Carbon steel with corrosion-resistant internal coating	TRL 9
Gas Removal System	1. Steam Jet Ejectors (SJE): 316L stainless steel 2. Liquid ring vacuum pump (LRVP): 316 cast stainless steel, 316L separator tank 3. Intercondensers: 316L stainless steel	TRL 9
Cooling/Condensing System	Air-cooled Condenser	TRL 9
Blowdown tank	Carbon Steel	TRL 9
Drains Tank	Carbon Steel	TRL 9
Brine/wastewater pond	Impervious pond lining	TRL 9
Make-Up water system	Wells, pumps, gathering system, storage tank	TRL 9
Rock Muffler	Standard Rock muffler is a concrete structure	TRL 9
Diesel Genset	Standard 500kW – 1MW size	TRL 9
Fire protection system	1. Diesel, Electric and Jockey pumps 2. Firewater storage tank	TRL 9
Pumps	1. Condensate: 316 SS wetted parts 2. Cooling water: 316 SS wetted parts 3. Injection: Super Duplex SS wetted parts 4. Brine/wastewater pond: 316 SS wetted parts	TRL 9
H_2S Abatement System	(Excluded from this scope, specific needs to be determined by local environmental regulations) Potential technologies in current use: • Liquid redox (Lo-Cat, Lo-Cat II, Stretford)	TRL 9

System	Equipment	TRL
	• Recuperative thermal oxidizer (RTO) • BIOX • Upstream caustic washing • Burner-and-scrubber	

The materials chosen for major equipment are intended to resist corrosion from either short-term exposure to concentrated hydrochloric or sulfuric acid or long-term exposure to dilute solutions of the same. Equipment that does not list any materials does not need any special consideration, e.g., the fire protection system.

Most of the equipment outlined in Table 4 required for the surface facilities has a TRL between 7 (system prototype demonstrated in operational environment) and 9 (system proven in operational environment). The specific design of a steam turbine for the environments considered in this study should currently be considered to exist at a TRL of 5-6 (technology validated or demonstrated in a relevant environment) due to various details of the turbine design need to be adapted to the specific composition of the geofluid.

6.1 Geothermal Superheated Steam Turbine Design Considerations

Various aspects of the turbine design will need to be adapted to the considerations of the geofluid conditions. These are known technologies that are used where needed in a particular turbine application. For example, one manufacturer identified the design of the turbine internals for a particular geothermal application that included special materials specifications for the rotor and certain stage blades, special design of blades in specific stages, special design of blades for vibration control, special design of stage condensate removal components, and specific blade coatings for various stages. All these considerations are within the turbine supplier's knowledge base and have been incorporated either in production turbines or in test units in field conditions. Without requesting a quotation from a specific vendor for a particular geofluid resource, it cannot be determined exactly what design considerations might be used by that vendor for this application. Also, different vendors may address the design requirements using different technologies.

The chloride and hydrogen sulfide (H_2S) contaminants pose a threat of high corrosion in the turbine stages where steam condensation starts to occur, as the condensate droplets will have high concentrations of hydrochloric or sulfuric acid, respectively. The H_2S partitioning into the condensate from the steam is also affected by the ammonia gas (NH_3) content in the steam. The presence of these contaminants in the high pressure/high-temperature environment not normally seen in geothermal steam turbines also affects the consideration of issues such as Stress Corrosion Cracking (SCC) and creep strength. These factors will require evaluation of metallurgies such as ferritic stainless steel, duplex stainless steel, and high nickel alloys in the turbine design, in addition to currently used treatments such as stellite coatings on blade edges.

6.2 Recommendations for Further Study

Certain high-cost materials used in this design, such as duplex stainless steel or Inconel, could be replaced with next-generation materials or coatings. The geothermal environment presents significant challenges for materials, so any new materials should undergo extensive in situ testing before being used as a substitute for current materials.

7. Cost Estimate

The final phase of the study was to develop an American Association of Cost Estimators (AACE) Class 5 (rough order of magnitude, accuracy within -30% to +50%) cost estimate for the construction and operation of the representative SHR geothermal power plant (excluding the wells and gathering system costs) to determine the order of magnitude capital and operating costs. The unique requirements for the turbine increase the equipment cost and consequently increase the plant's overall cost. However, the remaining major equipment has a TRL of 9, so the cost of that equipment should not exceed that of a traditional geothermal plant. As the turbine vendors work to improve materials and bring down costs of the bespoke superheated geothermal steam turbine, the goal would be to bring overall inside the plant costs to ~$2,000 USD/kW.

8. Conclusions

The purpose of this study was to understand the remaining equipment technology gaps for developing superhot rock power plants with focus on the surface infrastructure. After modeling, analysis, and conversations with vendors, it was concluded that most pieces needed for a superhot rock plant already exist, either in power plant designs or in other industries. However, because a SHR test facility has yet to be constructed and commissioned, the TRL is 5 for the system as a whole.

Future research and development for superhot rock power production should focus on achieving cost reductions and moving from specialized equipment to off-the-shelf materials. Future research must focus on this equipment's cost reductions, but most technology gaps for superhot rock remain outside of the power plant system. A superhot rock power plant can be envisioned as a hybrid model between a traditional fossil fuel or nuclear power plant, which deals with high steam temperatures, pressures, and power output, and a geothermal power plant, which deals with the specific needs of accessing subsurface heat.

Investing in research and development for superhot rock energy holds significant promise, not only for providing the heat necessary for industrial processes but also for contributing substantial power to the grid, offering a sustainable and efficient solution to meet energy demands.

Increased Structural Integrity of Casings of High-Temperature Geothermal Wells using Novel Technologies

Gunnar Skúlason Kaldal[1], Steinþór Níelsson[1], Þorri Jökull Þorsteinsson[1]

[1]ÍSOR – Iceland GeoSurvey

Keywords

Geothermal, High-Temperature Geothermal Wells, Casings, Flexible Couplings, Stress Mitigation, Thermal Expansion

ABSTRACT

Well casings in geothermal wells that are used to produce from high-temperature fields are prone to fail due to a combination of factors, e.g. the quality of the cemented annulus and the degree of temperature change, that can result in structural overload. The main failure modes have been identified as collapse and tensile rupture of the casing. Casing collapse is an effect of annular pressure buildup in the cemented annuls primarily due to excess water and/or closed off water in the cement sheath that expands as the well warms up for the first time after drilling. Whereas tensile failure is an effect of permanent deformation in compressive (hot) state where the yield strength is surpassed generating plastic strain in the material that in tensile (cold) state results in tensile failure. Such casing failures can cause significant production problems, both in terms of wellbore flow restrictions and operational safety. Additionally, current lessons learned from drilling and producing from superheated/supercritical deep geothermal wells brings forward the conclusion that the metal casings are a bottleneck for reliable structure and/or a successful project. These challenges need to be solved to continue the pursuit of deep drilling into superhot conditions. Two technological advancements have been in development within ÍSOR, (i) Flexible Couplings are intended to solve the axial thermal expansion problem by allowing displacement of every casing joint into the connection and (ii) Casing Collapse Protection, a pressure relief system to relief temporary overpressure within a cemented annulus that is intended to prevent casing collapse. These two solutions work together in increasing the structural integrity of the casing throughout its lifetime. The patented Flexible Couplings have been developed within ÍSOR from the year 2015 within several research projects (EU Horizon 2020 supported GeoWell and DEEPEGS, and GEOTHERMICA project GeConnect) and the annular pressure relief system is being developed in the EU Horizon Europe supported project COMPASS.

1. Introduction

Design, drilling and operation of high-temperature geothermal wells has improved substantially over the years since utilization of high-temperature fields for electricity power production and combined heat and power utilization was initiated over a half a century ago. Materials and methods have improved and been adapted to conditions that can be quite different between fields as well as within fields. In most cases, the near steady state conditions during production are less demanding than transitional periods, such as conditions that form during warmup of wells and shut-in periods where the chemical attack can increase substantially, e.g. due to condensate and local cooling of the wells. While wells warm up, thermal expansion generates mechanical loads on the constrained casings where compressive stresses build up and lead to permanent (plastic) strains that are non-recoverable. This deformation of the casing material can lead to subsequent tensile failures if the casing is allowed to cool down again. Such tensile failures are oftentimes found around another failure mode of the casing, casing collapse. Such failures can occur if water is trapped in the annulus between casings or if excess water in the cement is high enough to generate annular pressure while the well warms up. During the first flow test of a well, the temperature can increase rapidly in the relatively cool shallow section of the well that is above the geothermal reservoir. This can result in a rapidly forming annular pressure that can result in a casing collapse. The combination of the rate and level of the temperature increase, well geometry, enclosed casing-to-casing annulus, casing material quality, etc. are the leading factors for risk of casing failures occurring. Well design aims to increase reliability of the structure and reduce the likelihood of casing failures by following the guidelines in standards, e.g. the New Zealand code of practice for deep geothermal wells NZS 2403:2015. However, there are limits in e.g. temperature or unforeseen conditions that can form. The two, tensile failure and casing collapse, have been identified as the main casing failures found in high-temperature geothermal wells.

To solve these issues, two technological solutions have been developed. The former is the Flexible Coupling (FC), that has been in development at ÍSOR since the year 2015, is designed to allow the production casing to intermediately thermally expand into the couplings that connect the casing joints together limiting the compressive stress to the elastic regime. FCs have gone through multiple R&D cycles of iterative design, full-scale prototype builds and testing for function and structural loads. Most of the R&D work was done within the EU Horizon 2020 supported research projects GeoWell (no. 654497) and DEEPEGS (no. 690771). The FCs have also been tested in a relevant environment at well conditions of 260°C @ 60 bar-g within the GEOTHERMICA research project GeConnect (no. 731117) where the connection was cemented into a full joint length into a casing-to-casing experimental setup and function tested with repeated thermal cycles. The experiment showed that the inner 9-5/8” casing adapted with a Flexible Coupling expanded and moved in the cement sheath closing the thermal gap inside the coupling, confirming the function and keeping the stress level in the casing below the yield point of the K55 casing material. Flexible Couplings are due to be run in hole for field testing in ON Power a subsidiary to Reykjavik Energy geothermal field Nesjavellir in SW-Iceland in the fall of 2024. The Flexible Couplings will be run in a full production string, replacing the conventional couplings. The casing integrity will be monitored with downhole caliper- and video logs before thermal recovery of the well and the closure of the connections after well heat-up will be monitored with a high-temperature caliper logging tool. Since the closure gap within the connections is only 15 mm, this may become tricky, therefore it is important to log the initial position of the casing before cold injection is stopped and the well is allowed to warm up. The latter developed technology is the annular pressure relief

technology with a working title “Casing Collapse Protection” that has been in development at ÍSOR within the EU Horizon Europe supported project COMPASS (no. 101084623) that is coordinated by ON Power a subsidiary of Reykjavik Energy. The annular pressure relief Casing Collapse Protection is being developed to prevent casing collapse of thermally expanding annular fluids. A patent application has been filed for the novel technology. Combined, the patented “Flexible Couplings” and the patent pending annular pressure relief system the “Casing Collapse Protection”, aim to prevent the most common casing failures and by that increase the structural integrity of the production casing in high-temperature geothermal wells.

2. Structural Integrity

Drilling into high-temperature geothermal areas requires the use of cemented steel casings that enable well control during drilling of the next stage. The last casing, the production casing, that typically reaches up to the surface is the permanent conduit of the geothermal fluid and steam to the surface. Drilled with constant circulation of drilling fluid, the casing is relatively cool when cement locks it into place. Thermal recovery results in thermal expansion of the downhole structure, made of several steel casing strings and cemented annuli. The casings are constrained in the cement, a permanent plastic strain is produced as they thermally expand. Furthermore, if fluids are present in the confined casing-to-casing annulus it can also expand and develop high annular pressure.

A previous study has shown that load history and sequence of loading is important to understand formation of stress and strain that lead to various failure mechanisms (Kaldal G. S., Jonsson, Pálsson, Karlsdóttir, & Thorbjornsson, 2011). The level of permanent (plastic) strain that is developed in the casing is governed by temperature difference and if thermal cycling occurs the strain produced depends highly on the material properties of the casing material. Casing expansion at elevated temperatures, where stresses surpass yield and permanent strain is produced, has called for strain-based mechanical design (Miller & Dall'Acqua, 2023). A diagram shown in Figure 1 describes the problem where if the temperature is high enough the casing material will pass the yield point and deform and if the well cools down again for example for workovers or cleaning, the casing contracts and high residual tensile forces are generated that can lead to tensile failure. An example of such failure is shown in Figure 2.

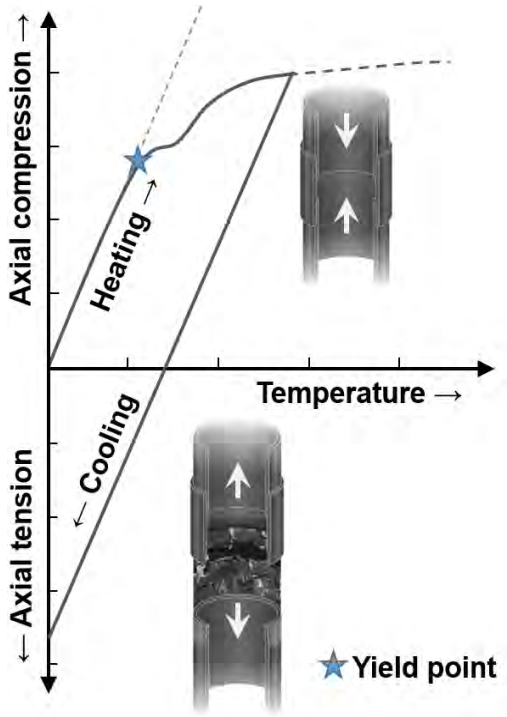

Figure 1: Concept diagram for the failure mechanism where axial tension is generated subsequent to strain that formed in compression, adopted from a diagram by Rahman & Chilingarian (Rahman & Chilingarian, 1995) (Kaldal & Thorbjornsson, Thermal expansion of casings in geothermal wells and possible mitigation of resultant axial strain, 2016).

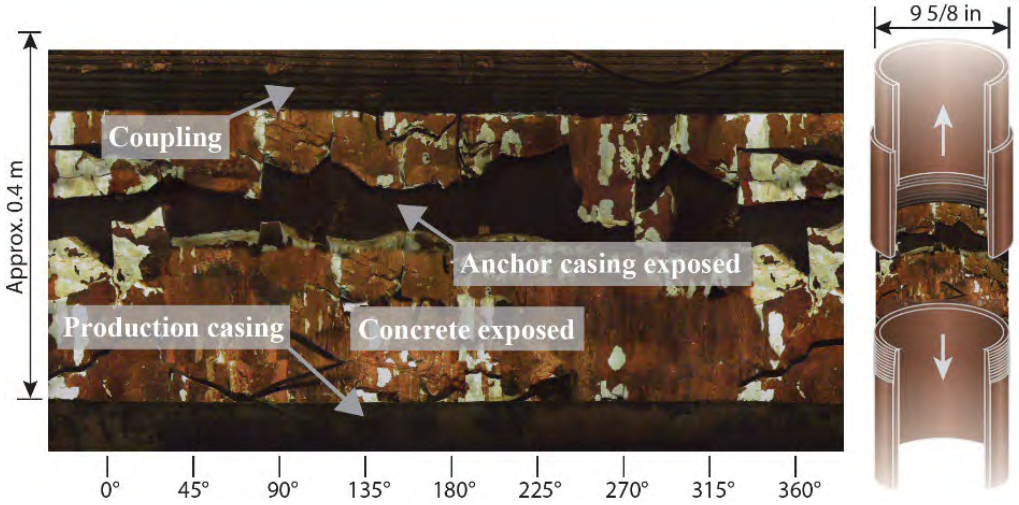

Figure 2: Coupling failure due to casing thermal contraction in the production casing of the IDDP-1 well. The failure occurred while the 450°C hot well was killed with cold water (Kaldal G. S., Jonsson, Palsson, & Karlsdottir, 2016).

Annular pressure buildup (APB) has been extensively studied in uncemented casing-to-casing annulus in oil and gas wells (Jandhyala & Chiney, 2014). Collapse due to annular pressure buildup (APB) in casing pipes of deepwater oil and gas wells in the Gulf of Mexico led to shutdown of the oil field. Control measures for trapped annular pressure (TAP) have been evaluated and reviewed, including increasing casing strengths, eliminating trapped annular pressure, releasing trapped pressure at surface or by using rupture disks, balancing the expansion volume and blocking heat transfer (Dong & Chen, 2017). Suryanarayana et al. 2020 evaluate casing collapse due to APB of trapped fluid pockets in cement between casings and present quantitative basis of design such that the outer string bursts and relieves APB before the inner string collapses. They note that the design basis in NZS 2403 of maintaining ratio of 1.2 between API collapse rating and API burst rating is not adequate basis of design as the burst rating is not representative of the rupture limit of the outer casing. Instead, they propose to use a probabilistic design, however, noting that it may sometimes lead to infeasible choices for the outer or inner string, where the recourse is to ensure good cementing (Suryanarayana, Bowling, Sathuvalli, & Krishnamurthy, 2020). Results from finite-element model analyses of casings have shown that casings supported by cement have higher resistance to collapse, and that non-uniform geometry and/or loads can severely impact the structural stability and cause premature collapse (Figure 3). An example of casing collapse caused by APB is shown in Figure 4. The collapse was punched out leaving the anchor casing exposed to the wellbore fluids.

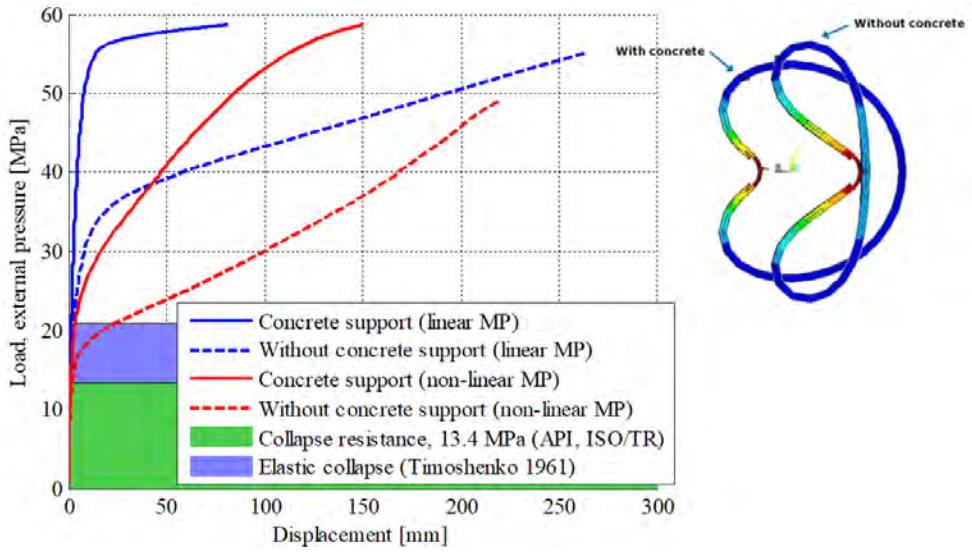

Figure 3. The effect of concrete structural support to the casing. Load-displacement collapse and post-collapse curves of a cement supported casing versus a non-cemented casing showing that cement support increases the collapse resistance of the casing substantially (Kaldal et al. 2013).

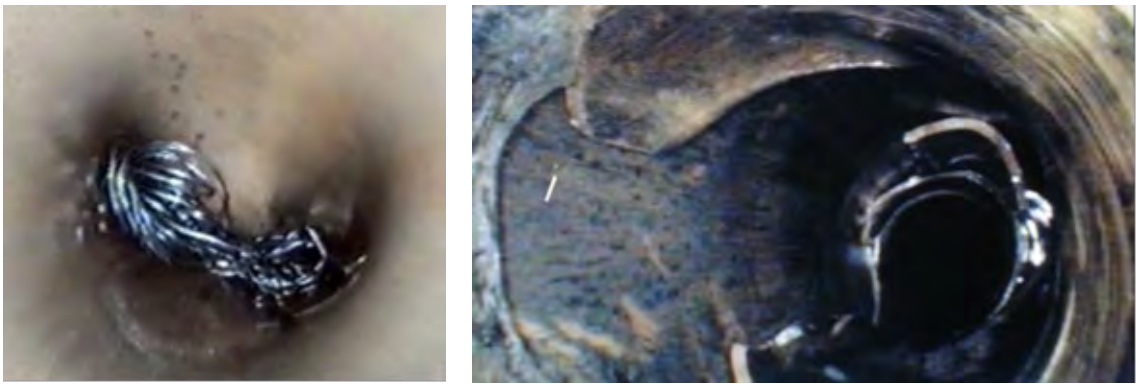

Figure 4. Example of a casing collapse of a 9-5/8“ production casing in a high-temperature geothermal well with remains of slick line from a stuck logging tool (left). The collapse was later punched out leaving the anchor casing exposed to the wellbore fluids (right), by courtesy of Reykjavik Energy and ON Power.

If excess water is high enough or if a water pocket exists, pressure in a cemented casing-to-casing annulus will be generated as the well warms up after being drilled with circulation of cold drilling fluids. In a casing-to-formation cemented annulus the evolution of the pressure can be much less severe than in a casing-to-casing annulus as the rock formation is likely to take excess pressures. The most severe pressure raise is shown in the diagram in Figure 5 where an isochoric process is assumed for a water pocket at initial conditions at point A follows the path to point B. However, the pressure buildup is likely to be less severe due to slight volume change and relief of pressure through the cemented annulus shown in a potential path from A to C. The collapse resistance of two typical production casings (at RT) is shown for reference.

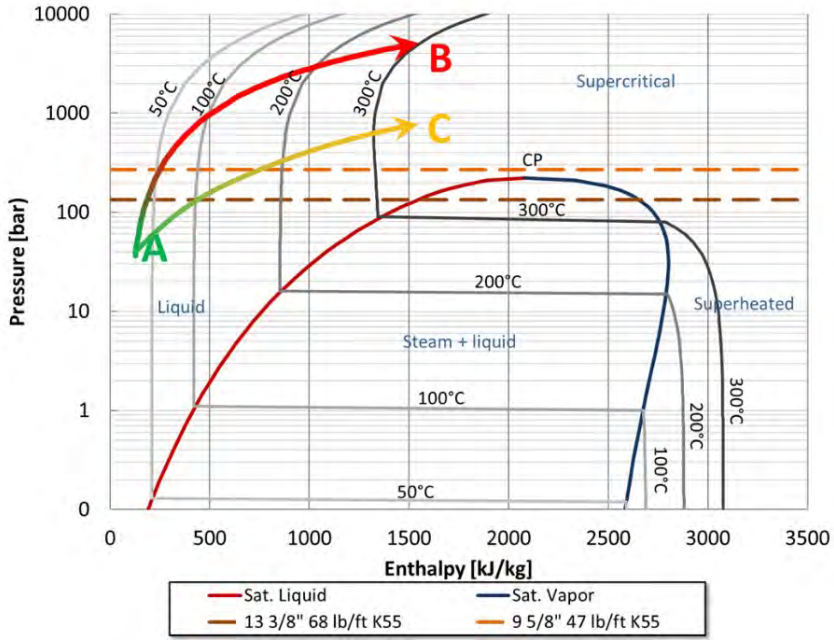

Figure 5. Annular pressure build-up in a casing-to-casing fixed volume is shown in the path A to B, however the pressure buildup is likely to be less severe due to slight volume change and relief of pressure through the cemented annulus and to the rock formation shown in a potential path from A to C. The collapse resistance of two typical production casings (at room temperature) is shown for reference.

Figure 6 shows results from a study conducted at ÍSOR, where out of 136 high-temperature production wells 75 wells have noted incidents whereof 13.3% are confirmed tensile failures and 6.7% are casing collapses (bulge) (Sveinbjörnsson, Kaldal, & Thorbjörnsson, 2015) (Lohne, et al., 2017) (Thorbjornsson, Kaldal, & Ragnarsson, 2019). These problems have been observed during downhole logging and some have been video logged. However, well failures can go unnoticed if no obstruction is observed during downhole logging. Therefore, it can be concluded that the number of failures is likely higher.

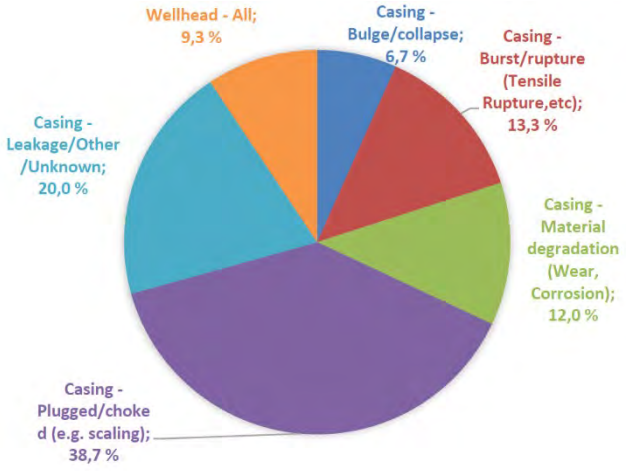

Figure 6. Downhole well problems that have been found in downhole logging. Problems, e.g. casing collapse, casing tensile failure and plugged casing or scaling, were identified in 75 wells out of a set of 136 high-temperature production wells (Sveinbjörnsson, Kaldal, & Thorbjörnsson, 2015) (Lohne, et al., 2017).

3. Mitigation of Casing Failures

The severe casing failures discussed above have called for improved reliability of the downhole structure. The nature of the harsh chemistry of geothermal wells limit material selection for casings. Materials are selected for resistance to H_2S attack to minimize the possibility of failure due to hydrogen embrittlement and sulfide stress corrosion. The New Zealand code of practice for deep geothermal wells states that materials should conform to ANSI/NACE MT 0175/ISO 15156; e.g. K55, L80 type 1, C90 and T95. This constrains the selection and increasing the yield strength unfortunately can produce such negative effects as hydrogen embrittlement that in turn can lead to premature failures.

Flexible Couplings were designed for mitigation of casing failures caused by constrained thermal expansion. The novel connection has been developed for two common sizes for production casing sizes 9 5/8” (244.5 mm) and 13 3/8” (339.7 mm). A prototype that was built within the GeoWell project and a drawing showing the sliding mechanism are displayed in Figure 7. The development and testing of the Flexible Coupling has been thoroughly described in previous conference papers (Kaldal & Thorbjornsson, Thermal expansion of casings in geothermal wells and possible mitigation of resultant axial strain, 2016) (Thorbjörnsson I. Ö., Kaldal, Gunnarsson, & Ragnarsson, 2017) (Thorbjornsson, Kaldal, & Ragnarsson, 2019) (Thorbjörnsson & Kaldal, 2020) (Kaldal & Thorbjornsson, Improved Integrity of the Production Casing in Moderate- to Ultra-High-Temperature Geothermal Wells using Flexible Couplings, 2022) (Kaldal, et al., 2022).

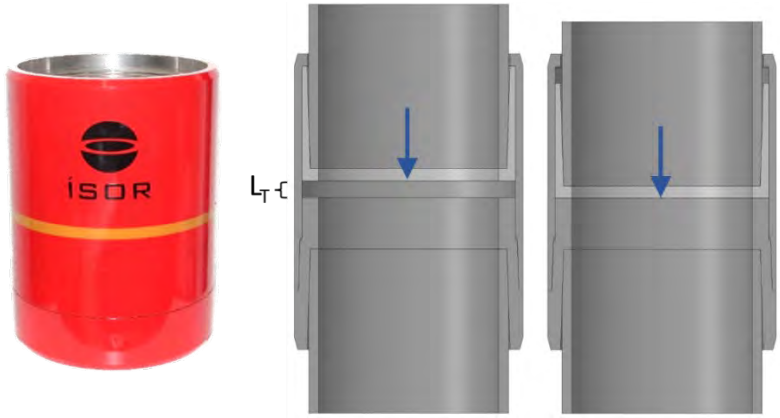

Figure 7: Flexible Coupling prototype – 9 5/8" (left). Sliding principle of FC enabling expansion of cemented-in casings (right).

Flexible couplings have been considered as a solution for thermal strain problems for wells drilling into superhot conditions in the Iceland Deep Drilling Project (IDDP) (Gunnarsson, Pálsdóttir, Ragnarsdóttir, & Friðriksson, 2024) and wells that will be drilled with the objective of in situ magma observatory in the Krafla Magma Testbed (KMT) project (Hólmgeirsson, et al., 2018). The casings of the first two wells of the Iceland Deep Drilling Project, IDDP-1 drilled for Landsvirkjun in Krafla 2008-2009 and IDDP-2 drilled for HS Orka in Reykjanes in 2015-2016, failed due to thermal cycling of the casing and or casing collapse due to expanding annular fluids. The third well is planned to be drilled in the Hengill geothermal system, either Nesjavellir, Hellisheiði or Hverahlíð, for ON Power a subsidiary of Reykjavik Energy. Since both former cases showed that the casing structural integrity is one of the most critical factors to successfully drill and operate the well, different aspects of the well structure is being investigated for improvement in the COMPASS project, e.g. mitigating thermal loading on the casing, collapse prevention, corrosion prevention and increased flexibility and lighter cement for cementing long casing strings. The objective is to improve the well integrity and increase its flexibility in terms of structural loading and chemical attack with cost-effective solutions. It should be noted that mitigation of casing failures also goes hand in hand with selection of good quality casings and cement for the production casing, e.g. selection of round casings (high collapse grades), low free water content in cement and most importantly, careful operations of the well by the operator, e.g. by limiting thermal cycling of wells.

As discussed above, two of these challenges that need to be tackled are casing collapse and tensile ruptures that both are an effect of thermal expansion of materials. Annular Pressure Buildup Relief (APBR) element has been designed to relieve annular pressure in cemented annulus. A patent application has been filed (Icelandic Patent application no. 050685). The invention works on the principle that the pressure propagates through the micro annulus that is formed between the production casing and the cement sheath and into the element that is placed in the casing wall (Figure 8). If high enough, the pressure will activate the element and pressure will be temporarily relieved into the wellbore. This will likely only occur once in the lifetime of the well as it warms up to operation temperature during thermal recovery after drilling. When the annular pressure has been reduced to a level that is acceptable the pre-set element shuts off and seals again. The APBR casing collapse prevention "patent pending" technology shown in Figure 9 is in development within ÍSOR to mitigate annular pressure development in a cemented annulus in high-temperature geothermal wells. Prototypes have been built and are being tested for operational loads and

function. Operational testing within a cemented annulus will be performed in a full-scale test setup within the COMPASS project where questions regarding pressure relief through cemented annulus and through the collapse prevention system that is placed in the innermost casing will be answered.

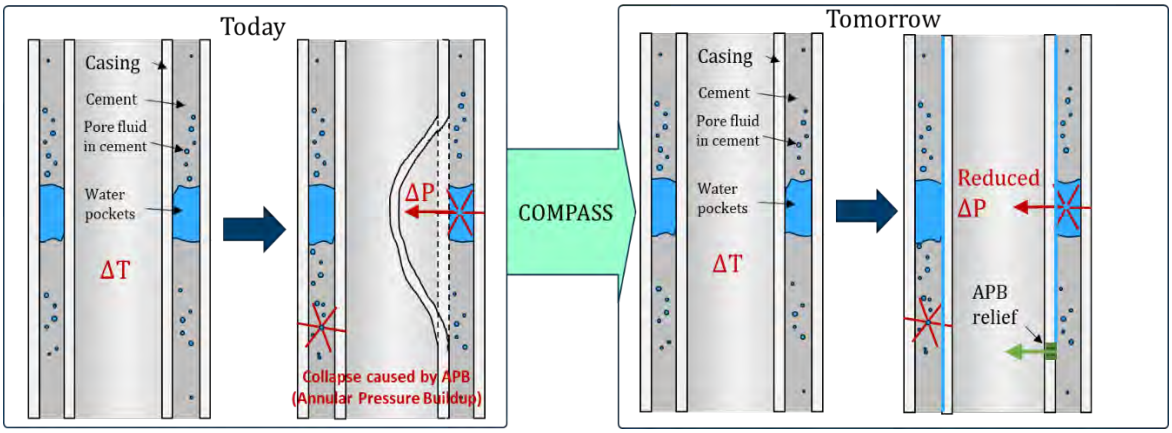

Figure 8. Illustration of the principle of the APBR pressure relief concept for collapse prevention developed within the COMPASS project. Left: casing collapse form annular pressure buildup due to thermal expansion of entrapped annular water. Right: Temporary pressure relief through the Casing Collapse Protection leaving the casing intact.

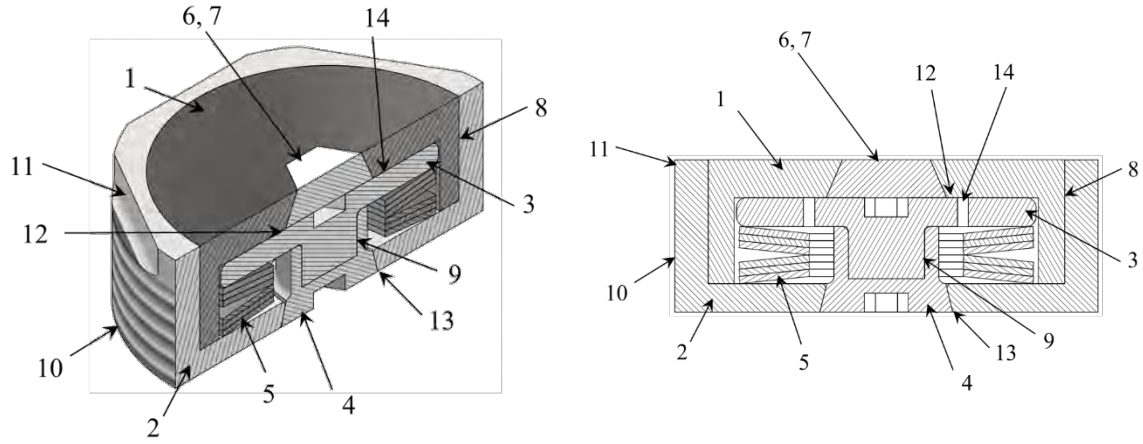

Figure 9. The patent pending Casing Collapse Protection technology for Annular Pressure Buildup Relief (APBR) intended for High-Temperature Geothermal Wells to mitigate casing collapse of the production casing that can occur if enclosed or excess water exists in a cemented casing-to-casing annulus.

Conclusions

Two novel technologies were presented in this paper. Namely, the Flexible Coupling that has been developed for mitigation of casing failures caused by constrained thermal expansion and will be field tested in a new high-temperature geothermal well in the Nesjavellir field that is operated by ON Power this year, and the not yet as well-advanced Casing Collapse Protection technology that

is currently being developed and will be tested in a field condition experiment next year. Both technologies are not yet commercially available but aim to advance the integrity of high-temperature geothermal wells as well as to enable the drilling and operation of future superhot wells, e.g. IDDP and KMT wells.

Acknowledgement

The work presented here has been supported by EU Horizon Europe through project COMPASS (no. 101084623). Previous work on development of the Flexible Coupling was supported by GeoWell (no. 654497) and DEEPEGS (no. 690771), and the GeConnect (no. 731117) project funded through the ERANET co-fund GEOTHERMICA, from the European Commission, Technology Development Fund (Iceland), Bundesministerium für Wirtschaft und Energie aufgrund eines Beschlusses des Deutschen Bundestages (Germany) and Ministerie van Economische Zaken (The Netherlands). We would like to kindly thank our project partners for their valuable contributions to the previously mentioned projects.

ABSTRACT

For half a century Landsvirkjun, the national power company of Iceland, has been exploring and utilizing some of world's hottest geothermal resources. Wells drilled into superheated resources believed to be around or above 360°C have proven to be very powerful but hard to operate due to various challenges including corrosion, particle erosion, silica scaling potential, thermal expansion etc. The most significant effort to date was well IDDP-1 drilled into 950°C hot magmatic body in the Krafla Geothermal Field in 2009. The well was flowtested in 2010-2012 where various tests were carried out providing valuable learning for future projects. The well was flowtested with various wellhead pressure but enthalpy was constant around 3150 kJ/kg and superheat of 160°C (above boiling temperature). Landsvirkjun is currently considering next steps towards utilisation of superhot geothermal in near-magma environment.

This paper presents a brief overview of the experience, challenges and learning from drilling and operating superhot geothermal wells in Iceland and outlines the outlook for further efforts in the near future, including the Krafla Magma Testbed project, KMT, planned in 2025-2029.

THE KRAFLA STORY

In the early hours of May 17th 1724, 300 years ago, a big blast echoed over North Iceland. Inhabitants of the town of Akureyri woke up and thought someone had blasted a cannon in town. The following day, some 65 km away, a few men from the village of Reykjahlíð hiked the 10 km distance to the central volcano Krafla to see what had happened and witnessed an erupting explosion crater, now called Víti, meaning Hell. Víti only erupted 1-2 days but over the next 7 years, several volcanic eruptions occurred in the nearby Mt. Leirhnjúkur, producing lava flows that extended some 10 km south towards the lake Mývatn and village Reykjahlíð. This episode period was named *Mývatn Fires*. Since the end of Mývatn Fires in 1731, the Krafla volcanic system when quiet for 240 years.

In the early 1970's, increasing oil prices caused increased demand for electricity in Northern Iceland. When a protest caused the dam of a hydroelectric power plant close to lake Mývatn to be lowered, resulting in the power outcome to be only quarter of the originally planned capacity, the government started to explore the geothermal field in Krafla. Following surface measurements since the early 1970's the Icelandic parliament decided in 1974 to establish a parliamentary committee, "Kröflunefnd", to build the Krafla Geothermal Power Station. The committee drilled two approximately 1200 m deep exploration wells in 1974 and bought two 30 MW Mitsubishi turbine units, dual pressure, double flow, designed for medium enthalpy. Drilling continued in the summer of 1975, first well K-3, down to 1200 m and then the first deep well, well K-4 in Vítismór, on the plateau at the end of the Hlíðardalur valley, between the Víti crater to the east and Mt. Leirhnjúkur to the west.

August 1975 proved eventful for Krafla. That month, construction of the powerhouse for Krafla Power Plant started. Later that month, drilling of the first well exceeding 1300 m, well K-4 concluded at 2003 m depth after having intersected a powerful feed zone at 1940 m, that started flowing up into an upper feed zone at 700 m. This caused wellhead pressure exceeding pressure rating of the mastervalve, and drillers postphoned completing the well until new wellhead valve had been replaced. In January 1976, steam started leaking between wellhead flange and mastervalve, cutting the bolts and the wellhead blew off, resulting in uncontrollable blowout of steam and highly acidic liquid for several months until the well eventually collapsed. Well K-4 was the first superhot well to be countered in Krafla and possibly also in Iceland.

In December 1975, Mt Leirhnjúkur, some 2 km Northwest from the power station started volcanic eruption, and over the next 9 years, until 1984, in total 9 volcanic eruptions and 18 underground eruptions occurred in the Krafla system. None of the event had direct impact on the Krafla project but CO_2 increase significantly in several wells, magma did enter wells in both Krafla and in Bjarnarflag, 10 km south of Krafla and land elevation changes were 2-3 meters. It was soon decided to only complete installation of turbine unit 1 due to difficulty of getting usable steam. The first trial operation of Krafla was in autumn 1977 and the plant was officially commissioned in February 1978. Only 7 MW of usable steam was available at the beginning. Part of that steam was from a superheated well K-3 and as the wells were equipped with wellhead separators, there was no water phase to scrub the steam and first to turbine rotors were severely damaged during the first year by particle erosion, before a decision was made to install a central separation station to mix wet steam with dry to improve scrubbing.

Drilling efforts were moved further away from the erupting Mt. Leirhnjúkur, to east towards the southern slopes of Mt. Krafla, and to the south to the Hvíthólar area. The Hveragil canyon appeared to divide the Krafla reservoir, west of the canyon, the field followed almost constant temperature of 180-220°C down to 1200-1600 m depth (upper reservoir) and below that temperature followed boiling point curve (lower reservoir). East of the canyon, the field followed boiling curve from 800 m.

The Krafla power station finally reached full capacity of 30 MW in 1984. By then, in total of 23 wells had been drilled, thereof 15 had been connected to the steam gathering system. Around the same time, Landsvirkjun, the national power company of Iceland, bought Krafla and the nearby Bjarnarflag, its first geothermal power stations.

In 1996, Landsvirkjun reached the conclusion that the geothermal reservoir had recovered sufficiently from the Krafla fires to allow installation of unit 2, followed by drilling of wells K-27 to K-34. Many of the deeper wells, exceeding 1800 m true vertical depth, started quite powerful but declined rapidly in power as an obstacle was discovered around 1200-1500 m depth, or around the intersection between the hot and dry lower and wet upper reservoirs. Initially, these obstacles were believed to be caused by silicate scaling, but later analysis suggested heavy corrosion did also play a role. The 2002 m deep vertical well K-34, just east of Víti, was an exception, delivering steam equivalent of 20 MW for several years, before starting to cough black fluid at start of flowtests and declining to 4-5 MW. Highly corroded bits of liner pipes and connections have been discovered in the separator that have been traced to well K-34. This unknown phenomenon in the wells was called “black death”. To date, wells that are known or suspected to suffer from “black death” symptoms are: K-4, K-8, K-10, K-25, K-26, K-29, K-34, K-35, K-36, K-38, K-39 and IDDP-1 (Einarsson, 2010).

Well K-39 was drilled in autumn of 2008. The well is in total 2865 m long, directionally drilled with 30° angle under the southern slopes of Mt. Krafla. After drilling through rather hard rock, as common in the southern slopes, rock suddenly became rather soft at around 2810 m depth and the section from 2830-2845, the rock was very soft, almost no resistance, before the rock became harder again. After two further drill pipe lengths, drilling was stopped at 2865 m depth. Soon after, while circulating, the drill string got stuck around 2848 m depth. After several days of attempts to free the string, where circulation was lost several times but regained after significant pressure before giving up. At one point, temperature log inside the drill string at 2815 m depth (bottom of drill string) showed 386°C at over 220 bar pressure, indicating supercritical conditions, while pumping 47 l/sec through the string (Olafsson, 2010).

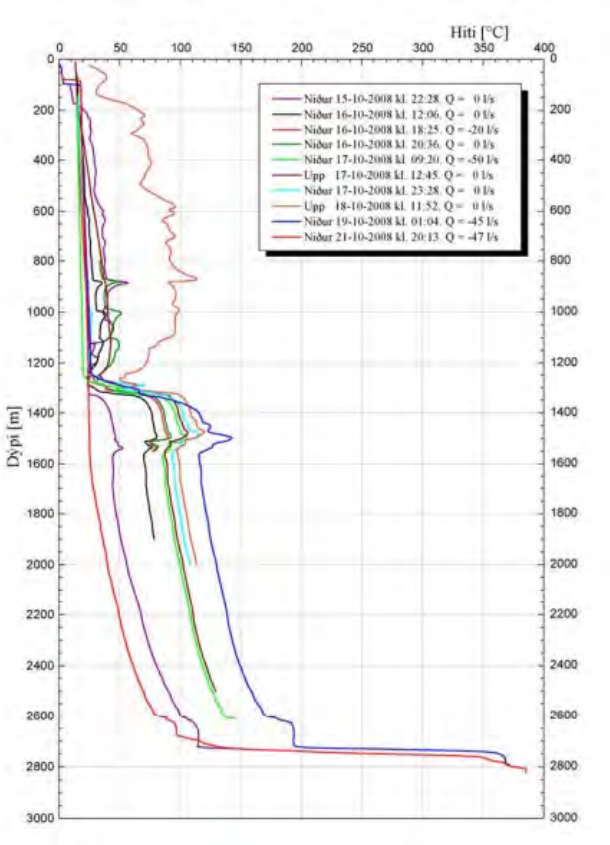

Figure 1: Temperature vs. depth log in well K-39 during attempts to free drillstring (Olafsson, 2010).

A charge was applied to help unscrew the drill string at the 2740 m depth. However, a collar at 2808 was unscrewed, providing longer section of the drill string to be free. When at surface, the bottom three collars were packed with a mix of drill cuttings a fresh quenched silicic glass (Mortensen, 2010). As the wellhead rating of ANSI Class 900 was not considered sufficient to allow the well to flow with the anticipated pressure, the bottom 250 m were cemented before completing the well and opening for flow test. The flow test was carefully monitored and fluid chemistry indicated downhole corrosion due to hydrochloric acid. After three week of flow test, the well was closed and the slotted liner was pulled to surface to analyze its condition. Several sections of the liner proved to be severely corroded, whereas in between were pipes that did not show indication of corrosion. The liner broke apart at around 1500 m depth when half out of the well and the bottom part fell to the bottom of the well. The last pipes to surface showed the greatest signs of corrosion.

In the center, the Krafla geothermal power station. The green field in the center is the drill pad for well IDDP-1. Photo: Mr. Hreinn Hjartarson, project manager at Landsvirkjun.

THE THEISTAREYKIR STORY

The Theistareykir geothermal field is approximately 20 km Northwest of Krafla, named after the Theistareykir shield volcano. The main surface activity is in the Eastern part of the rift valley between the shield volcano and mountain ridge Lambafjöll, under the Mt. Bæjarfjall and Mt. Ketilfjall. The area is large, characterized by faults, fractures and active geothermal surface activity.

Following surface exploration over several decades, first exploration drilling program started in 2002 and to date 20 deep wells have been drilled in the area. In total 12 wells are connection to the 90 MW power plant and further 3-4 wells will be connected when further steam is required. The Theistareykir geothermal power plant was commissioned in 2017 and 2018 and Landsvirkjun is currently preparing a 70 MW expansion.

The first well, ÞG-1, hit overpressure at 190 m depth, causing crossflow and blowout before the well was managed with several cementing attempts. Overpressure and blowout was also experienced in wells ÞG-3, ÞG-4, ÞG-6, ÞG-7, ÞG-9 and finally in well ÞG-10 where blowout could not be controlled until the well was filled with cement and drill string was left in hole. The following wells were drilled with barite which has helped with well control during drilling. Almost all the wells exceed 300°C at 2000 m true depth and average enthalpy is 2100 kJ/kg with several wells completely dry. Several wells have shut-in pressure exceeding 100 bar. The fluid is characterized by low levels of geothermal gasses and minerals, but the high enthalpy wells have

high levels of silica in the separation water, exceeding 1000 mg/kg in two wells, causing significant silica scaling risk. As a precaution, the high enthalpy wells are operated at wellhead pressure of 20-30 bar to minimize risk of downhole precipitation (Hauksson, 2021).

Highest bottom hole temperature was logged in the 2659 m deep vertical well ÞG-3, 380°C. The well is superheated with temperature around 20° above boiling temperature blow approximately 2200 m depth. The well pulsed significantly during the first few years with the up to 30 MW pulses 2-3 times a day. Next well logging after end of pulsing indicated the well was plugged below approximately 1500 m depth or just below the uppermost feed zone.

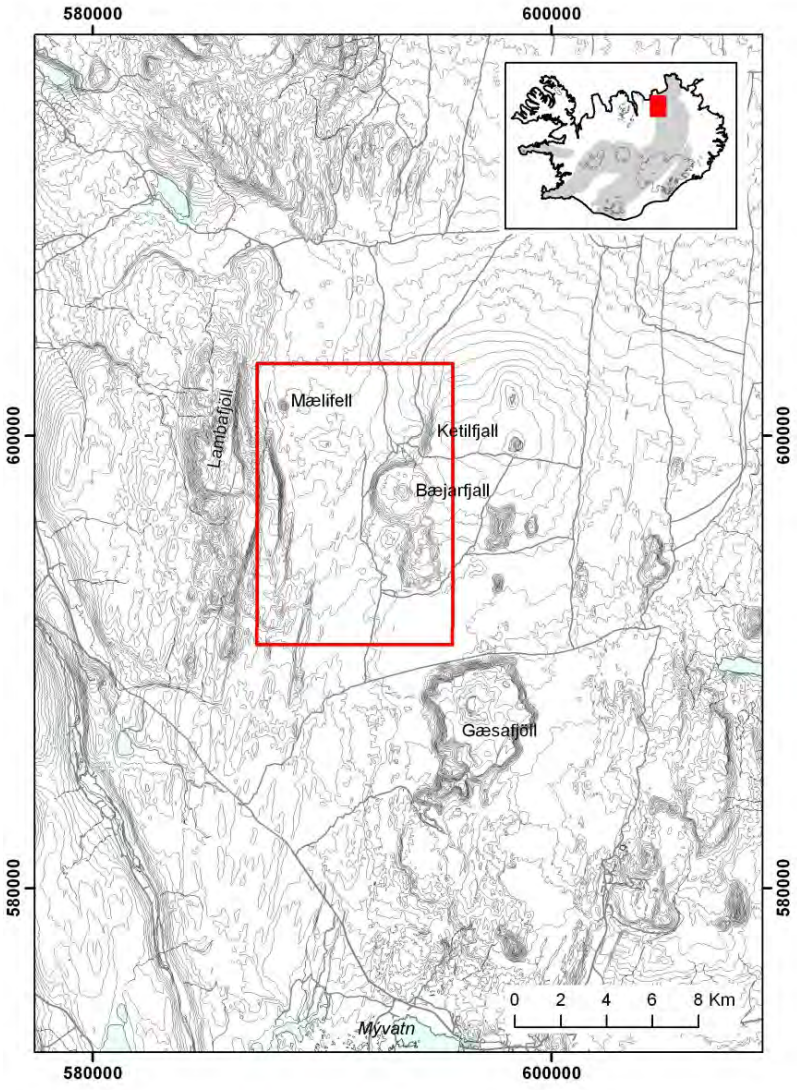

Figure 3: Overview map of the Theistareykir geothermal field (Gautason, 2010)

The high well temperature and enthalpy at Theistareykir is a very strong indicator of the potential for superhot geothermal resource at relatively shallow depth.

ICELAND DEEP DRILLING PROJECT, IDDP

The Iceland Deep Drilling Project, IDDP, has been excessively covered in the literature and various news and documentaries, but understandably as it is the most ambitious geothermal exploration project in recent years. The initial idea behind the IDDP project was to look back at several well that had been drilled in Iceland and had hit resource with such a high pressure and temperature that they could not be handled, such as wells K-4 and K-25 in Krafla, reported above, and well 11 at Nesjavellir geothermal field, drilled in 1985, where over 380°C temperatures was measured around a feed zone at 2200 m depth that caused an underground eruption to a feed zone at 1100 m depth that could only be managed by cementing.

The main objective of the IDDP project is to study the feasibility of extracting geothermal fluid from a resource closer to the roots of the geothermal system, at supercritical conditions, temperature >374°C and pressure >220 bar for benign water but higher temperature and pressure for saline water. The fluid would reduce in pressure as it flows to surface and be handled as superheated fluid. To allow commercialization of the IDDP methodology, the properties of the supercritical have to studied, drilling technology has to be advanced and new fluid handling and evaluation systems need to be designed and applied.

The IDDP consortium was established by three leading energy companies in Iceland, Landsvirkjun, Reykjavik Energy, HS Orka as well as the government through the National Energy Authority (Orkustofnun) in 2000. Later, Equinor (previously Statoil) and Alcoa joined the project.

The first well of three proposed by the Iceland Deep Drilling Project (IDDP) was drilled in the Krafla Geothermal Field in 2008–2009 by Landsvirkjun. The well was designed to reach supercritical conditions at 4500 m, temperatures above 374 °C and pressures above 22 MPa. Drilling progress was as planned down to around 2000 m when drilling became quite challenging, including becoming stuck at 2094 and 2095 m depth, followed by twist offs and subsequent side tracking. Finally, drilling came to an end at 2096 m depth in the third leg when cuttings of fresh glass indicated the presence of a magma body at the bottom. As the well had such a rigorous well design, the steering committee of the IDDP decided to complete and flow test the well, rather than abandoning it. The well was flow tested from 2010-2012 with several different setups. The flow was superheated by 120°C above boiling temperature and wellhead temperature followed wellhead pressure but enthalpy was constant around 3150-3200 kJ/kg (Markusson, 2013). When flow was limited to 17 kg/sec with a small orifice, wellhead flowing pressure was 145 bar and wellhead flowing temperature was 450°C.

IDDP hit several challenges. The key drilling challenges were to drill with a wider diameter than normally done to various different depths to add additional casing strings, wellbore integrity while drilling superhot rock with relatively cold drilling fluid, cementing long casing strings in hot rock environment and finally, avoiding getting stuck when drilling into magma. When flowing the well, the fluid proved to be highly corrosive, flow velocity of the dry steam was very high causing erosion by corrosion particles, cuttings and other particles in the steam. Thermal expansion of casing, surface flowlines and all equipment in contact with the superhot steam, including valves, was also a big challenge. The high flow velocity of the superhot and dry steam did also cause fine vibration that caused extra strain on surface equipment and loud noise. Eventually, the well had to be shut in when a leakage was discovered on flanges and both TIX master valves failed to shut-in. When the well was quenched by pumping 20°C cold water slowly (5 l/sec) on the well, the Tenaris

563 casing connections failed in at least four different locations. When in an attempt to clean the well with a drill rig, metal debris at the bottom of the well prevented full workover and when the well got completely plugged, the only option was to fill it up with cement and gravel.

The well was very powerful and the project proved to be a valuable experience for drilling supercritical wells in the future and what happens when magma is encountered. Most importantly, it proved that it is possible to drill and complete a well in a very hot zone and produce fluid from an environment near a magma body. If sustained long term production proves possible, the drilling of well IDDP-1 will mark a new era in power production in Krafla.

Well IDDP-2 was drilled in 2016-2017 in the saline Reykjanes geothermal field in SW Iceland. An existing 2.5 km deep production well, RN-15, was deepened and cased to almost 3 km depth, and then drilled to 4,650 m slant depth, corresponding to about 4.5 km vertical depth from surface. Supercritical conditions (426°C at 340 bars) were measured during drilling at approximately 4,550 m depth. The well was deepened by additional 100 m, a liner inserted, and a 6” pilot hole and 3 successive drill cores retrieved from the very bottom of the well. Coring was attempted 13 times below 3 km depth, altogether returning some 27 m of drill cores. As the well was drilled with total circulation losses most of the time these core samples comprise almost the only rock samples from the well below 2.5 km depth. Petrological studies, on mineral assemblages, chemistry and fluid inclusions from the drill cores, show absolutely a unique data set from a sheeted dike complex currently at temperatures up to 600°C near the bottom of the well (Fridleifsson, 2021).

The company Reykjavik Energy is currently planning well IDDP-3 at the Hengill area, SE of the capital of Reykjavik in the next coming years. Exact location and well configuration has not yet been fully decided on (Gunnarsson, 2024).

KRAFLA MAGMA TESTBED, KMT

Well IDDP-1 did not only prove to be a great success with regard to providing information about the challenges and potential for superhot geothermal energy production, it also proved unique information about the physics of magma and geological, geophysical and geochemical properties of near-magma formations. Following up from the experience from IDDP a group of leading volcanologists from several different countries teamed up with Landsvirkjun to found the Krafla Magma Testbed project. Landsvirkjun is providing access to the unique conditions at Krafla, with not only unique geological settings but also excessive experience and research data that has been gathered in the field for half a century.

The aim of the project is to improve the knowledge about:

- Volcano monitoring, aiming at better forecasting for future volcanic eruptions
- Geothermal potential in near magma formations
- Geoscience, understanding magma chamber dynamics
- Innovation and technology for superhot and corrosive conditions that could i.e. benefit space industry etc.

The KMT consortium, lead by the geothermal research cluster GEORG, officially founded the KMT Non-Profit Organization, KMT NPO, last year, and Mr. Björn Þór Guðmundsson, a

geologist specialized in Krafla, with vast financial background, was hired as the CEO. Preparation for drilling two exploration wells and setting up a world class volcanological testbed is now completed and the new organization is currently in funding phase. The aim is to drill a monitoring well towards the magma in 2027 and place sensors preferably into the magma body. Two years later, the plan is to drill a "manipulation well" that can be applied to do various tests and studies, i.e. for energy generation in near magma environment.

It is the long term aim of KMT project that the site becomes a long term observatory for magma chamber below to test methods to explore and predict volcanoes and magma energy resources. It is also the long term aim of Landsvirkjun to team up with the energy industry to drill a commercial magma energy well in Krafla and hopefully also in other volcanic geothermal fields.

SUPERHOT GEOTHERMAL IN ICELAND

Superhot geothermal energy is in high demand in the world to power the energy transition needed. Iceland is in the lead for its recent developments and Iceland is open for cooperations with likeminded ambitious international technical companies and science institutions.

It is quite clear that sites with such shallow depth to the roots of geothermal systems, open minded power companies and supportive society are hard to find. Societies like New Zealand, Japan, USA and in particular Hawaii, and others, should consider superhot geothermal as an alternative for future generation of green power and they should consider developing this resource with Iceland.

Acknowledgement

The author would like to than all the numerous participants in the various research and development projects that have been adding to the knowledge of superhot geothermal in recent decades, including but not limited to the participants and sponsors of the Iceland Deep Drilling Project (abovementioned in addition to ICDP and NSF), Deep Roots of Geothermal Systems (The Icelandic Centre for Research), DeepEGS (EU), Image (EU), Improve (EU) and KMT (The Icelandic Centre for Research, NERC, ICDP, Government of Iceland, GEORG).

Hybrid Renewable Energy System, MATLAB Simulation, Bowman County, Wind Energy, Solar Energy, Geothermal Energy, Sustainability, Levelized Cost of Electricity (LCOE), Greenhouse Gas Emissions Reduction

ABSTRACT

Bowman County, North Dakota, currently relies heavily on coal power, accounting for over half of its electricity generation and leading to substantial greenhouse gas emissions. This study utilizes advanced MATLAB modeling to evaluate the potential of transitioning the county to a renewable energy system comprising wind, solar photovoltaics (PV), geothermal, and energy storage. The proposed hybrid system is tailored to Bowman County's growing electricity demand, with nameplate capacities of 85.7 MW for wind, 24.4 MW for solar PV, 2.03 MW for geothermal, and 195 MWh for storage. Simulations verify that by 2040, this custom-designed system could supply over 90% of the county's projected daily loads, with an estimated levelized cost of $105.226/MWh over 15 years that is cost-competitive with conventional power. Implementing this plan would reduce Bowman County's daily carbon dioxide output by approximately 97% relative to continued coal usage. More broadly, this hybrid model serves as a versatile template for other communities striving toward clean, locally focused energy self-sufficiency. It provides a sustainable and adaptable roadmap to support the renewable transition while meeting regional electricity needs, demonstrating one pathway toward a greener future.

1. Introduction

1.1 Background on the Global Energy System

The global energy landscape has been predominantly shaped by the utilization of fossil fuels, which, despite their abundance and historical ease of extraction, have led to significant environmental and climatic challenges. According to the BP Statistical Review of World Energy (2021), fossil fuels account for over 80% of the world's primary energy consumption. This heavy

reliance has resulted in elevated levels of greenhouse gases (GHGs) in the atmosphere, contributing to global warming and climate change (Intergovernmental Panel on Climate Change [IPCC], 2021).

The International Energy Agency (IEA) (2021) reports that global energy demand has been increasing at an annual rate of approximately 1.3%, driven by population growth and industrialization. This surge in demand exacerbates the environmental impact, highlighting the urgent need to transition to more sustainable energy sources. Renewable energy, including solar photovoltaics (PV), wind turbines, hydropower plants, and geothermal heat, presents a promising solution to these challenges. These sources of energy are abundant, sustainable, and have a significantly lower environmental footprint compared to fossil fuels (Chen, Wu, & Wang, 2022).

1.2 Inefficiency of Traditional Energy Systems

Traditional energy systems, particularly those based on coal and natural gas, are inherently inefficient. The energy conversion processes in these systems result in substantial losses. For instance, the average efficiency of coal-fired power plants is around 33%, meaning that two-thirds of the energy content of the coal is lost as waste heat (Patil, Kulkarni, & Kshirsagar, 2018; US Energy Information Administration [EIA], 2020). This inefficiency is compounded by transmission and distribution losses, which further reduce the net energy delivered to end-users.

On the other hand, tri-generation systems offer a more efficient alternative by simultaneously producing electricity, heating, and cooling from the same energy source. These systems can achieve overall efficiencies exceeding 80%, making them significantly more effective in utilizing fuel (Wu & Wang, 2006). By capturing and using waste heat, tri-generation systems improve energy efficiency and reduce greenhouse gas emissions, contributing to environmental sustainability.

1.3 Addressing the Need for Sustainable Energy Solutions in North Dakota

With its vast renewable energy resources, North Dakota is well-positioned to lead the transition to a more sustainable energy system. The state is endowed with significant wind and geothermal resources, which, if harnessed effectively, can provide a substantial portion of its energy needs. Despite this potential, over 70% of North Dakota's electricity generation currently comes from coal-fired power plants characterized by high carbon dioxide emissions and other environmental pollutants (US EIA, 2020b; Zygarlicke et al., 2006).

The heavy reliance on coal has significant environmental and public health implications. Coal combustion releases carbon dioxide, sulfur dioxide, nitrogen oxides, and particulate matter, which contribute to air pollution and associated health problems (Parker, 1979). Transitioning to a hybrid renewable energy system in Bowman County can mitigate these issues by leveraging the region's renewable resources, including wind, solar, and geothermal. This study explores the feasibility of such a transition, providing a comprehensive analysis of the technical, economic, and environmental benefits of a hybrid renewable energy system.

This research evaluates the feasibility of implementing a hybridized tri-generation energy system that combines geothermal, wind, and solar resources to meet the electricity needs of Bowman County, North Dakota. While studies have explored integrating complementary technologies like wind and solar photovoltaics, few have comprehensively analyzed the combination of these three

renewable sources into a unified system. This study contributes an original feasibility assessment tailored to North Dakota's specific renewable energy potential.

The significance lies in exploring a sustainable energy pathway that could reduce greenhouse gas emissions and air pollution by displacing fossil fuels, creating environmental and public health benefits. The proposed tri-generation system presents an opportunity to enhance energy security, drive economic development, and contribute to climate change mitigation efforts. This research offers valuable insights to policymakers and industry stakeholders regarding the viability of investing in innovative renewable energy infrastructure.

Through an interdisciplinary approach, the study synthesizes data and modeling techniques from engineering, geosciences, economics, and environmental science to deliver a robust analysis. The methodology encompasses simulations of energy output, economic cost-benefit evaluations, and quantification of environmental impacts associated with the proposed system. By holistically assessing the technical, economic, and environmental dimensions, this research aims to provide a comprehensive feasibility evaluation.

The integrated tri-generation system leveraging North Dakota's abundant renewable resources could serve as a model for other regions pursuing sustainable energy initiatives. This study's findings may guide policymakers and industry in implementing hybridized renewable solutions that provide consistent and reliable energy.

2. Energy Portfolio of North Dakota

2.1 North Dakota's Wind Energy Potential

North Dakota possesses immense wind energy resources, ranking among the top US states. The state's high wind speeds, flat and expansive lands, low population density, and abundant rural areas provide ideal conditions for large-scale wind projects (Zhang et al., 2014). North Dakota's installed wind capacity has grown exponentially from just 25 megawatts (MW) in 2000 to over 3,000 MW today, currently supplying approximately 26% of the state's total electricity (American Clean Power Association, 2021).

North Dakota's wind resource ranks 5^{th} in the nation, with average wind speeds of 9.9-11.0 m/s at 80-meter hub heights across much of the state (Lopez et al., 2012). The strongest winds are most abundant in the central and north-central regions. The National Renewable Energy Lab has confirmed that North Dakota has some of the best wind resources in the US, with capacity factors exceeding 50% (Figure 1). Higher capacity factors result in greater energy production per turbine.

The state's topography and low surface roughness due to sparse human development allow unobstructed wind flow. Cold winters and warm summers create seasonal wind patterns that are conducive to wind generation. Wind output is typically highest in winter when heating demand is most significant (Raupach & Finnigan, 1997). North Dakota's wind resources can support a significant expansion of wind power.

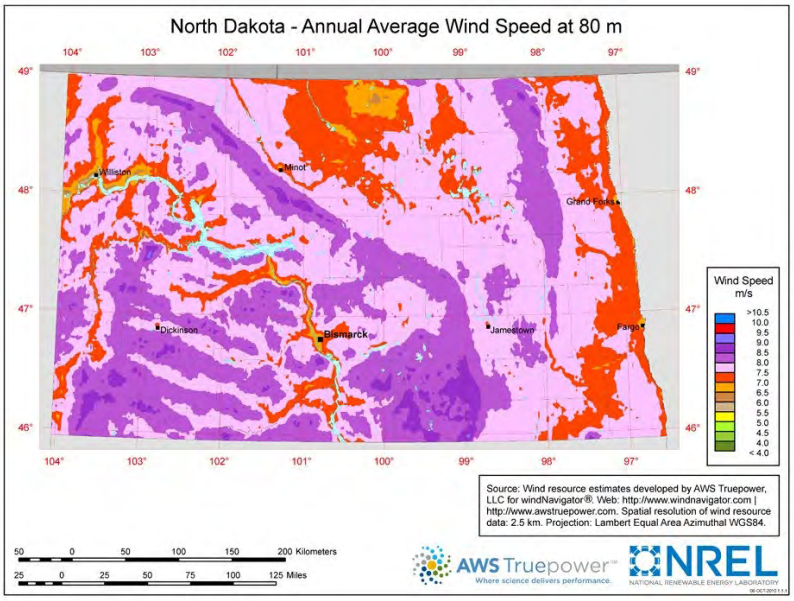

Figure 1. North Dakota's annual average wind speed at 80 m height (NREL, 2021).

North Dakota's first utility-scale wind farm, the 25 MW Lyonsdale project, was built in 1998. Wind growth accelerated after 2000 as technology improved and policy incentives were enacted. As of 2021, North Dakota has over 40 wind power projects in service, comprising 3,065 MW of capacity (American Clean Power Association, 2021). The most significant developments are concentrated in the central and south-central regions with strong winds. Some of the important existing projects are (Wind Energy Database, 2023):

- Baldwin Wind Farm (102 MW), Williams County
- Ashtabula (196.5 MW), Barnes County
- Thunder Spirit Wind Farm (115 MW), Adams County
- Rugby Wind Farm (149.1 MW), Pierce County
- PrairieWinds (115.5 MW), Ward County

Wind accounted for 26.5% of North Dakota's total electricity generation in 2020 (EIA, 2021). The top counties for wind capacity include Ward, Williams, and Barnes in central North Dakota. Wind power has become an essential contributor to the state's electricity portfolio.

Wind project development in North Dakota has yielded substantial economic benefits through investment, tax revenue, income generation, and job creation. Land lease payments provide direct income to farmers and ranchers hosting turbines. Counties also gain property tax revenue from installed projects. From 2000 to 2020, North Dakota wind projects attracted over $5.7 billion in private investment into the state (American Clean Power Association, 2021). Project owners pay property taxes to local governments, providing critical funding for schools, infrastructure, and services. The first ten years of a wind project's operation are estimated to generate $1 million per year in local property tax revenue and $4 million annually over the entire 20-30-year lifespan (Shoeib et al., 2021).

Wind energy supports local jobs in manufacturing, construction, operations, maintenance, consulting, and support services. According to Wiser et al. (2023), a 250 MW wind project requires 1,079 full-time workers over the development and construction period. After that, approximately 24 full-time local workers are needed for operations. Wind projects thus create economic diversity, growth, and revitalization for rural communities in North Dakota. Farmers gain a stable income source while retaining lands for agriculture. Wind contributes to the tax base, infrastructure, schools, and services. Taylor et al. (2019) determined that just five counties in North Dakota realized $59 million in cumulative wind project investments through 2008, corresponding to $21 million in income to farmers and nearly $15 million in local and state income taxes. Unlocking more of North Dakota's extensive wind potential can provide even greater economic benefits statewide.

North Dakota aims to continue expanding its wind energy portfolio to promote economic growth and meet renewable energy targets. In 2020, the state set a goal to generate 1,000 MW from solar and wind by 2030 (Willis, 2021). With only 89 MW of current solar capacity (EIA, 2021), most new renewable generation will likely come from wind. The National Renewable Energy Lab estimates North Dakota has the potential for 907,522 MW of land-based wind energy capacity (Lopez et al., 2012). Less than 1% of this has been utilized so far.

Further wind energy development can bring additional economic activity to North Dakota communities. Key regions with high potential include the Missouri Coteau, Turtle Mountains, and Valley City area (Figure 2). Substantial untapped resources remain across the state. Accessing more wind energy would support continued rural economic development.

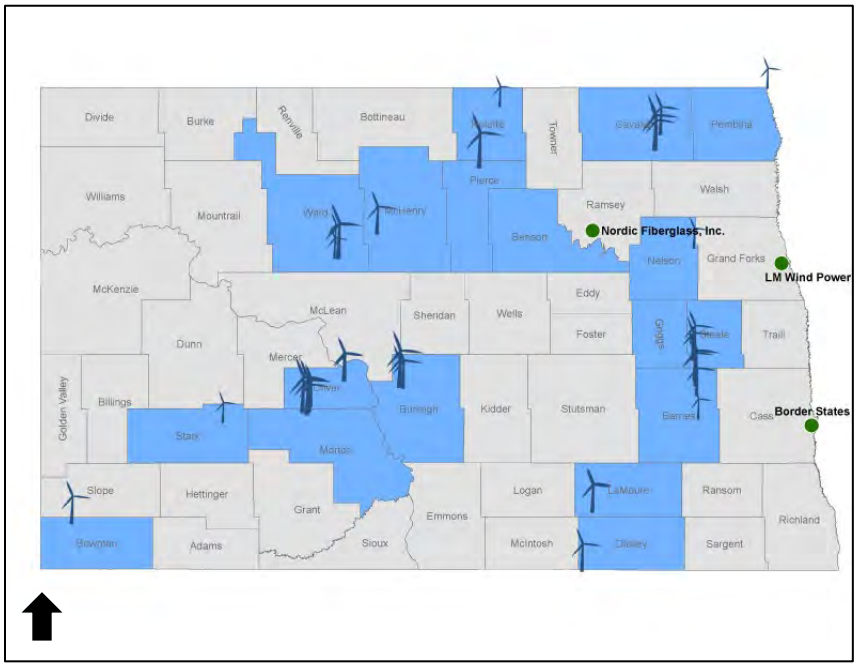

Figure 2. Map of North Dakota wind projects and manufacturing facilities (American Wind Energy Association).

Wind energy expansion faces some challenges. Transmission capacity needs strengthening to deliver remote wind power to population centers. Cold winters pose icing issues for turbines. There is also competition from fossil fuels - North Dakota produces more oil than any state besides Texas

(US EIA, 2022). Still, declining costs, energy diversification, and environmental benefits motivate us to further harness North Dakota's bountiful wind resources. North Dakota can realize its tremendous wind power potential with supportive policies and infrastructure.

2.2 North Dakota's Solar Energy Potential

Despite solar energy's immense potential as a sustainable power source, North Dakota has been slow to adopt it compared to leading states. With only about 12 megawatts (MW) of installed solar photovoltaic capacity, North Dakota ranks 36th nationally for solar development (SEIA, 2023). The state's current solar power capacity can power approximately 1,600 typical homes (Figure 3). In contrast, neighboring Minnesota boasts over 800 MW of solar capacity, more than 60 times that of North Dakota. Germany, a global solar energy leader, has an impressive 45,000 MW of total installed solar capacity (Vaidyanathan, 2013). Most of North Dakota's existing solar arrays are relatively small, with capacities under 2 MW. However, as solar costs continue to decline, some electric utilities are starting to develop larger, utility-scale solar farms in the state. The North Dakota Public Service Commission has implemented policies such as net metering to encourage solar growth, which provides credits to homeowners and businesses for the excess solar power they generate. Despite these efforts, North Dakota has significant potential for further development in its solar energy market.

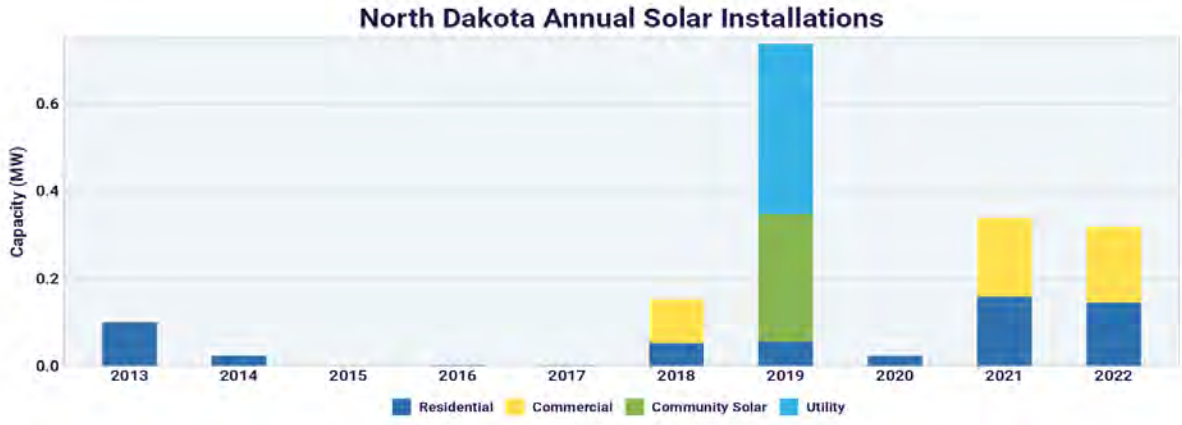

Figure 3. The annual solar installation in North Dakota (North Dakota Solar | SEIA, 2022).

Several factors suggest North Dakota has strong potential for substantially expanding its solar energy capacity. Firstly, the state has reasonably good solar resources, receiving an average of 4 to 5 kWh/m^2/day of solar radiation (Figure 4), which is comparable to Germany's solar resources (NREL, 2020). Even the colder northern regions of North Dakota receive usable levels of sunlight. Secondly, as solar panel manufacturing has scaled up and technology has advanced, costs have decreased significantly, making solar power more economically viable and competitive. Thirdly, federal tax credits and state incentives in North Dakota help reduce the cost of new solar installations, stimulating market growth.

Furthermore, North Dakota has vast rural land areas that could accommodate large, utility-scale solar farms. The declining cost of battery storage technology also complements solar growth by helping to address the intermittent nature of solar power. While solar energy peaks during the day, batteries can store excess power for use at night or on cloudy days. More robust policy mechanisms from state governments, such as renewable portfolio standards, could further incentivize solar

adoption. Given its solar resource potential and available space, North Dakota has the opportunity to significantly increase its solar power generation with the help of continued cost declines.

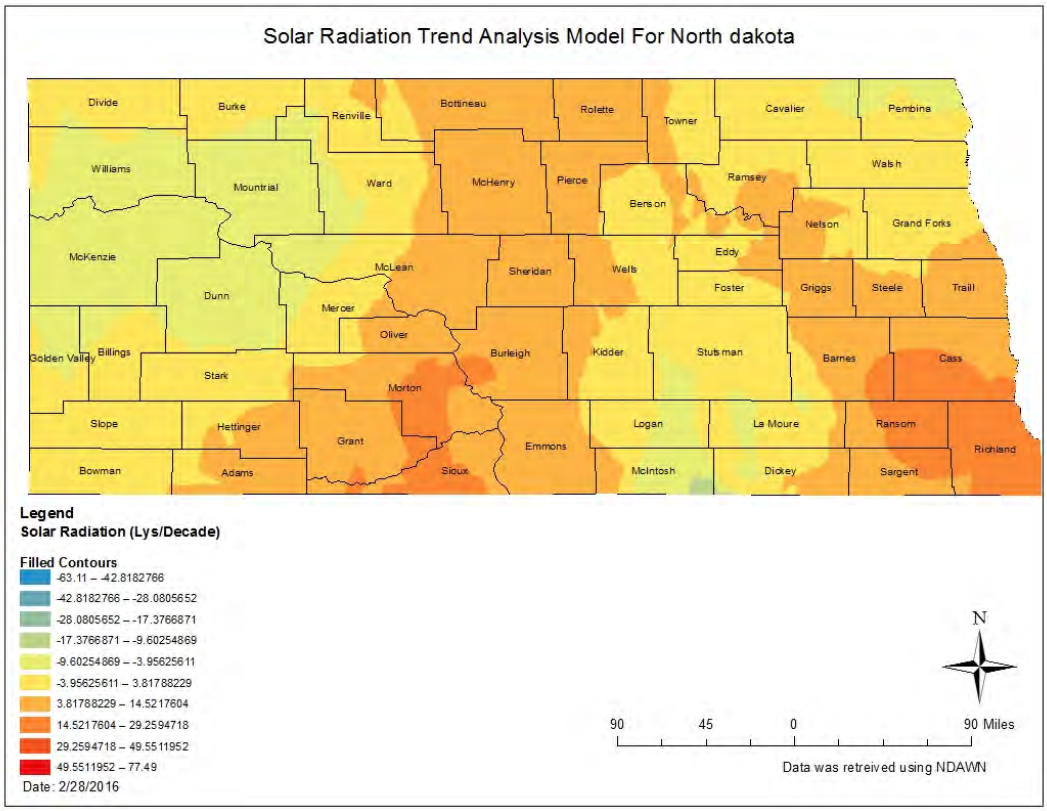

Figure 4. Solar Radiation Trend in North Dakota (Change in Solar Radiation North Dakota, 2016).

However, North Dakota still faces obstacles to substantial solar expansion. The state's cold northern climate reduces solar panel productivity compared to warmer regions like Arizona and Florida (Kim et al., 2017). Additionally, North Dakota's electricity prices have remained relatively low due to abundant local coal and hydraulic fracturing natural gas resources, making alternative sources like solar less competitive. In conclusion, while North Dakota appears well-positioned for growth in solar energy generation, further policy support and cost declines are necessary to enable large-scale solar development in the state.

2.3 North Dakota's Geothermal Energy Potential

Geothermal energy utilizes heat from the Earth's interior to generate electricity and provide direct-use applications such as district heating and heating and cooling of buildings via geothermal networks. North Dakota's geothermal resources, particularly in the Williston Basin, offer significant potential for integration into a hybrid renewable energy system (Matek, 2015). Geothermal energy provides a reliable baseload power source, which is essential for balancing the intermittent nature of wind and solar energy.

Studies have demonstrated the economic and environmental benefits of geothermal energy. Blanco and Faaij (2018) highlight the low greenhouse gas emissions associated with geothermal power, which are typically less than 5% of those from coal-fired power plants. The high capacity factors

of geothermal plants, which can exceed 90%, make them a dependable source of continuous power, complementing wind and solar energy variability.

The subsurface of North Dakota contains high temperatures associated with hot sedimentary aquifers in the Williston Basin. Temperatures above 150-200°C (Figure 5) have been encountered by oil and gas drilling at depths between 3-5 km (Gosnold, 1991). The Williston Basin features many attractive characteristics for geothermal energy development, including deep circulation of saline waters, regional heat flow, thermal gradients, and basement fault systems providing heat transmission (Gosnold, 1984).

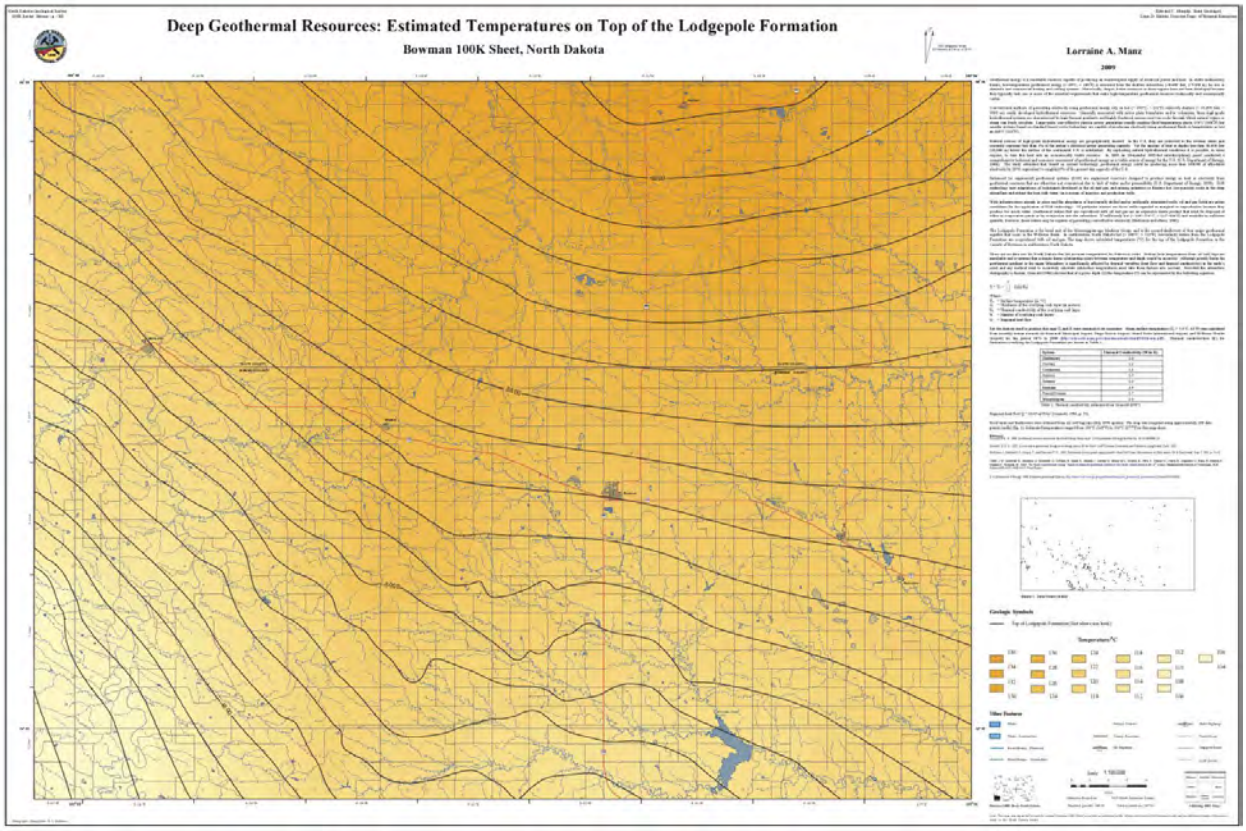

Figure 5. Estimated Temperature on Top of the Lodgepole Formation (Manz, 2008).

The technically accessible geothermal resource base beneath North Dakota has been estimated at 120 MW (Van Brummen et al., 2022). This possible resource excludes even higher temperature resources likely available deeper than current drilling (Williams et al., 2008). While no geothermal power facilities currently operate, promising hot aquifers widespread across the state could support various direct-use applications even at temperatures as low as 50°C.

Developing North Dakota's geothermal resources could deliver significant energy, economic, and environmental benefits. The baseload power potential alone represents over 100 times the state's current electricity consumption. Geothermal heat could be used for district heating systems and industrial applications across North Dakota. Tapping this consistent indigenous resource would provide energy security and price stability. Constructing geothermal power plants and distribution networks would create jobs and revenue in rural areas with energy production and related industries.

Compared to fossil fuels, geothermal energy results in negligible CO_2 and local pollutant emissions when utilized (Fridleifsson et al., 2008). Geothermal could allow North Dakota to continue diversifying its energy mix with homegrown renewable sources like wind and biofuels. Even moderate growth could make geothermal heat and power a significant component of the state's energy portfolio. Further geological surveys, technology improvements, policy incentives, and public-private partnerships can help access this vast clean energy resource.

2.4 Hybrid Systems

Hybrid energy systems combine multiple renewable energy technologies to improve overall system reliability and efficiency. Hybrid systems can provide a stable and continuous energy supply by integrating wind, solar, and geothermal energy with storage solutions. Previous research demonstrates the advantages of hybrid systems in achieving sustainable energy solutions, reducing greenhouse gas emissions, and enhancing energy security (Chen et al., 2022).

Hybrid systems offer the flexibility to optimize energy generation and consumption, ensuring that energy supply matches demand more effectively. This study builds on existing literature to develop a MATLAB-based simulation model for a hybrid renewable energy system tailored to the specific conditions of Bowman County. The hybrid approach also allows for integrating advanced storage technologies, which are crucial for managing the intermittency of renewable energy sources.

3. Methodology

This study employs a comprehensive MATLAB-based simulation to model the proposed hybrid energy system. The research methodology (Figure 6) involves a systematic data collection, system design, simulation, and analysis approach. The key steps in the research methodology include:

3.1 Data Collection

Gathering historical weather data, energy consumption patterns, and renewable resource assessments for Bowman County. This involves obtaining detailed wind speed, solar irradiance, geothermal gradient data, and electricity consumption profiles from various sources, including the National Renewable Energy Laboratory (NREL) and the US Geological Survey (USGS).

3.2 System Design

Defining the capacities of wind turbines, solar PV panels, geothermal energy sources, and storage systems based on the collected data. This step includes selecting appropriate technologies and determining optimal configurations to maximize efficiency and reliability. The design process considers factors such as resource availability, system efficiency, and energy demand patterns.

The system (Figure 7) includes wind turbines, solar PV panels, geothermal energy sources, and storage capacities. The MATLAB model simulates energy production, storage, and consumption based on real-time data and predictive algorithms. The hybrid system is designed to optimize energy production from each renewable source while ensuring a continuous and reliable energy supply.

- *Wind Energy Modeling*: The wind energy component of the model uses historical wind speed data and turbine performance curves to simulate energy production. The model accounts for factors such as wind speed variability, turbine efficiency, and capacity factors.

The performance of different turbine models is evaluated to select the most suitable option for the site.

- *Solar Energy Modeling:* The solar energy component utilizes solar irradiance data and PV module characteristics to estimate energy production. The model includes factors such as panel orientation, tilt angle, shading effects, and temperature coefficients. Different PV technologies are compared to determine the optimal choice for the hybrid system.
- *Geothermal Energy Modeling:* The geothermal energy component simulates heat extraction from the Earth's subsurface and its conversion into electricity. The model incorporates geothermal gradient data, well characteristics, and conversion efficiencies. The potential for direct use applications, such as district heating, is also evaluated.
- *Storage System Modeling:* The storage system is designed to balance supply and demand, ensuring a continuous energy supply. The model simulates the charging and discharging cycles of the storage system based on energy production and consumption patterns. Different storage technologies, including batteries and thermal storage, are analyzed to determine the most effective solution.

3.3 Simulation

In this study, we use MATLAB to model and simulate the hybrid system's energy production, storage, and grid integration. The simulation incorporates various scenarios to assess system performance under different conditions. Key parameters, including capacity factors, energy conversion efficiencies, and storage capacities, are integrated into the model to ensure accurate simulations.

3.4 Analysis

This research evaluates the proposed system's technical feasibility, economic viability, and environmental impact. This analysis includes calculating the levelized cost of electricity (LCOE), assessing greenhouse gas emissions reductions, and conducting sensitivity analyses to determine the impact of different variables on system performance. The analysis comprehensively assesses the hybrid system's potential benefits and challenges.

The economic analysis involves calculating the levelized cost of electricity (LCOE) for the hybrid system. This analysis includes capital, operation, maintenance, and financing costs. The LCOE is compared to traditional coal-based energy systems to assess the economic viability of the hybrid system. The analysis also considers potential cost savings from policy incentives and technological advancements.

The environmental analysis assesses the reductions in greenhouse gas emissions achieved by the hybrid system, which involves comparing the lifecycle emissions of each hybrid system component to a baseline scenario of coal-based energy production. The analysis includes the emissions associated with the system's manufacturing, installation, operation, and decommissioning.

The sensitivity analysis models various scenarios to assess the impact of different variables on the system's economic and environmental performance, which includes changes in capital costs, energy prices, policy incentives, and technological advancements. The sensitivity analysis helps

to identify the most critical factors influencing the viability of the hybrid system and provides insights into potential risks and opportunities.

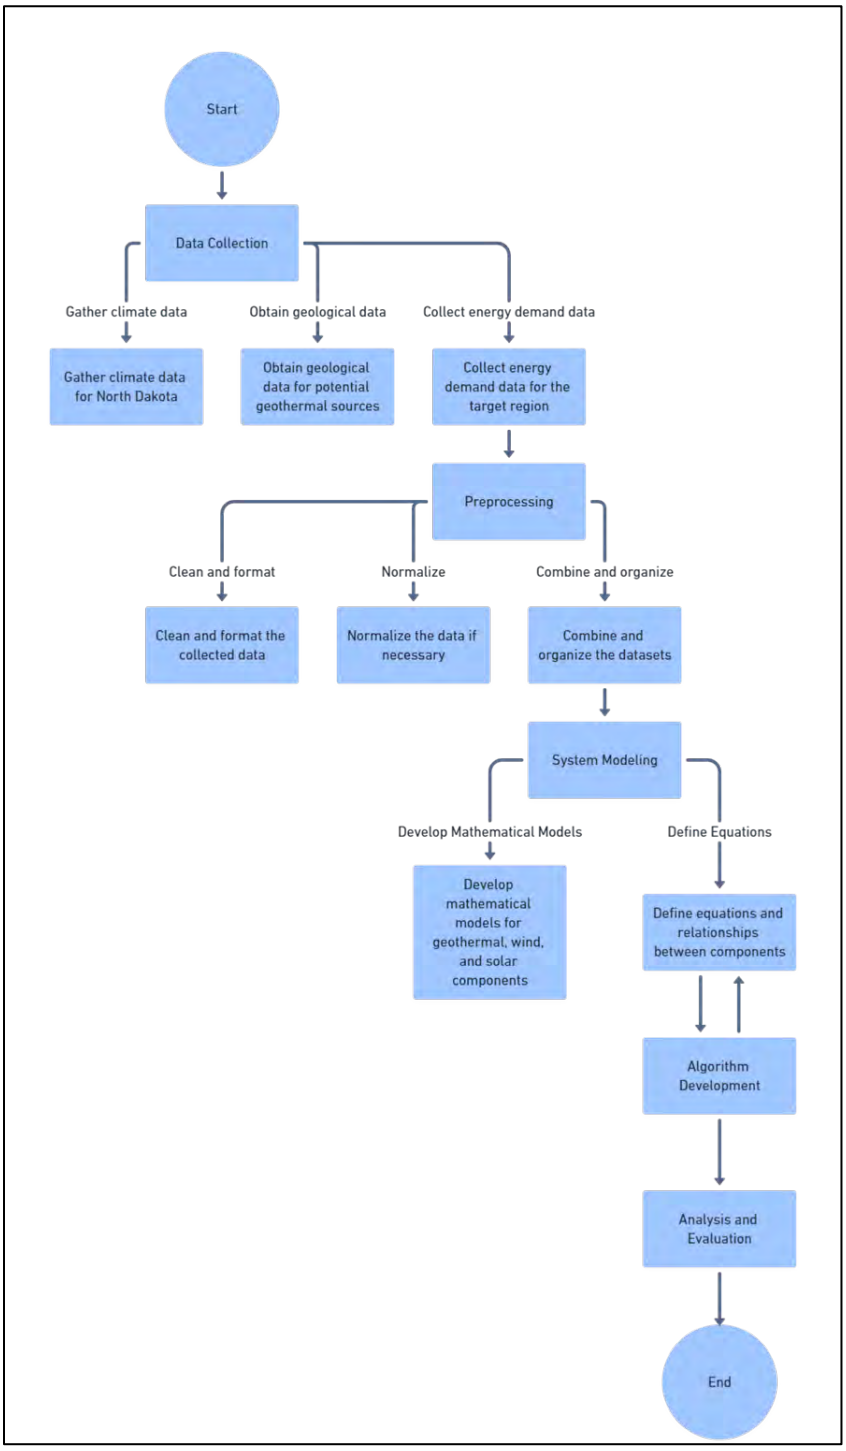

Figure 6. Flow chart for System Modeling and Simulation.

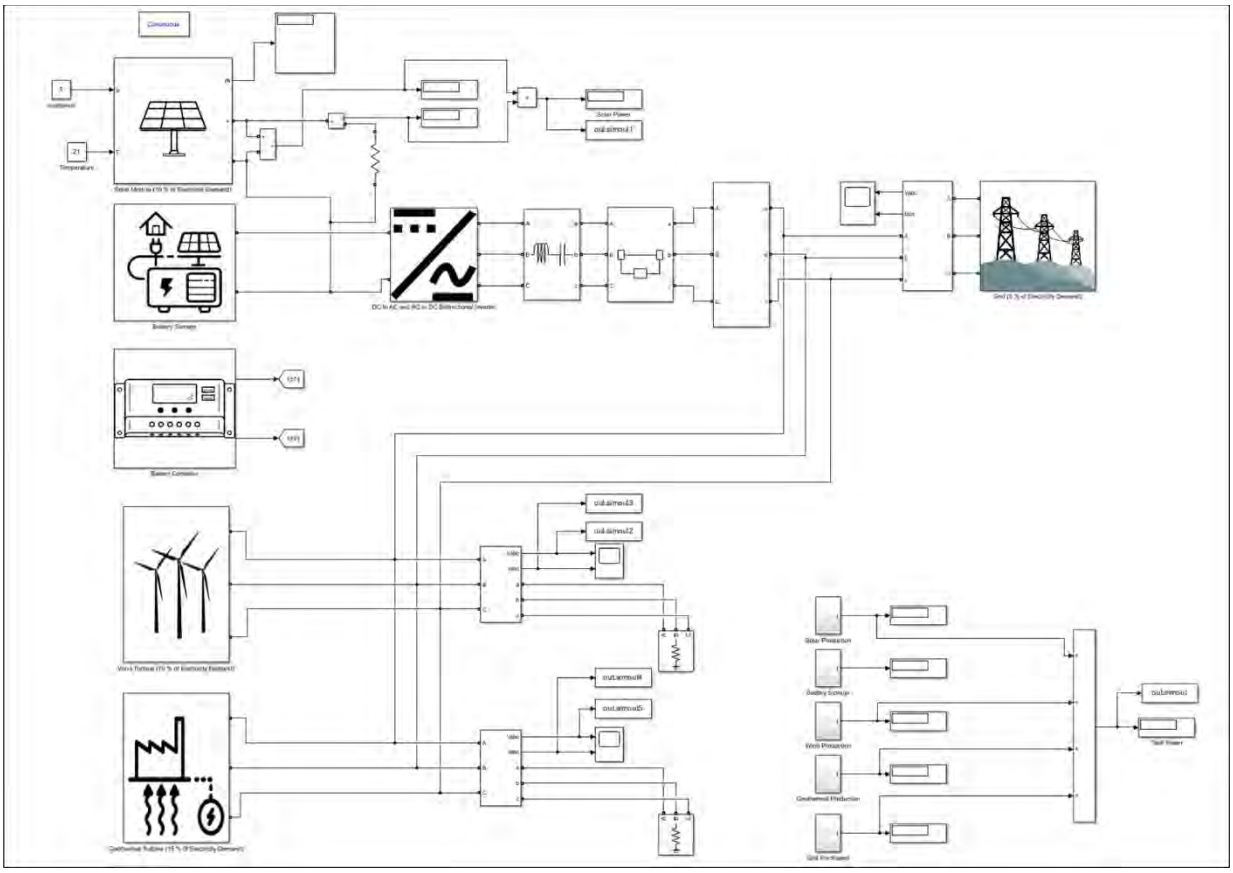

Figure 7. The hybrid system was designed for Bowman County, ND, using Simulink, MATLAB, 2023.

4. Results and Discussions

4.1 Feasibility of the Hybrid System

A proposed hybrid renewable energy system for North Dakota combines wind, solar, geothermal, storage, and grid purchases to meet an assumed local annual electricity demand of 106,865 MWh (Table 1). The system is designed to supply 70% of the total demand from wind, 10% from solar, and 15% from geothermal, with the surplus coming from storage and 5% from grid purchases.

- The wind component of the hybrid system has a capacity of 85.4 MW, with an estimated capital cost of $107,347,800 and an annual operation and maintenance (O&M) cost of $3,561,180. The wind turbines are expected to generate 74,805 MWh of electricity annually.
- The solar PV component has a capacity of 24.4 MW, with an estimated capital cost of $26,181,200 and an annual O&M cost of $458,720. The solar panels are expected to generate 10,688 MWh of electricity annually.
- The geothermal component has a capacity of 2.03 MW, with an estimated capital cost of $13,010,270 and an annual O&M cost of $212,338. The geothermal plant is expected to generate 16,029 MWh of electricity annually.

- The solar storage component has a capacity of 194 MWh, with an estimated capital cost of $243,605.8 and an annual O&M cost of $6,072.2. The storage system will store surplus energy generated by the solar panels for use during periods of low solar output.
- To supplement the renewable energy sources, the system will also purchase 5,343.25 MWh of electricity annually from the grid at an O&M cost of $5,343,250.

Table 1. Monthly production of the hybrid system, Bowman County, North Dakota, by 2040.

Month	Wind (MWh)	Solar (MWh)	Geothermal (MWh)	Grid (MWh)	Total (MWh)
Jan	9,000	500	1,600	300	11,400
Feb	8,500	600	1,600	250	10,950
Mar	9,500	800	1,600	100	12,000
Apr	8,000	900	1,600	150	10,650
May	6,500	1,100	1,600	250	9,450
Jun	5,000	1,300	1,600	350	8,250
Jul	4,500	1,500	1,600	400	8,000
Aug	5,000	1,300	1,600	350	8,250
Sep	6,500	1,100	1,600	250	9,450
Oct	8,000	900	1,600	150	10,650
Nov	9,000	700	1,600	200	11,500
Dec	9,500	600	1,600	100	11,800

The total annual electricity generation from these combined sources is estimated to be 112,210 MWh, which exceeds the assumed local demand of 106,865 MWh. This hybrid renewable energy portfolio is designed to provide a reliable and sustainable source of electricity for North Dakota while minimizing reliance on fossil fuels and reducing greenhouse gas emissions. Simulations indicate that the proposed hybrid system can meet over 90% of Bowman County's daily energy demands by 2040 (Figure 8). The wind and solar components produce the bulk of energy, while the geothermal component offers a stable baseload power source. The storage system effectively balances supply and demand, ensuring a continuous energy supply. The results demonstrate the technical feasibility of integrating multiple renewable energy sources to create a reliable and efficient hybrid system.

This significant expansion leverages complementary resources and storage to surmount intermittency barriers that would constrain further growth of standalone wind or solar. The findings demonstrate hybrid configurations technically enable the vast majority of local load from Indigenous variable generation to be fulfilled via holistic design and control.

However, the geothermal plant specification requires confirmation of sufficient hot aquifer temperatures and flows at depth. Additional geological surveys and test wells would reduce uncertainties. The modeled grid purchases will likely underestimate the need for firming without complete backup. Transmission capacity limits could also constrain renewable penetration. More

granular demand data would improve simulations. Nonetheless, the analysis substantiates that hybrid renewable systems can achieve high penetrations with careful planning.

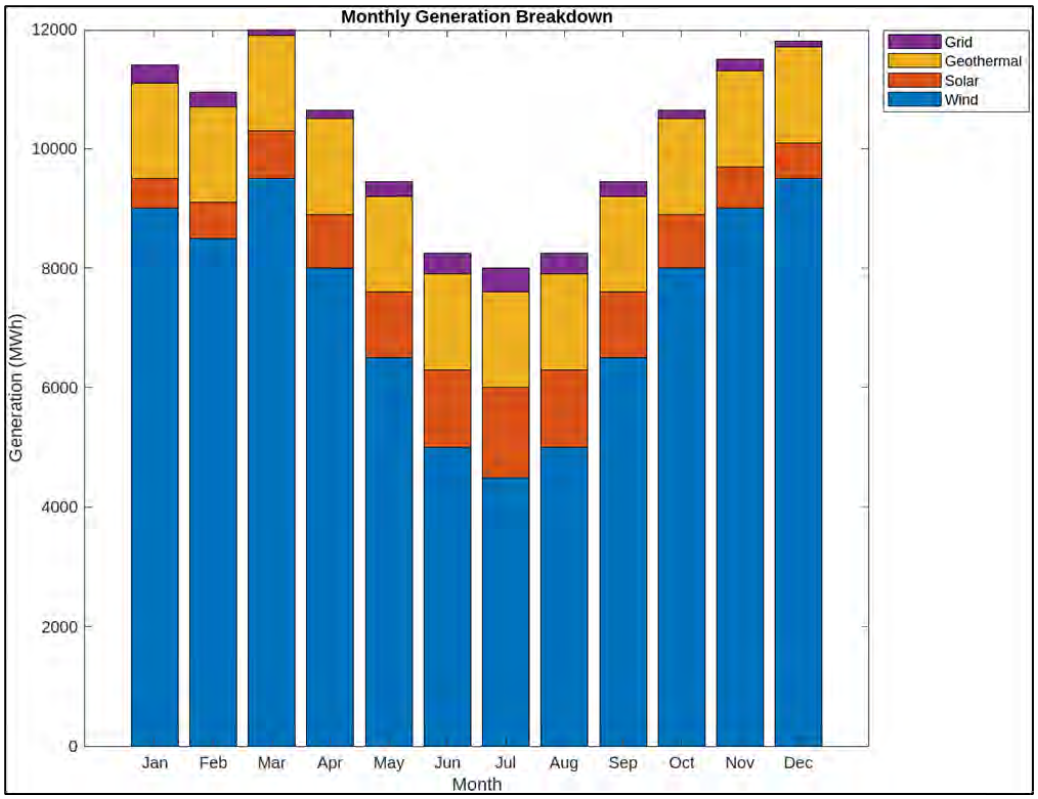

Figure 8 . Monthly electricity generation from the hybrid system by 2040.

4.2 Economic Assessment

The proposed hybrid renewable energy system for Bowman County, North Dakota, demonstrates economic solid viability, with a projected Levelized Cost of Electricity (LCOE) of $105.226/MWh over a 15-year period (Figure 9). This cost is comparable to or lower than traditional coal-based energy systems, making the hybrid system an attractive alternative from a financial perspective. Sensitivity analyses conducted as part of the economic assessment reveal that the hybrid system remains economically viable under various scenarios, including fluctuations in capital costs, energy prices, and policy incentives. Integrating multiple renewable energy sources enhances the system's resilience and reduces dependency on a single energy source, further improving economic stability. The study also highlights the potential for cost savings through policy incentives and technological advancements, which can further improve the hybrid system's economic performance. These findings provide valuable insights for policymakers and investors considering the transition to renewable energy systems. Overall, the economic assessment emphasizes the financial benefits of adopting a hybrid renewable energy system in Bowman County, demonstrating the potential for cost-effective, stable, and environmentally friendly energy production.

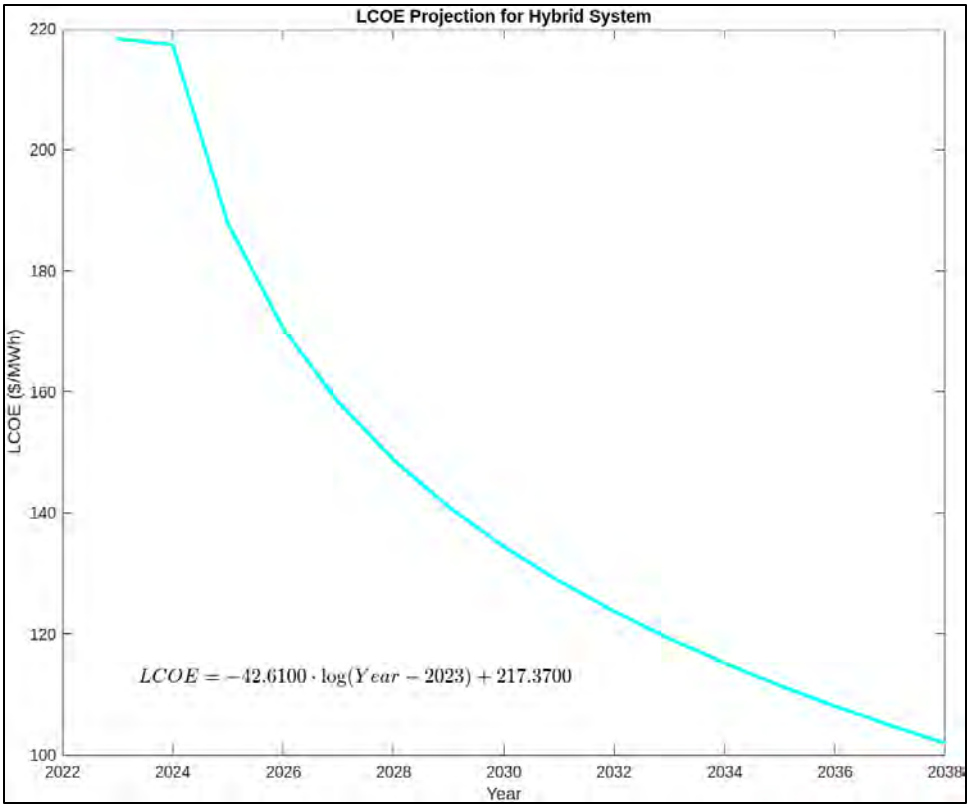

Figure 9. Levelized Cost of Electricity Projection for Hybrid System.

4.3 Environmental Impact

The proposed hybrid renewable energy system for Bowman County, North Dakota, offers significant environmental benefits by reducing daily CO_2 emissions by 97% compared to coal-based energy systems (Figure 10). This substantial reduction in greenhouse gas emissions aligns with global sustainability goals and contributes to the mitigation of climate change (Blanco & Faaij, 2018). The displacement of coal-based energy with clean, renewable energy sources is the primary driver behind the reduction in emissions. By harnessing wind, solar, and geothermal resources, the hybrid system minimizes the environmental impact of energy production and helps improve air quality in the local community. The environmental impact assessment underscores the wide-ranging benefits of reducing greenhouse gas emissions and other pollutants. In addition to combating climate change, the hybrid system can enhance public health by reducing the incidence of respiratory illnesses and other health problems associated with air pollution. Furthermore, the study highlights the potential for renewable energy systems to provide long-term environmental sustainability. Bowman County can contribute to global efforts to create a more sustainable and resilient energy future by transitioning to a hybrid renewable energy system.

5. Conclusions

5.1 Overview of the Study

This study provides a comprehensive analysis of a hybrid renewable energy system tailored to the specific needs of Bowman County, North Dakota. By integrating wind, solar, geothermal energy, and storage technologies, the proposed system aims to meet the growing energy demands while significantly reducing greenhouse gas emissions. The study employs advanced MATLAB-based simulations to model and evaluate the system's performance under various scenarios, ensuring a robust and reliable analysis.

5.2 Key Findings

The simulations and analyses conducted in this study yield several key findings:

- *Technical Feasibility:* With its diverse mix of renewable energy sources, the hybrid system is technically feasible for Bowman County. The integration of wind, solar, and geothermal energy ensures a stable and reliable energy supply that meets over 90% of the county's projected daily energy demands by 2040. Including a storage system effectively balances supply and demand, addressing the intermittency issues associated with wind and solar energy.

- *Economic Viability:* The levelized cost of electricity (LCOE) for the hybrid system is projected to be $105.226/MWh over 15 years, making it competitive with traditional coal-based energy systems. The economic analysis demonstrates that the hybrid system is financially viable, with the potential for cost savings through policy incentives and technological advancements. Sensitivity analyses confirm the system's economic robustness under various scenarios, highlighting its resilience to changes in capital costs, energy prices, and policy environments.
- *Environmental Benefits:* The hybrid system significantly reduces greenhouse gas emissions, with a projected 97% reduction in daily CO_2 emissions compared to coal. This substantial decrease in emissions aligns with global sustainability goals and contributes to mitigating climate change. The environmental analysis also highlights the additional benefits of improved air quality and public health, underscoring the importance of transitioning to renewable energy.

5.3 Implications for Bowman County

The successful implementation of the proposed hybrid renewable energy system has profound implications for Bowman County. It offers a pathway to achieving energy independence and sustainability, reducing reliance on fossil fuels and enhancing energy security. The system's economic viability and environmental benefits make it an attractive option for local policymakers, investors, and the community.

- *Energy Independence:* Bowman County can reduce its dependency on imported fossil fuels by leveraging local renewable resources, which enhances energy security and resilience and protects the community from the volatility of global energy markets and potential supply disruptions.
- *Economic Development:* Developing and deploying renewable energy technologies can stimulate local economic growth. It creates job opportunities in constructing, operating, and maintaining renewable energy facilities, contributing to the local economy. The potential for cost savings and revenue generation from excess energy production further enhances economic benefits.
- *Environmental Stewardship:* Transitioning to a hybrid renewable energy system positions Bowman County as a leader in environmental stewardship. It demonstrates a commitment to sustainability and climate action, serving as a model for other communities. The environmental benefits, including reduced emissions and improved air quality, contribute to the overall well-being of the local population.

5.4 Broader Implications and Future Research

The findings of this study have broader implications beyond Bowman County, providing valuable insights for other communities and regions seeking to transition to renewable energy. The hybrid model serves as a versatile template that can be adapted to different geographic and climatic conditions, offering a scalable solution for sustainable energy development.

- *Scalability and Adaptability:* The hybrid system model can be adapted to various scales, from small communities to larger urban areas. It is flexible enough to incorporate additional renewable energy sources and advanced storage technologies, enhancing its

applicability across different contexts. The model's adaptability makes it a valuable tool for planning and designing renewable energy systems worldwide.

- *Policy and Investment:* The study underscores the importance of supportive policy frameworks and investment in renewable energy. Policy incentives, such as subsidies, tax credits, and feed-in tariffs, play a crucial role in enhancing the economic viability of renewable energy projects. Investment in research and development is also essential to drive technological advancements and cost reductions in renewable energy technologies.
- *Further Research:* While this study provides a comprehensive analysis, further research is needed to explore additional aspects of renewable energy integration. Future research should focus on optimizing system configurations, incorporating emerging technologies, and assessing the long-term sustainability of hybrid systems. Studies on renewable energy transitions' social and cultural impacts are also critical to ensure community acceptance and engagement.

In conclusion, the proposed hybrid renewable energy system offers a viable and sustainable solution for Bowman County, North Dakota. It effectively meets the growing energy demands while significantly reducing greenhouse gas emissions, contributing to environmental sustainability and climate action. The study demonstrates the hybrid system's technical, economic, and environmental feasibility, providing a comprehensive roadmap for its implementation. The findings underscore the potential for renewable energy systems to drive the transition to a sustainable and resilient energy future, offering valuable insights and a model for other communities seeking to achieve clean, locally focused energy independence.

ABSTRACT

Geothermal energy production is attractive since it is dispatchable, has low emissions, and low environmental impact. In the advent of scalable next generation geothermal systems, repurposing of depleted oil and gas wells can be a contributor to the energy transition. Wells can be repurposed for closed loop borehole heat exchange (BHE) for direct geothermal use or electricity production in areas with sufficiently high geothermal gradient. Repurposing old wells for BHE cuts capital expenditure on drilling and has little reservoir uncertainty compared to conventional open loop geothermal. In this paper we look at design and operational parameters for wells circulating water injected in the annulus space and the core tube feeding hot water to an organic Rankine cycle for energy production. An integrated asset model consisting of a multiphase flow simulator and a process simulator is used to optimize the produced electrical power. The aim is to show how commercial oil and gas simulators, and methodology can generate techno-economic studies that lead to successful geothermal project design and operation.

1. Introduction

Among the thousands of oil and gas wells drilled globally, a certain subset has been drilled in regions with geothermal gradients above the average. These hot wells can become geothermal energy resources, by repurposing them to borehole heat exchangers extracting heat by closed loop circulation of a fluid such as water. Old wells, not producing oil and gas anymore can aid the energy transition and provide a segue for oil and gas companies into a sustainable and environmentally friendly industry. Conventional geothermal operators drill wells that for various reasons will never be operated but can be hot candidates for BHE. Figure 1 shows regions where higher geothermal gradient can occur, and where conventional power plants are located, this indicates where there could be potential for BHE in old wells.

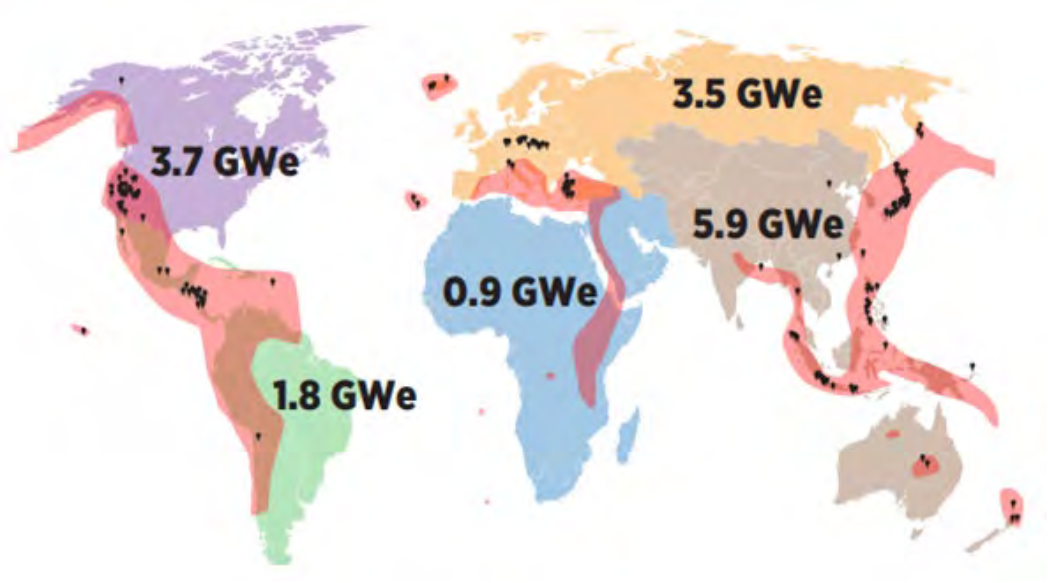

Figure 1: Installed electrical capacity from geothermal plants in 2021. Each black dot is a plant while the red zones indicate high-temperature geothermal zones. Data from IRENA and IGA (2023).

Many factors such as location, depth and number of wells and the available temperatures will determine whether the resource is best applied for direct use of the heat and/or electricity production. Direct use of the heat has a high efficiency and can cut emissions on industrial applications or district heating. For wells with sufficiently high temperatures, borehole diameter, and measured depths, electricity production may be feasible using a steam turbine. Geothermal energy is a firm power source and has a big advantage over other intermittent renewables such as wind and solar. Big capital expenditure is a drawback for geothermal energy, that is why proper tools and workflows to find the optimal design is key for any project.

Previous work by Chaves et al. (2023) showed how a multiphase flow simulator has been adapted and can be used to model well design and operational aspects for closed loop borehole heat exchangers. Expanding on this work, it shows how to apply integrated asset simulation to optimize design and operation of a geothermal plant. A well and network simulator is tightly integrated with a process simulator which is again orchestrated using a Bayesian optimizer. Running multiple simulation scenarios, the workflow will converge toward optimal design and operating conditions that maximizes the net power generation of the plant.

2. Method

In this section the domain specific technical foundation regarding reservoir model, well model, process model and orchestrator software is outlined. The simulators used are Aspen METTE, Aspen HYSYS and Aspen Tempest, and will respectively be referred to as well simulator, process simulator and simulation orchestrator.

2.1 Well and Reservoir Model

A BHE transfers heat by circulating fluids inside a hot well. The fluid used is water in this case. Figure 2 shows the heat transfer effects in the well as the water is heated in the annulus and maintained through the core tubing. Mass is conserved, as there is no mass transfer with the sub-

surface, which also means there is little to no risk of inducing seismicity. The well used in this work has a measured depth of 2000 meters and is nearly vertical. The annulus diameter is 8,5 inches, and it is assumed this can be used as is without drilling a new well. The core tubing diameter and insulation are the main design variables considered for recompleting the well in addition to deciding the circulation rate which is an operating variable. Figure 2 indicates a big temperature difference between the fluid in the annulus and the tubing near the top. Using a vacuum insulated tubing (VIT) near the wellhead will mitigate the temperature loss from the core tubing.

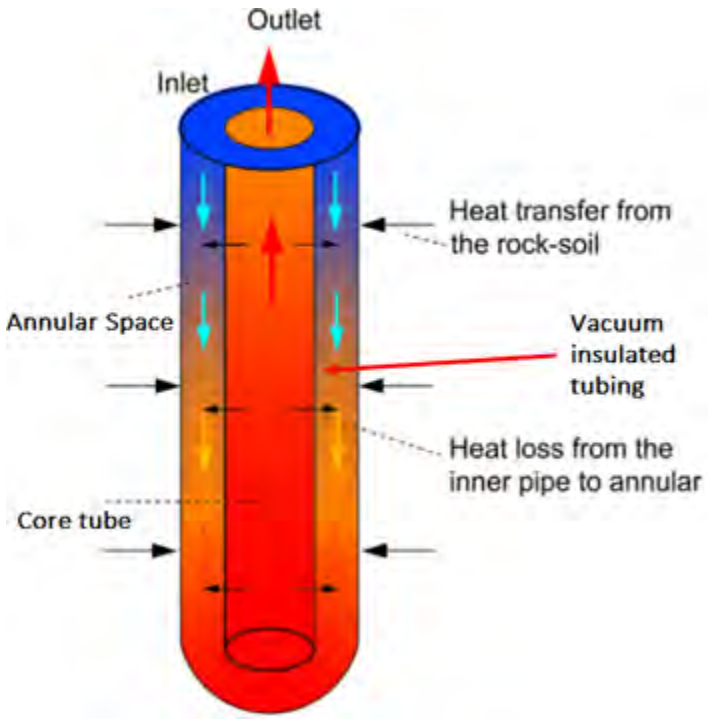

Figure 2: A schematic illustrating heat transfer for the borehole heat exchanger (BHE). Cold fluid (water) is injected into the annulus and gets heated via conduction from the hot casing and rocks surrounding the well. In the bottomhole, the heated fluids transfer into the core tubing, bringing it back to the surface. Using a vacuum insulated tubing helps to maintain the temperature on the return. The figure is taken from Chaves et al. (2023).

The well model has a geothermal gradient as shown in Figure 3, going from 20 °C at the surface to 250 °C at 1800 m TVD. The well simulator is used to model the thermal convection and conduction effects in wellbore material and fluid as well as the rocks/reservoir surrounding the wellbore. The simulator uses a proprietary drift-flux flow model for the pressure loss, and a transient radial model for the heat transfer into the rocks. No reservoir simulator is used in this case, as it is a hot dry rock example with conduction, and no convection effects modeled in the rocks. The model is explained in more detail in Chaves et al. (2023) for reference. Figure 4 shows how the well model is discretized for a cross section of the well. Convection of heat is modelled in the water for the annulus (in grey) and the core (in red) in the center of the well. Between them, where it says “vacuum”, conduction of heat is modeled. The outer layers indicate a discretized model into the rocks or “Formation” which is 10 meters in radius with conduction modeled until an ambient temperature boundary at the outmost circle. The well model has a choke valve and a pump available to meet its target flow rate. At lower flow rates the thermosiphon effect is enough keep the well circulating, and the choke valve is used to balance pressure. At higher flow rates, the

additional frictional loss will become greater than the delta pressure from the density difference between the annulus and the core, at which point the pump can be used to add more head to circulate the wanted rate.

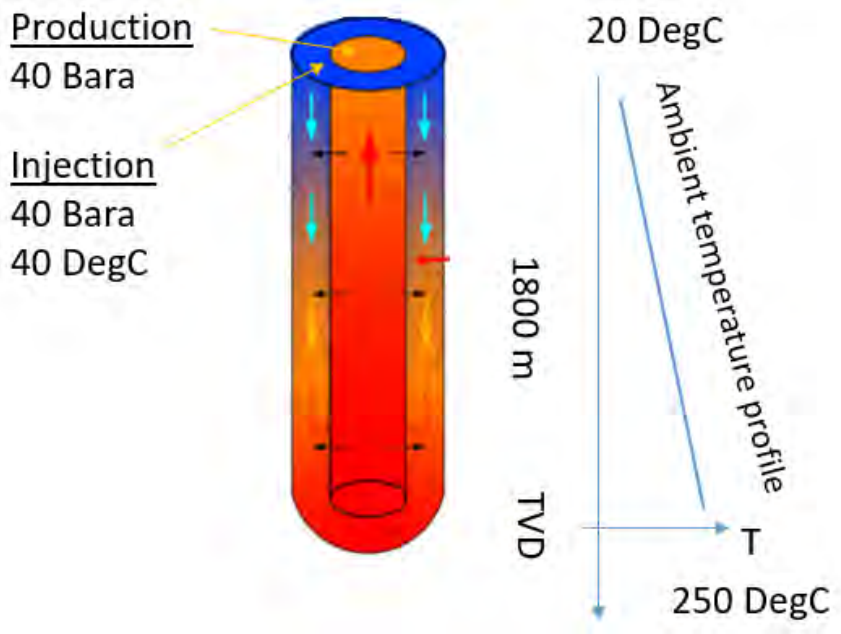

Figure 3: The constant boundary conditions for the model are shown. The model is run from a cold start initial condition at ambient temperature. Flow rates and other parameters are variables in the simulations.

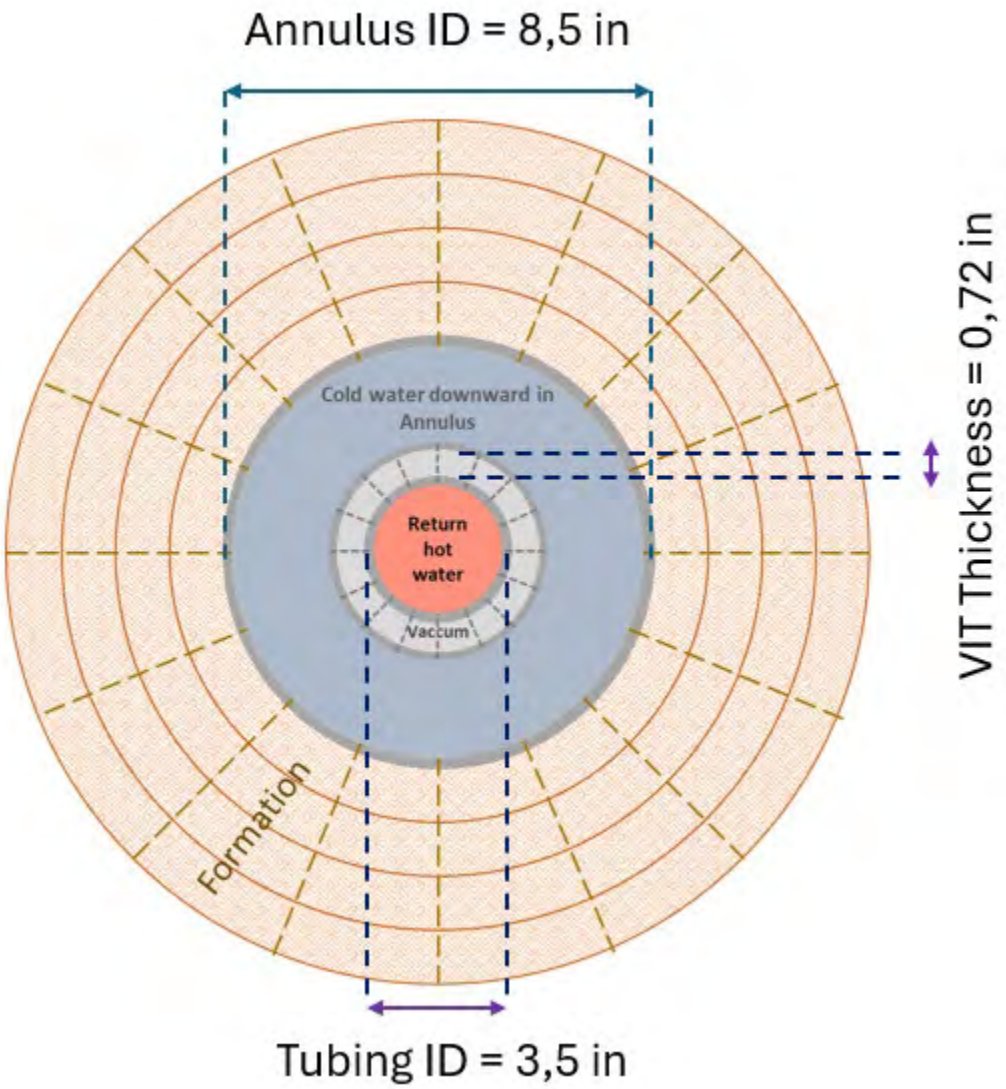

Figure 4: Simplified cross-sectional view of the simulation domain in the well and surrounding rock formation. The annulus inner diameter (ID) is fixed in this work, but the tubing ID is a control parameter for the optimization study. The figure is based on Chaves et al. (2023).

2.2 Process Model

The integrated model consists of an ORC built in the process simulator which has an extension to interface the well simulator, see Figure 5. The integrated model has a consistent handling of pressure, PVT properties, mass and energy balances between the simulators. Each simulation scenario is run for five days with the well simulator giving transient temperatures into the process simulator. For the techno-economic results, a simulation is run for a longer period. The ORC model is inspired by the work of Beckers et al. (2022). Since we only have one well with a realistic model, we multiply the flow coming from this well to account for additional wells feeding into the plant. In Figure 5, two set blocks SET-TEMP and SET-FLOW are used to set the boundary conditions for the MAKEUP stream based on the GF_IN stream from the well simulator. The total number

of wells is set to 10. It is assumed the wells are far enough apart to avoid considerable thermal influence.

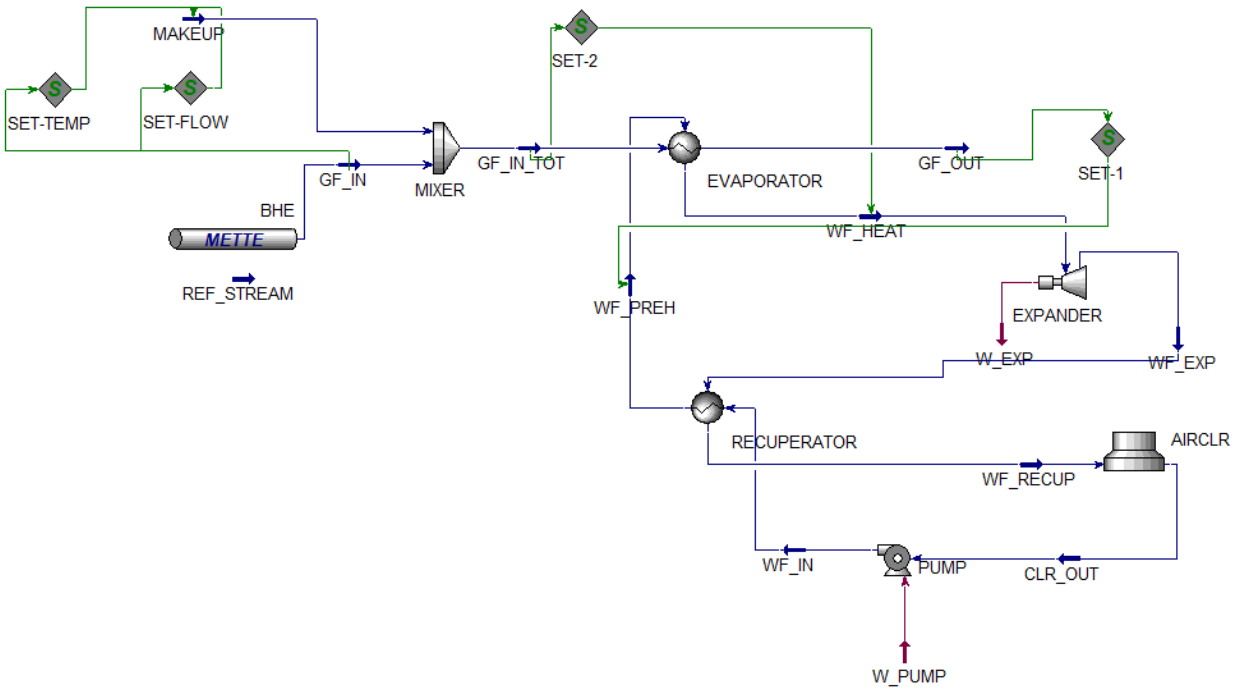

Figure 5: The integrated process model of an ORC with butane as working fluid and water as BHE fluid.

2.3 Orchestrator and Optimizer

The simulation orchestrator is a Bayesian optimization framework described in Bordas et al. (2020) and Taha et al. (2024). The Bayesian approach is effective when optimizing functions that are costly to evaluate. The orchestrator starts an initial set of simulations, called Scoping Runs, which are used as training data to fit an emulator function for the objective function. In this case, the objective function is the net power generation of the ORC plant. Additional batches of simulations, called Refinement Runs, are then run to fine-tune the control parameter values while the emulator function is continuously updated. The orchestrator will explore the solution space and converge towards an optimal solution with an increasing precision as more runs are executed. Relevant control parameters for the optimization are shown in Table 1 with reference to streams in Figure 5. The control parameters are key operating boundary conditions for the ORC and the BHE.

2.3.1 Table 1: Control Parameters for the Optimization with Ranges

Name [control parameter name]	**Description []**	**Value Range [min, max]**
Rate GF_IN.	Well flow rate from the BHE	1– 4 kg/s
Pressure at WF_EXP	Pressure of the working fluid downstream the expander	2 – 5 Bara
Pressure at WF_IN	Pressure of the working fluid downstream the pump	10 – 40 Bara
Temperature at WF_PREH	Temperature of the working fluid into the evaporator	20-50 C°
Depth of VIT	Depth where VIT stops and normal tubing is used for the remaining depths	Six discrete alternatives used: [1,2,3,4,5,6] representing [450 m, 850 m, 1055 m, 1720 m, 1800 m] TVD
Diameter BHE Tubing	Inner diameter of the core tubing in the BHE	0.07 – 0.135 m

2.3.1 Levelized Cost of Electricity

The levelized cost of electricity (LCOE) is calculated for the investment of a new ORC plant including the workover of 10 wells by installing new tubing. The estimated costs of various activities and commodities are tabulated in Table 2 below and are used to calculate the LCOE. ORC cost is taken from Beckers et al. (2022), and well activities are inspired by Lowry et al. (2017). The plant is assumed operable after three years, and the total period is 30 years.

2.3.2 Table 2: Cost Assumptions

Description	**Cost**
ORC Capital Cost	$2500/kWe
Vacuum insulated tubing	$400/m
Normal tubing price	$100/m
Discount rate	7 %
Well logging	$180 000/well
Workover	$30 000/well
O&M Cost	$320 000 k/kWe
O&M Cost Yearly Increase	2%
Parasitic Electricity Cost	$0.3/kWe

3. Results

3.1 Well Simulations

A simple simulation varying the flow rate in the well as seen in Figure 6. The well simulator is efficient for screening design, and well operation but does not model the ORC process rigorously to estimate plant electrical output.

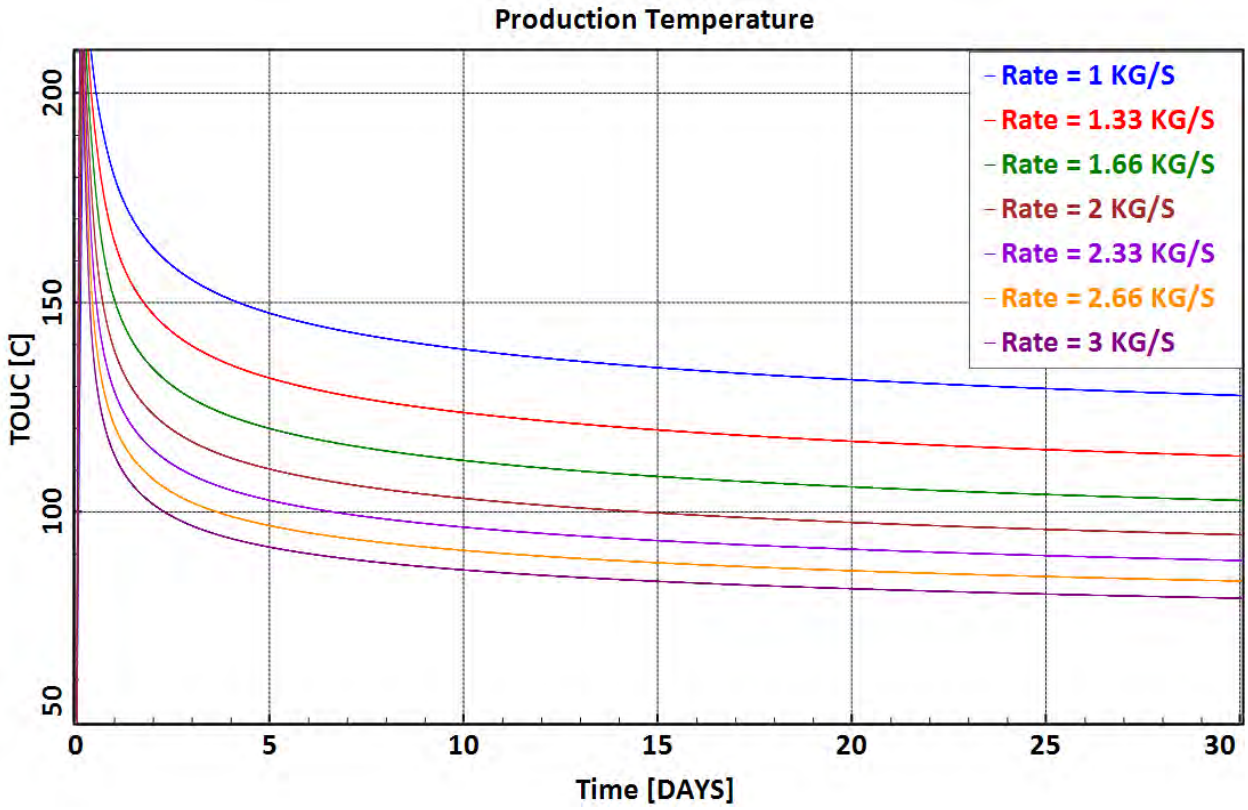

Figure 6: Flow rate sensitivity in the well simulator stand alone. Low rates yield a high outlet temperature, but less thermal energy. The process model is needed to estimate the generated power, and the integrated model is required to estimate the optimal design and operation.

3.2 Optimizing Power Generation

Results are shown where the net power generated is maximized. Figure 7 shows the solution space and maps the combination of control parameters to the wanted net power output. The optimal runs produce more than 950 kWe. As the optimizer explored the solution space it found local optima characterized by different rate and diameter configurations. The best solutions are found when selecting the minimum tubing size paired with a quite low flow rate. Flow rate and tubing diameter are tightly linked, as a lower diameter results in higher velocity through the tubing, with the cost of increased pressure loss. When selecting a lower tubing diameter, the annulus space becomes bigger, resulting in lower velocity through the annulus and higher temperature as the fluid has more time to be in contact with the hot casing and rocks. The low flow rates yield high temperatures and thermal efficiency, but the total power becomes restricted by the amount of mass

transferred. The optimal runs also select the lowest temperatures feeding into the evaporator. A slightly lower solution is found by selecting a higher flow rate and a medium size tubing, as seen in the dark blue distribution. More mass is circulated and the dependency on the downhole pump can be eliminated, but the temperature becomes lower and with it the efficiency drops. The light blue solutions all select the lowest flow rate. The depth of the VIT is consistently giving the best results for a fully insulated tubing, as seen by the fact that most runs converge to this configuration. The pressure at WF_IN is dependent on the temperature from the BHE, as it will result in liquid in the expander, if it is too high. The three distribution tops of this pressure are due to the three distributions of temperatures resulting from the rate and diameter changes. The best runs find a pressure around 25 Bara.

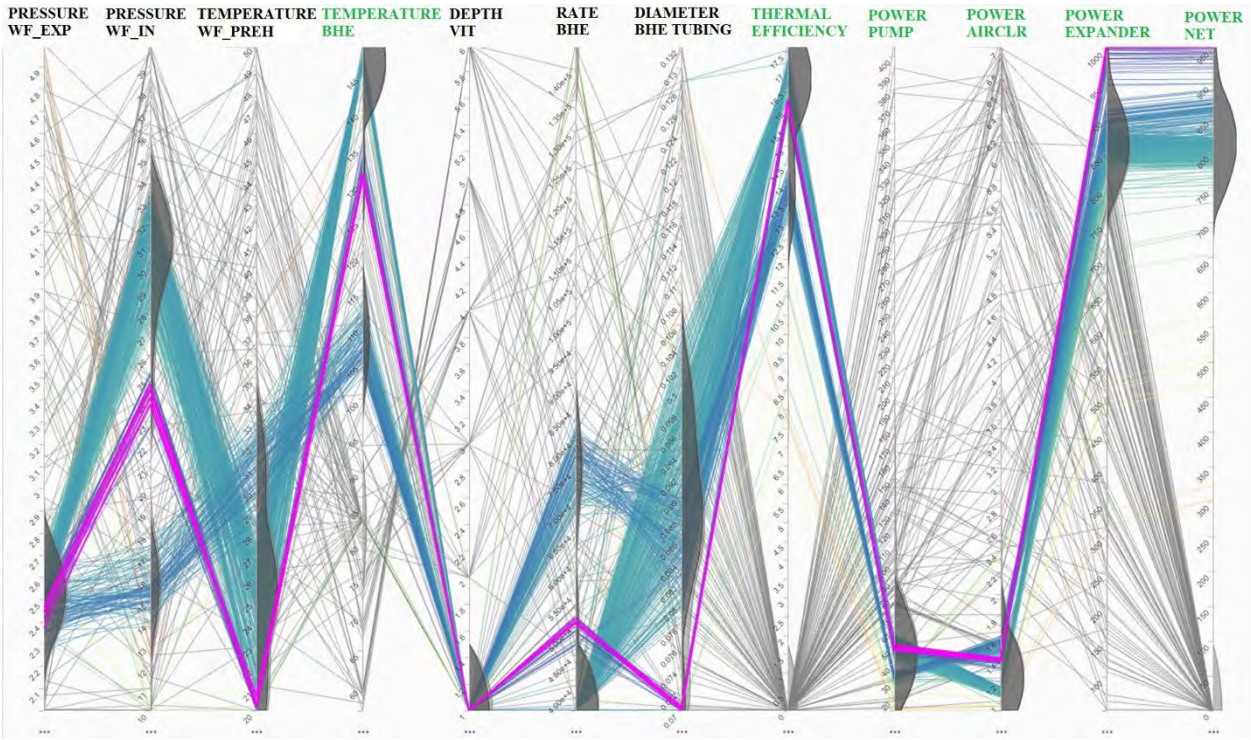

Figure 7: Parallel coordinate plot mapping key asset design and operational variables to the net power generation on the far-right column. Each line represents an integrated simulation run. The black headers notify control parameters while the green headers are dependent variables of interest. The purple lines represent the best scenarios, while blue lines indicate valid scenarios yielding the high power, and the gray lines represent runs that result in non-physical boundary conditions, or the net power generation is zero.

In Figure 8, the evolution of the simulation runs is shown from start to finish. The runs show different local optima before finding the best result as discussed in the above paragraph.

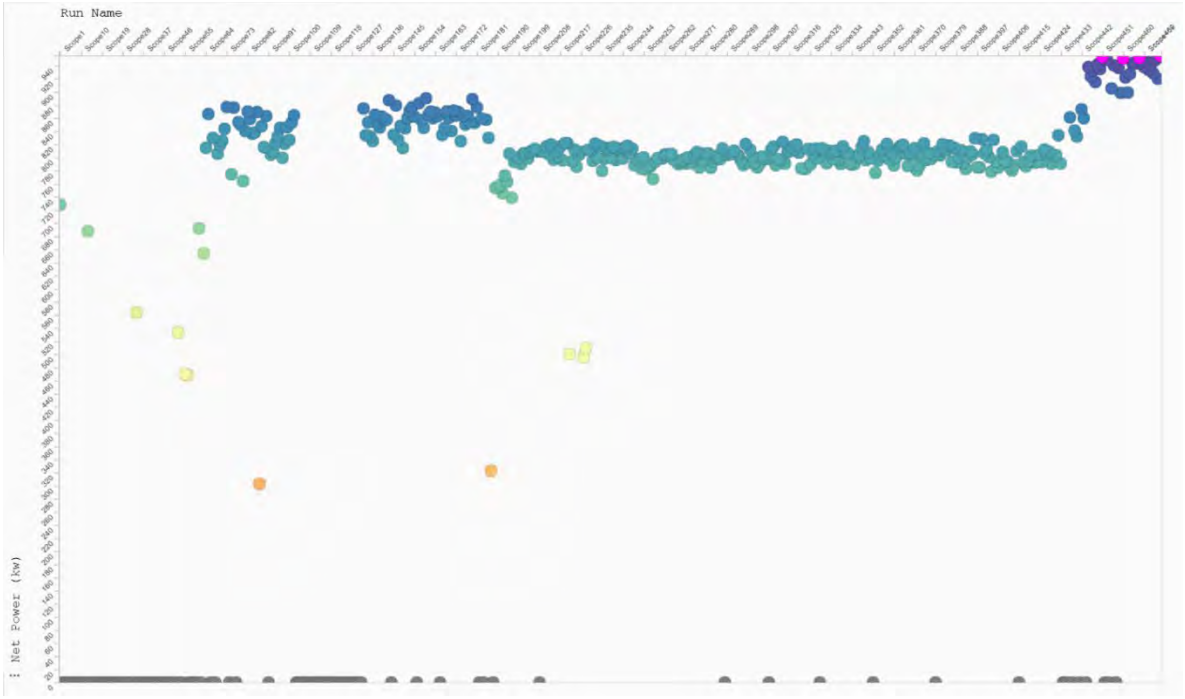

Figure 8: The objective function is plotted vs simulation runs, each dot represents the net power produced for each optimizer run as it progress from start to end. The initial Scoping Runs to the left shows varying results as the optimizer is exploring. On the far-right, the optimal solution is found.

The optimizer is also increasing the thermal efficiency by adjusting the ORC boundary conditions. In Figure 9, a collection of simulation runs is shown together with the best run (yellow) and worst run (green). The best run is obtaining a thermal efficiency just above 16 %.

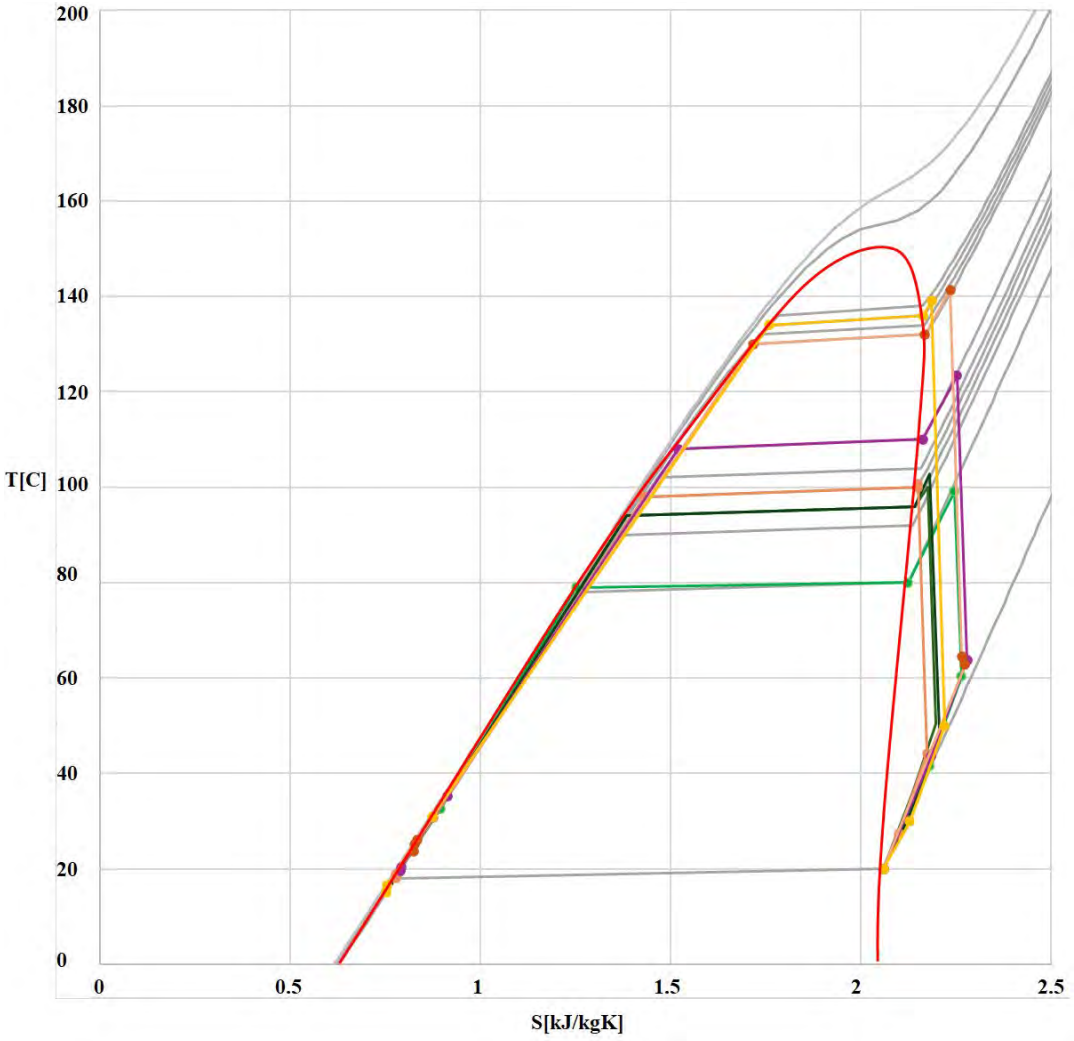

Figure 9: The temperature vs. entropy diagram for butane with a selection of runs from the optimizer. The worst run follows the green curves, and the optimal run follows the yellow line. The other colors represent some arbitrary runs.

3.3 Final Simulation Run and Calculating Levelized Cost of Electricity

A simulation inspired by the optimal runs in Figure 7 has been run standalone to estimate the power generation for 27 years to generate a LCOE estimate for 30 years. The yearly average temperature and power is shown in Figure 10. After 3.5 years of simulation the gradient in temperature starts to drop off at which the temperature for the remainder of the 30 years is extrapolated. The temperature and power generation are averaged over each year and used for yearly input to the LCOE calculation. The average power generation in the first year is 625.7 kWe, and after 3 years it stabilizes at roughly 500 kWe. A downhole pump was not needed, as a choke valve with a DP of 3.5 Bara was needed to balance the pressure, indicating a big enough thermosiphon effect in this case. The LCOE calculation for this scenario is 0.393 $/kWh with the well VIT being the biggest investment.

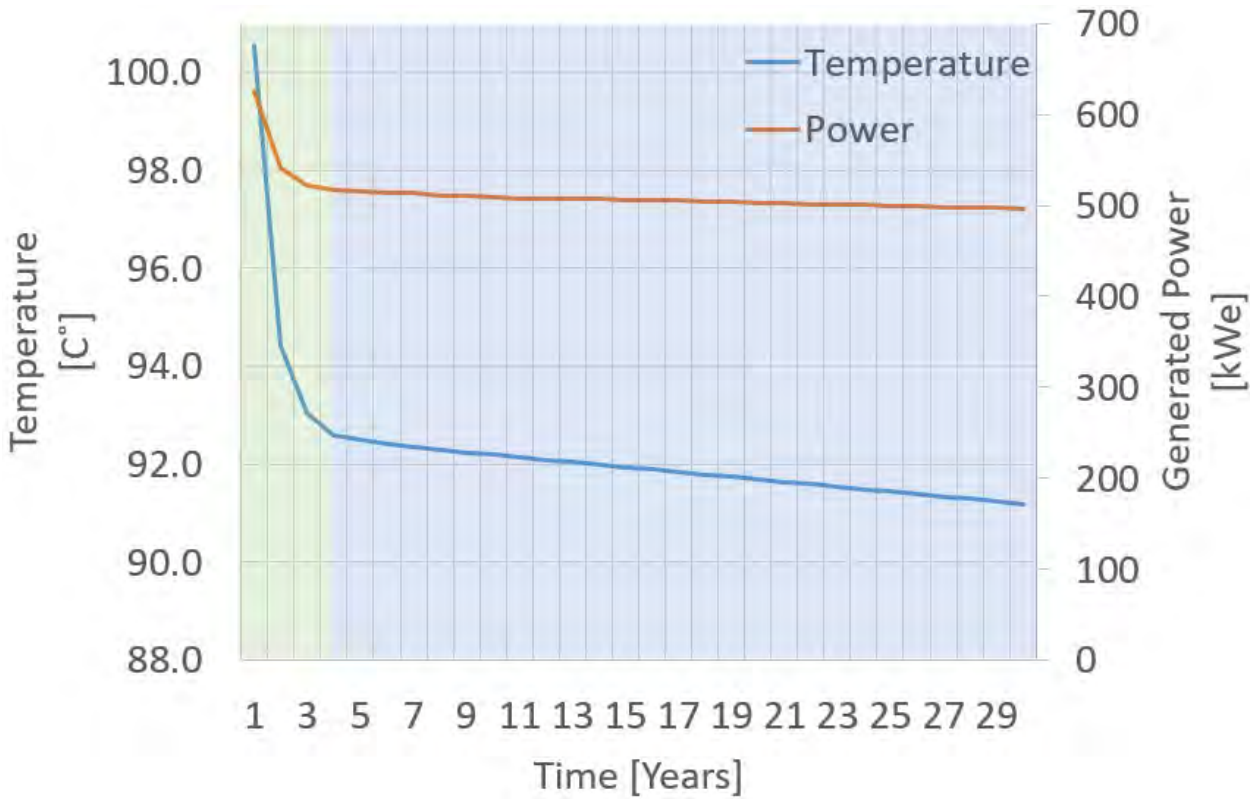

Figure 10: The yearly averaged temperatures and expander power generation used to calculate LCOE for the investment. The simulation is based on the best boundary conditions found in the integrated optimization from Figure 7. The green part is 3.5 years of simulation, and the blue part is extrapolated after the temperature gradient became less than 0.3 degrees per year.

4. Conclusion

A geothermal plant relies on many design parameters that will affect the final power output. This work highlights how integrated modeling with automatic orchestration can aid project teams during the important design phase of a plant. A techno-economic study was performed to assess the feasibility of repurposing old wells for closed loop geothermal power. The optimizer efficiently explores the space of solutions and can aid engineers by considering multiple alternatives. For a 30-year period the LCOE is calculated to 0.393 $/kWh, producing stable power around 500 kWe from hot dry rock. There are many benefits of a closed loop system and an ORC, as mentioned in the paragraph below, which is not factored into the LCOE.

4.1 Benefits of Closed Loop BHE and ORC

While a low LCOE is important for project feasibility, it does not factor in some of the unique political, social and environmental benefits of geothermal power. Closed loop BHE does not require big amounts of water which is good for the economy of the project and the environment, as water can be a restrictive resource in many regions of the world. Corrosion is less of a problem for BHE since clean water can be used, rather than corrosive brine, which may extend the potential life of the asset. Using an ORC and a closed loop BHE in hot dry rock can cut nearly all emission,

since the process is fully closed from the atmosphere. The benefits of geothermal energy which separates it from other energy sources have not been quantified here. Emissions, land usage and loss of nature do have a cost, but it is hard to quantify in an economic study.

4.2 Future Work

A study with LCOE as the objective function for minimization would be interesting to compare with the net power maximization. Another improvement is to run each simulation run for a longer period during the optimization, to provide more realistic results. Geothermal projects have big CAPEX, and optimization under uncertainty of additional parameters is another scenario of interest. In Chaves et al. (2023) the sensitivities of reservoir/rock properties are shown to not be as important, but it would add to the confidence of a thorough techno-economic study.

Abbreviations

Abbreviation/Term	Description
BHE	Borehole Heat Exchanger
CAPEX	Capital Expenditure
DP	Delta Pressure
HDR	Hot Dry Rock
ID	Inner Diameter
VIT	Vacum Insulated Tubing
ORC	Organic Rankine Cycle
LCOE	Levelized Cost of Electricity
kWe	Kilo Watt Electrical
kWh	Kilo Watt Hour
O&M	Operation and Maintenance
PVT	Pressure, Volume and Temperature, referring to fluid properties at different conditions.
TVD	True Vertical Depth

Resource characterization, Reservoir Simulation, Co-production, Wells of opportunity, Blackburn Nevada, Organic Rankine cycle

ABSTRACT

Geothermal electricity co-production is a viable option for oil reservoirs producing large water cuts with elevated wellhead temperatures. Repurposing existing oil wells significantly reduces initial investment costs historically associated with geothermal resource utilization. The National Renewable Energy Laboratory (NREL), partnering with Gradient Geothermal, Inc. (formerly known as Transitional Energy) and Grant Canyon Oil and Gas, has been tasked to evaluate the feasibility of geothermal electricity co-production at the Blackburn Oil Field with Organic Rankine Cycle (ORC) generators. The Devonian steady-state reservoir has historically been producing high water cuts of 240°F (115.6°C) observed at the wellhead without documented pressure drawdown or thermal breakthrough. An estimated initial reservoir temperature of approx. 260°F (126.7°C) has been observed in the field and history-matched in a wellbore production analysis and reservoir simulation. Our objective was to develop a conceptual geological model of the subsurface, simulate a natural-state reservoir, model production scenarios, and complete a technical feasibility analysis to accomplish this task. Through extensive modeling and the use of available proprietary and public data, it was possible simulate three scenarios that indicated minimal thermal decline over the duration of a simulated ten-year production and re-injection scheme.

1. Introduction

The Wells of Opportunity: Nevada (WOO Nevada) initiative aims to generate electricity at the Blackburn Field using the co-produced waters associated with the field's oil production. Blackburn Field is an oil field situated in Sections 7 and 8 of Township 27N Range 52E in northern Eureka County, Nevada. The field is in Pine Valley, approximately 45 miles ESE of Elko, NV.

Historical production records (NDOM 2023) indicate that from 1982 to 2022, Blackburn Field yielded 4.3 million barrels of oil and 43.5 million barrels of water. This resulted in an overall cumulative water-to-oil ratio of 91%. In 2022, the annual water cut was 98.98% (Kutun et al., 2023). The reservoir is a naturally fractured reservoir with a strong hydraulic drive, where water naturally recharges the reservoir. Wells historically drilled into the fractured Nevada dolomite

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

reservoir were typically completed at the shallowest (upper) depths to mitigate water encroachment from below.

An overview of the Blackburn Field wells is presented in Figure 1. Blackburn No. 12, 20, and 21 are three candidate injectors; Blackburn No. 4, 16, 18, 19, and 22 are candidate producers for the WOO Nevada project. Bucy No. 1 is also a candidate injection well located NNW of Blackburn No. 12.

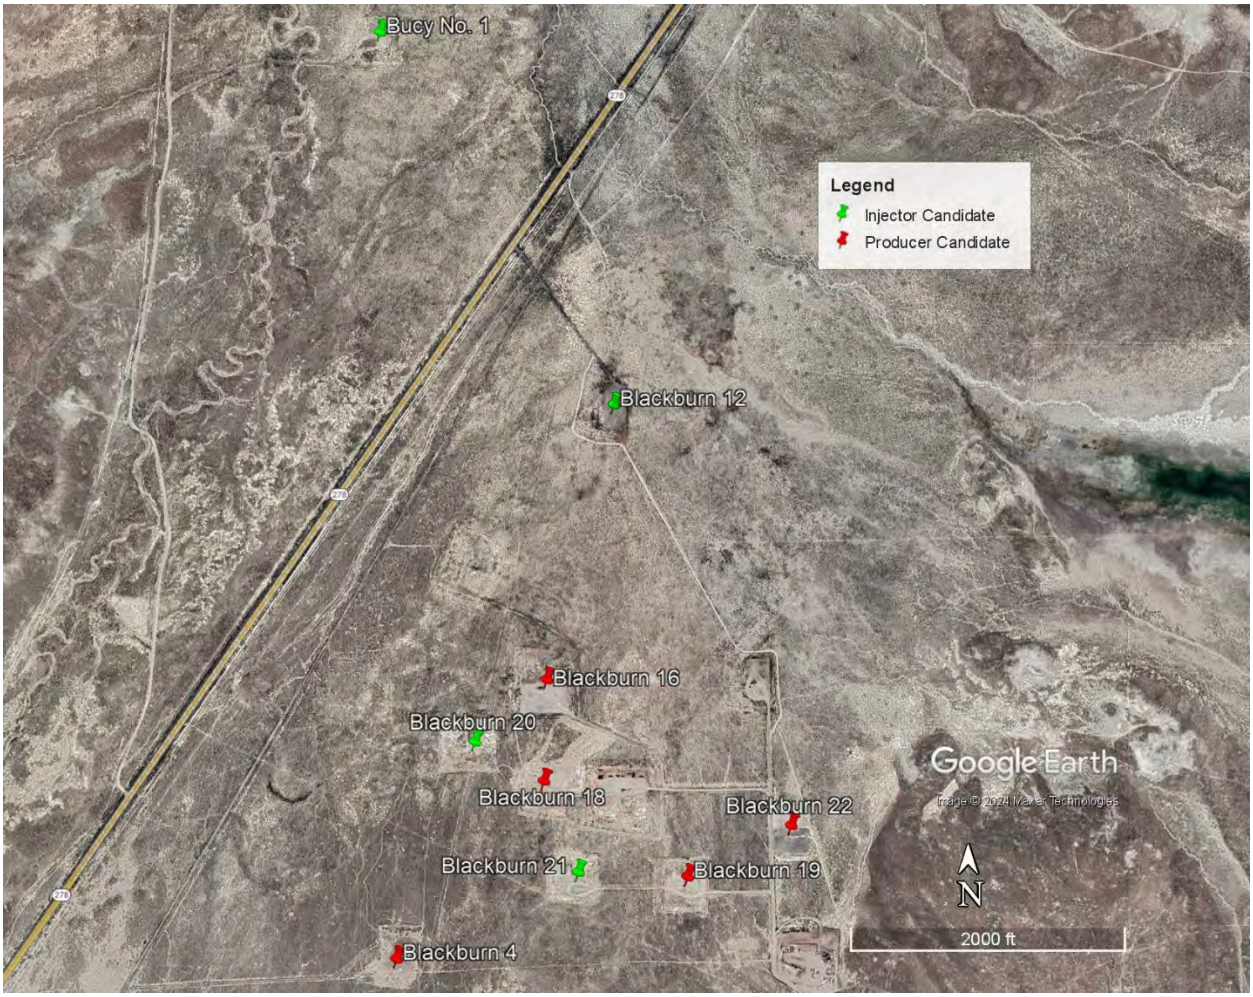

Figure 1: Map showing the locations of the Blackburn project co-production candidate wells.

2. Geological Modeling

The lithologies in the Blackburn field are, in stratigraphic order: the target reservoir Devonian Nevada dolomite, the reservoir-overlying Chainman shale capping layer (deposited post-Antler orogeny), the late Cretaceous quartz monzonite pluton that intruded during a 300 Ma unconformity, the Oligocene Indian Wells tuff, the Oligocene-Miocene lacustrine and conglomerate Humboldt, the Miocene basalt sill, the post-Miocene Hay Ranch (valley fill), and overlying alluvium (Flanigan 1994; Hulen et al. 1990; Scott & Chamberlain 1988). The quartz

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

monzonite pluton is referred to as the basement because it is the first metamorphic formation underlying the target Devonian reservoir.

A stratigraphic column with associated lithological descriptions is provided below in Figure 2. Formation tops from well completion reports and logs (hosted online by NBMG 2023), Taverna (2019), and our own interpretation (where no data were available), were honored as our primary data source in the creation of this conceptual model.

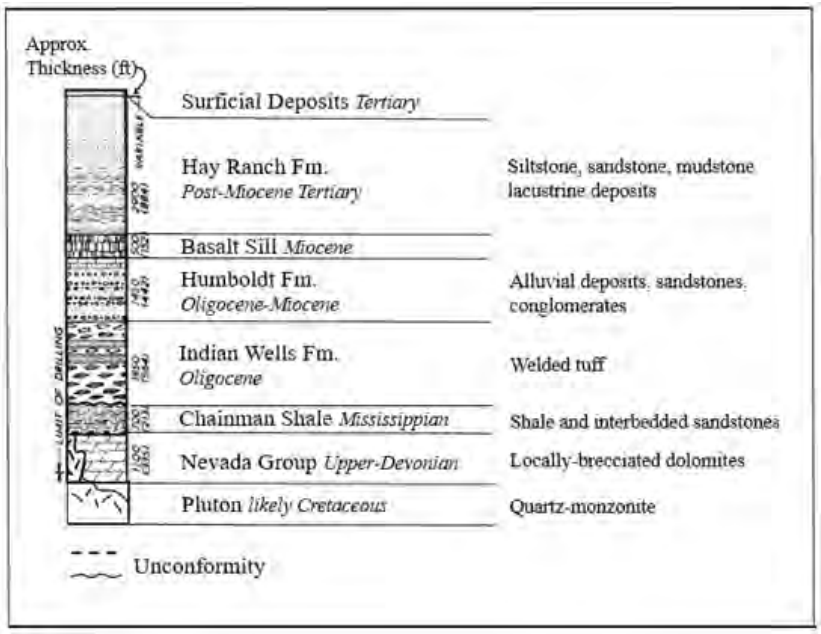

Figure 2: Stratigraphic column and description of formations in the Blackburn Field subsurface, adapted from Hulen et al. 1990.

The crust in this depositional basin is thinner than in other regions of the United States. This phenomenon is attributed to extensional plate tectonics. Extension causes fault dilation, allowing for fluid to flow in larger volumes along intricate fracture and fault pathways. An elevated thermal gradient is observed through the subsurface at the Blackburn Oil Field. It is likely that the heat source for the resource is deep-seated (Hulen et al. 1990). Geothermal fluids rise from depth along fault intersections. Dilated faults also facilitate secondary permeability. Many of the dilated faults in the Blackburn Field subsurface may have been infilled with sedimentary overburden. Future tracer research will offer further insight regarding fault permeability.

In the development of a 3D conceptual geological model, the cross-sections from Hulen et al. (1990) were utilized because they offered NNE and ENE views of the subsurface, whereas other publications did not offer as in-depth an interpretation. Determination of the quartz monzonite pluton contact is variable throughout the publications, because only two wells within the model area struck the pluton: Blackburn No. 1 and No. 6. The basement map from Scott & Chamberlain (1988) showing the quartz monzonite and Devonian surfaces was utilized in addition. As more data became available, the model evolved (Gold et al. 2024).

The next available data source utilized to influence model construction was a time-evolved structural fault map interpreted from a legacy seismic survey that was acquired in previous years (Flanigan, with modifications by the Blackburn field operator). This map was compared to

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

observed surface structures to provide a level of certainty in fault locations at depth (Gold et al. 2024). For numerical modeling purposes, faults were not extended beyond the top contact of the capping shale layer. All data sources were combined, with more confidence placed in the time-interpreted structural fault map, in the final version of the conceptual geological model and target reservoir contour surface (Figure 3 and Figure 4). The model boundaries were extended to the north and west to facilitate numerical simulation.

As formation tops data became sparse toward the outer boundaries of the model, the contacts were interpreted. Trends in the data were extrapolated from formation top data-dense clusters outward toward the less populated areas in the model.

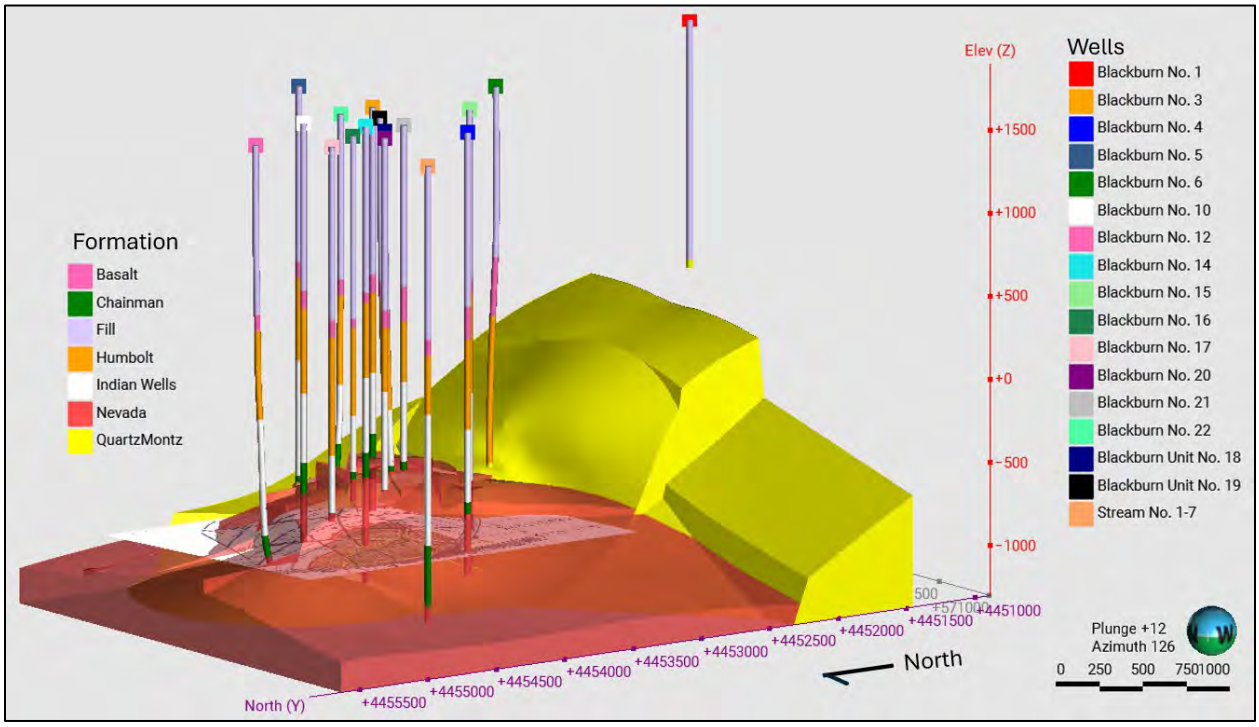

Figure 3: 3D conceptual geological model of the Blackburn Oil Field Nevada dolomite (red) reservoir and underlying quartz monzonite (yellow), with boundaries extended laterally to the north and east.

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

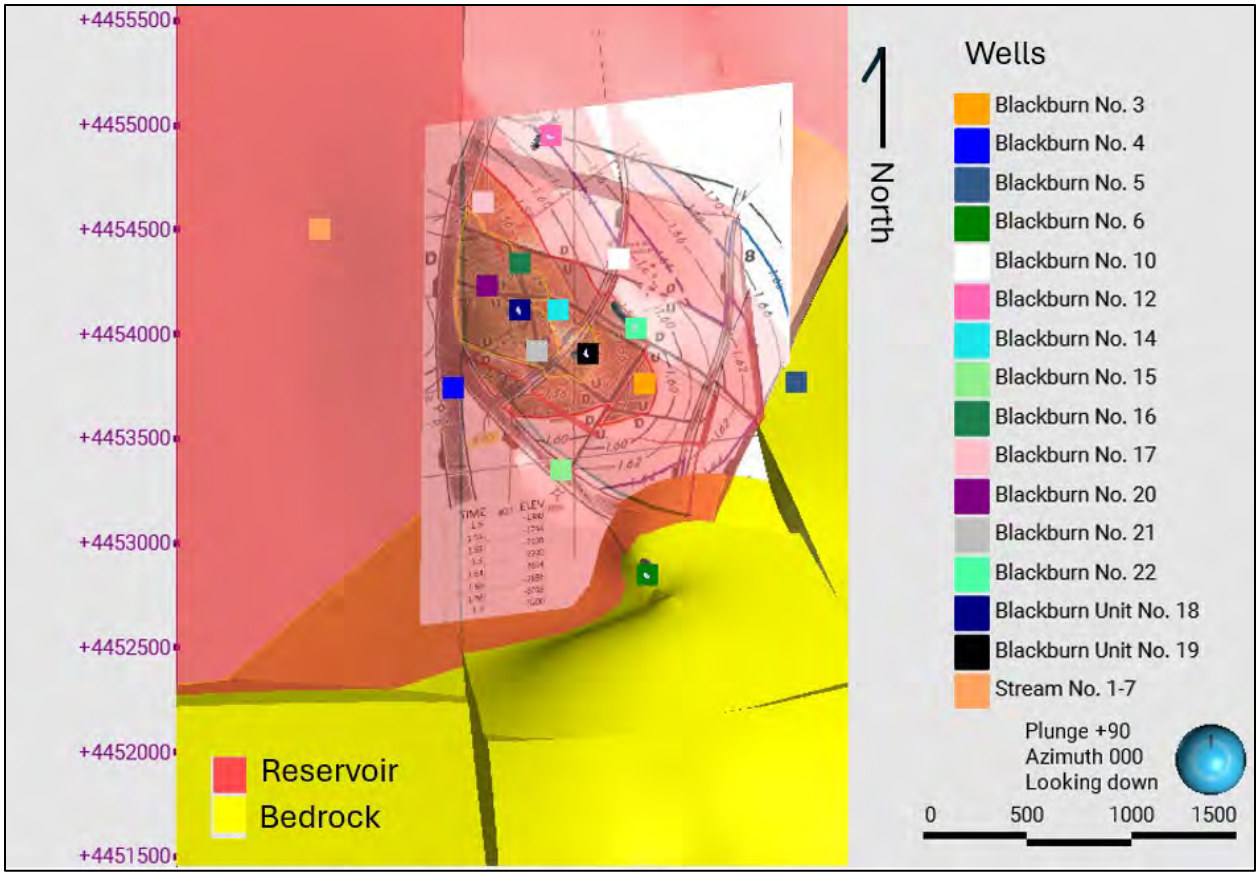

Figure 4: Well locations at depth imposed on the geological model of the reservoir and the basement, underlaid by structural illustration data. The model extents have been edited to exclude Blackburn No. 1 because of reservoir termination prior to the well.

3. Reservoir Modeling

To numerically model the reservoir, the reservoir simulator VOLSUNG Brynhild was utilized. The simulator grid was populated with rock thermophysical properties, flow properties, and boundary conditions to reflect the Blackburn Field subsurface conditions.

The reservoir modeling study consisted of two parts. In the first part, a static reservoir model was created to match the temperature observations obtained from various sources. The purpose of the static modeling was to calibrate the numerically modeled reservoir domain to capture the natural state found in the system. In the second part, the calibrated model was subjected to different production scenarios to estimate the production temperatures for a ten-year project lifetime.

3.1 Reservoir Model Input Parameters

3.1.1 Thermophysical Properties

The thermal conductivity data, λ (W m^{-1} K^{-1}), are mainly from lab analyses of rock types and formation samples obtained from the state of Nevada excepting basalt, the Humboldt, and the Hay Ranch (fill), for which no data points were found (UNR 2021; Blackwell & Steele 1989; Sass et

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

al. 1988). Specific formation data, if available, were used instead of averaging the range of rock type data measured from associated rocks obtained in the state of Nevada.

Measurements for formation heat capacities, cp (kJ kg^{-1} K^{-1}), and formation densities, ρ (kg m^{-3}), from rock samples collected in the state of Nevada were not available. In this case, averages of ranges of general rock type-specific properties were utilized (Zhu et al. 2022; Schön, 2015, 2011; Waples 2004; Manger 1963). The thermophysical rock properties used in the model are presented in Table 1.

Table 1: Thermophysical properties of formations in the Blackburn Oil Field. Properties were utilized for numerical modeling purposes.

Formation	Designation	*Thermal Conductivity*	*Heat Capacity*	*Density*
		W m^{-1} K^{-1}	**kJ kg^{-1} K^{-1}**	**kg m^{-3}**
Quartz monzonite	Basement	3.05	0.879	2,640
Nevada Group	Reservoir	4.90	0.950	2,712
Chainman	Capping Layer	1.50	1.180	2,585
Indian Wells	Overlying Layer	1.74	0.943	2,416
Humboldt	Overlying Layer	1.82	1.109	2,525
Basalt	Overlying Layer	1.82	0.880	2,800
Hay Ranch & tertiary deposits (fill)	Overlying Layer	1.72	1.089	2,547

3.1.2 Flow Properties

The numerical model considered the flow of water only, i.e., no oil flow was modeled. The oil to water ratio (i.e. approximately 98% to 2%) was low, so excluding oil from the simulation did not influence the results significantly. This decision was determined in consideration of i) model software limitations (lack of water and oil equation of state), ii) relative permeability data unavailability, and iii) the observed 98% (or higher) water cut in the Devonian Nevada dolomite penetrating wells.

The layers above the Nevada Group were modeled as impermeable to fluid flow. The permeability of the Nevada dolomite and the quartz monzonite were chosen as 322 millidarcy based on the Drill Stem Test (DST) results reported for Blackburn well No. 18, October 12–13, 1992 (NBMG, 2023). The Nevada dolomite was set to have homogenous and isotropic permeability. The quartz monzonite basement was set to have homogenous permeability in the vertical direction only, i.e., the formation was incorporated as impermeable in horizontal directions.

Both the Nevada dolomite and the quartz monzonite basement were represented in the model as single porosity because no conclusive data was available to characterize the natural fracture and matrix permeability separately. The porosity of the two permeable formations were set as 5%. Pore compressibility values were set to 7.25×10^{-10} Pa^{-1}. Thermal pore expansivity was not modeled.

The faults modeled in the geological modeling section of this work were not implemented in the numerical grid as no-flow barriers because no conclusive data was available. If these faults are in

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

fact no-flow barriers, omission of the faults in the numerical model will provide a worst-case scenario for thermal breakthrough concerns. Furthermore, the Blackburn field operator estimated that the faults are non-sealing at depth.

3.1.3 Boundary Conditions

Numerical boundary conditions were applied to the model on the grid top and grid bottom. The top boundary was set as a constant temperature at 55°F. This temperature was estimated from the spatially closest soil temperatures, which are values collected over 4 years at an elevation of 6,000 ft ASL approximately 80 mi away from the Blackburn Field (NRCS 2023).

The bottom boundary was constant temperature (at 273°F) and pressure (at 4,225 psi). Both the top and the bottom boundary conditions span the entire top and bottom surfaces of the grid, respectively. The side faces of the model were set as a no-flow boundary considering heat and fluid flow.

The temperature and pressure combination at the boundary conditions were chosen to impose a match in the reservoir model to multiple parameters. The observed Blackburn No. 18 well flowing field temperature data at the bottom of the wellbore, the overall temperature trends observed in the historical well log and DST temperature data, and the reservoir pressure estimation provided by Gradient Geothermal, Inc. were target parameters to be matched.

3.1.4. Grid Geometry

The grid layer spacing chosen is given in Table 2. The vertical layer spacing was chosen to provide higher resolution at the modeled reservoir layer and near the model's top and bottom boundaries, while staying within the limits of our resources' computational capabilities. Figure 5 presents a N-S cross-section of the grid.

Table 2: Grid layer spacing used in this study. X and Y layers expand with given thicknesses in easterly and northerly directions, respectively. Z layers extend from the model's top surface (5295 ft ASL) to the model's bottom surface (-4300 ft ASL); i.e., layer 1 spanned from 5295 ft ASL to 5290 ft ASL, layer 86 spanned from -4100 ft ASL to -4300 ft ASL.

Extents	Layer Thickness, ft	Layers	Total Extent, ft	Total Layers
X	200	52	10538	53
	138	1		
Y	400	34	13714	35
	114	1		
Z	5	1	9595	86
	122.5	4		
	250	2		
	400	6		
	200	16		
	50	56		
	200	1

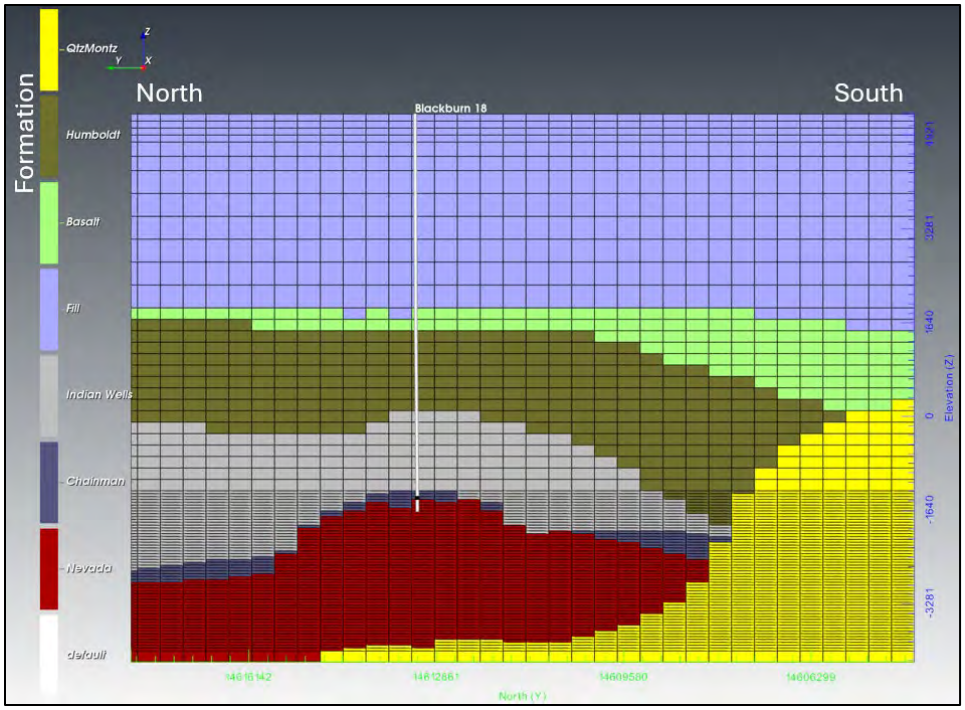

Figure 5: North-south cross section of the constructed grid showing the lithology designation. The axis of the grid coincides with the location of Blackburn No. 18.

3.2 Natural State Modeling

The objective of the static simulation was to calibrate the pressure and the temperature state of the model domain for dynamic production simulations. The static simulation was initialized with a temperature gradient of 0.030°F/ft and a pressure gradient of 0.44 psi/ft. Following the initialization, the simulation was run for 10,000 years, allowing the temperature and the pressure states to stabilize under the influence of the top and bottom boundary conditions. The relative temperature and pressure changes at the last time step of the simulation were 2.3×10^{-8} s^{-1} and 3.3×10^{-12} s^{-1}, respectively. These values indicated a reasonable numerical stabilization of the temperature and pressure distribution in the model domain.

The first targeted parameter match was to the temperature and pressure information obtained from the well flowing test conducted by the Blackburn field operator in August of 2023. In this test, the well flowing temperature and pressure profiles in the tubing were measured during stabilized flow. The observed well flowing temperature inside the tubing at 6,750 ft was 261.9°F; this temperature value was the target for the temperature match.

The observed well flowing pressure at the bottom of Blackburn No. 18 tubing (6,750' MD) was 3,040 psi. The test did not report a static reservoir pressure measurement. A static reservoir pressure estimate, which was based on the flow test, was provided by Gradient Geothermal, Inc., as 3,100 psi at the bottom-hole of Blackburn No. 18. This pressure estimate was the target pressure match for the static simulation run.

Figure 6 presents a N-S cross section of the temperature distribution, and Figure 7 presents a close-up screenshot of the temperature and pressure values obtained at the bottom of Blackburn 18 after

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

the static simulation was run. The average temperature of the four grid layers below the bottom of the tubing was observed as 261.7°F (in contrast to the 261.9°F observed in the flowing well test).

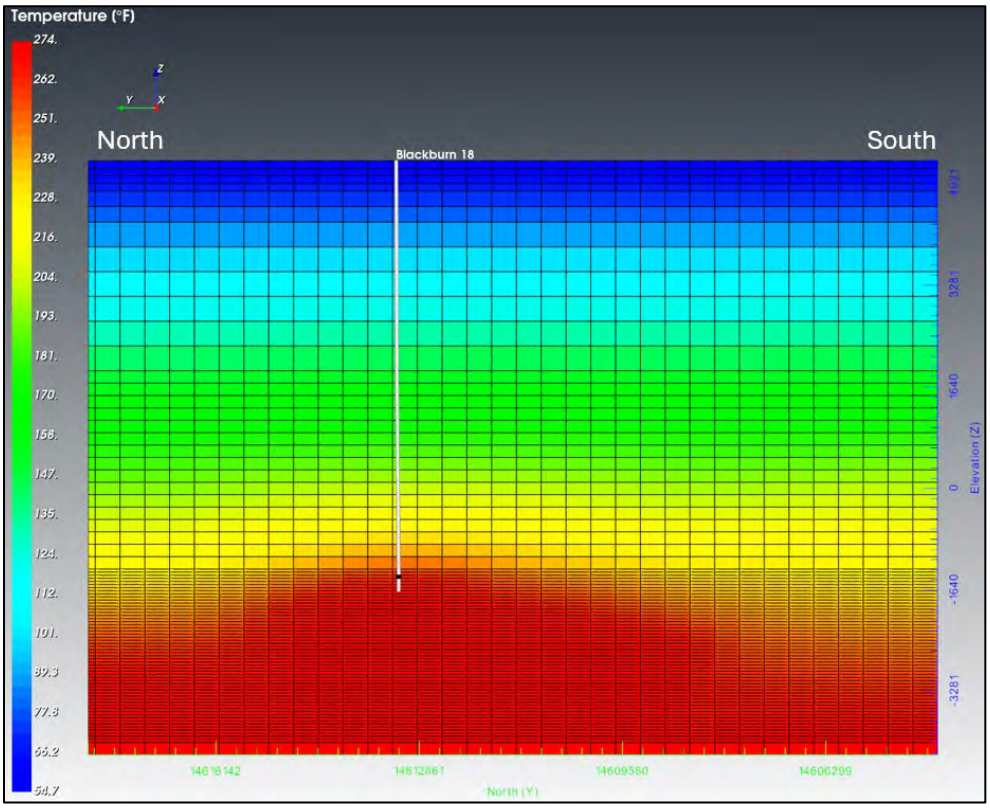

Figure 6: N-S cross section of the stabilized natural state reservoir model. The cross-section line passes through the surface location of Blackburn 18. This well was not actively flowing during the stabilization of the natural-state model.

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

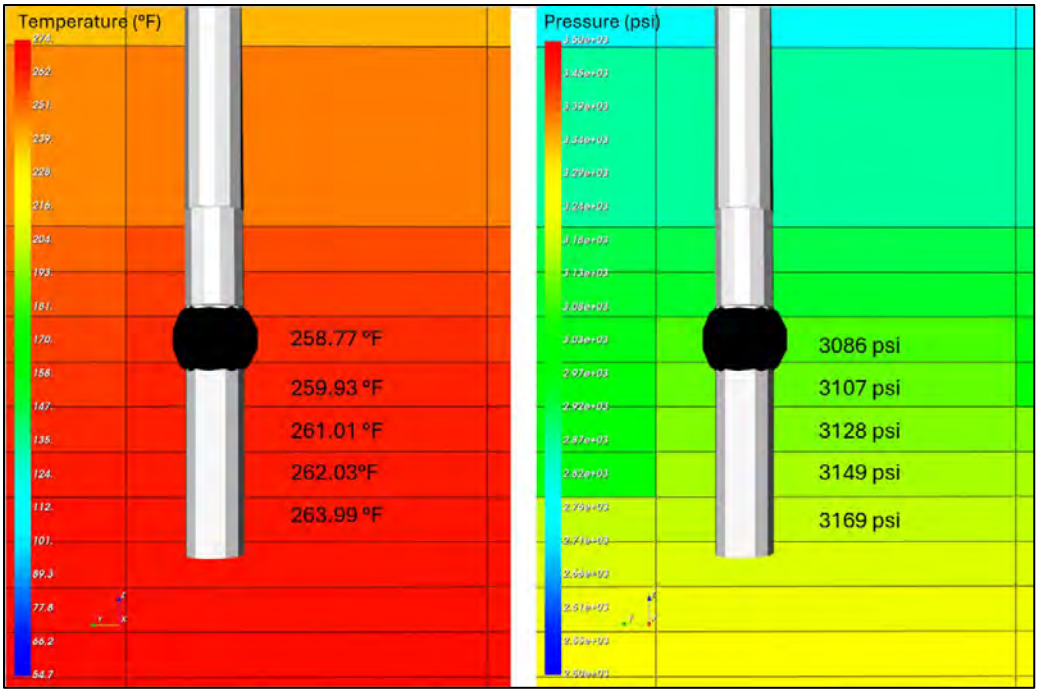

Figure 7: (Left) Modeled temperatures at the center of each grid cell along the Blackburn No. 18 wellbore. (Right) Modeled pressures at the center of each grid cell along the Blackburn No. 18 wellbore. The black ellipsoid denotes the bottom of the tubing at 6,750 ft MD.

Modeled temperature profiles for Blackburn No. 3, 4, 6, and 10 are compared to historic well log temperature profiles in Figure 8. The first Blackburn No. 3 log was taken on March 23, 1982, one week after drilling stopped on March 16, 1982. The second Blackburn No. 3 log was taken July 1, 1982, an estimated 3 months after the well was completed and in production. All other logs were taken within days of completion or drilling: Blackburn No. 4 was taken 3 days after completion, No. 6 was taken 3 days after completion, and No. 10 was taken the day after total depth was reached.

The temperatures from these logs are likely not reflective of the actual subsurface thermal gradient because of post-drilling mud circulation: i.e., the top of the wellbore heats up when mud is circulated from deeper depths to the surface, and the bottom of the wellbore cools as mud is circulated from the surface to deeper depths. The second log of Blackburn No. 3 was suspected of being affected by production-related heating. Model profiles for Blackburn No. 3, 4, 6, and 10 were generated from selecting the temperatures in the center of each calibrated reservoir grid cell along the respective well tracks. The modeled profiles show agreement with historic DST data collected for Blackburn No. 3, 18, 19 Log Header, and 21.

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

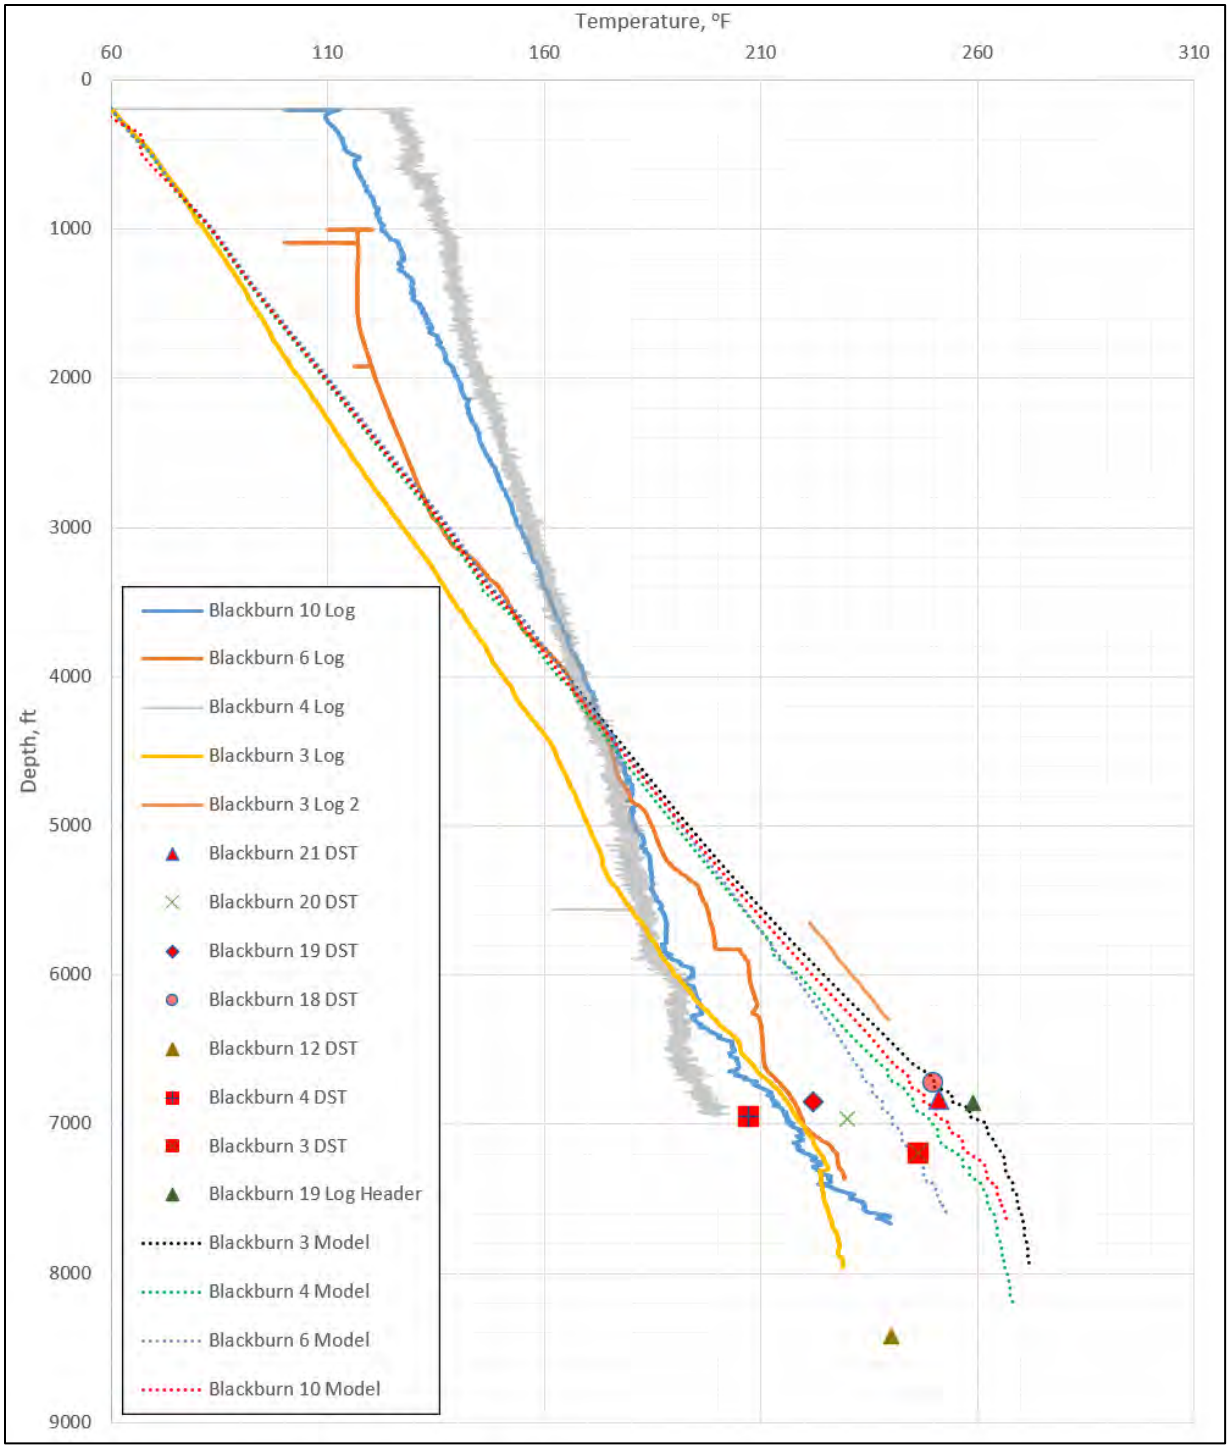

Figure 8: Stabilized temperature profiles modeled by the static reservoir simulation for Blackburn No. 3, 4, 6, and 10 shown alongside historic well log and DST data.

3.3 Production Modeling

The objective of the dynamic reservoir modeling was to simulate production/injection scenarios being considered for field deployment. The focus of this part of the study was to determine whether

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

detrimental thermal breakthrough or pressure depletion would be present during the lifetime of the project.

Three dynamic production scenarios were selected to simulate production and injection well schemes. These scenarios were chosen mainly to determine the co-production water rate that the Blackburn field can support while considering operational constraints associated with the ongoing oil production. A summary of the scenario details is shown in Table 3. An overview of the well locations with respect to the reservoir is shown in Figure 9. All scenario flow rate inputs were converted from volumetric rate to mass rate using a density of 947.7 kg/m^3; this value represents the density of pure water at 260°F and 3,000 psi.

Table 3: Summary of dynamic production scenarios. All wells denoted with numbers alone are Blackburn Field wells.

Scenario	Producing Wells	Injecting Wells	Total Production	Total Injection
			BPD	BPD
1	16, 18, 19	12, 21	14,200	14,200
2	16, 18, 19, 22	12, 21	24,200	24,200
3	4, 16, 18, 19, 22	12, 20, 21; Bucy No. 1	34,200	34,200

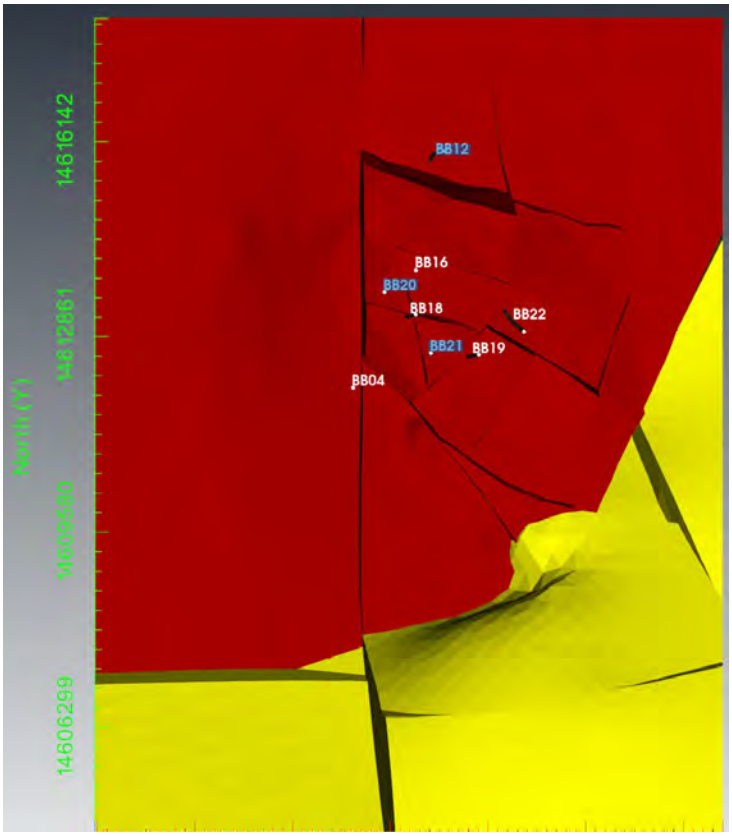

Figure 9: Scenario wells imposed on the geological model. Rock formations depicted in red and yellow colors represent the Nevada and the quartz monzonite formations, respectively. Injector well names are highlighted with blue.

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

Injection temperatures for scenarios depended on the surface operations and losses encountered at the surface. We assumed a fixed reinjection temperature of 179°F for all scenarios based on ORC performance analysis done by Gradient Geothermal, Inc. We did not incorporate Bucy No. 1's injection into the model because it is located outside the model domain.

The production wells were fully implemented into the numerical simulator to calculate the pressure and temperature changes along the wells. The injection wells were abstracted in the reservoir model by implementing mass sources located in the numerical grid, coinciding with the bottom-hole locations of the injection wells.

To develop wellbore geometry (hole and tubular dimensions), we used our best estimation from well completion reports and reports from the Blackburn field operator (publicly hosted by NBMG, 2023). Well completion reports were most heavily relied upon, because they offered the most comprehensive understanding of the well geometries. Regarding work not included in the well completion reports, specifically deepening of wells, the information obtained from Gradient Geothermal, Inc. and the operator was relied on.

3.3.1 Scenario 1

The details of this co-production scenario were as follows:

- The total production is 14,200 BPD.
- The total injection is 14,200 BPD.
- The combined production target temperature is 250°F.

Table 4: Summary of Scenario 1 dynamic production scheme. All wells denoted with numbers alone are Blackburn Field wells.

Scenario	Producing Wells	Injecting Wells	Target Flow Rate BPD
1	16	-	10,000
	18	-	2,100
	19	-	2,100
	-	12	10,000
	-	21	4,200

The flow rates stated above were incorporated into the respective production wells and injection mass sources in the Brynhild reservoir simulator. Figure 10 presents the temperature behavior of the produced fluids in respective scenario wells. A volumetric rate-weighted combined average temperature was also calculated.

In this scenario, the combined production temperature was 262.4°F at the end of four years, and the average of the combined production temperature was 262.5°F during this period. At the end of the ten-year production period, the combined production temperature was 261.8°F. No significant thermal decline was observed. The design target temperature of 250°F was met. The reservoir pressure support was sufficient to sustain flow naturally at the production wells within the simulated timeframe.

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

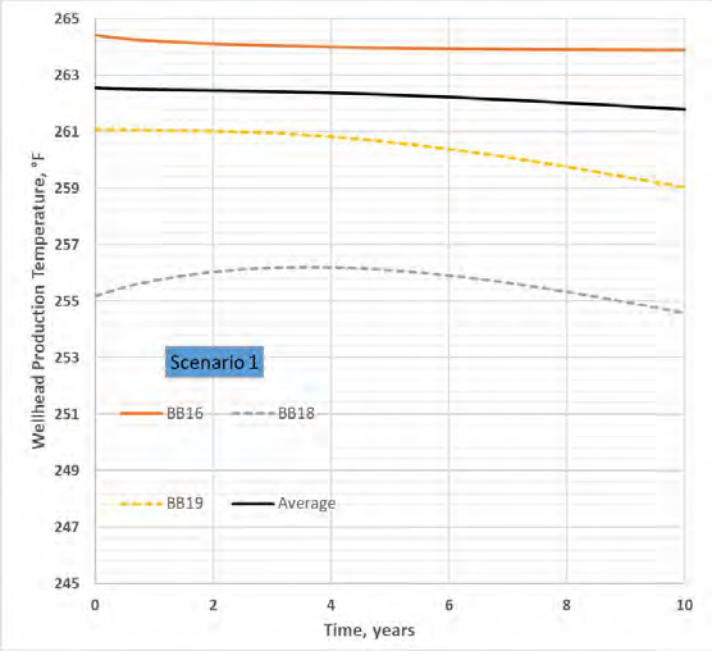

Figure 10: Wellhead production temperatures associated with Scenario 1. The black line represents the volumetric weighted average production temperature. BB denotes Blackburn wells.

3.3.2 Scenario 2

The details of this co-production scenario were as follows:

- The total production is 24,200 BPD.
- The total injection is 24,200 BPD.
- The combined production target temperature is 260°F.

Table 5: Summary of Scenario 2 dynamic production scheme. All wells denoted with numbers alone are Blackburn Field wells.

Scenario	Producing Wells	Injecting Wells	Target Flow Rate
			BPD
2	16	-	10,000
	18	-	2,100
	19	-	2,100
	22	-	10,000
	-	12	12,100
	-	21	12,100

The flow rates stated above were incorporated into the respective production wells and injection mass sources in the Brynhild reservoir simulator. Figure 11 presents the temperature behavior of the produced fluids in respective scenario wells. In this scenario, the combined production temperature was 262.7°F at the end of four years, and the average of the combined production temperature was 263.0°F during this period. At the end of the ten-year production period, the combined production temperature was 260.8°F. The design target temperature of 260°F was met.

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

The reservoir pressure support was sufficient to sustain flow naturally at the production wells within the simulated timeframe.

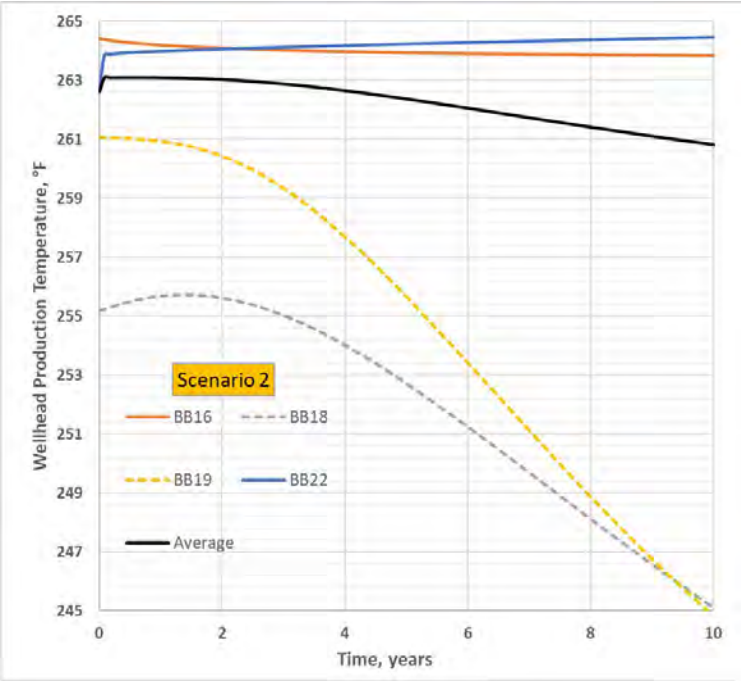

Figure 11: Wellhead production temperatures associated with Scenario 2. The black line represents the volumetric weighted average production temperature. BB denotes Blackburn wells.

3.3.3 Scenario 3

The details of this co-production scenario were as follows:

- The total production is 34,200 BPD.
- The total injection is 34,200 BPD.
- The combined production target temperature is 270°F.

Table 6: Summary of Scenario 3 dynamic production scheme. All wells denoted with numbers alone are Blackburn Field wells.

Scenario	Producing Wells	Injecting Wells	Target Flow Rate
			BPD
3	4	-	10,000
	16	-	10,000
	18	-	2,100
	19	-	2,100
	22	-	10,000
	-	12	8,550
	-	20	8,550
	-	21	8,550
	-	Bucy No. 1	8,550

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

The flow rates stated above, except Bucy No. 1, were incorporated into the respective production wells and injection mass sources in the Brynhild reservoir simulator. Bucy No. 1 is located 0.6 mi NNW of Blackburn No. 12 and hence is located outside the constructed geological (and hence the reservoir) model. Our model analysis showed that Blackburn No. 12's reinjection did not affect the production wells in all scenarios. The fluids injected at this location predominantly sank down to the constant pressure boundary condition because of the density contrast of the injected fluid. We concluded that, similar to Blackburn 12, injection at Bucy No. 1 would not induce a significant temperature drop at the modeled production wells because of its location.

Figure 12 presents the temperature behavior of the produced fluids in respective scenario wells. In this scenario, the combined production temperature was 262.0°F at the end of four years, and the average of the combined production temperature was 262.1°F during this period. At the end of the ten-year production period, the combined production temperature was 259.5°F. The target production temperature of 270°F was not met. The reservoir pressure support was sufficient to sustain flow naturally at the production wells within the simulated timeframe. Compared to Scenario 2, there is less thermal decline in Blackburn 18 and 19; however, cooling was also observed at Blackburn 16 because of the injection at Blackburn 20, which was only active in this scenario.

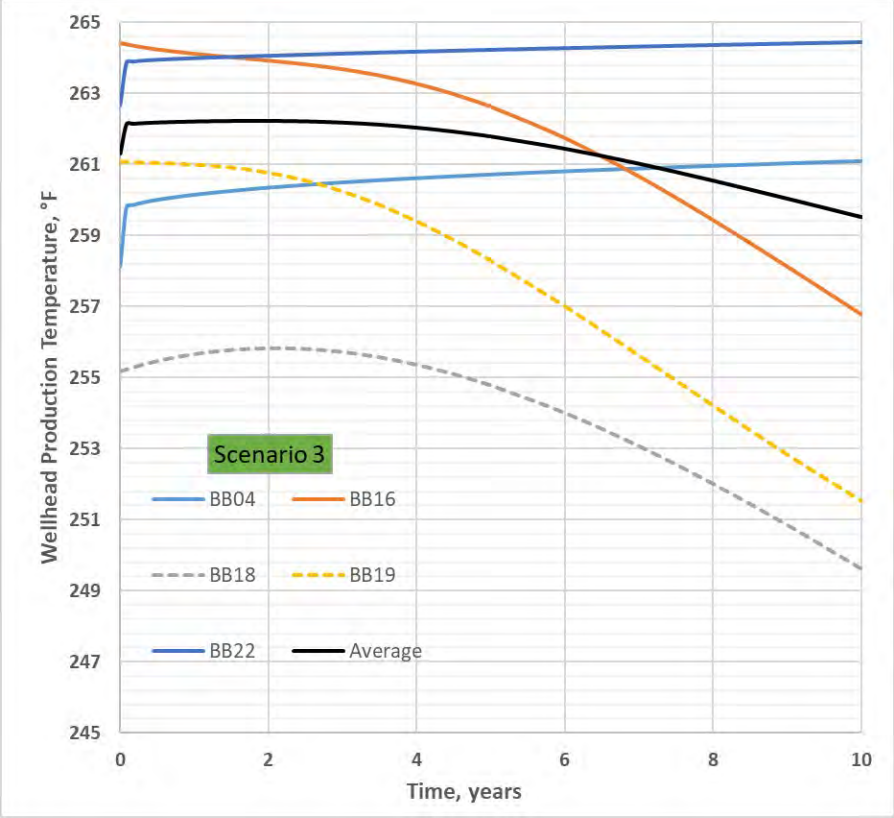

Figure 12: Wellhead production temperatures associated with Scenario 3. The black line represents the volumetric weighted average production temperature. BB denotes Blackburn wells.

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

3.3.4 Scenario Summary

Presented below are tabulated and graphical summaries of the combined temperatures associated with the three design scenarios, for quick reference.

Table 7: Combined production temperature values associated with three design scenarios.

Scenario	Combined Production Temperature Statistics			
	4-Year Term		10-Year Term	
	End of Term, °F	Term Average, °F	End of Term, °F	Term Average, °F
1	262.4	262.5	261.8	262.4
2	262.7	263.0	260.8	262.7
3	262.0	262.1	259.5	261.9

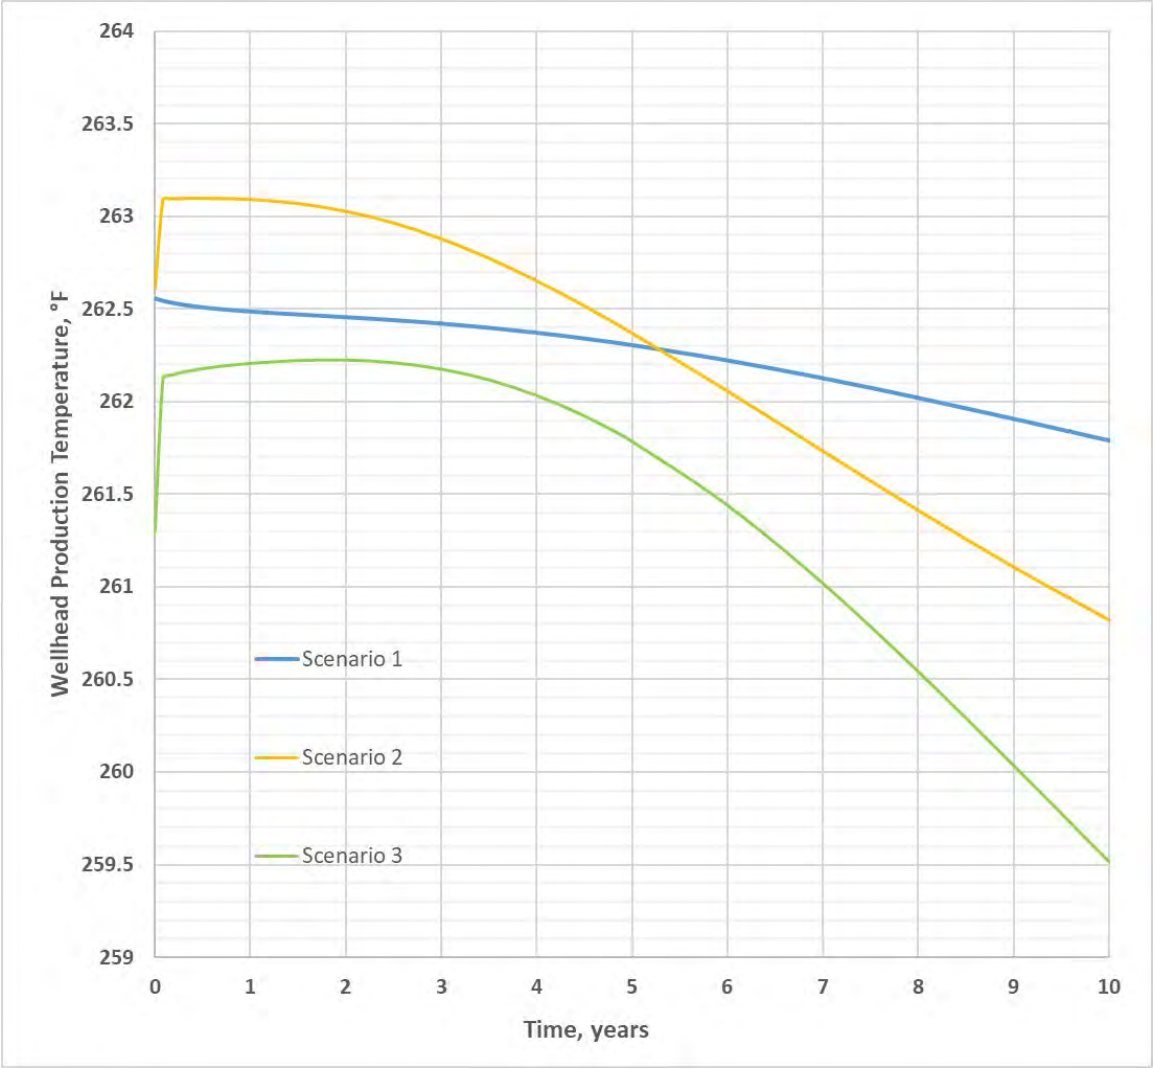

Figure 13: Combined production temperatures associated with three simulated design scenarios.

4. Conclusions

This study presents the results of geological and reservoir modeling work done to support the feasibility analysis study of geothermal co-production at the Blackburn Oil Field. We simulated three production scenarios in the numerical reservoir model. The three scenarios indicate negligible to minimal thermal decline over the duration of a simulated 10-year production and re-injection scheme. The first and second scenarios matched respective production temperature targets. Simulations for the third scenario showed that a target combined production temperature of 270°F cannot be achieved. The first production scenario is the likely deployment candidate for the second phase of the WOO Nevada project. Planned future work for the second phase includes technical design support and data collection from field tests.

ABSTRACT

Existing oil and gas fields are much more widespread than conventional (hydrothermal) geothermal fields. Many oil fields are desirable places to exploit Hot Sedimentary Aquifers (HSAs) for geothermal electricity generation and/or direct use, for these, and other, reasons:

- High temperatures are required to mature hydrocarbons, so subsurface temperatures of oil and gas fields are often (but not always) warmer than those of surrounding regions. Also, hydrocarbon-bearing intervals are good insulators that trap heat below them.
- HSAs have higher energy density than equivalent temperature hot dry rocks due to the higher heat capacity of brine compared to dry rocks. This brine is produced directly and does not require inefficient conductive heat transfer.
- The petroleum industry routinely collects large amounts of high-quality data, much of which is publicly available. Such large, detailed data sets include well and seismic reflection data, geophysical logs, stratigraphy, structure, fluid chemistry, flow and pressure, stress, core, rock mechanics data, and other data types. Such data sets enable rapid, economical exploration and are not always available for conventional geothermal exploration.
- Sedimentary basins that host petroleum typically have porous, permeable strata. Such strata host petroleum deposits in traps, and porous, brine filled strata are often present. Consequently, the same rocks that host oil and/or gas commonly host even larger amounts

of brine in multiple strata that can be exploited for geothermal electricity generation and/or direct use.
- HSAs are much more widespread than traditional hydrothermal targets.
- HSA geothermal wells rely on porous, permeable strata that may not need expensive stimulation to produce large volumes of brine, which represents a substantial cost savings over stimulated wells. Non-stimulated wells have a reduced risk of stimulation-induced seismicity.
- The large volumes of water available in HSAs, coupled with new proprietary methods of high-rate extraction and modern Organic Rankine Cycle generating systems (ORCs), results in long well lives due to the stable temperature of the produced fluid, and hence favorable economics, even though HSAs are cooler than hydrothermal geothermal fields because high temperatures over geologic time promote cementation which destroys porosity.

We describe a workflow for HSA exploration and reservoir simulation that resulted in the first deep geothermal well permits granted by the State of Colorado. The project is in the "hot spot" of the prolific Wattenberg oil field in the Denver-Julesburg (DJ) Basin and targets the Permian-age Lyons Sandstone. Geothermal brine will be extracted from beneath existing oil and gas production.

A single producer-injector well pair was simulated with multiple production/injection rates, well spacings, and lateral lengths using both the COMSOL™ and FracMan™ software packages to determine prospective drilling targets. COMSOL was used to build simple, rapid, uniform porosity-permeability models. FracMan simulations were based on a detailed, 3D static model developed from representative density-porosity logs from the area and was used for well design and optimization (Cottrell et al, 2023). Both simulation efforts showed that the produced water temperature is stable for more than 20 years. The similarity between the two models likely results from the high porosity and permeability of the formation and the thickness of the Lyons (~40m) relative to the modeled well spacings (600m and 800m).

1. Introduction

Conventional (hydrothermal) geothermal electricity generation is clearly economic. The first commercial hydrothermal plant commenced operation in Tuscany, Italy in 1913. Since then, commercial hydrothermal fields have been developed in many countries around the world. Unfortunately, suitable hydrothermal fields require a unique set of geologic conditions and hence are rare – suitable conditions occur over only 2% - 3% of the earth's surface. Figure 1 shows the locations of existing hydrothermal power plants in the U.S.

Thermal energy is present in rocks and fluids beneath the 97%-98% of the earth's land surface that is not suitable for conventional geothermal plants. Efficiently extracting the heat from these other areas is a challenge. Geothermal resources sufficient for electric power generation are found both in "hot dry" rocks and in Hot Sedimentary Aquifers (HSAs). Currently, there is a strong industry focus on heat extraction from Hot Dry Rocks (HDR) while extraction of thermal energy from HSAs has been mostly ignored because of their more moderate temperatures (typically <150°C). However, recent technological developments allow electrical power generation at much lower temperatures than in the past, but only if coupled with high flow rates (~100L/s). Interest in HSA geothermal electricity generation is growing, e.g. Stautberg and Sonnenberg (2023).

Figure 2 shows both locations with identified hydrothermal potential and areas favorable for Enhanced Geothermal Systems (EGS) or Closed Loop Geothermal Systems (CLGS) in hot dry rock. Hydrothermal sites are limited to the western U.S., most often in areas with recent volcanic activity, and are very localized.

Figure 1: Energy Information Agency map of hydrothermal electricity plants in the US and Mexico.

In theory, EGS and closed-loop geothermal systems can be built anywhere on Earth if either the geothermal gradient is high enough or the wells are drilled deep enough to reach sufficiently high temperatures, providing that the combination of geothermal gradient, drilling depth, and number of wells required is economically favorable. However, both EGS and closed-loop geothermal systems depend on the conduction of heat through rock over substantial distances and hence suffer from a fundamental challenge: rock is a serious insulator and thus conduction of heat is notoriously slow, commonly taking ~1 month to go 1 m.

Figure 2 indicates that Enhanced Geothermal System (EGS) potential is widespread, however EGS has yet to be proven at commercial scale despite a recent experiment (Norbeck and Latimer, 2024). The term “Enhanced” in “EGS” denotes stimulation by hydraulic fracturing. In an EGS system, geothermal waters flow through artificial and natural fractures from an injector well to a producer well. Fluid flow in the fractures heats the fluid but cools the fracture surfaces leaving heat stranded in the interior of rock masses between fractures so that the production temperature declines quickly with time (e.g., Figure 4, Norbeck and Latimer, 2024). Also, experiments to date show that EGS systems in dry rock lose water into the natural fracture network at a rate of 15% or more per day (~7,000 barrels) so that they consume water (e.g. Norbeck and Latimer, 2024). Water consumption is potentially problematic everywhere, but especially in arid to semi-arid regions such as the western U.S.

In closed-loop systems, a working fluid flows through a deep network of sealed wellbores so that heat is transferred to the working fluid through only the wellbore wall. Over time, this results in a cool, insulating volume of rock around the wellbore(s) that conducts heat to the working fluid

only slowly. Moreover, at the industry standard flow rate of 100 kg/s (0.1 m^3/s) necessary to produce ~4 MWe, the fluid in the pipe spends only ~5 minutes at depth, absorbing almost no heat. For significant heating the fluid must spend an hour or more at depth, which reduces the flow rate to 5 kg/s, eliminating this system as a potential provider of electrical power. Consequently, closed-loop geothermal systems suffer from limited power output and high construction costs (Beckers et al, 2022; White et al, 2024). Closed-loop systems do not consume water, but may be suitable for direct-use.

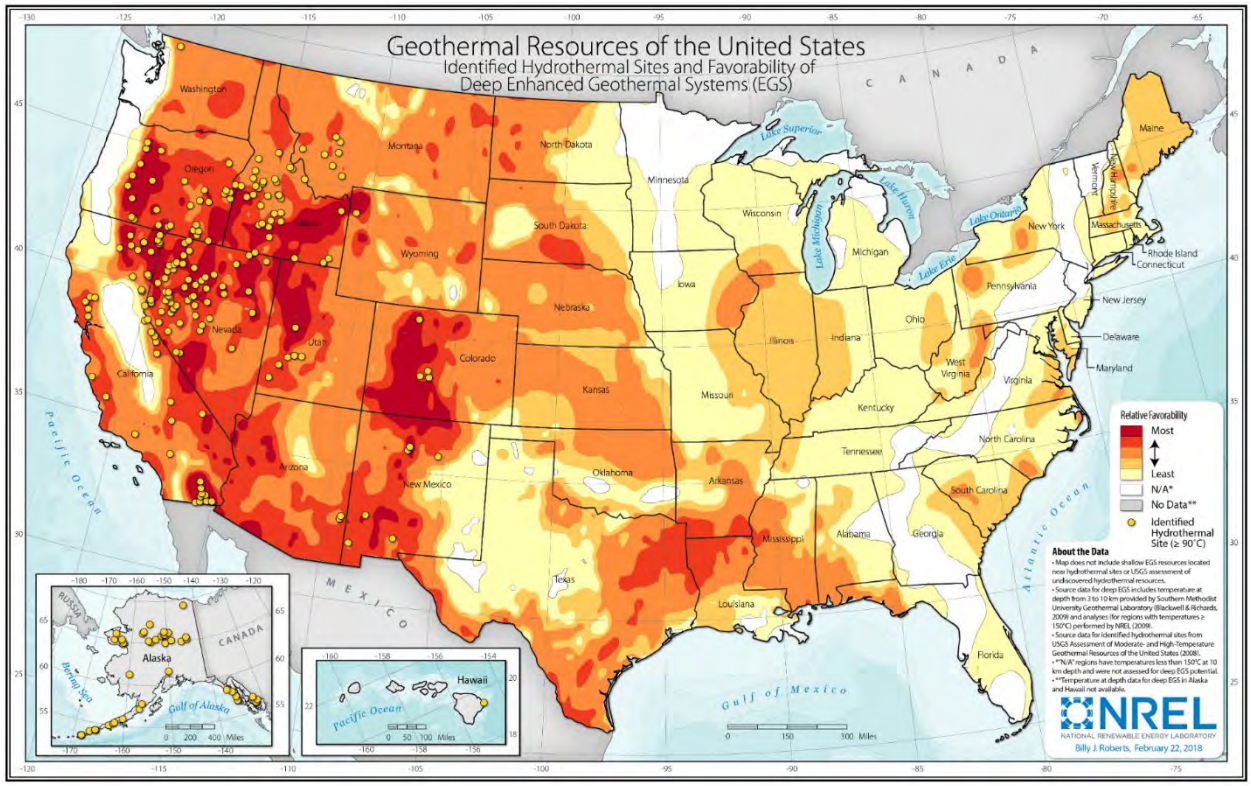

Figure 2: National Renewable Energy Laboratory (NREL) map showing identified hydrothermal sites (yellow dots) and locations that are favorable for Enhanced Geothermal Systems (shading).

In contrast:

- Any sedimentary basin is potentially prospective for HSA geothermal. Figure 3 shows the distribution of oil and gas wells in the United States, which outlines sedimentary basins. Oil and gas wells occur in sedimentary basins, all of which have abundant available data both from the oil and gas wells and additional data sets such as reflection seismic and other geophysical data (e.g., gravity and magnetics).
- HSA geothermal systems flow water through the pore space of the producing strata so that heat is efficiently extracted from the rock mass by the cooled, produced water after injection because conduction occurs essentially instantaneously over grain-scale distances. Heat transfer at the grain scale is much more efficient than conductive heat flow to fractures or closed loop boreholes.
- HSAs have higher energy density than equivalent temperature hot dry rocks due to the higher heat capacity of brine compared to dry rocks. The heat in the in-situ brine is

produced directly from a vast volume of the reservoir with no long distance downhole conductive heat transfer required.

- HSA systems do not consume water because they exploit saturated aquifers and all water extracted from the well is reinjected into the reservoir.

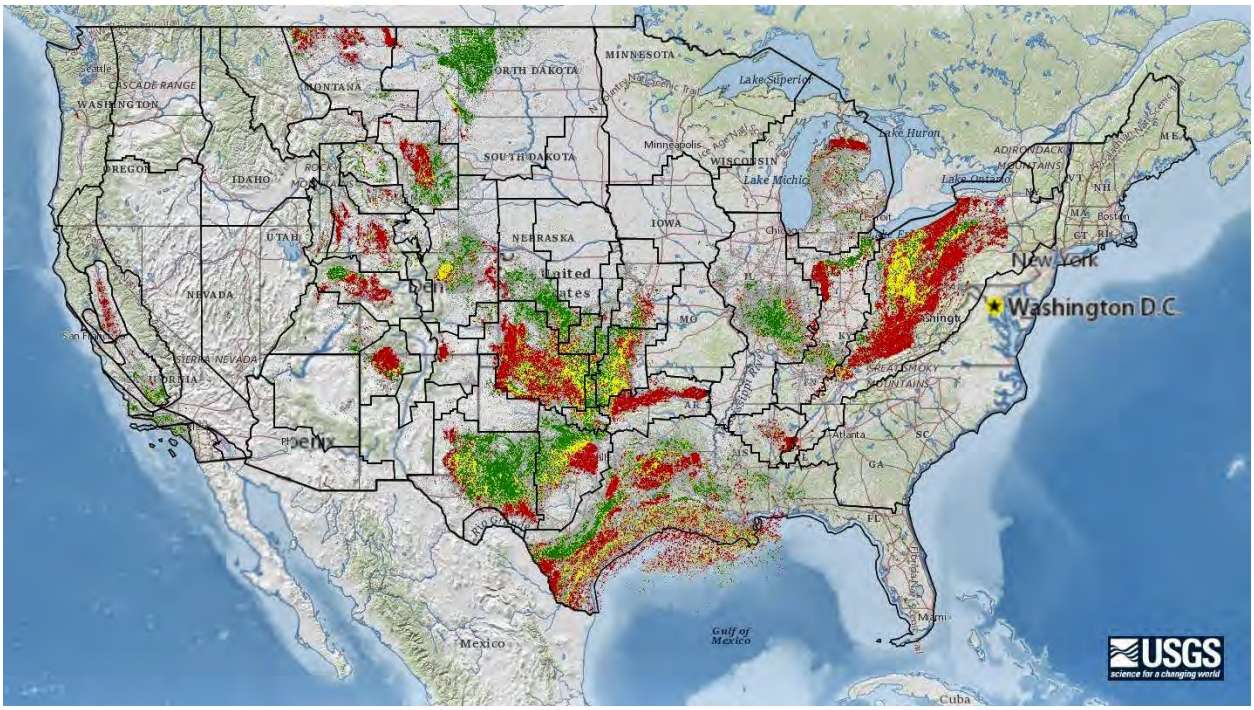

Figure 3: U.S. Geological Survey map of oil and gas wells in the United States.

This paper describes how to use the abundant data collected by the oil and gas industry to explore for Hot Sedimentary Aquifers in oil and gas basins and expands on work of Cottrell et al (2023) and Lacazette et al (2024) which provide additional detail on modeling procedures and location of a specific prospect. However, those papers are focused on a specific prospect while this paper describes exploration on a larger scale.

2. Using Data from Oil and/or Gas Wells

Critical data sets from oil and/or gas wells include bottom-hole temperatures, rock properties from logs, core data, fluid pressure, and fluid chemistry. Reflection seismic and potential fields data (gravity, magnetics) are also commonly collected by the oil and gas industry. This contribution focuses on well and potential fields data. Geothermal Technologies, Inc. is currently developing a geothermal electricity generation project in the Denver-Julesburg (DJ) Basin of Colorado that provides examples of how oil and gas data is used for HSA exploration. Figure 4 is a location map of the study area in the DJ Basin.

2.1 Temperature data

The first, and one of the most important tasks, for geothermal exploration is mapping geothermal gradients. Bottom-hole-temperature data is a standard measurement collected in all oil and gas wells. These measurements must be corrected for cooling by the drilling mud to provide an estimate of the undisturbed reservoir temperature. Cased-hole temperature logs are commonly

collected well after a well has been drilled and cased, so that the temperature log accurately reflects the undisturbed reservoir temperature.

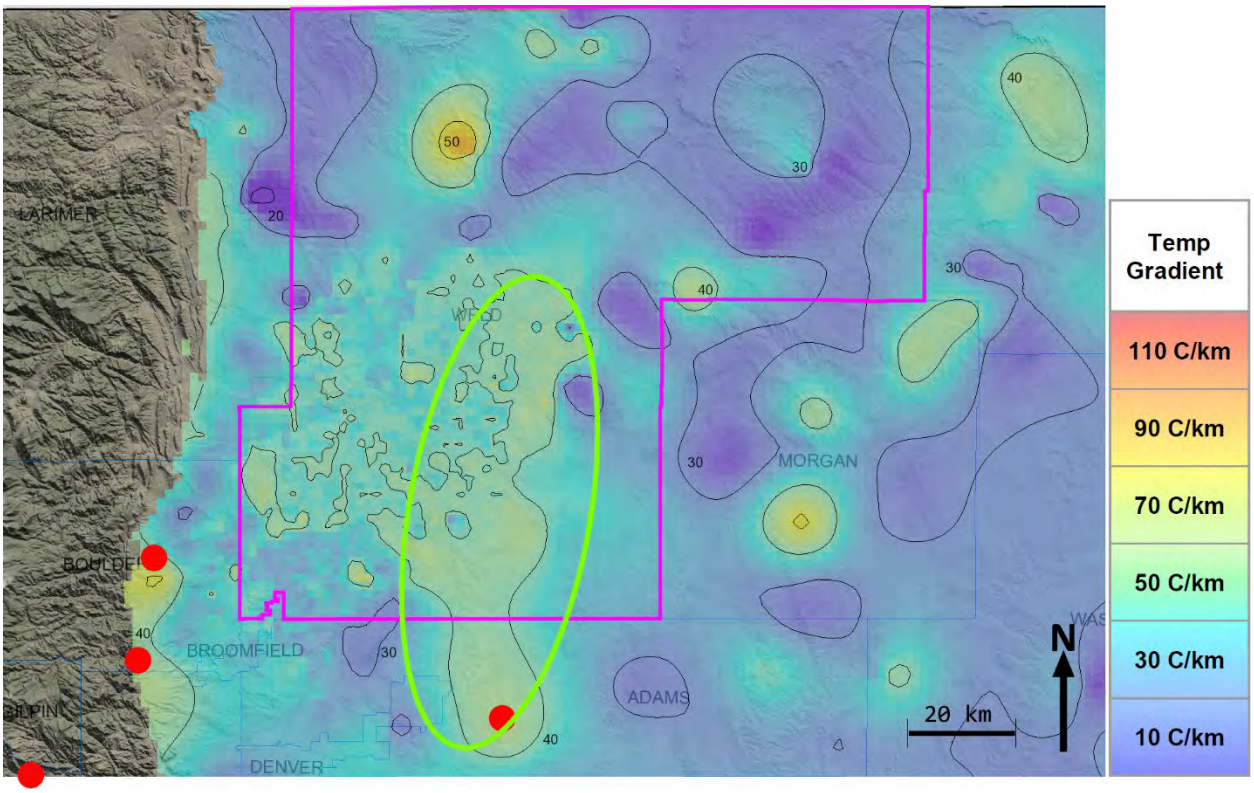

Figure 4: Location map of the study area after Colorado Geological Survey interactive online GIS map. Magenta outline: Weld County, Colorado, U.S.A. Green oval: Indicates the general location of the Wattenberg hot spot. Shading and contours east of the mountain front: Geothermal gradient between the Cretaceous-age Mancos and Dakota Formations. Red dots: Hot springs.

This study tested several temperature correction methods, and found that the correction of Corrigan and Bergman (1996) and Corrigan (2003) provided the best fit to cased-hole temperature logs (Figure 5). The geothermal gradient was computed by first using log data to estimate the thermal properties of the rocks to build a model, then using the corrected bottomhole temperature and a surface temperature map to extrapolate the gradient upwards.

Oil and gas are produced when organic-rich source rocks undergo thermal maturation hence temperature data is of great interest to the oil and gas industry. Correcting bottom-hole-temperature data is subject to errors and the measurements themselves are often of questionable accuracy. Predicting the occurrence of oil and gas depends on the temperature history of an area, not necessarily the present-day temperatures; and the temperature changes of a rock volume over geologic time cannot be measured directly. Consequently, the oil and gas industry uses proxy data (measures of organic matter maturity, e.g. virinite reflectance) to estimate the thermal maturity and maximum formation temperature of an area. Such proxies are sometimes used as guides to the present-day temperature but are not suitable for geothermal exploration, as we show here.

One of the standard and most accurate guides to the cumulative temperature-time history of an area is the reflectance of vitrinite particles in rock samples. Figures 6 and 7 compare the vitrinite reflectance data of Coskey and Cumella (2015) from the Dakota Fm. to the present-day geothermal

gradients of the Wattenberg hot spot and the GOR (ratio of gas to oil in the first 6 months of production of oil and gas wells). The GOR is sometimes taken as a maturity indicator because higher ratios indicate a greater source rock maturity due to higher maximum formation temperatures and time-temperature history. However, GOR also reflects the composition of organic source rocks, the insulating effect of overlying oil/gas deposits and organic-rich beds (Coskey and Cumella, 2015), and other causes. As Figure 6 shows, the GOR is a poor predictor of the cumulative time-temperature history indicated by the vitrinite reflectance data.

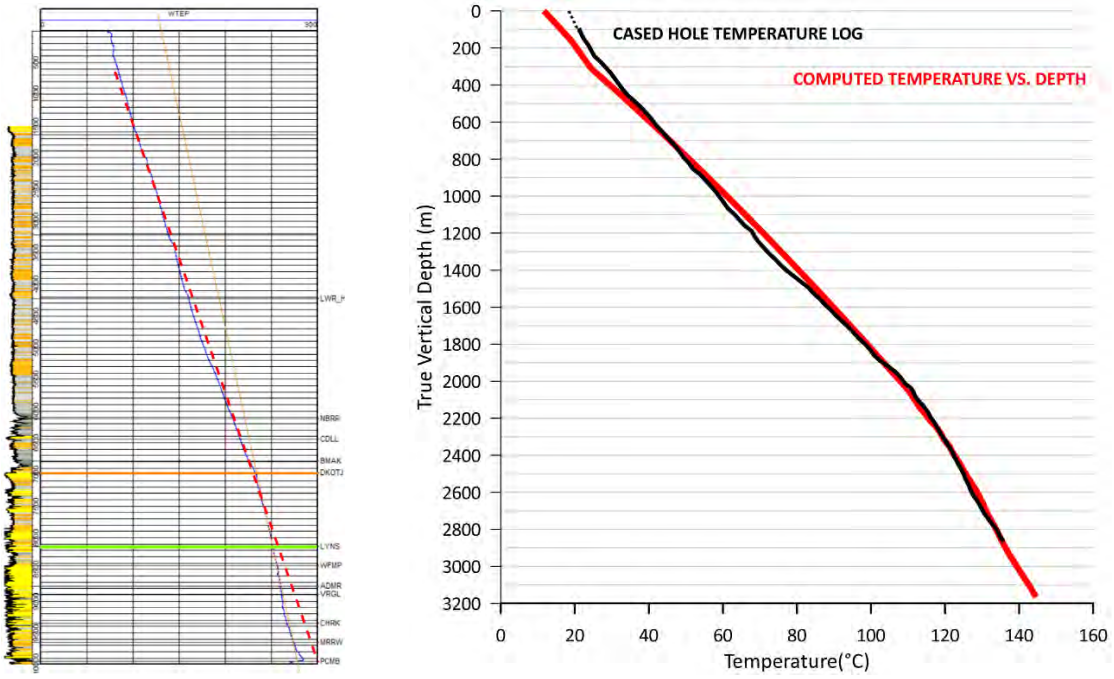

Figure 5: Cased hole temperature log from an oilfield and a one-dimensional thermal model used to validate the temperature correction. LEFT – Temperatures in °F, depths in ft. Blue line-cased hole temperature log. Yellow line – trend of the deep section. Dashed red line – trend of the shallow section. Green line – Lyons top. Orange line – Dakota top. RIGHT – Comparison between a cased-hole temperature log and a one-dimensional thermal model.

The vitrinite reflectance data reflects broadly the geothermal gradient data (Figure 7) but lacks detail compared to the geothermal gradient map for several reasons:

- The geothermal gradient map appears complex, but most of the bull's eyes on the map are supported by several measurements, so that they cannot be attributed to the often-poor quality of bottom-hole temperature data.
- The vitrinite data is sparse compared to the temperature data.
- More importantly, the vitrinite data shows the cumulative effects of temperature over geologic time so that present-day temperatures and spatial temperature variations through time are not captured.

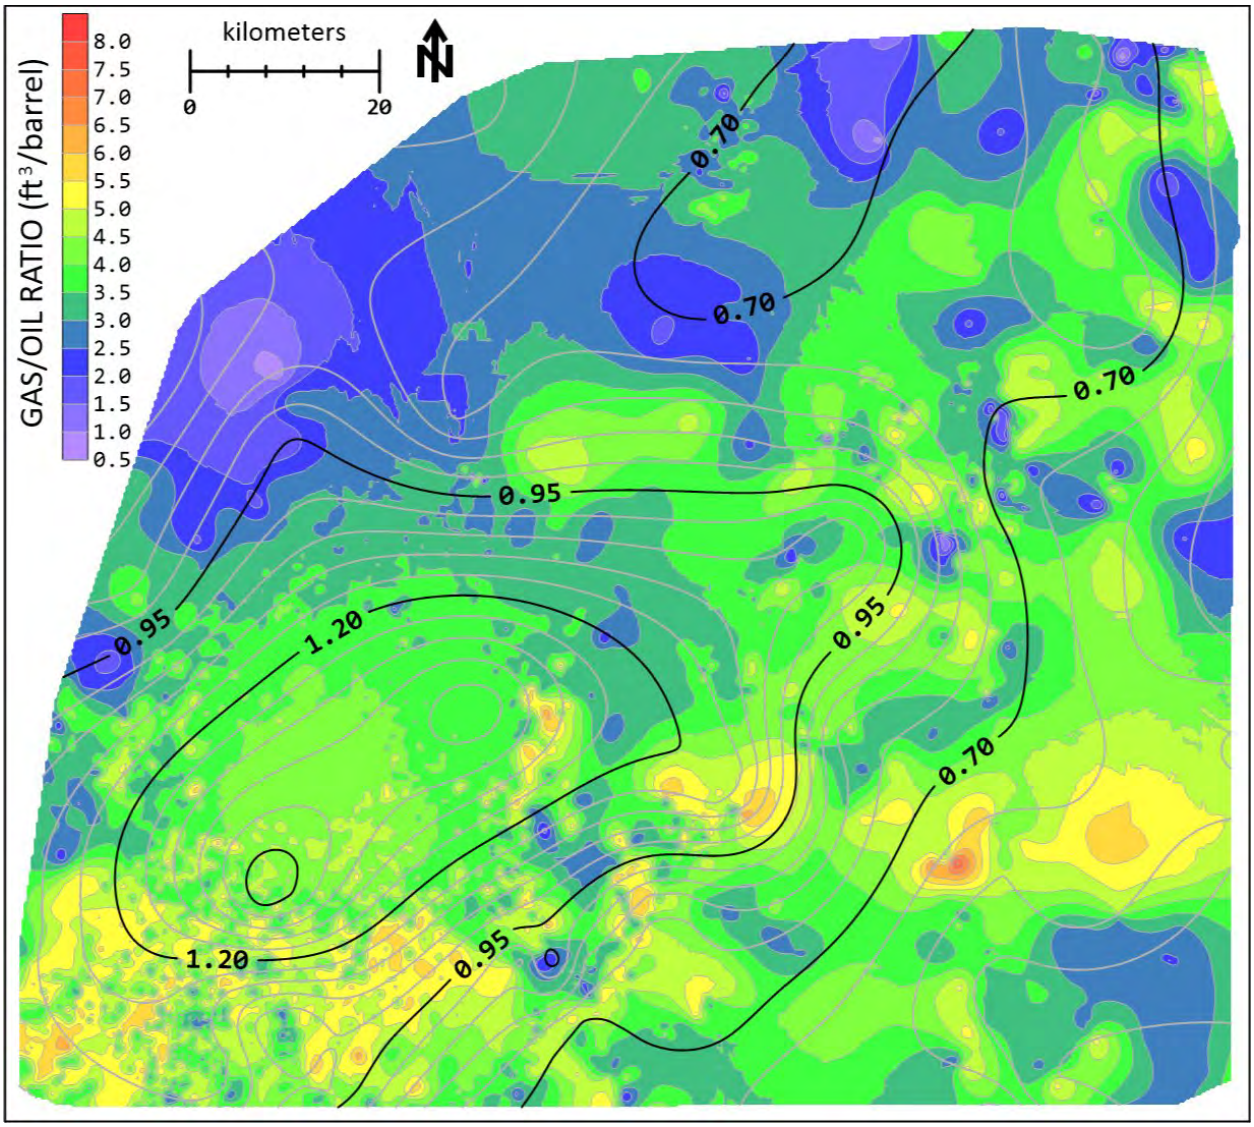

Figure 6: Map of the "hot spot" in the Wattenberg Field and some of the surrounding area. Color shading shows the GOR (gas/oil ratio in the first 6 months of production) from 798 wells in the Niobrara and Codell Fms. Heavy contours are the Dakota Fm. vitrinite reflectance contours of Coskey and Cumella (2015) in %VR_o.

The variability of the present-day geothermal gradients is likely due to hydrothermal fluid movements associated with deep igneous intrusions. Although direct evidence of intrusions has not been published, geologists working the basin have long suspected that intrusions are present at depth. Wattenberg and Redtail fields lie along the trend of the Colorado Mineral Belt (CMB) (see summary by Eaton, 2024) and Eaton (2024) shows that the Lyons Fm. has been altered by mineralizing hydrothermal fluids spatially associated with faulting and temporally associated with CMB intrusions.

Siting an HSA geothermal plant requires specific, local knowledge of present-day temperatures at the scale of typical horizontal well lengths (1-2 km). We conclude that proxy measurements of hydrocarbon maturity are not adequate for siting a plant so that temperature measurements are

required. Petroleum industry vitrinite reflectance maps may be suitable for locating broad regions of interest.

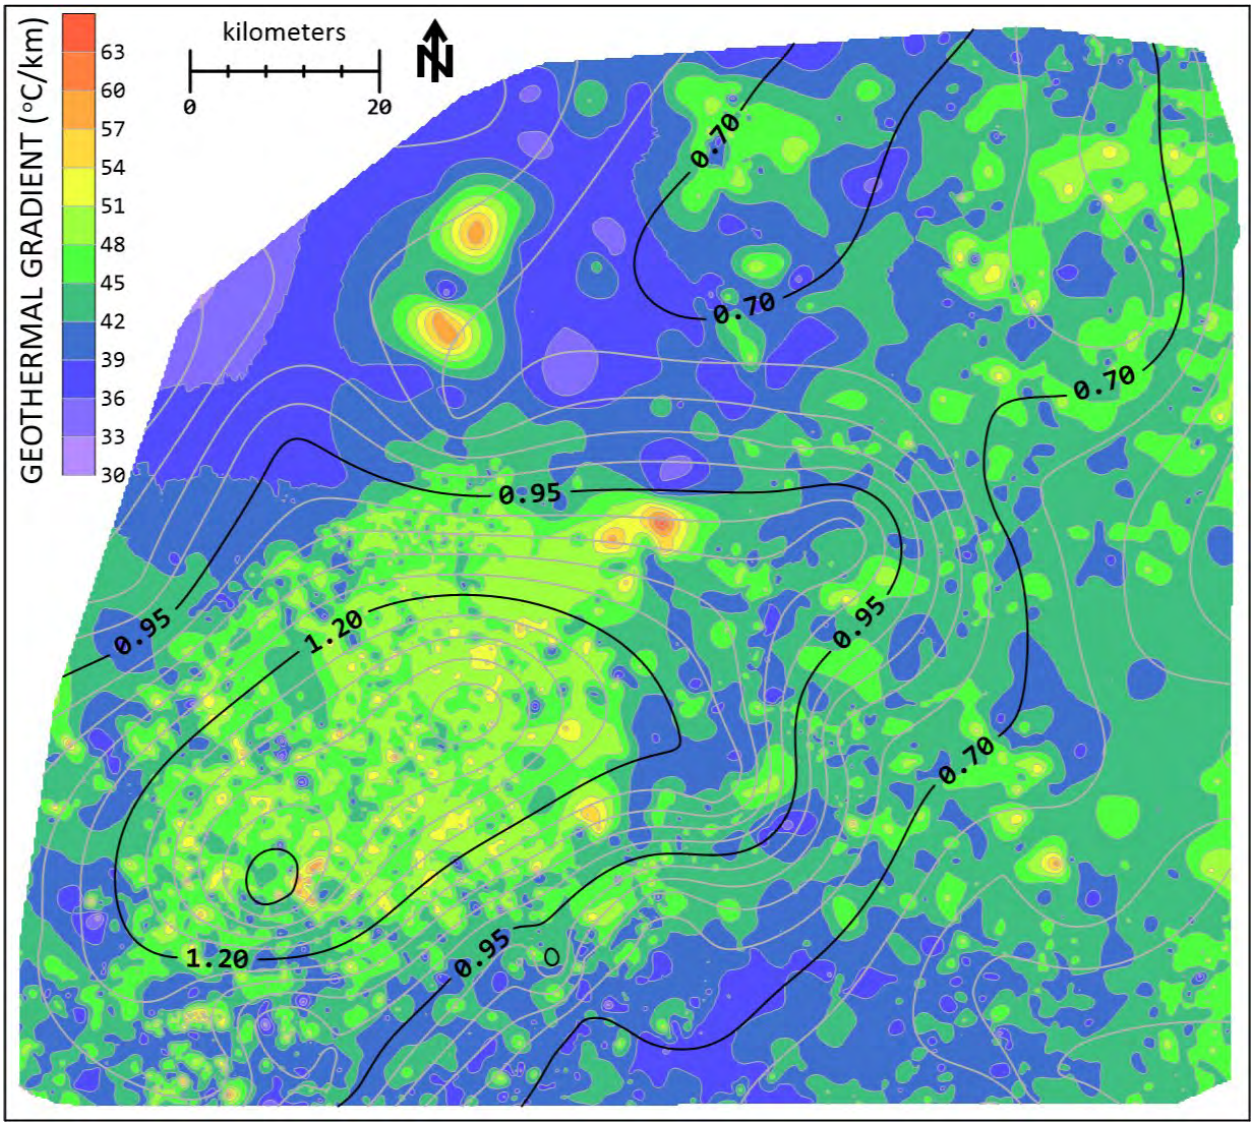

Figure 7: Map of the "hot spot" in the Wattenberg Field and some of the surrounding area. Color shading shows the geothermal gradient determined from 6,181 corrected bottom-hole temperature measurements. Heavy contours are the Dakota Fm. vitrinite reflectance contours of Coskey and Cumella (2015) in %VR_o.

3. Potential Fields Data

Figures 8 and 9 compare gravity and magnetic data (Oshetski and Kucks, 2000) to the present-day geothermal gradients. The gravity map tracks the long-wavelength pattern of the hotspot, but that is not obvious at the scale of figure 8.

In the hot spot, two magnetic anomalies, a low and a high, are centered on geothermal highs while the hot spot occupies a low.

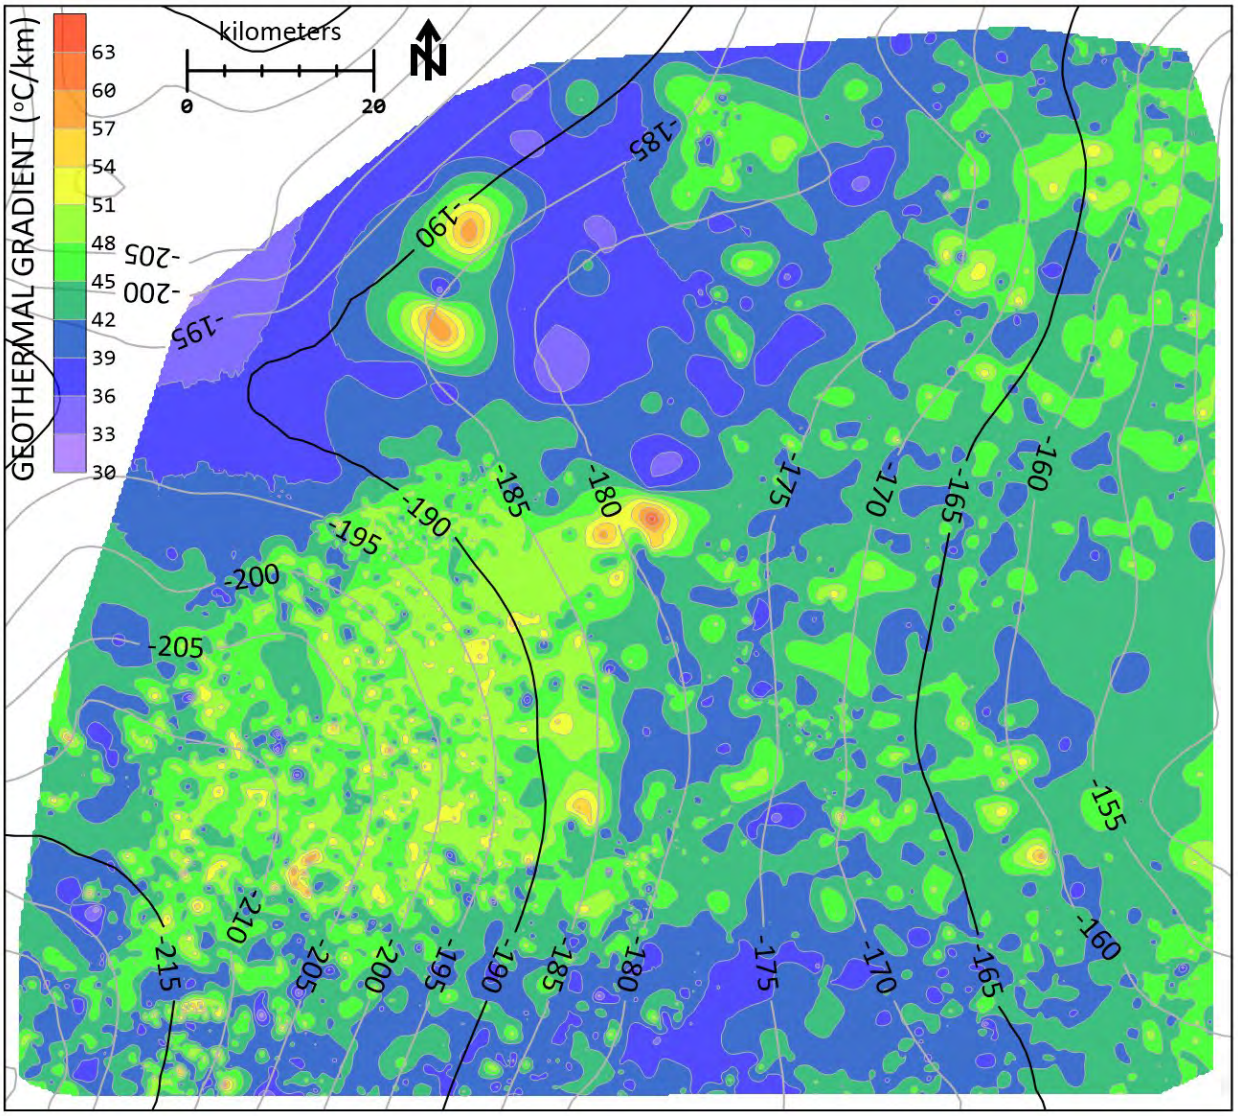

Figure 8: Bouger gravity contours over geothermal gradients.

4. Rock Properties

Unlike hydrothermal production, HSA production depends both on harvesting the existing heated fluids and harvesting the heat in the solid rock matrix via flow through the pore space of producing strata. Therefore, exploration programs rely on knowledge of matrix porosity and permeability of target strata. Existing oil and gas fields have abundant geophysical well logs that provide porosity, and in some cases permeability data, from core measurements. The log data is available from state agencies such as geological surveys and from commercial data providers.

Knowing the volume of the existing hot brine available for power generation is essential. Figures 10 and 11 provide examples of porosity and permeability mapping of the Lyons Sandstone Fm., a Permian age eolian sandstone in the area shown in Figures 6 and 7. Figure 10 shows the porosity-thickness (termed phi*h), which is calculated by multiplying the fractional porosity measurements of a porosity log (density-porosity in this case) by the log sampling interval for all measurements

in the formation of interest and then summing the values for the formation. The result is therefore in length units and represents the thickness of the brine layer that would result if the rock was compacted to eliminate all porosity. For further discussion see Lacazette et al (2024). A phi*h map therefore shows the distribution of water available for power generation.

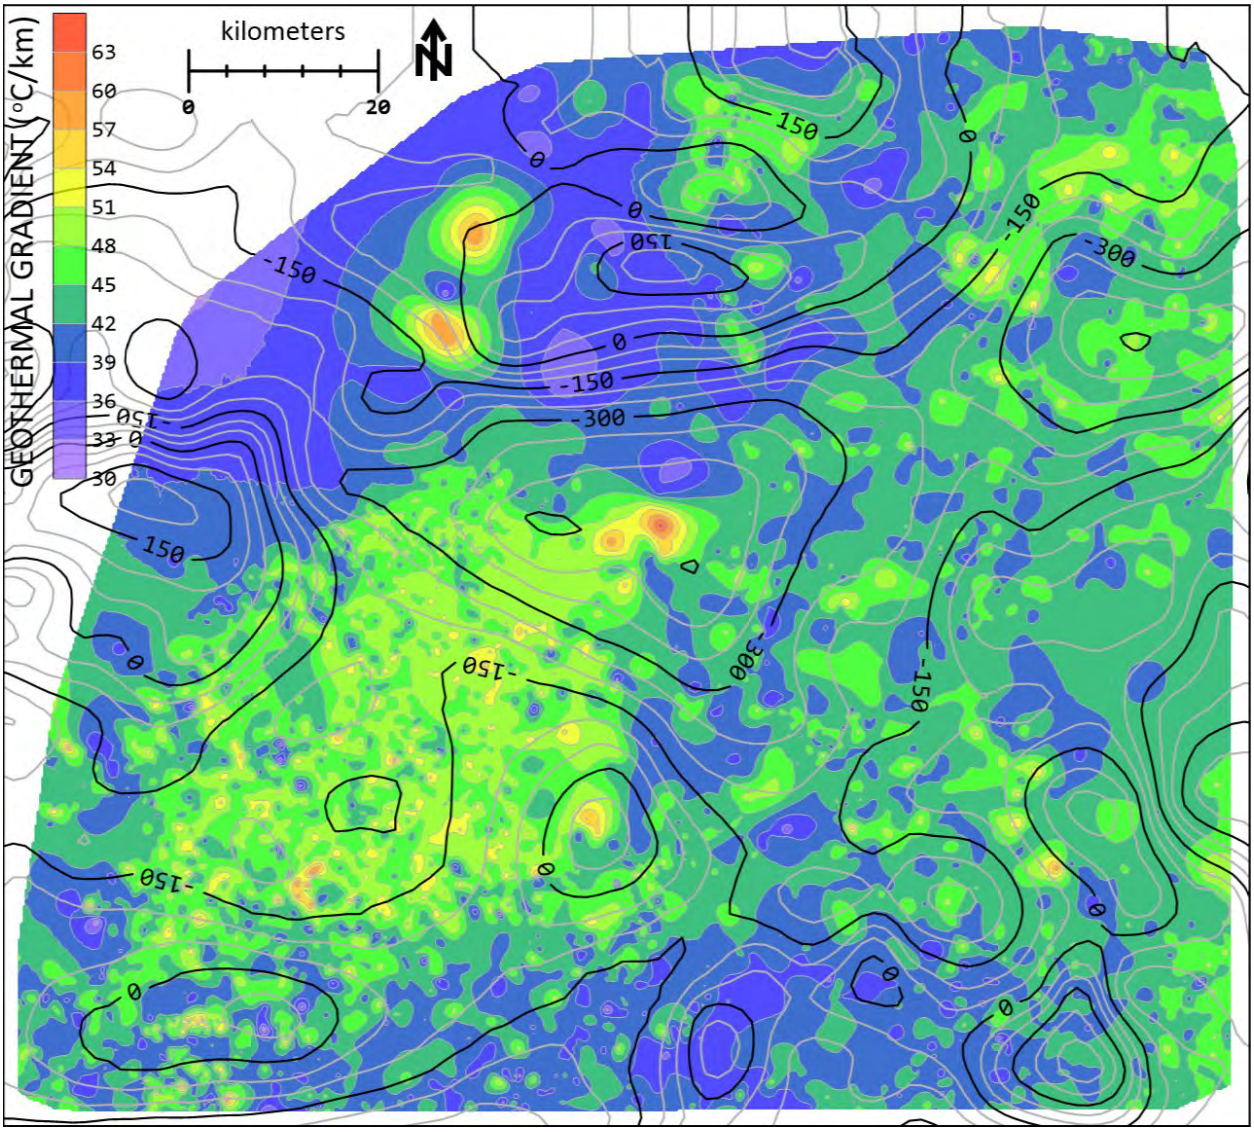

Figure 9: Magnetic anomaly contours over geothermal gradients.

Bulk reservoir permeability is important for determining optimum well spacing and lateral lengths. Permeability can be mapped using the porosity logs if a core-derived porosity-permeability transform is available. Figure 11 is a map of the flow-capacity, which is computed by using a porosity-permeability transform to compute permeability from porosity. Similarly to phi*h, each permeability (i.e. transformed porosity) is multiplied by the log sampling interval and the values are summed for the formation of interest. Figure 11 was computed using the horizontal permeability transform described in Lacazette et al (2024). Again, the Lyons Fm. is an eolian sandstone so that the porosity-permeability data in Lacazette et al (2024) is from those lithologies. Figures 10 and 11 differ because the porosity-permeability transform is non-linear. Reservoir

simulations using the COMSOL™ and FracMan™ software packages indicate that including anisotropic vertical and horizontal permeability yield very similar results to simulations using only the horizontal permeability.

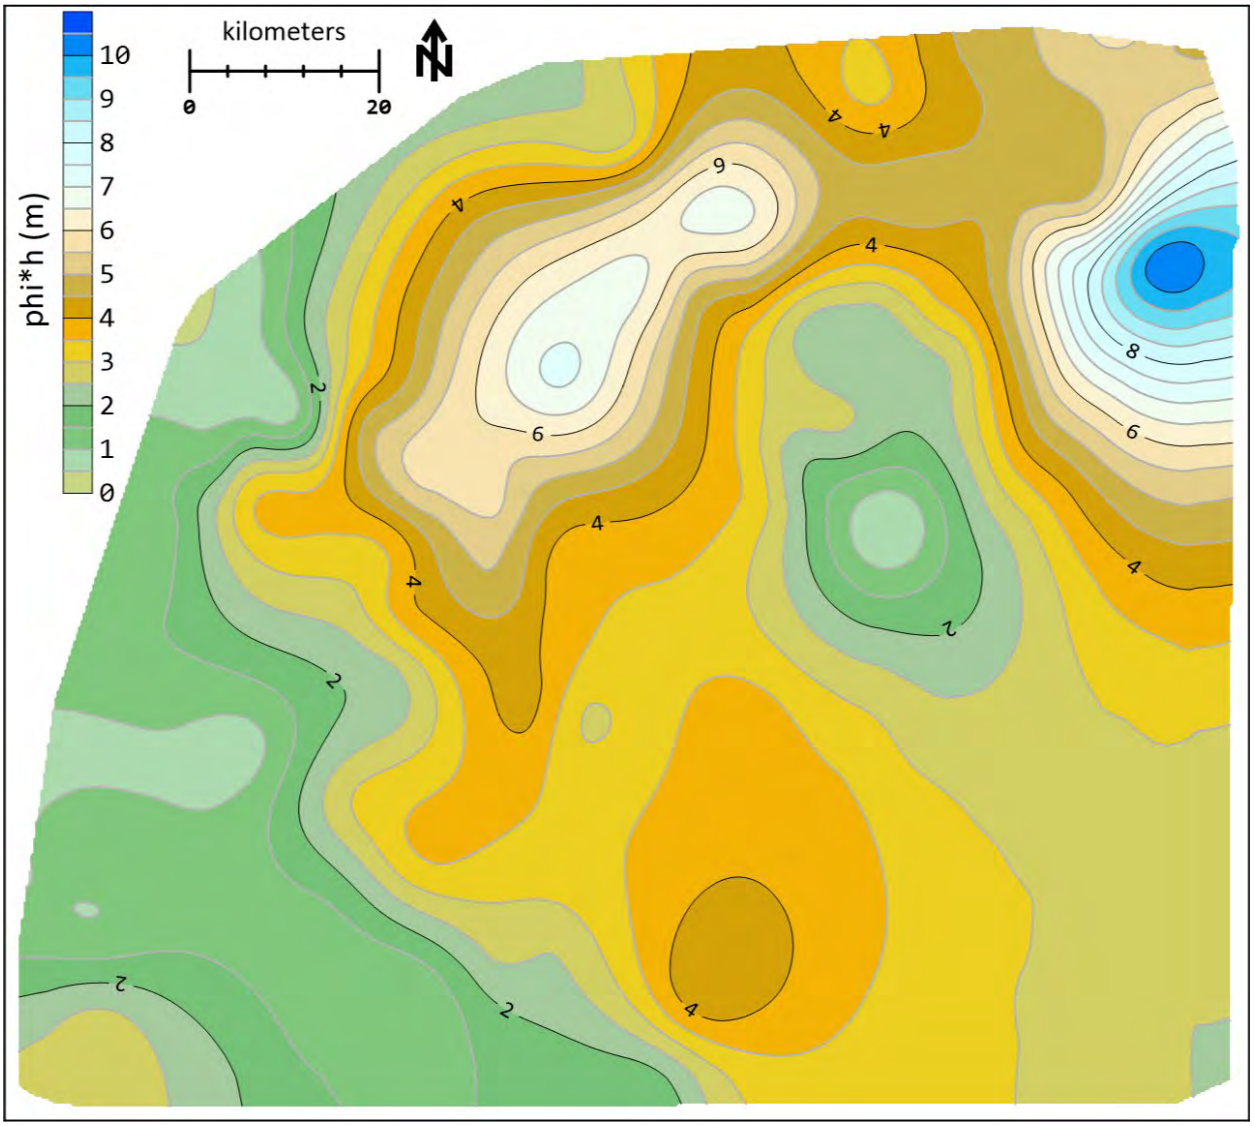

Figure 10: Porosity-thickness (phi*h) map of the Lyons Sandstone.

The heat available for power generation is given by:

$Q = \text{mass } C_p \Delta T$

Where Q is the heat, Cp is the heat capacity, ΔT is the temperature drop in the heat exchanger of an Organic Rankine Cycle generator (ORC). Figure 12 is a map of the available heat from all brine in the Lyons Fm. Such maps can be computed for the heat in the mobile brine, the heat in the solid portion of the rock, and other quantities (Lacazette et al, 2024). Maps such as those in Figures 6 and 10 through 12 are used to identify prospective areas. Suitable sets of conditions are defined by reservoir simulations.

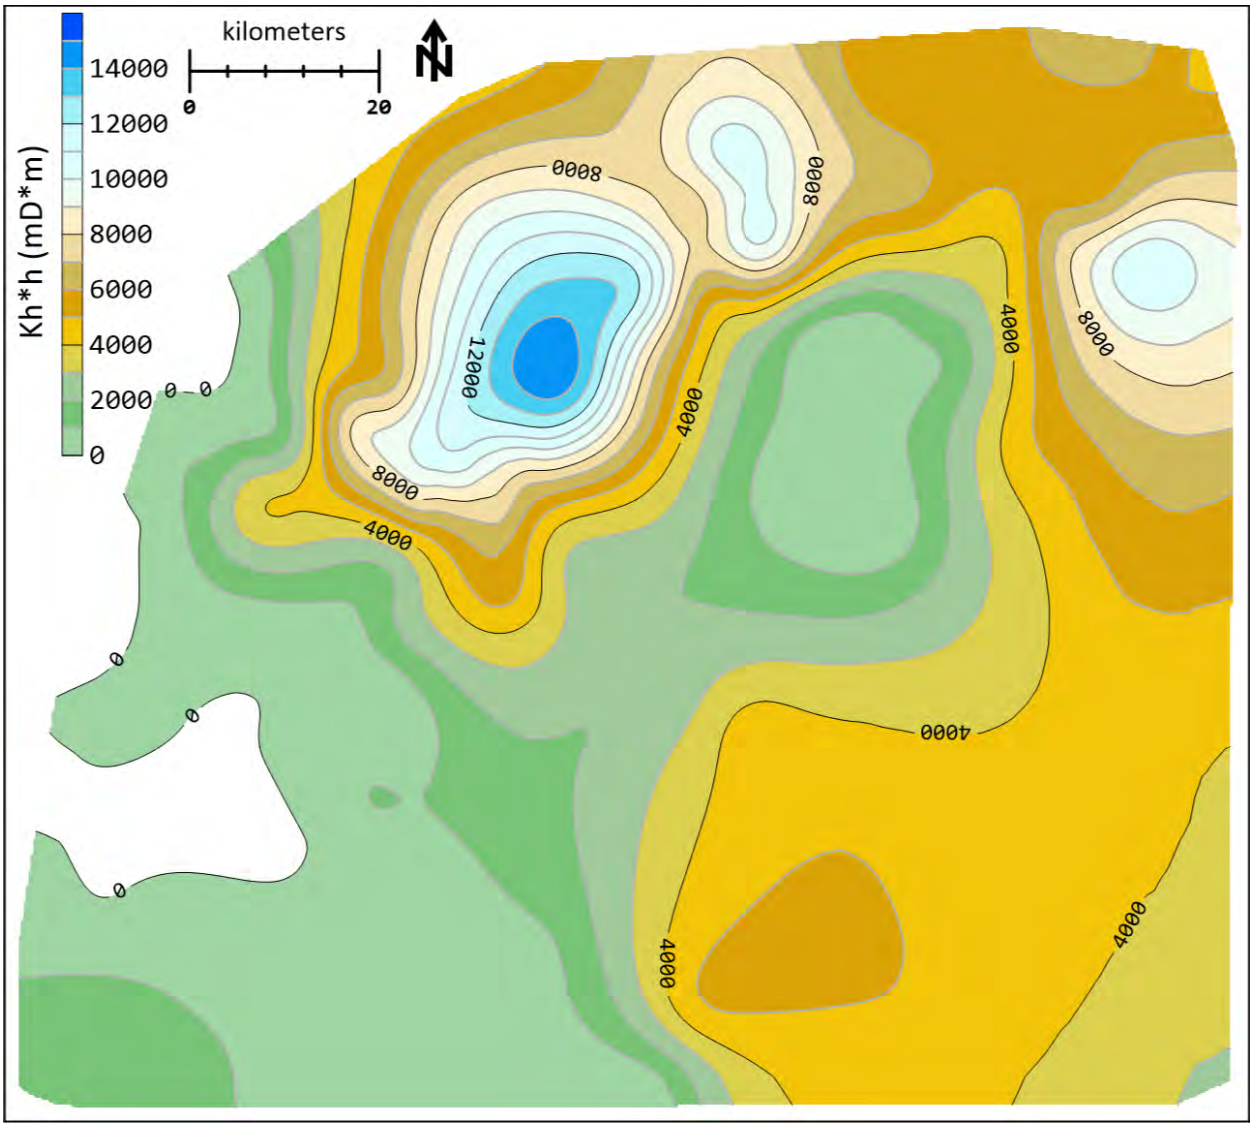

Figure 11: Flow-capacity (Kh*h) map of the Lyons Sandstone.

5. Simulation

Reservoir simulation (flow modeling of the geothermal waters) is required to determine the sets of conditions suitable for power generation. We undertook two simulation efforts: 1) rapid simulations with uniform porosity and permeability in the COMSOL numerical package to determine suitable sets of conditions for power generation at map scale and 2) detailed simulations based on a detailed static reservoir model of the reservoir in a targeted area using the FracMan software package (Lacazette et al, 2024). The methodology of the detailed simulations are described in Cottrell et al (2023).

Once promising areas are identified, the reservoir models are built with the rock properties estimated from regional mapping. Producing an HSA requires returning all of the produced water to the reservoir to maintain the reservoir pressure. Figure 13 shows a depth slice of a COMSOL reservoir simulation at the depth of two parallel horizontal wells. The wells set up a dipole pressure

field stimulating a vast convection cell, as shown in Figure 13. The areal footprint between the wells is about 125 acres and the stimulated recharge zone is about 3,500 acres, which represents a vast supply of hot fluid for over 20 years before significantly cold injected water reaches the production well.

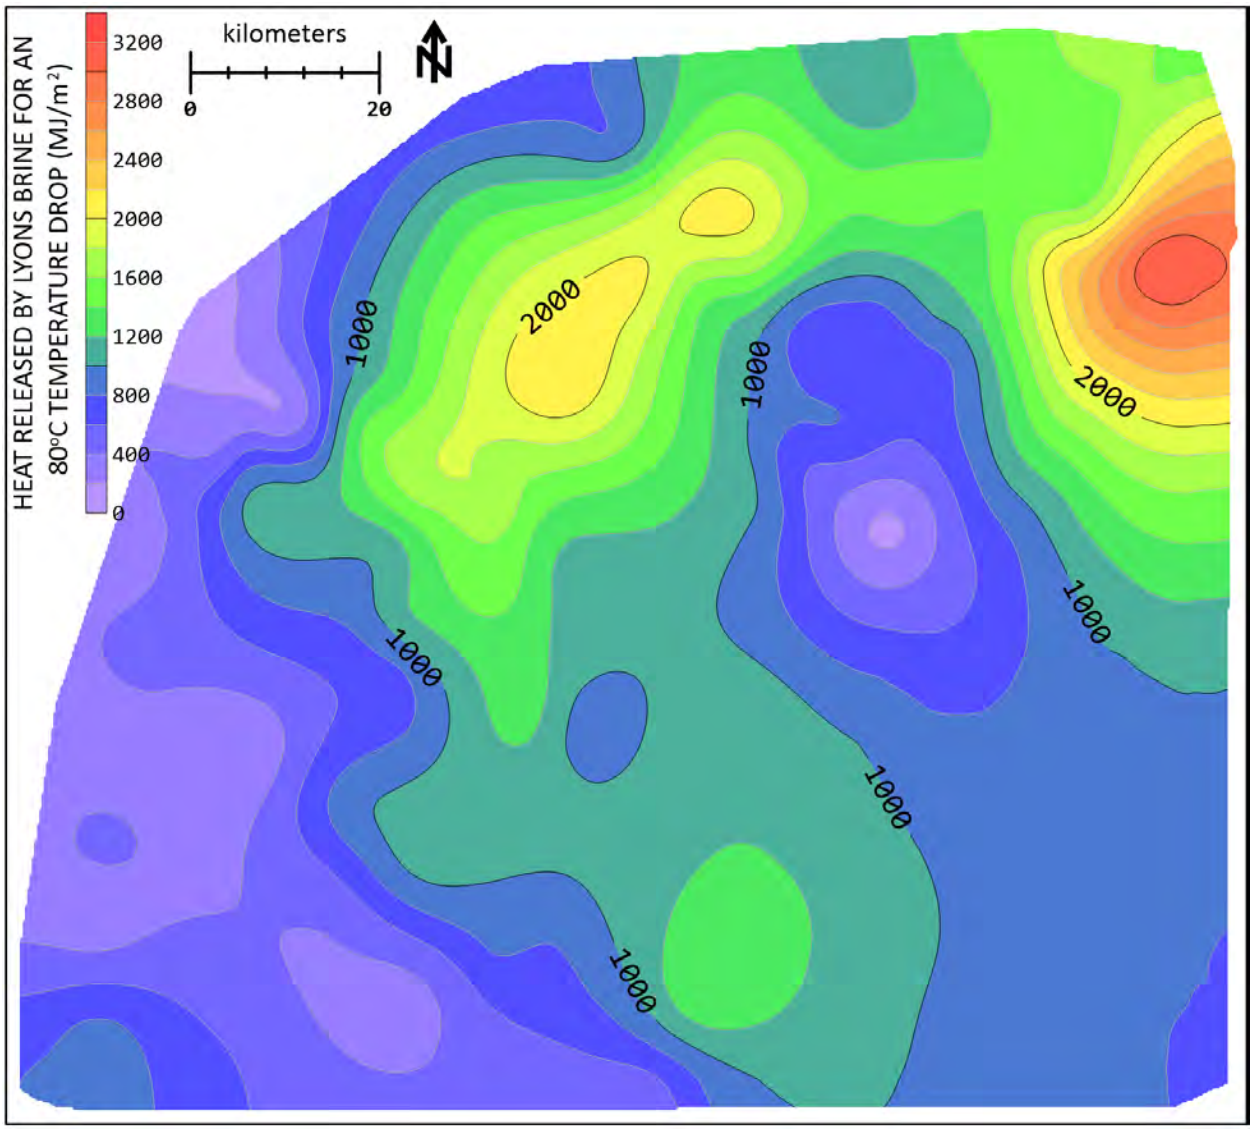

Figure 12: The heat yield for an 80°C temperature drop for all brine in the pore space of the Lyons Fm per square meter of formation.

Figures 14 and 15 show the performance of our planned pilot system over 20 years. Both simulations show that the temperature of the produced water remains economical for at least 20 years. The uniform porosity and permeability model shows less temperature drop than the simulation of the detailed static reservoir model because of thermal breakthrough through a high permeability sandstone streak. Such short-cutting can be managed with downhole flow controllers (Lacazette et al, 2024), which were not used in the simulations.

The long well life from constant production temperature results from two causes:

- Produced water flows through the pore space of the rock completely extracting the heat, from the solid rock matrix.
- Convective circulation continuously brings additional virgin reservoir water to the producing well (Figure 13). GTI's GenaSys™ system for geothermal heat harvesting incorporates these effects and other proprietary GTI technologies.

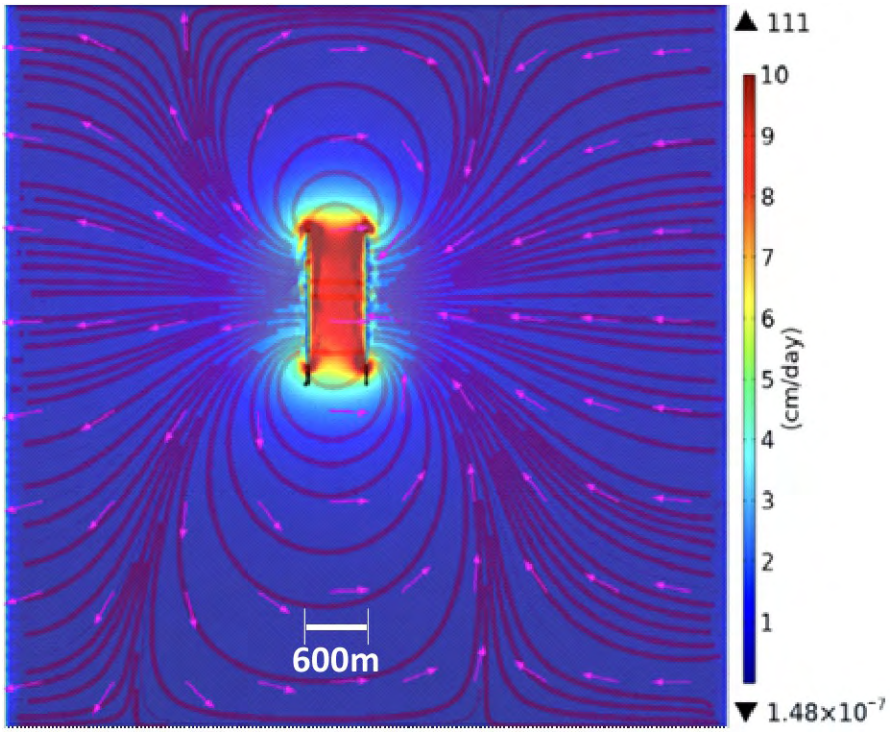

Figure 13: Horizontal slice of a COMSOL reservoir simulation at the depth of the production and injection wells after 20 years of production. Colors show fluid flow velocity in cm/day. Arrows show flow direction.

6. Summary

We provide an example workflow for geothermal exploration in oil and gas basins using existing data collected by the oil and gas industry. Geothermal gradients must be determined with local temperature data because measurements of hydrocarbon maturity that are sometimes used as proxies for temperature are insufficiently precise for siting a geothermal plant. Rock properties measurements such as porosity are available from well logs. Core-derived porosity-permeability transforms allow conversion of porosity data to permeability. Combinations of temperature and rock properties suitable for electricity generation are determined by reservoir simulation. Example reservoir simulations for a planned project show that HSA geothermal wells have long wells life, and this overall system is easily scalable and suitable globally.

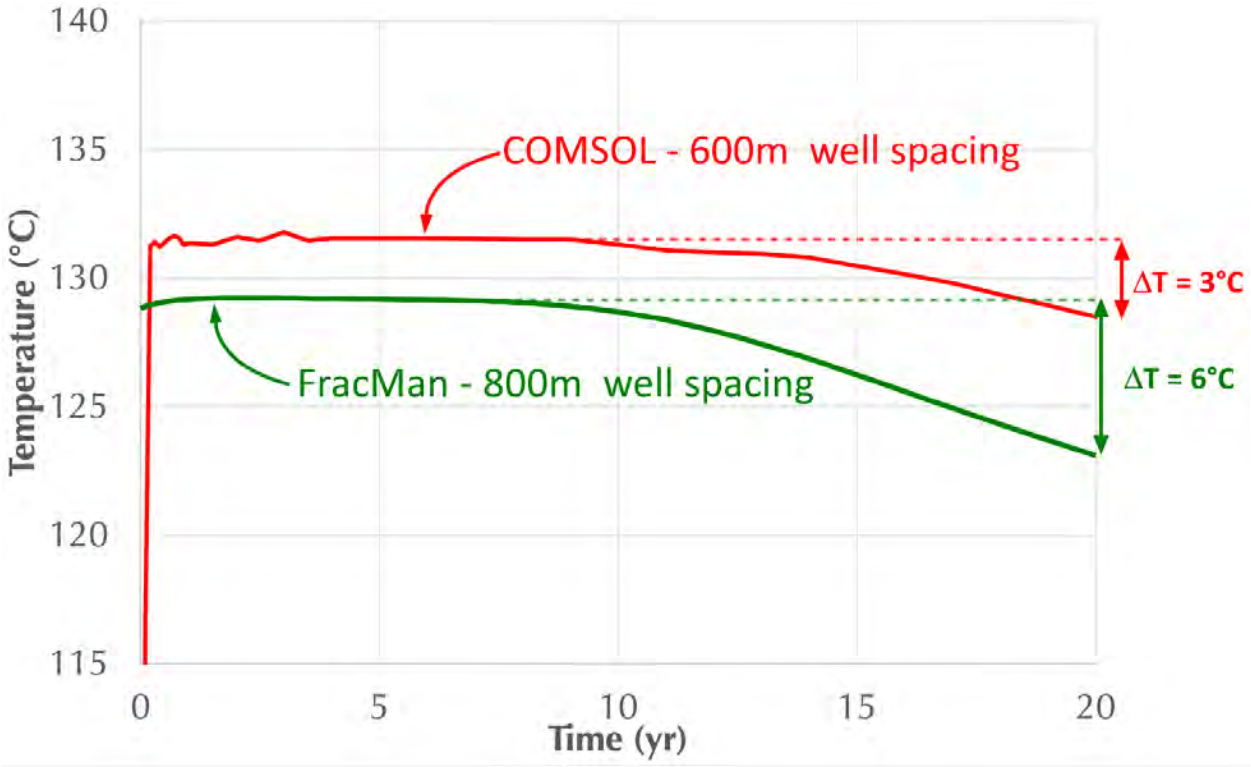

Figure 14: Produced water temperature over 20 years. The two models have different starting temperatures. Although the temperature declines slightly it remains adequate for commercial electricity generation in both cases. The produced water temperature is only slightly below the temperature of the reservoir compared to published EGS and CLGS produced water temperatures, which are a fraction of the reservoir temperature. The heat extraction efficiency potential of HSAs makes them extremely attractive for power generation.

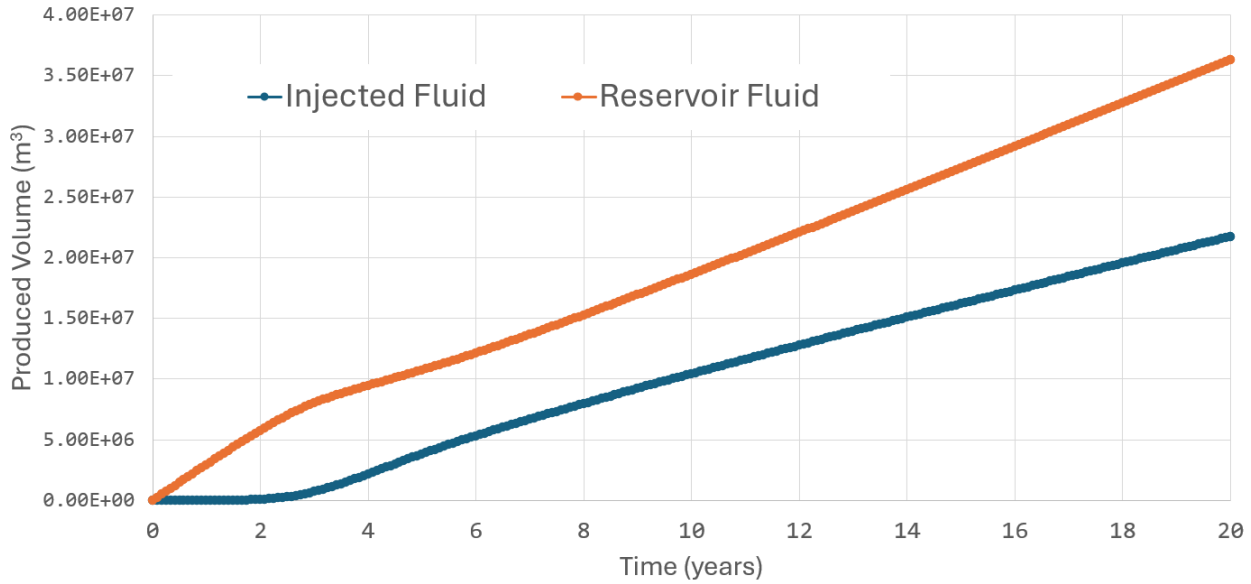

Figure 15: Plot of produced fluids volume from a FracMan reservoir model. The plot shows the volumes of reservoir fluid and injected fluid produced over 20 years.

ABSTRACT

Flexibility is the capability of the power grid to maintain a balance between electricity generation and variable demand. This study presents preliminary results evaluating the impact of geothermal district heating systems on the flexibility of microgrid in Tuttle, Oklahoma. Heating demand profiles were modeled using EnergyPlus for the district that includes two schools and 250 single-family houses. Then, geothermal energy production was modeled using GEOPHIRES to estimate how much heating demand in the district can be supplied by five different geothermal system scenarios. The results indicated that geothermal energy production varied depending on the resource temperature at different depths, system configurations, and flow rates. For the grid flexibility analysis, electricity consumptions in the five geothermal systems were estimated for pump operations to circulate water from the wells to radiators, while electricity consumption by air-source heat pump in the base case was estimated to supply the same heating load. Electricity consumption in the geothermal systems was significantly lower than those in base cases. The electricity saved by the geothermal system was then incorporated into the microgrid electrical load profiles where variable renewable electricity generation is significantly high. The results visually showed that geothermal district heating system can improve grid flexibility as a baseload during the winter season. The results also highlighted potential opportunities to save energy costs that will be further analyzed in future study.

1. Introduction

An electrical grid is defined as an interconnected network where electricity generated from power stations is delivered to end users and varies in size from microgrid to wide area synchronous grid,

or super grid that is trans-continental or interconnected throughout several countries. The microgrid represents a local grid that can be connected or disconnected from the grid, while conventional grid is a large-scale synchronous grid. The power stations connected to microgrids and/or grids in the United States consist of a wide variety of power sources including renewable energy sources particularly wind and solar energy where the resource availability may vary significantly depending on the geographical and environmental conditions. The variable renewable electricity generations increase an uncertainty of the net load met by conventional generators in the grid (i.e., non-renewable electricity generations). The grid thus needs to have a sufficient amount of flexibility to maintain a balance between power supply and variable demand and reliably supply electricity to end users especially if the grid incorporates variable renewable power generations at a high penetration. Grid flexibility describes the system capability to respond to the variability and maintain a balance between demand and supply.

The grid flexibility has been extensively studied by previous researchers, especially for the impact of variable electricity generation from wind and solar energy systems. Denholm and Hand (2011) evaluated the flexibility of an isolated region where the grid is significantly dependent on variable wind and solar power generation (up to 80% of the electric demand) and concluded that the grid requires a variety of enabling technologies including load shifting, thermal storage, or electricity storage to accommodate variable renewable electricity generation at 80% penetration and to avoid excessive curtailment. Similarly, Deetjen et al. (2017) reported growing wind and solar capacity in the electric grid shows only minor impact on the grid flexibility even though growing solar capacity improves the grid flexibility requirements at the early stages. Specifically, solar power generation of 14.5 GW increased maximum 1-h ramp rates by 135%, 3-h ramp rates by 30%, ramp factors by 140%, 1-h volatility by 100%, and 1-day volatility by 30%.

To mitigate the net load ramping and optimize the grid flexibility with variable wind energy, Fang et al. (2020) designed flexible ramping products from wind power using a probabilistic wind power ramp forecasting method. Their results demonstrated that the system operating and ramping cost can be reduced with the flexible ramping products especially when wind power provides flexible ramping products in the day-ahead market. Analogously, although geothermal electricity systems have been traditionally incorporated into a power grid for baseload, the power supply using geothermal energy can improve grid flexibility when flexibly operated. Millstein et al. (2021) reported that simple curtailment of geothermal power system operations during negative pricing episodes could increase the energy value by $1 to $2/MWh on average (up to $4/MWh depending on the amount and type of curtailment and enhancement) resulting in an increase in power production during limited peak rate hours. Moreover, the flexibility can be further optimized with in-reservoir energy storage system (Ricks et al. 2022, Ricks et al. 2024).

In addition to the flexible operations of geothermal power systems, geothermal resources have great potential to improve grid flexibility particularly using geothermal district heating system where thermal energy is supplied from the subsurface to a group of buildings through a distribution network (i.e., large-scale heating system). For example, pumps may be the only component where electricity is consumed in the geothermal system to circulate water from wells to heat exchangers or radiators for heating, while electric boilers and furnace in non-geothermal heating system may consume more electricity for the same heating load. However, there are very limited studies to analyze how much electricity could be saved with the geothermal district heating and how the geothermal district heating can contribute to grid flexibility. This study evaluated the impact of

geothermal district heating system that has five different production scenarios on the flexibility of a conceptual microgrid in Tuttle, Oklahoma. Electricity consumed for circulating pumps in the geothermal system was estimated for the five production scenarios and then incorporated into Cambium data sets, which contain modeled hourly emissions, costs, and operational metrics in Southwest Power Pool (SPP) south region where the study area is located (p50). The results were also compared with a base case where the same heating load is supplied by air-source heat pump (ASHP).

2. Geothermal District Heating System in Tuttle, Oklahoma

The study area includes one primary school, one secondary school, 250 single-family homes, and four inactive oil and gas wells, approximately 1.5 km away from the district (Figure 1). As demonstrated by Oh et al. (2024), this study assumed that geothermal energy is reliably and continuously produced from the four oil and gas wells for space heating using radiators.

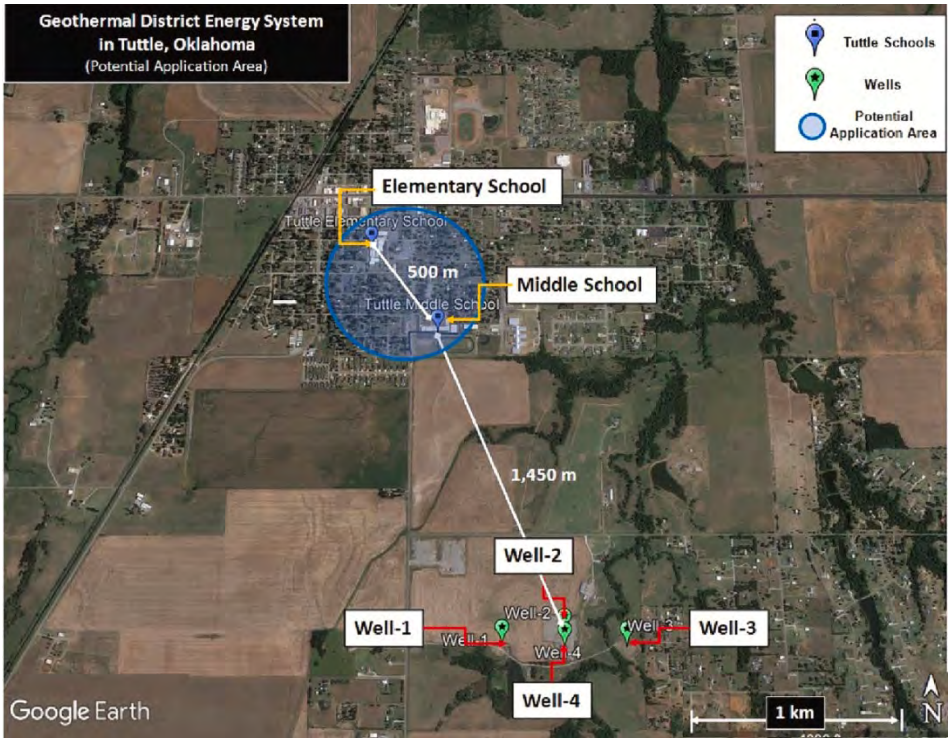

Figure 1. Geothermal district heating system in Tuttle, Oklahoma (Oh et al. 2024).

This study leveraged the reservoir and building energy modeling results in Oh et al. (2024). For geothermal energy production, there were five scenarios that have different well configurations, depths, and flow rates (Table 1). Regional geothermal gradient in the study area was estimated as 25.3 °C/km, and the production temperature, power ($MW_{thermal}$), and energy ($MWh_{thermal}$) varied depending on the configurations and flow rates. Figure 2 shows the variable geothermal energy production with five scenarios. As discussed in Oh et al. (2024), none of the five scenarios fully supply the district heating demand when the system size underwent techno-economically optimization. Peak loads required supply of natural gas to fire boilers during peaking periods (see red bars in Figure 2). The analysis in this study did not consider heating demand supplied by the natural gas boiler but compared power consumptions for each of the same load profiles in the five

scenarios by ASHP (i.e., base case) and by circulating pumps, following the logic: 1) how much geothermal energy can be produced in each scenario, 2) how much electricity is consumed by circulating pumps to produce the energy in each scenario, and 3) how much electricity is consumed by ASHP to supply the same loads.

Table 1. Geothermal district heating system with five production scenarios

Models	Scenario 1	Scenario 2	Scenario 3	Scenario 4	Scenario 5
Number of Production Wells	1	3	1	3	1
Number of Injection Wells	1				
Well Depth (m)	2,100				3,300
Geothermal Gradient (°C/km)	25.3				
Flow Rate per Production Well (kg/s)	9.3	3.1	6.2	6.2	9.3
Initial Reservoir Temp. (°C)	68.1	68.1	68.1	68.1	98.5
Max. Production Temp. (°C)	63.7	55.1	61.8	59.9	87.9
Avg. Production Temp. (°C)	61.3	53	61.3	45.8	87.1
Avg. Heat Production (MW_{th})	0.71	0.39	0.43	0.35	1.42
Avg. Annual Heat Production (GWh_{th}/yr)	1.92	1.33	1.43	1.12	2.49

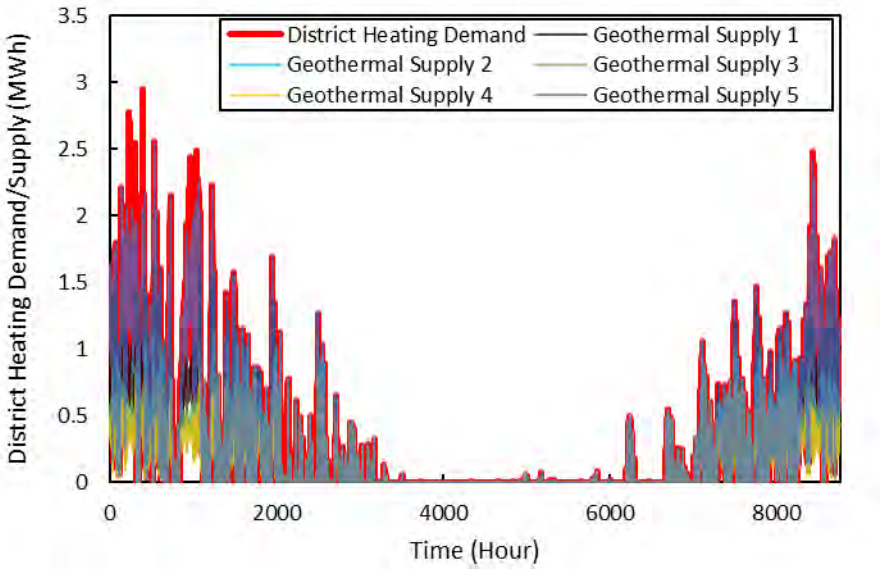

Figure 2. District heating demand and thermal energy supplied by the geothermal system using five production scenarios.

3. Estimating Electricity Consumption in a Base Case and the Five Geothermal Systems

As mentioned, the ASHP was assumed in the base case (i.e., non-geothermal heating system) as a heating equipment to supply the district heating demand and assumed to have a constant coefficient of performance (COP) of 2 (i.e., the ratio of thermal energy generated from the ASHP to electricity consumed in the ASHP is always 2 throughout the year). Solid lines in Figure 3 represent the district heating demand in example days ($MWh_{thermal}$), and the dashed lines demonstrate electricity consumption by the ASHP to supply the demand ($MWh_{electric}$).

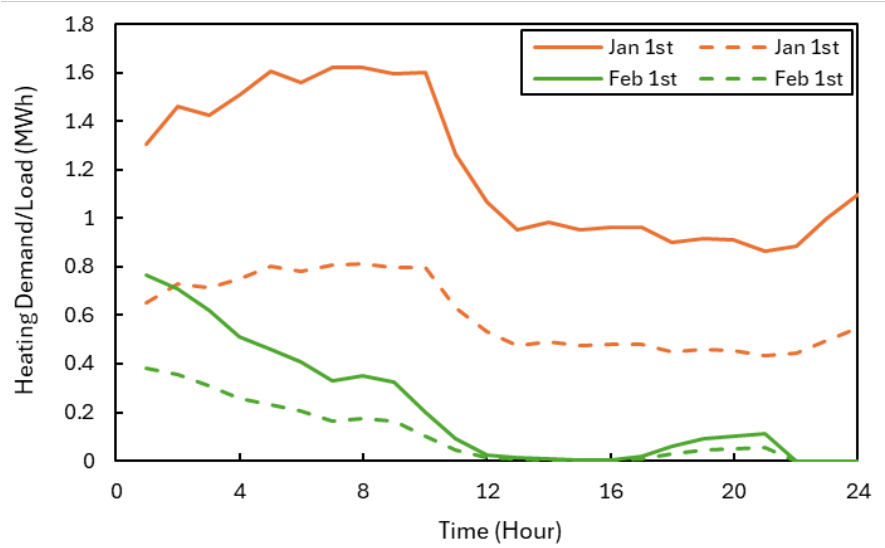

Figure 3. Heating and electrical load profiles in example days. Note that heating demand profiles ($MWh_{thermal}$) are represented as solid lines and dashed lines represent electrical loads by air-source heat pumps for the district heating demand ($MWh_{electric}$).

While electricity consumption in the base case was calculated with the demand profile and COP assuming the ASHP is the only component where electricity is consumed to generate thermal energy for space heating, this study assumed that the geothermal district heating system supplies the heating demand by circulating water throughout the geothermal wells using circulation pumps implying that there is no other energy consumption for generating thermal energy. The pumping power was estimated using Eqn. (1).

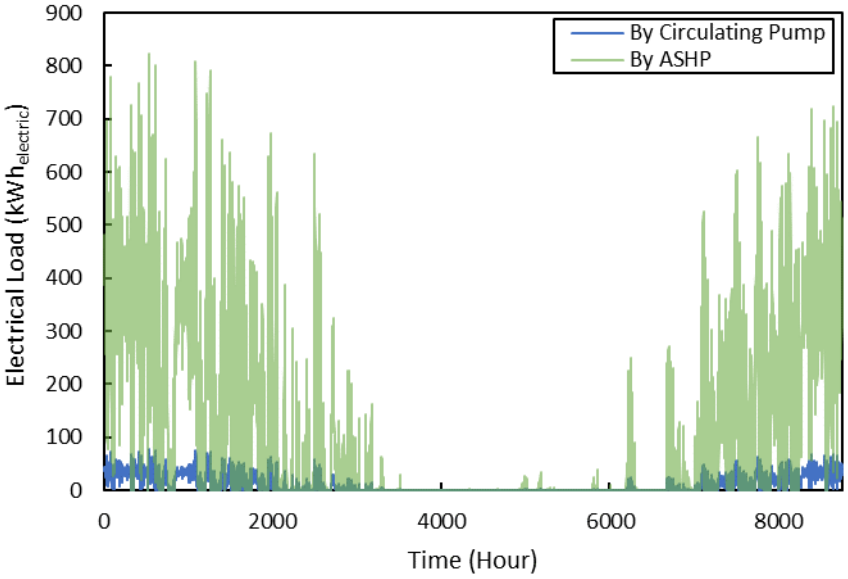
$$P = Q \cdot \Delta P / \eta \tag{1}$$

where P = pump power (W), Q = volumetric flow rate (m^3/s), ΔP = pressure drop (Pa), η = pump efficiency, which was assumed as 80% in this study. ΔP was calculated using Darcy-Weisbach equation (i.e., pressure drop caused by friction):

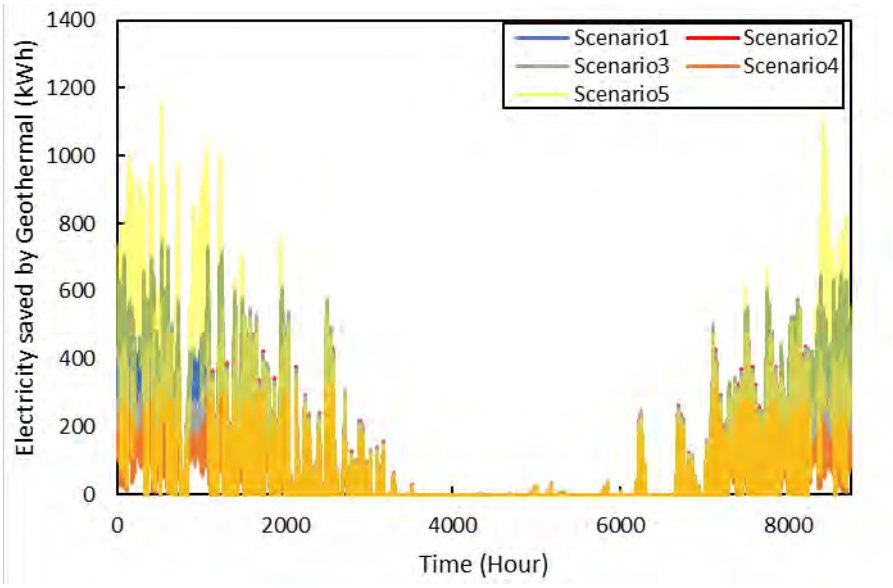
$$\Delta P = \frac{f L V^2 \rho}{2 D} \tag{2}$$

where f = Darcy's friction factor, L = length (m), V = flow velocity (m/s), ρ = fluid density (kg/m^3), D = diameter (m), which was 2.5 in. The calculated pumping powers in the five scenarios were 84.91 kW, 14.29 kW, 26.71 kW, 102.08 kW, and 130.45 kW, respectively. The calculated pumping powers were considered as maximum (i.e., the highest flow rate, such as 9.3 kg/s for Scenario 1 in Table 1) and then reallocated in hourly electrical load profiles in terms of percentage of geothermal system operations (from zero to peak). Figure 4(a) compares electrical load profiles

of the base and geothermal cases in Scenario 1. As the geothermal system does not require power consumption for thermal energy, electrical load in the geothermal system was significantly lower than that in the base case (about 10 times), particularly in Scenario 5 where the heating load supplied by geothermal system was the highest among the five scenarios (Figure 4(b)).



(a)

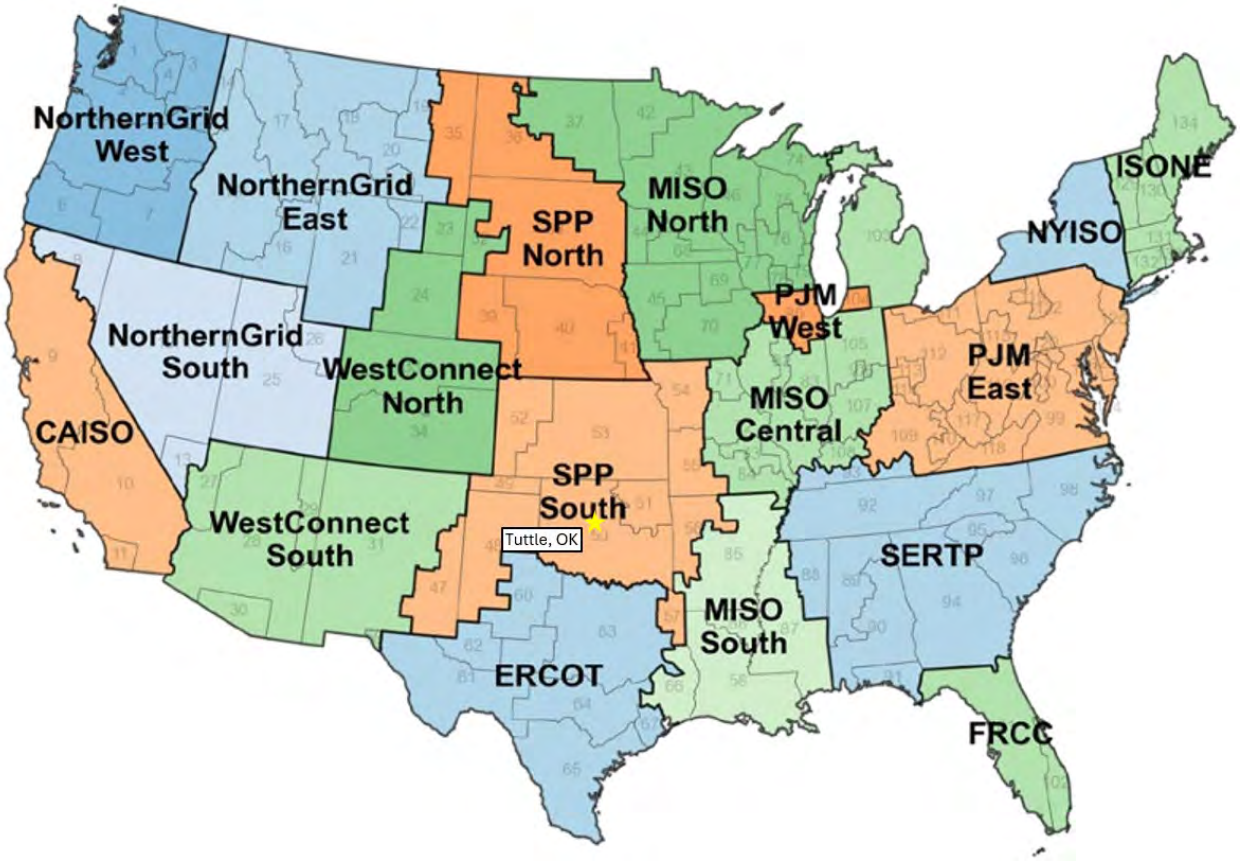


(b)

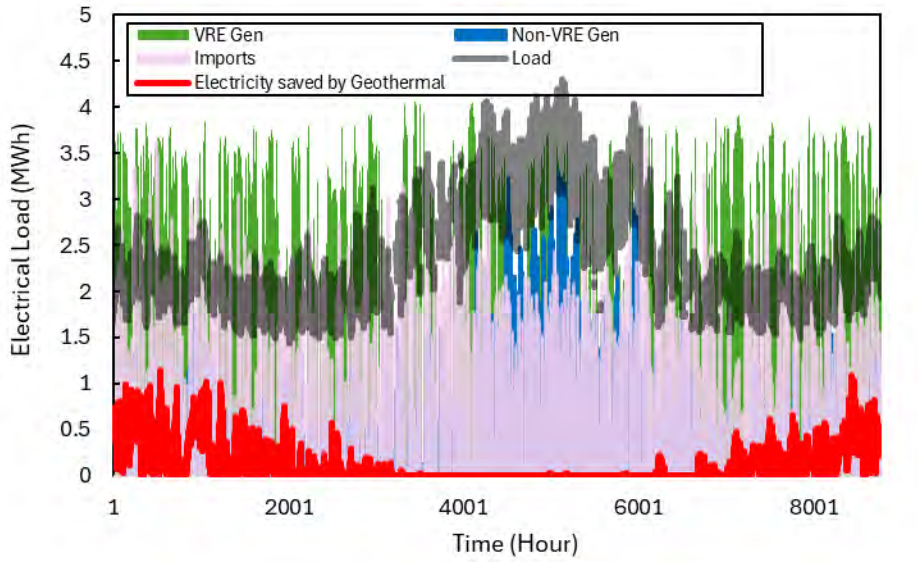
Figure 4. (a) Electrical load profiles in Scenario 1. Blue bars represent electricity consumed by circulating pump in the geothermal system and green bars represent electricity consumed by ASHP in the base case to supply the same district heating demand. (b) electricity saved by the geothermal district heating system in the five scenarios.

4. Impact of the Geothermal District Heating System on the Microgrid Electrical Load

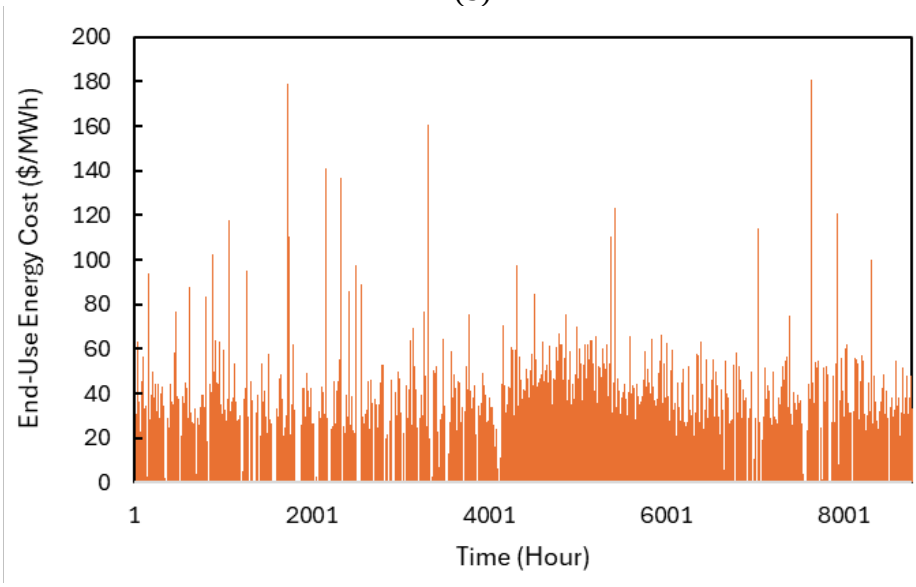
In addition to the comparison of electricity consumption by circulating pump in the geothermal system and by ASHP in the base case to supply the same heating load, the benefit of geothermal district heating system on the microgrid was evaluated with Cambium, which is a dataset annually released by the National Renewable Energy Laboratory for simulated hourly emissions, cost and operational data of the U.S. electric sector (Gagnon et al. 2024). Balancing area is the smallest geographic resolution for which Cambium data are reported (i.e., model nodes, not perfectly aligned with balancing authority defined by the North American Electric Reliability Corporation). Figure 5(a) shows that the study area is in p50 in Southwest Power Pool (SPP) south region. For the analysis in this study, the Cambium data for p50 was further scaled down to the study area in terms of the populations. Figure 5(b) represents electrical load, imports (into the microgrid through interregional transmission lines), and variable renewable electricity (VRE) and non-variable electricity generations in the microgrid. As an example, electricity saved by the geothermal system scenario 5 was also added in the graph to visualize how the geothermal district heating system may improve the grid flexibility. For example, electrical load in the microgrid was significantly supplied by VRE sources (represented as green bars), particularly including wind and solar energy that may not be always available, while the graph shows that certain amount of electricity can be saved with the geothermal district heating system. In future study, this ongoing effort will be extended more quantitatively.



(a)



(b)



(c)

Figure 5. Cambium dataset used for grid flexibility analysis: (a) the U.S. map for generation and emissions assessment regions. The study area is represented with yellow star sign in p50 in SPP South (Gagnon et al. 2024). (b) electrical load profiles in the microgrid. (c) marginal costs induced by an increase in demand, or costs avoided from a decreased demand, for energy and capacity end uses in p50.

Figure 5(c) shows end-use marginal costs induced by increased demand or costs avoided from a decreased demand in p50. The end-use energy cost represents short-term marginal costs to provide the energy for a marginal increase in load including short-run costs that vary as a function of load, inter-balancing area transmission losses, and inter-balancing area transmission congestion, while other operational costs are not reflected in the energy cost (Gagnon et al. 2024). This is another ongoing effort of this study to quantitatively evaluate the impact of geothermal district heating system on energy cost in the microgrid.

5. Summary and Conclusion

The impact of geothermal district heating system on flexibility of microgrid in Tuttle, Oklahoma was discussed in this study. The annual heating demand profile in the microgrid was modeled using EnergyPlus and geothermal energy production was modeled with five different scenarios to estimate how much the heating load can be supplied by the geothermal systems. Then, electricity consumption by pumps to circulate water from the wells to radiators was estimated for the five scenarios, while electricity consumption by ASHP in base case was estimated to supply the same heating load. Electricity consumptions in the geothermal systems were significantly lower than those in base cases (about 10 times), and electricity saved by the geothermal systems was then calculated. Scenario 5, where the production depth was 3.3 km, showed the greatest geothermal energy production and electricity saving. The electricity saving from the geothermal scenario 5 was incorporated into the electrical load profiles in the microgrid showing potential improvements in grid flexibility especially during the winter season. The analysis will be further extended in future study to quantify the flexibility improvements and energy cost savings.

District heating, heat storage, numerical modelling

ABSTRACT

DeepStor envisions the demonstration of a geologic thermal energy storage system with a return flow temperature of 110°C. The connected district heating network at the North Campus of the Karlsruhe Institute of Technology runs with a base load of 2.1 MWth and reaches up to 50 MWth at peak load.

The subsurface of the campus comprises a series of sandstone horizons with a thickness of a few meters between 800 and 1,300 m depth, which connect to the depleted oil reservoirs of the former Leopoldshafen field. These sandstone layers are embedded in the marly Niederrödern and Froidefontaine formations and have numerically proven contain most of the heat in the reservoir layers when operated as a aquifer thermal energy storage (Stricker et al., 2020). The reservoir temperatures are between 60 and 90°C. At an injection temperature of 140°C and production and injections rates of 2 L/s that were extrapolated from the former oil production, the necessary return temperature is reached after 6 years during the entire production period.

This study investigates what proportion of renewable geothermal heat can be achieved in the district heating network of this campus by adding stored heat from the respective sandstone layers during the six cold months (October to March). In the summer months, the storage system is fed by the excess heat from the deep and fractured reservoir, which is operated in continuous mode.

1. Introduction

Moderate climatic conditions often require the provision of considerable amounts of thermal energy for heating purposes in the winter months, which leads to a seasonal imbalance between heat supply and demand when supply is constant, as it is the case with base load-capable geothermal heat. This discrepancy requires thermal storage systems with a large capacity.

The Upper Rhine Graben exhibits elevated geothermal gradients, which can locally reach up to > 100°C km^{-1} and offer favorable geothermal conditions (e.g., Baillieux et al., 2013; Vidal and Genter, 2018). Currently, 16 geothermal wells are in operation for production and reinjection of thermal brine from Tertiary Formations (2 wells), Muschelkalk Formation (2 wells), Muschelkalk Formation to the Variscian basement rock (2 wells), Buntsandstein Formation to the Variscian basement rock (6 wells), and only Variscian basement rock (4 wells, Frey et al., 2022). The causal close connection between hydrocarbon and geothermal reservoirs is indicated by the spatial proximity of temperature anomalies below hydrocarbon reservoirs and the coexistence of geothermal fluids and hydrocarbons in fractured Mesozoic reservoirs (e.g., Böcker, 2017). The numerous depleted oil fields in the Upper Rhine Graben are proven reservoirs that are well characterized in terms of their depth, geometry and reservoir properties. Moreover, seismicity and environmental impacts have been minimal during hydrocarbon production and have been minimized during reservoir engineering and operation in the deep geothermal systems (e.g., Schill et al., 2017; Genter et al., 2012).

At present, there are numerous storage applications in near-surface underground systems, ranging from gravel pits to aquifer thermal energy storage (ATES). The state of the art is in borehole thermal energy storage, in which the heat pump cycle is reversed to store excess heat. Worldwide, > 2,800 ATES systems are in operation, mainly in the Netherlands, providing more than 2.5 TWh a^{-1} for heating and cooling purposes (Fleuchhaus et al., 2018). The operating temperatures of ATES are generally < 50 °C and cover low-temperature heat applications. There are only a few plants worldwide that operate at higher temperatures. Holstenkamp et al. (2017) describe the conditions and experiences of the two German plants in Berlin and Neubrandenburg. High-temperature heat storage for industrial applications or district heating supply, for which temperatures of up to >110 °C are required, have not yet been developed on a commercial scale.

Assuming a doublet system with seasonal injection and production cycles, a numerical potential study for the injection of 140 °C water into a typical 70°C reservoir shows an annual storage capacity of up to 12 GWh per well and significant recovery efficiencies increasing up to 82 % after ten years of operation (Stricker et al., 2020). Around 90 % of the reservoirs investigated in the Upper Rhine Graben can be converted into such high-temperature ATES (HT-ATES). In summary, this indicates a total storage capacity in depleted oil reservoirs of about 10 TWh a^{-1}, which represents a considerable part of the thermal energy demand in this area.

In the Very-High-Temperature Heat Aquifer Storage (VESTA) project, we numerically investigate the heat extraction from a deep fractured reservoir at the DeepStor site (www.geoenergiecampus.kit.edu) in combination with the seasonal storage of heat at the edge of the depleted Leopoldshafen oil field. One motivation for this study is our concept to mitigate the induced seismicity during operation of the deep fractured reservoir through stable and moderate flow rates (Schill et al., 2017; Genter 2012). To keep the flow rates in the deep fractured reservoir stable, although the heat demand in summer is significantly lower, we propose heat storage in a

porous reservoir with comparatively low potential for induced seismicity (Stricker et al., subm.). This concept has the positive side effect of automatically reducing the flow rates required to cover the heat demand in winter in the deep, fractured reservoir, which has a higher potential for induced seismicity. Compared to conversion into electrical energy, heat storage makes it possible to provide a higher proportion of carbon-neutral heat, which is a major challenge in Germany.

2. Geothermal Setting At The DeepStor Site

The DeepStor site is located in the central segment of the NNE trending, essentially non-volcanic Upper Rhine Graben, formed approximately 47 Ma between Germany, France and Switzerland (Figure 1). 3D seismic data from the northern part of the central Upper Rhine Graben segment show deep-rooted NNE-striking faults controlling early, syn-rift 1, extensional basin evolution from about 47 Ma to 27 Ma (Bauer et al., subm.). The change in stress field at about 27 Ma and subsequent reactivation of these deep-rooted faults resulted in a new set of shallow-rooted en-echelon faults. On a larger scale this change in stress field was accompanied by a shift of regional depocenters and the onset of regionally distributed, minor alkaline volcanic activity. The shallow-rooted en-echelon faults nucleated in 32-28 Ma old strata and are linked by conjugated relay ramps that control the development of latest Oligocene to early Miocene syn-rift 2 basins trending N-NNW.

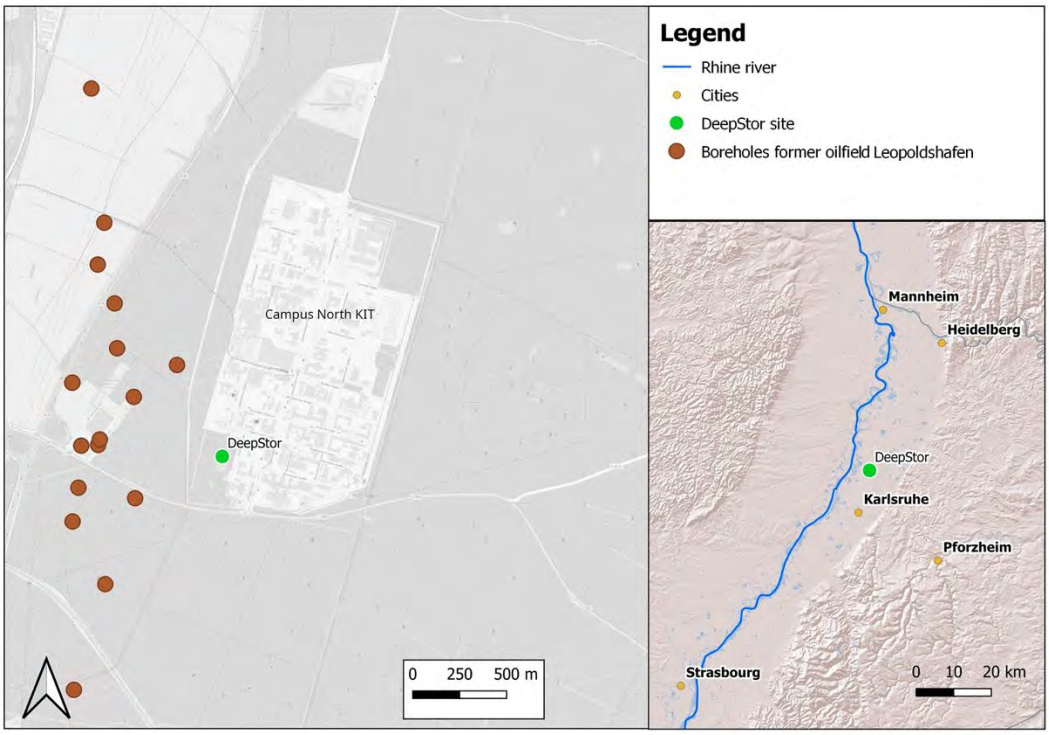

Figure 1: Location of the DeepStor site in the central segment of the NNE trending Upper Rhine Graben between Germany, France and Switzerland.

DeepStor is located in the hanging wall of the Main Eastern Boundary Fault. In the central graben, the Cenozoic sediments reach a thickness of up to 3,500 m (Geyer et al., 2011) and are subdivided into Pliocene to Holocene fluviatil siliciclastics that unconformably overlie late Eocene (Lutetian)

to early Miocene (Burdigalian) syn-rift sequences. These sequences were deposited in a generally low-energy environment under alternating marine, brackish, fluvial and lacustrine conditions and contain deposits of carbonates, sands, silts, clays, marls and locally intercalated evaporites.

The DeepStor site is adjacent to the eastern edge of the depleted Leopoldshafen oil field in the footwall of the Leopoldshafen fault. This NNE-striking normal fault (Wirth, 1962) is part of the Main Eastern Boundary Fault and exhibits a syndepositional normal faulting from the Oligocene to the early Miocene, with the synrift layers dipping shallowly to the NE (Schad, 1964). A total of around 188,000 tons of oil were extracted from several, a few meters thick, fine-grained, mica-rich calcareous sandstones, which are intercalated with hundreds of meters thick, mostly marly Meletta and Bunte Niederrödener layers (Wirth, 1962; Böcker, 2015). The Meletta layers are part of the Froidefontaine Formation and were deposited under marine conditions during a regressive phase. They show coarsening upward trends in the late Rupelian (ca. 29 Ma), followed by a transgressive phase in which the finer upward trends in the upper part of the Meletta strata merge into the marly, still marine to brackish Cyrena strata. These strata show a further phase of regression and further development into the fluvio-lacustrine Niederrödern Formation (Schad, 1962; 1964; Grimm et al., 2011; Pirkenseer et al., 2011; 2013).

The Leopoldshafen oil field was explored by around 20 boreholes to a depth of approximately 3,000 m. The corrected temperature data (Sauer et al., 1981), which yield about 100 °C at a depth of 2,000 m, include measurements in the Meletta and Bunte Niederrödern sandstone layers. Maximum temperatures of 170 °C at a depth of about 3,000 m are reported from the Leopoldshafen-20 borehole.

3. Numerical Modelling Of Heat Cycling

The numerical modeling of optimized heat cycling between the deep fractured reservoir and the porous reservoir at intermediate depth through the surface is based on two individual 3D geological models (Schill et al., 2024). For the two sub-models, the flow and heat transport were calculated for various management scenarios using COMSOL Multiphysics® Finite Element software, version 6.0. The two models are numerically connected via a single node that represents the heat exchanger and connects to the district heating (Zwickel et al., 2022).

For the heat transport model, a Dirichlet boundary condition with a constant mean annual surface temperature of 10 °C is applied at the surface. At the lower boundary of the models a Neumann boundary condition of constant heat flux of 60 mW m^{-2} are used. The flow model simulates hydrostatic conditions with Dirichlet boundary conditions at the base and the ground surface.

3.1. Heat Extraction from the Deep Fractured Reservoir

The drilling target of the deep fractured reservoir is the Mesozoic branch faults in the hanging wall of the main normal faults. They are rooted in the crystalline basement, reach the base of the Tertiary units and show displacements of up to 100 m. Permeabilities are assumed to be elevated in the hanging wall due to the presence of a damage zone of up to 200 m. Comparable to the Soultz-sous-Forêts EGS project (Kohl et al., 2000), a mean permeability of the damage zone was estimated to be $1 \cdot 10^{-13}$ m^2 based on the temperature distribution in the Leopoldshafen-20 well. The full set of parameters used in the modelling are provided in Tables 1 and 2.

The calibration of the model is based on bottom-hole temperature measurements. Temperature adjustment was achieved by varying thermal conductivities, heat production rates in the basement, and basal heat flux.

3.2. Heat Storage in Porous Reservoir at Intermediate Depth

Following Stricker et al. 2020, the heat storage reservoir of the Meletta layers is accessed by horizontal injection and production wells at a depth of around 1,300 meters. The faults crossing these Tertiary formations are assumed to be sealed and thus limit the lateral extent of the reservoir. The low permeability and thermal conductivity of the cap rock insulate the sandstone reservoir.

Given the significant influence of permeability on the effectiveness of the reservoir, one variant was calculated with a reservoir permeability of $2.5 \cdot 10^{-14}$ m^2 (mean permeability of a well close to the modelled production well), where 5 L/s were injected and produced. The second scenario includes a permeability of about $7 \cdot 10^{-14}$ m^2 (Stricker et al., 2020), allowing extraction/injection rates of 10 L/s. The production/injection rates are defined via a maximum drawdown of < 400 m. Injection and production modeling was performed over a period of 10 years heating up the underground storage system to a plateau of performance according to Stricker et al., 2020.

Table 1: Hydraulic parameters used for the thermo-hydraulic modelling of the individual units of the two models, the deep fractured reservoir, and the porous reservoir for heat storage.

Unit	Permeability (m^2)	Porosity (%)
Tertiary marls	$1 \cdot 10^{-18}$	15
Tertiary sandstones	$2.5 \cdot 10^{-14} – 6.6 \cdot 10^{-14}$	15
Jurassic/Keuper (claystones)	$1 \cdot 10^{-18}$	15
Muschelkalk (limestone)	$5.9 \cdot 10^{-15}$	2.7
Buntsandstein (sandstone)	$1 \cdot 10^{-15}$	3
Permian (conglomerates/sandstones)	$1 \cdot 10^{-16}$	5
Basement (granite/metamorphic units)	$5 \cdot 10^{-16}$	5
Damage zone of faults	$1 \cdot 10^{-13}$	15

Table 2: Thermal parameters used for the thermo-hydraulic modelling of the individual units of the two models, the deep fractured reservoir, and the porous reservoir for heat storage.

Unit	Heat conductivity ($W\ m^{-1}K^{-1}$)	Heat capacity ($MJ\ kg^{-1}K^{-1}$)	Heat production rate (μWm^{-3})
Tertiary marls	1.4	2.4	0.0
Tertiary sandstones	2.5	3.2	0.0
Jurassic/Keuper (claystones)	1.4	2.4	0.0
Muschelkalk (limestone)	3.2	2.2	0.0
Buntsandstein (sandstone)	3.3	2.2	0.3
Permian (conglomerates/sandstones)	3.3	2.2	0.9
Basement (granite/metamorphic units)	3.25	2.2	0.9-2.13
Damage zone of faults	3.25	2.2	0.9-2.13

4. Results

Figure 2 shows the undisturbed formation temperatures down to a depth of 8,000 m resulting from a temperature model that accounts for heat conduction, heat production and advection along the higher permeable fault zones.

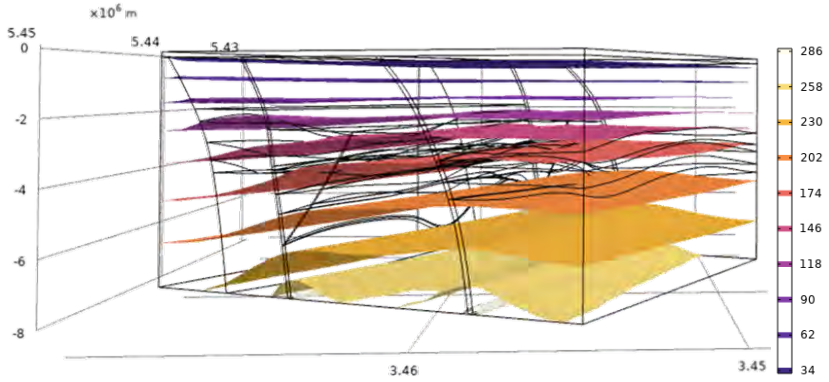

Figure 2: Isotherms in deep underground of the DeepStor site. Black lines outline the sedimentary layers and major faults.

The simulation of a geothermal doublet with a 1,000 m long open hole section in the Muschelkalk, Buntsandstein and Upper Permian Formations and a production rate of 25 L/s that the differential pressure on the main faults remains below 2 MPa. The production temperature at the well head is

approximately 180 °C. About 9 MW thermal output was calculated by the modeling including a buffer for uncertainties and heat losses. In the following section, we model how the expected excess heat can be stored at intermediate depth. Figure 3 shows the pressure and temperature development in the Meletta reservoir for flow rates of 10 L/s and a pressure limit of < 2 MPa at the major faults. After 4 years of operation the target recovery temperature of 110 °C is fully reached.

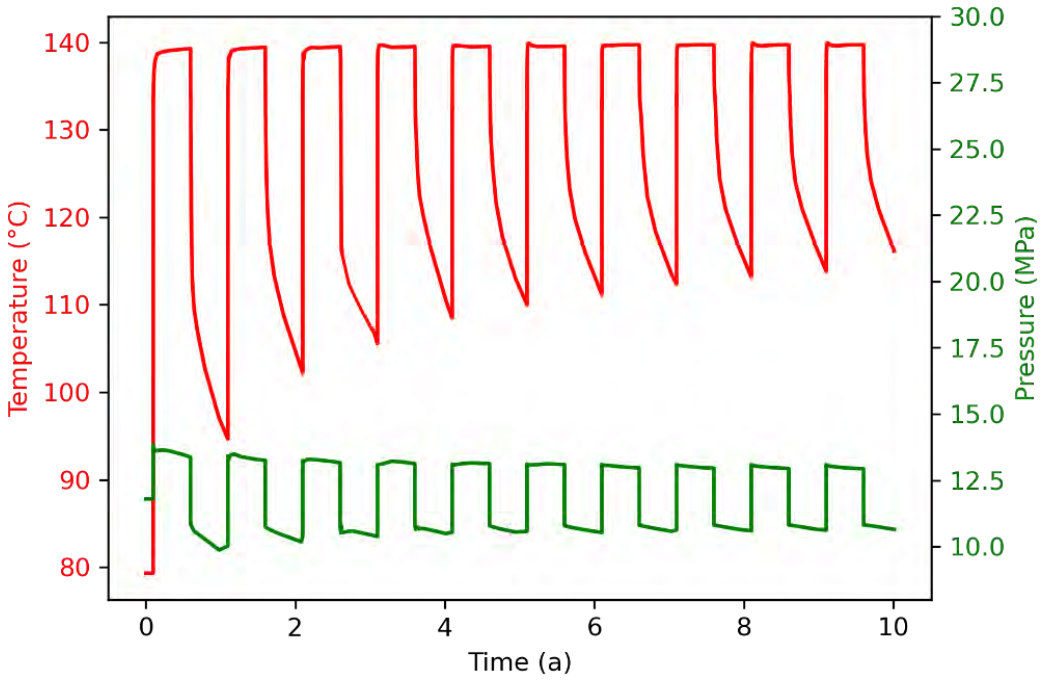

Figure 3: Temperature and pressure evolution during 10 years of operation of the DeepStor reservoir.

5. Conclusion

The storage scenarios are based on a continuous (8000 h) and low-risk (at 25 L/s) heat extraction from the deep fractured reservoir at a thermal load of 9 MW_{th}, which results in an available thermal energy of 72 GWh_{th}. Compared to the total demand of 80 GWh_{th}, which is mainly required during the heating period, this means an overproduction of 21 GWh_{th} during the summer period, which is to be stored in the porous reservoir at intermediate depth. At this point, it appears that approximately 65% of the heat demand can be covered by the deep fractured geothermal system.

With the aim of technically increasing the climate-neutral heat supply in the district heating network, two scenarios of high-temperature heat storage with different capacities are compared in Table 3. Scenarios 1 and 2 assume a low and high permeability of $2.5 \cdot 10^{-14}$ m^2 and $6.6 \cdot 10^{-14}$ m^2, respectively and work with flow rates of 5 and 10 L/s, respectively. When considering one storage doublet, the capacity of the storage system can reach approximately 4.5 GWht at a pumping rate

of 5 L/s and 9 GWht at 10 L/s. With two storage doublets, an 8-20 % of the heat demand can be added to the 65% expected from the deep fractured system.

These results show that the proportion of carbon-neutral geothermal energy at KIT Campus North can be increased from 25 % in a scenario that only takes base load heat into account to around 85 % by storing the excess heat. Assuming realistic costs for the realization of such a plant, (i.e., about $45 million USD or € for access to the deep fractured system and an additional $8 or $15 million USD for one or two doublets in the porous reservoir at medium depth and operating costs of $1 million USD per year), we have calculated heat costs of 3 cents per kWh, which is in the range of heat from natural gas today.

Table 3: Thermal parameters used for the thermo-hydraulic modelling of the individual units of the two models, the deep fractured reservoir and the porous reservoir for heat storage.

	Scenario LOW storage capacity (25 mD, 5 L/s)		Scenario HIGH storage capacity (70 mD, 10 L/s)	
	GWh per yr	% of the total heat demand	GWh per yr	% of the total heat demand
Heat demand at KIT-Campus North	80		80	
Available energy from the deep fractured system at 25 L/s	72		72	
Direct use	51	64	51	64
Storage doublet 1	4.5 (186 days)	5.6	9.1 (186 days)	11.3
Storage doublet 2	2.5 (186 days)	3.1	7.3 (130 days)	9

Tribal Communities

Indigenous Participation in Geothermal Projects: Learnings from Aotearoa New Zealand

A. Blair[1], M. Climo[1], A. Campbell[1], L. Lovell[2]

indigenous, New Zealand, stakeholder engagement, business strategies, investment, geothermal

ABSTRACT

Māori, Aotearoa New Zealand's indigenous people, have a recognized and powerful constitutional role in New Zealand society, and a critical and increasing role in the national economy. Since the early 1900s, access to Māori owned land and the geothermal resource beneath, has been sought for power generation. Māori and their organizations have participated in a range of ways in such developments, from landlords to equity owners, providing substantial returns for Māori whanau (family groups) with commercial interests in these projects.

But Māori-owned businesses are not only motivated by financial outcomes; they are also driven by the tikanga (philosophies and principles) inherent in Māori belief systems. Financial goals must be balanced with social, environmental and cultural aspirations. Creating wealth is not seen as an end in itself. Māori are driven to invest in projects that provide intergenerational prosperity, and to care for the sustainability and health of the resources and environment they are responsible for. This core principle of 'kaitiakitanga' (guardianship) strongly aligns with geothermal reservoir management necessary for long-term (30+ years) sustainable commercial operation, the decarbonization of manufacturing, and catalyzing economic development and employment opportunities. The social benefits of these projects (including electricity security) then extend more broadly to the local communities and the region within which they reside.

This paper provides an actionable guide for indigenous groups on how to participate in geothermal projects, beginning with critical internal pre-work before engaging with developers. It is also for developers to grow their knowledge and capacity to effectively and appropriately engage with indigenous groups.

1. Tīmatanga kōrero | Introduction

E tū ki te kei o te waka, kia pakia koe e ngā ngaru o te wā

Stand at the stern of the canoe and feel the spray of the future biting at your face

Māori have a domestic resident population of 978,246 ca. 19.6% of the general population (Statistics NZ, 2024). Demographically, the Māori population is relatively young, with 70% aged less than 40 years compared to 50% for non-Māori. Importantly, the Māori population is growing at approximately more than triple the rate of non-Māori (Statistics NZ, 2024).

The Treaty of Waitangi is New Zealand's founding document. Signed on the 6th February 1840, the Treaty is an agreement made between the British Crown[1] and Māori rangatira (chiefs) to found a nation state and build a government in New Zealand.

Referenced in Acts of Parliament, and acknowledged as a part of New Zealand's common law, the Treaty reflects the partnership contemplated between Māori and Crown. Set up by the Treaty of Waitangi Act 1975, the Waitangi Tribunal is a permanent commission of enquiry that makes recommendations on claims brought by Māori relating to Crown actions that breach the promises made in the Treaty of Waitangi.

Traditional Māori social structures consist of Iwi (tribes), Hapū (sub-tribes) and whānau (extended families). They are held together by kinship with each other and a shared common ancestor.

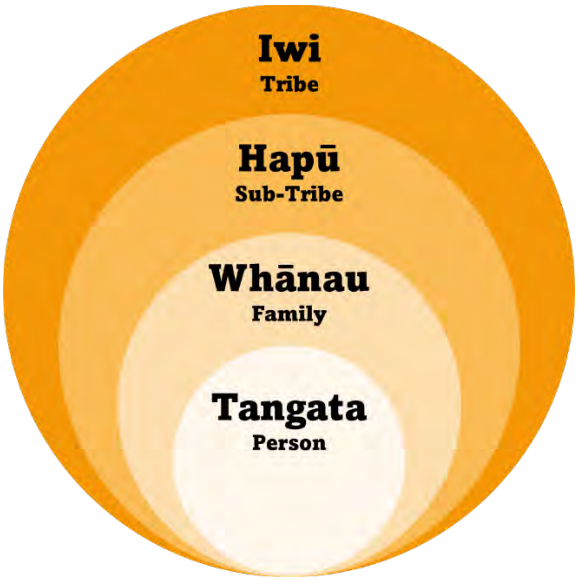

Figure 1. Māori social structures.

Māori-owned businesses are not only motivated by financial outcomes, they are also driven by philosophies and principles inherent in Māori belief systems i.e. they need to balance financial goals with social and cultural aspirations. Creating wealth is not seen as an end in itself (Blair *et al.*, 2018).

A core tikanga is the principle of 'kaitiakitanga'; the exercise of guardianship, of natural resources such as the land, sea and waterways, as well as flora and fauna and of people. Kaitiakitanga requires that sustainability and environmental protection is valued and prioritized. As kaitiaki (guardians of natural resources), those in leadership roles are responsible for protecting (and/or growing) resources for future generations. Kaitiakitanga reinforces why Māori are less likely to sell land, especially where they are mana whenua, that is, where they have customary authority.

[1] The meaning of "the Crown" varies according to the context in which it is used. The premise is that it was the Crown, through Queen Victoria, that signed the Treaty of Waitangi with Iwi Māori. This notion of an ongoing pact derived from that partnership of Māori and Crown has remained with the reference "Crown" transferred to subsequent New Zealand Governments as executive and their administrative arms (e.g. public Service Agencies and Departments).

'*Māori land is not simply a commodity*' (Savage, 2013). Shares in Māori freehold land are rarely transferred, they are usually succeeded to through inheritance.

Reflecting their tikanga, Māori invest in projects that promise intergenerational prosperity, prioritizing sustainability and the well-being of their resources and environment. This perspective and philosophy aligns with geothermal resource development. Their investment strategies focus on long-term returns rather than short-term cash flow, which complements the extended operational lifespan of geothermal power plants (>30 years) and geothermal reservoirs (>100 years).

For international readers, Section 2 below provides a brief overview of how geothermal resources are managed in New Zealand, the constitutional rights of Māori, and how Māori land and assets are managed. For a more detailed review on these topics, readers are directed to Eru and Lovell, 2020.

Section 3 outlines pathways that Māori have taken to be partners in geothermal projects and operations in Aotearoa New Zealand.

Sections 4 and 5 provide advice for other indigenous groups and share lessons and learnings arising from Māori participation in geothermal projects and operations, beginning with critical internal pre-work before doing due diligence on the geothermal landscape and its players.

2. New Zealand Context

2.1 A brief summary of rights to geothermal resources in Aotearoa

No-one can 'own' geothermal resources, but the government can manage them

'Ownership' of natural resources is a highly contentious area, and legal frameworks are ever in flux. The concept of geothermal resources being a sub-surface energy resource arose mid-twentieth century due to the development of engineering technology becoming available to access and harness the energy. Prior to this, any legal regimes in New Zealand were related to the geothermal surface features and tourism; the Thermal Springs District Act 1881 and Scenery Preservation Act 1903 effectively ensured that the Crown (i.e. NZ Government) controlled geothermal areas. The Geothermal Energy Act 1953 created the resource 'ownership' approach still in use today.

Within New Zealand it is generally accepted that water (including geothermal water) is not "owned". The Crown however sets the method and manner by which geothermal resources are *managed,* effectively bypassing the question of who owns the resource. Currently, therefore, geothermal resource use is managed at a regional government level through the Resource Management Act (RMA, 1991) (Kissick, *et al.*, 2021).

Geothermal projects are 'water take' not 'mining'

While geothermal resources are not owned per se, the discharged fluid can be (by the consent holder; Barton, 2015). Likewise, built plant and the underground and surface infrastructure (e.g. wells, piping, other examples, etc.) are owned. Geothermal resources are treated similarly to natural water (rather than petroleum and minerals which are owned by the Crown) whereby volume

takes (t/day) are consented, and thus, there is no present royalty payment charge to the government for the extracted geothermal energy.

Landowners determine access to geothermal resources

While landowners do not own geothermal resources, permission from the landowner is required to access geothermal resources beneath their land. The landowner can defend their rights against an unauthorized intrusion (i.e. trespass). There is no depth at which an intrusion ceases to be trespass, including through the use of directional drilling. There is no rule that restricts the depth to which the owner of land can assert his or her rights to the land (Barton, 2015; Kissick *et al.*, 2021).

Kaitiakitanga is acknowledged in the regulation of geothermal utilization

Successive pieces of New Zealand legislation and governments have attempted to extinguish Māori customary title to geothermal resources. This has been argued in the Waitangi Tribunal and remains a matter of contention between Iwi / Hapū and the Crown.

Under the Resource Management Act, consent holders must have regard to the relationship between Māori, as kaitiaki, and the land. Statutory Acknowledgements (Kissick, *et al*., 2021) are the instrument within Treaty Settlements[2] used to acknowledge particular cultural, spiritual, and traditional associations of Iwi / Hapū with a site of significance, including geothermal fields, or resources identified as a statutory area. In practice, Iwi / Hapū whose traditional lands are located above geothermal reservoirs, and irrespective of whether or not they are the current owners of that land, may be included in resource consent (permit) consultation and decisions regarding utilization of geothermal resources.

2.2 A brief summary of Māori land in Aotearoa

Distinct from land owned by Iwi or Hapū through Treaty Settlements or other means, the land subject to Māori Land Court oversight and held under individual Māori ownership still constitutes a very small proportion of New Zealand's total land area. However, in the central North Island and at Ngawha in Northland, approximately 17 high temperature geothermal systems reside under Māori land and therefore the collective ownership of Māori landowners.

New Zealand's history of colonization resulted in a systematic process of sale, confiscation and fragmentation of Māori land. In pre-European times, Māori land was communally owned, based on traditional Māori custom. In this shared ownership model, there were no specific, identifiable share parcels or interests. After the signing of the Treaty of Waitangi in 1840 the Crown quickly obtained Māori land through acquisition or confiscation, utilizing a purpose-built Native Land Court, which subsequently became the current Māori Land Court. Eventually there was little land remaining in Māori ownership. From the 1950's various reforms attempted to improve the situation by giving the Māori Land Court a stronger focus on protecting Māori land, but this was

[2] Treaty Settlements settle Iwi (tribal) and Hapū (sub tribal) claims of breach by the Crown of the Treaty of Waitangi, which have been considered and accepted by the Waitangi Tribunal.

not without issues; legislation intended to protect remaining lands also created barriers to development.

Te Ture Whenua Māori Act 1993 (TTWMA) remains the Māori Land Court's guiding legislation. It seeks to balance competing objectives of retaining Māori land in Māori ownership with land development. However, Māori land generally has multiple owners and over time as owners decease, their descendants succeed to their interests. Thus, the number of owners of a single piece of Māori land increases significantly and fragmentation of Māori land ownership remains an issue. With this in mind, over time the emphasis of both the Māori Land Court and landowners has been to identify and use appropriate entities to enable collective management of and decision making over Māori land.

Under TTWMA, there are a range of models for individual landowners to hold their interests collectively (e.g. Table 2). For example, utilizing the trust model, trustees are the legal owners of the trust property, which they hold on behalf of the Māori beneficial owners. Where Māori landowners have sought a more commercial model, the TTWMA has provided for a Māori Incorporation structure, with a Committee of Management acting as governors on behalf of its Māori shareholders. See Section 2.3 for further discussion of structures.

Notwithstanding the structures however, there have been barriers to development of Māori land. Common problems encountered by Māori wishing to develop or use their land is described in Table 1.

Table 1. Six barriers to the development of Māori land (MLC, 2024)

BARRIER	SPECIFIC PROBLEM
Multiple ownership	This can lead to problems with obtaining agreement about land use and development, and also reduces the economic return to individual owners.
Governance and management issues	While appropriate management structures for the administration of Māori land may exist, there is a lack of expertise to plan and make decisions about administration.
Access to information	Data on the current use of Māori land is not comprehensive, and it is costly to obtain information on potential use of Māori land.
Access to finance	Multiple ownership of land makes it difficult to use land as security when seeking finance for land development.
Access to land	A large proportion of Māori land is landlocked, reducing the options available for its use and/or reducing the options to lease the land.
Rating of Māori land	Some local authorities are more determined than others to collect rates on Māori land. In cases of arrears, some local authorities have tried to sell the land or place charging orders on the land to recover outstanding rates.

2.3 Māori Organizations

As discussed above, there are governance options available to administer Māori land (Lovett & Eru, 2020). The most commonly used in geothermal developments are Māori Incorporations and

Ahu Whenua Trusts (or 'Māori Trusts' as they are often called). Some different examples of Māori organizations used in geothermal operations are noted in Table 2.

Table 2. Types of legal business entities with investment, shareholding or ownership in industrial scale geothermal development (Source: Climo *et al.*, 2022).

Type	Descriptor	Example
Ahu whenua trust	A common land trust, established under the Te Ture Whenua Māori Act 1993, designed to promote the use and administration of one or more Māori land blocks or general land owned by Māori on behalf of its owners.	Tauhara North No.2 Trust
Community Trust	A community trust, as outlined in their trust deed, with the trust able to hold shares in a Company on behalf of the Consumers and distribute to the Consumers in their capacity as owners, the benefits of ownership of the shares in the Company.	Top Energy Consumer Trust
Joint Venture (JV)	An alliance between two or more parties working to accomplish a specific task or project. Each partner retains their independence while contributing towards mutually shared goals. An incorporated joint venture is a limited liability company. Being a separate entity, the incorporated JV company owns the assets of the venture, enters into contracts, incurs obligations and liabilities, and makes profits or losses.	Unincorporated: Nga Awa Purua Joint Venture (Tauhara North No. 2 Trust & Mercury NZ Ltd) Incorporated: Rotokawa Joint Venture Ltd (Tauhara North No. 2 Trust & Mercury NZ Ltd)
Māori Incorporation	Māori incorporations are constituted by the Māori Land Court over one or more blocks of Māori freehold land provided that at least one of the blocks has more than two owners. They have the powers of a limited liability company and become the legal owner of any lands or assets vested in it.	Taheke 8C Inc.
Mixed Ownership Model Company	A company where the Crown owns at least 51% of the shares and no one other person owns more than 10% of the shares. These partly state owned are monitored by Treasury but are not state enterprises.	Mercury NZ Ltd
NZ Limited (Liability) Company	A separate legal entity liable for all legal and financial obligations. The liability of shareholders is limited.	Ngāwha Generation Ltd
Partnership	A partnership is when two or more people or organisations form a business. Partners set out in a partnership agreement how they share profits, debts and work. Partners are personally liable for all business losses.	Te Ahi O Maui Ltd Partnership (Eastland Group Ltd & Kawerau A8D Ahu Whenua Trust)
Private Company	A firm held under private ownership. Private companies may issue stock and have shareholders, but their shares do not trade on public exchanges, and they have no obligation to release a financial report every financial year.	Tuaropaki Power Company Ltd
Publicly Listed Company	Shares can be bought and sold, and the Company is required by law to annually publish a financial statement.	Contact Energy Ltd

3. Pathways to Participation

Meaningful active participation is a true partnership, which is mutually beneficial. It's not just about being informed or consulted. As described in Figure 2, social license and project acceptance increases when the community is playing a real role in the project.

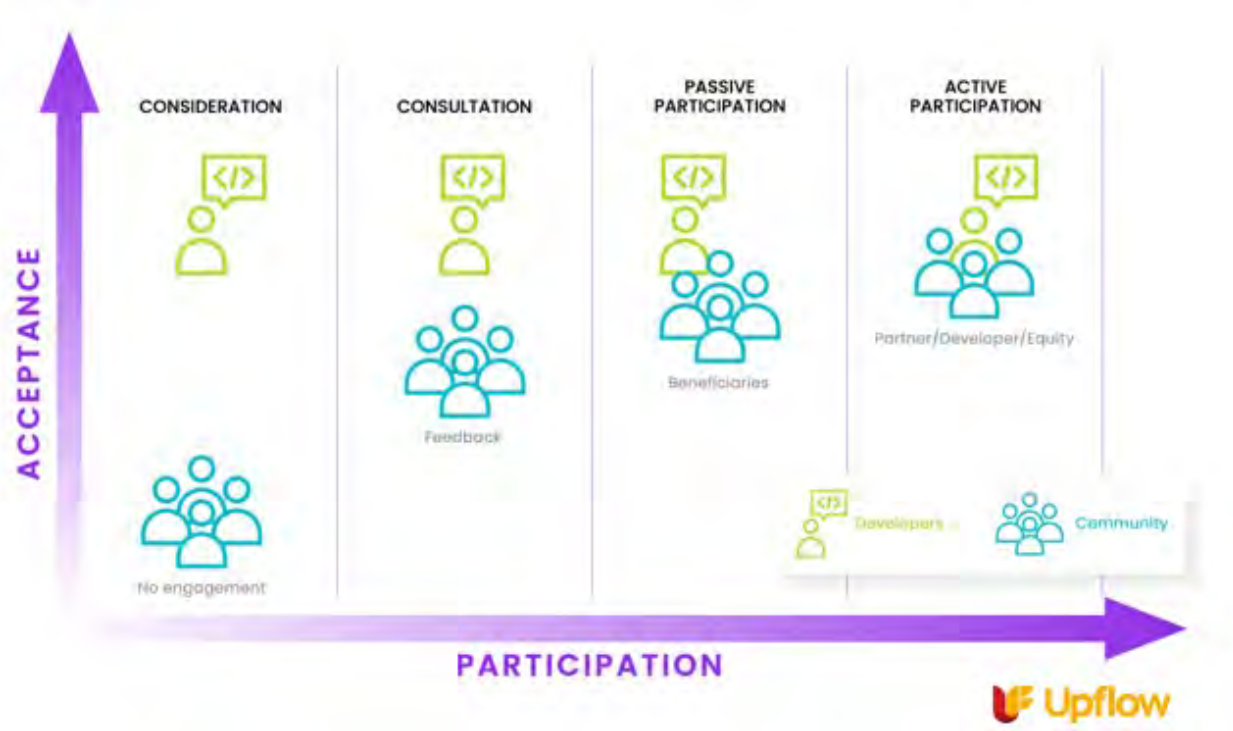

Figure 2. Relationship between participation and acceptance.

There are a variety of bespoke arrangements between private companies, public companies, community trusts and Māori organizations that own and operate large geothermal power stations and industrial scale direct use facilities in Aotearoa New Zealand (Climo *et al.*, 2022). Examples of ways in which Māori have been able to participate in geothermal developments, which varies by project, are outlined below.

3.1 Transfer of government geothermal assets to corporate entities

Geothermal assets (e.g. wells and infrastructure) developed by the Crown on Māori land through to the late 1980's were subsequently transferred out of Government ownership and into Māori ownership via a process of corporatization and deregulation of the New Zealand electricity sector in the 1990's.

Example: Kawerau & Ngāti Tuwharetoa Geothermal Assets

> The Kawerau Crown-owned steam-field assets were transferred to Mighty River Power through an agreement with the Crown in 2005 (Beehive, 2005) with the assets immediately on-sold as part of a commercial acquisition to Ngāti Tūwharetoa Geothermal Assets Ltd (NTGA). This was a commercial arrangement and not as redress under a settlement with the Crown (McClintock *et al.*, 2021).

NTGA supply steam and water to the TOPP power plant and supplementary steam to the Mercury KGL power plant, as well as supplying geothermal energy for processes including wood products processing, timber drying (Sequal Lumber, Carter Holt Harvey), fibre production (Oji), tissue paper manufacture (Essity) and dairy processing (Waiū) (McClintock *et al.*, 2020).

Figure 3. Kawerau Industrial Complex and businesses utilizing geothermal energy (McClintock *et al.*, 2021).

3.2 Equity for landowners

Some geothermal operations have brought together landowners with access to geothermal resources and experienced geothermal operators as development partners for electricity generation.

Example: Rotokawa & Tauhara North No2 Trust

Tauhara North No.2 Trust (TN2T) are an Ahu Whenua Trust within the rohe (region) of Ngāti Tahu – Ngāti Whaoa. They have 11,000 owners and beneficiaries and own 326 hectares of land in Rotokawa, Taupō. The Trust and people are kaitiaki of the whenua, Rotokawa geothermal reservoir, and the surrounding natural resources. At Rotokawa, the Trust landowners retain ownership of the land on which the two power stations were built (McLoughlin *et al.*, 2010).

In seeking to secure a long-term revenue stream for the benefit of their people, TN2T established a joint venture arrangement with generation company Mighty River Power (now Mercury). This structure has provided the Trust with the opportunity, from a low capital base, to raise their own finance for buying into the project to agreed levels. It also provided Mighty River Power with the ability to develop and operate the project in partnership with the Trust as resource owner who, through joint ownership, has closely aligned commercial objectives from the power project (McLoughlin *et al.*, 2010).

Separate agreements relate to the fluid supply and generation units (power stations):

- Fluid Supply: TN2T is an equal joint venture partner (50:50) with Mercury in the Rotokawa Joint Venture (JV). This JV owns the steam-field assets that supply geothermal fluid on agreed rate to three geothermal power stations: Rotokawa Power Station, Ngatamariki Power Station, and Nga Awa Purua Power Station.
- Power Generation: The Nga Awa Purua Power Station is owned by Mercury (65%), and TN2T (35%). The Rotokawa and Ngatamariki power stations are owned by Mercury.

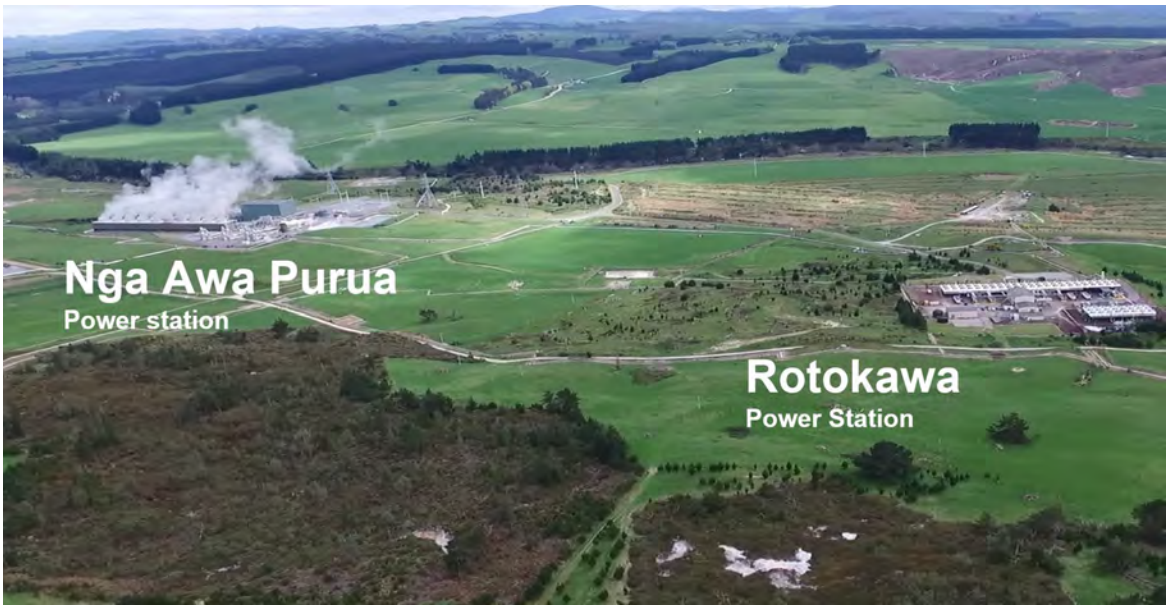

Figure 4. Nga Awa Purua and Rotokawa power stations at the Rotokawa Geothermal Field. Photo credit: Tauhara North No.2 Trust.

3.3 Partnering for direct use

Partnerships also occur with Māori landowners in the direct use of geothermal heat.

Example: Mokai and Tuaropaki Power Company

Since acquiring the Mokai geothermal investigation wells from the Government in 1996 (Menzies *et al*., 2001), Tuaropaki Power Company (Tuaropaki) has been an equity partner with Mercury in the Mokai Power Station (75:25).

Additionally, Tuaropaki are partners in, and supply heat to, a milk processing plant (Miraka), geothermally heated glasshouses (Mokai Gourmet), and the world's first green hydrogen plant (Halcyon Power, 1.25 MW). There are mutually beneficial relationships between the individual operations, for example:

1. The geothermal operation provides heat to the Miraka milk drying facility.
2. The biological residues from the milk drying process are sent to a worm farm, transforming this sludge into a highly valued fertilizer and soil conditioner known as vermicast, for use in agriculture, horticulture, nurseries, and recreation areas.

3. The vermicast is used in a native plant nursery, where plants are grown for riparian planting in the neighboring dairy farm operation for improved environmental performance.

Figure 5. Related operations at the Mokai Geothermal Field. (Photo Credit: MBC, 2024)

4. Internal Pre-work: Get your own house in order first

The first step towards participation in geothermal projects is not to engage with developers. There is a lot of internal pre-work that needs to be done before an indigenous group can have a meaningful conversation with a developer about participation in a geothermal project. Establishing leadership, decision-making processes, authority, legal structures and mandate to make decisions on behalf of the group needs to occur prior to any 'deal' or negotiation being discussed. It is critical to do this early and deeply to establish the 'right' foundation to provide a pathway forward – it is possible to change things later, but it's a lot harder to 'fix' something than to spend time early in the process to build a strong foundation for success.

4.1 Strategy

What is your group's vision and strategic plan for the future?

There must be a mandate from beneficiaries/owners to participate in geothermal development, and that mandate has to be sustained long term (as these projects can take decades to eventuate). This requires an indigenous group to know what they want and how they intend to operate. Identify up front what the priorities are and have a strong sense of who you are. This includes tikanga (protocols), but also the appetite for risk, priorities for investment, expectations about returns, when they might come and how they will be dispensed and managed.

Do we know what is important to us? What are our non-negotiables, for example the non-securitization of the land? What are we prepared to give up? Do our values align with geothermal projects? Is this really helping the future generations and succession planning?

Who do we want to work with and why? And, just as importantly, who do we not want to work with? This refers not just to developers, but also technical, financial, legal and governance expertise and advisers.

4.2 Leadership

Who are the champions? What kind of leader do you need?

The direction of ambitious future projects will differ depending on who is in charge, if they hold the vision and whether or not they are prepared to make, at times, decisions that will be challenged. These leaders may respond to a calling, or be volunteered, but it is critical that their personal vision and values align with the goals of the entity (e.g. trust, business) first and with the implementation of the project. Implementation must be in accord with the entity's, and its leaders', expectations because leadership is a long-term commitment and requires bravery.

In Māori culture, woman are often the leaders who bring people with them. This is why we see many women in critical enabling and influential roles in Te Ao Māori. Whilst they may not always have official titles, they certainly have strong influence upon outcomes.

Collective asset ownership will never reach a consensus so strong leadership is essential. Visionary leaders are required to manage the complexity of negotiating with family – because the people involved are tied to the same place and each other for the long-term. Conflict must be managed – it can't be avoided. This requires time and ongoing honest conversations where the participants keep pushing (peel the layers back) to get to the core issues.

Good leaders will see the multiple views and drivers of others, understand their positives and negatives, and put a plan in place to ensure (notwithstanding differing perspectives) that everyone can choose to join the journey. Leadership will often come with adversity, dealing with different perspectives on strategic direction, backlash on decisions, and critique on, for example, where/when to spend money now versus saving funds for future generations. Geothermal projects require significant investment in capital costs and expertise, but this is necessary for successful outcomes. Whilst the need for financial rigor is paramount, so too is the confidence needed to spend these large sums of money for the future good.

Everyone knows the disruptors within their own organizations. To avoid hostile takeovers, do your homework and hold yourself and these individuals to account. Understand the legal frameworks you and your Māori entity operate within and the limits – get good advisors and advice.

Some projects may require the same leadership to stay in place for longer than usual rotations to maintain continuity and achieve the early development goals. For example, TN2T had the same leadership (i.e. no elections) between 1994-2008 while the geothermal developments occurred at Rotokawa. Then, once the power station was operational, elections resumed. This was achieved by changing the trust order (deed) on two occasions (Note: this is not always legally possible).

During the different stages of geothermal projects, different thinking may be required i.e. in the early exploration phase, leaders need to be comfortable with managing significant risk and the unknown, whereas during power production and (the more predictable) operational phases, a different leader may be more appropriate. Understanding the leadership potential within beneficiaries/shareholders and building capacity and succession are also essential components of leadership within Māori, always thinking to what will be needed in the future.

4.3 Internal Legacy Issues

Does your organization have the legal power to engage in a development?

Indigenous land ownership, as noted in the sections above, differs from private ownership. Typically, mainstream lawyers and financial institutions don't understand indigenous systems and are risk adverse to what is seen as unusual, so you have to know your legal position well from the start and be able to confidently discuss and explain it to others.

Understand your legal rights, laws and legislation. Understand how this works in the regulatory space. Also, if you know how you want to participate in a geothermal development (e.g. equity, lease, royalties), are you legally/structurally ready for each of those approaches? Is your ship in order? Are your land titles appropriately in place? Is your shareholding or beneficiary register up to date? Do you have your systems in place for communicating with your whānau?

Sort out structural legal legacy issues. Where are the gaps? Can the organization actually do what it wants to structurally and legally within existing trust/entity powers and constitution/deeds etc? Internal legacy issues can hold up the future, because everyone is so busy looking at development they forget to resolve internal issues. This is very common and could delay projects for years.

Example

> A Māori organization interested in a geothermal project had a constitution that did not include the powers to establish geothermal activities on its land. Powers were limited to traditional agricultural activities, such as forestry and farming. This meant the Committee of Management did not have a mandate for geothermal development. In the absence of that power, the Committee could not enter into commercial geothermal arrangements and risked Māori Land Court review if shareholders sought a decision for deviation from the Incorporation's constitution. The Constitution was, therefore, subsequently amended. However, this took 12 months and caused delays to development aspirations.

Māori Trusts (more so than Māori Incorporations which are more commercially focused) are broadly risk adverse – they are holding assets for future generations to benefit from. In recent times, these trusts have been more likely to seek to separate risk to their assets by setting up subsidiary investment companies or entering limited partnership arrangements with developers. This however raises a number of questions such as: how do you ensure the appropriate people are appointed to those companies? How does the Trust ensure that the relationship between company or general partner (developer) and Trust (asset owner) is maintained, that delegations are clear, and reporting and oversight is robust?

Review the internal health of the organization to make sure that internal systems support the vision and can't be 'misused' to stall or disrupt advancement. Do you understand your own internal systems policies and culture? How can you use them? How could they be used against you?

Many Māori trusts and incorporations in New Zealand's Bay of Plenty also have had a legacy of external accounting firms holding custodial governance roles or positions of influence whereby they made the decisions and the Māori governors were treated as figureheads. Colonial / patriarchal structures such as these are being slowly dismantled so that Māori entities can manage their own assets. However, there must be a high level of commercial competency at the decision-making

table. If the required skills are not present amongst existing board/trustees, regardless if they are indigenous or not, well-governed organizations will need to bring in external and independent board members and technical advisors where required. The key is to balance self-determination with reliance on external expertise – you need both to be successful.

4.4 He Tangata (people)

The advantage of being connected to the whenua (land) is that, unlike corporate organizations, Māori will always retain their inherent connection to their traditional lands (whether they are legal owners of that land or not). This means institutional knowledge and capabilities can be maintained, succession appropriately planned, and longer-term outcomes are acceptable (i.e. significant benefits from projects may be realized long past the lifetime of those that negotiated agreements). And this outcome may be regarded as success – a strength that indigenous intergenerational philosophies can bring to a negotiating table for long-term projects.

Who are your people? What is your plan for engaging your people, especially the next generation, in the development activities?

The skills required will change during course of the project, and the organization will have to adapt and evolve. This provides long term employment and personal / professional development opportunities to grow capability.

Māori women are good at identifying future leaders and succession. Elders will often tell the younger generation what skills are going to be needed in the future (e.g. legal, technical, resource management) and encourage them to pursue these areas.

4.5 Know the resource

What do you know about your geothermal resource?

Find out everything you can about your geothermal system. What are your traditional stories and long held beliefs relating to the geothermal resource? Look in public repositories for data and publications. Ask and understand. Build and maintain your own information repository – don't rely on others to hold your knowledge.

4.6 Know your neighbors

Can you work with your neighbors?

Geothermal operators look for access to reservoir (depending on the consenting framework), but the boundaries of sub-surface geothermal reservoirs don't match the fence/trust boundaries on the surface. This means that partnering with your neighbors is a likely prospect in order to have a strong landowner voice when negotiating with developers and operators.

It is really difficult to determine a split for benefit sharing when the exact split of the geothermal resource is unknown. The benefit sharing does not have to be equal, but no-one should get something for nothing. Fringe/minority elements shouldn't have unrealistic power/expectations. Those with the most to put in have the most to lose. You should coordinate with your neighbors and organize a structure in which to operate prior to any engagement with a developer.

Be aware of the impact developers can have and what they have done in the past. They can sour relations between neighbors (perhaps by only engaging with one landowner to the exclusion of others) or may even avoid prospects where the landowner relations are too fraught (because they haven't sorted it out between themselves).

5. External Pre-work: Engage with developers

Once you've done all the activities in the Section 4, you are ready to do the pre-work to engage with developers.

5.1 Trusted Advisors

Who do you trust? What skills or insights are missing from the leadership table?

Good advisors are critical. It's important to identify current and future gaps in knowledge, context, insights and capability. It's not only essential to find people and organizations that can supply this expertise, but also to have aligned ethics and values so you can build strong trusting relationships that can withstand being tested over time.

Geothermal utilization is deeply complex and ongoing management of successful operations requires the ability to make decisions in uncertainty. Unlike predictable factory environments, geothermal subsurface and surface operations require constant and agile decision-making frameworks to optimize outputs. Reservoir, steam-field and power production assets and operational decisions constantly interfere with the performance of each other – to manage these projects requires highly trained specialist teams. Therefore, Māori groups must have access to technical insights to provide context for decision making. This may be achieved by internal hiring, contracting external consultants/advisors, or through an independent board role. Either way, all trustees/governors should increase their geothermal literacy prior to and during geothermal developments.

5.2 Due Diligence: Geothermal Operator/Partner

Understanding the organization(s) you plan to engage with is a first step to understanding their purposes, powers and capacity to work with you. Are they willing to learn what's important to you? Who are the people that are leading the organization?

Study their track record. Do they have history you should know about? Do they have a good record in their dealings with other indigenous or community groups? Talk to those who have partnered with them. Some developers/operators can have both good and bad track record. This is subjective – it must align with your values. Have they changed recently? What is their future commitment?

Some geothermal resources have changed hands, and operators often change names and legal structures. Look into these changes and understand the 'real' story. Past behavior may leave both positive and negative impressions. Is this history remembered? Trace back the full history of organizational behavior to ensure you are comfortable with partnering.

There are many examples of 'land banking' whereby organizations secure land and rights to geothermal resources and then do not develop them. This can be for a variety of reasons and sometimes over long periods of time. Having a good agreement (see Section 5.4) that stipulates

investment requirements and timeframes for when activity must occur is important to avoid these situations.

Characteristics of a good geothermal development partner include:

- **True partnership** – respect means treating the indigenous group as a serious commercial entity, important to the success of the project.
- **Understands indigenous frameworks** – good partners don't expect you to teach them about Māori concepts. They recognize that values and barriers are not the same.
- **Respect the taonga (treasure)** - tikanga and the geothermal reservoir is the key concern for Māori groups. This is the resource they have to care for as kaitiaki – the power station on the surface will come and go but the resource will remain (if well managed).[3]
- **Meaningful participation is recognized** through a variety of equity and benefit options in agreements. Land and resource access are acknowledged as having real and tangible value. Provide opportunities for the indigenous group to participate in the project at a level that they want. Options are the rights to increase equity (%) position to a max level at certain times over the power plants life, based on fair market value, with rules around timing and excising.
- **Sustainability is core practice** – evidence of well managed resources for sustainability, good environmental track record, good internal policies and procedures and culture. Any agreement must talk to the health of the reservoir at the end of a power station project.
- **Staff are well regarded**, and they have worked for the company over a long period of time. The geothermal industry is a small industry, and individuals are well known.
- **High transparency** – the developer is open with challenges, issues and opportunities, shares information, and provides greater insight when asked.
- **Good communicators** are developers who have regular engagement with the indigenous group. This can be informal or formal channels, including structured regular meetings, informal chats, briefings on key upcoming investment decisions, etc.

Most importantly, indigenous groups don't want to spend the next 30 years convincing a geothermal development partner of their value. If the developer can demonstrate behaviors and real-life examples of the above thinking and actions, and put pen to paper on this basis, you may actually end up with an arrangement that meets both indigenous values and respects the structures you need for long term partnership.

[3] Examples of splitting access and utilization of the resource via separate fluid supply agreements and power station ownership has in some instances ensured that the Māori landowners interest in the reservoir are maintained. See the TN2T example in Section 3.2. Equally, other Māori entities have sought other arrangements to ensure their taonga is protected.

5.3 Funding Structures & Systems

Systems can be used to accelerate or stop development, to provide protection or to undermine authority of Māori landowners. We see this in the use of the RMA, the Māori Land Court, as well as through relationship structures.

Understand what legal structures are possible. Because of the high costs of development for a power station, parties focus heavily on the negotiation of building and operating power stations. This includes funders, i.e. banks, investors etc. However, the geothermal reservoir will last longer than the surface assets. Explore the structures that best suit a long-term vision and your values. Mainstream does not always mean best.

A point of change in New Zealand landscape that recognized a legal structure with more than one owner and the equity in the resource occurred during Tuaropaki Power Company's initial project to build the Mokai 1 geothermal power station. This was 100% debt financed by Westpac Bank (McLoughlin *et al.,* 2010; Menzies *et al.,* 2001), the first financial arrangement of its kind in New Zealand. Existing wells drilled by the Crown proved the resource and provided sufficient steam for the project's technical and economic feasibility to be demonstrated without further equity injection, and state-owned generation company Mighty River Power (now Mercury) held the power offtake agreement (McLoughlin *et al.,* 2010).

5.4 Good Agreements vs Bad Agreements

There isn't one perfect, 'right' legal agreement for participating in a geothermal development. But there are Good Agreements and Bad Agreements.

Good agreements are fair and equitable, acknowledging the respective values of the parties, and they will have a level of future proofing (and thus respond favorably to changing future scenarios).

Developers and operators may utilize changing entities and structures, based upon commercial expediency, and where projects no longer fit within their values or ethos they may dispose of those interests. In contrast, Māori landowners cannot leave the land or the geothermal resource; both are "taonga tuku iho" – eternal treasures.

Māori landowners are constant. This consistency, and therefore inability to implement the standard business solution to a failed relationship or partnership of sale, requires careful consideration and differing legal solutions when documenting developer/Māori entity partnership arrangements. A good analogy is sharing a house! Indigenous groups can't leave the house, so we need to ensure it is comfortable and we have to have the ability to review our tenancy agreements with the flat-mate/spouse and to ultimately divorce if need.

Examples of bad agreements are those which:

i. don't value your contribution or knowledge,
ii. sit on the asset without implementation (land banking) or
iii. fail to future proof the relationship.

They may lock in for long timeframes, often without meaningful financial or other recompense, and then don't allow an exit when you want/need to.

Contracting is about hoping for best but expecting/preparing for the worst. You have the most leverage and power at the beginning of the contract negotiations (assuming your legislative and constitution rights are supportive), so use this time to build strong legal arrangements that reflect not only the relationship at the start, but also the evolving relationship over the long term and ultimately, should the need occur, at termination. You can't easily change things later. Get it right the first time so you (or more likely your children or grandchildren) are not regretting your decisions later.

5.5 Time is an asset

Use time horizons to your advantage. Māori will utilize their land and resources for the benefit of future generations, so must diversify on site to increase benefits and reduce risk. This means being innovators, including, for example, not only direct use but in indirect use of geothermal heat. NTGA and Tuaropaki lead the way in large scale direct and indirect use in New Zealand and are focused on more than electricity production.

Operators come and go. Consents expire. But the resource and the tangata whenua (people of the land) are forever. Operators are focused on short-term returns for their shareholders, so commercial frameworks tend to be short-sighted.

This means that Māori can structure arrangements differently, because investment now doesn't have to be realized in the short term. Māori can outlast some industries. This might look like an option to take on the geothermal plant / operation at the end of an agreed term. So long as there are legal mechanisms in place to ensure the developer doesn't over exploit the resource or not maintain the plant, Māori groups can inherit assets in the long term which will generate many more years of revenue. Note that geothermal assets can become a burden at the end of their lives, so it's imperative to understand the true cost to maintain and utilize these assets prior to any agreement.

Longevity in location also means that Māori can also outlast market trends/cycles. When the interest in geothermal is high there are more opportunities and choice for selecting partners. Use time as leverage to get what you need for your people. You have more time leverage than most.

There is a constant tension within indigenous groups between spending revenues now to make the lives of current owners and beneficiaries better and investing/saving for future generations to ensure wealth and prosperity. Whilst there are tools to help consider this, it really comes down to the values and vision of the group.

5.6 Demand Respect

Be intolerant of bad partners, notwithstanding if you are the minority in the financial and equity relationship. The land and the resource are in your control and a developer can do nothing without both, and therefore you. It takes bravery to sit at the table – demand the space and then grow into it.

Your mana (authority and status) should be meaningfully acknowledged by a development partner and they should be willing to support you, and to have the structures and processes in place to ensure that you and your entity can participate. Meetings should be board chair to board chair, despite different size organizations.

Remember: Big opportunities can be turned down if they don't fit your values and vision. You have time and it's better to wait than to participate in unhealthy relationships. Geothermal projects are 30+ year relationships, choose wisely.

6. Whakamutunga | Conclusion

Te tū, ki te hoe,

Puritia, kia mau ki tō ngakau.

Whāia ngā whetū,

ki ngā hau

ki ngā au o te moana,

hoea whakamua.

Tihei mauri ora.

Seize the paddle,

hold it firmly to your heart.

Follow the stars,

with the winds,

with the currents of the ocean,

paddle forward.

Kuputaka | Glossary

Te Reo Māori Terms used in this paper.

Term	Description
Hapū	A group of a Māori people or community connected by whakapapa (genealogy). Hapū sometimes are sub-sets of Iwi (tribes) and in other instances they are self-determining groups in their own right.
Iwi	An extended kinship group, tribe, often refers to a large group of people descended from a common ancestor and associated with a distinct territory.
Kaitiaki, kaitiakitanga	Guardian of natural resources and the act of guardianship; principle of intergenerational sustainability and the practices to achieve it
Mana	Prestige, authority, status
Mana whenua	Customary authority; territorial rights
Māori	The Indigenous peoples of Aotearoa New Zealand
Mātauranga Māori	Knowledge, culture, values, and world view held by Māori
Rangahau	Research; to seek, search out, pursue, research, investigate.
Rangitira	Chief
Reo	Language
Rohe	Region
Tangata whenua	People of the land
Taonga	Treasure, property, asset
Te Ao Māori	Māori world views
Tikanga	Correct procedure, custom, practice, protocol - this customary system of values and practices has developed over time and are deeply embedded in the social context
Whanau	Family group
Whenua	Land

Ngā mihi | Acknowledgements

We would like to acknowledge Dr Saddiq Zarrouk and Dr Eylem Kaya from the University of Auckland for their leadership and encouragement of this work and ensure it is a valued aspect of the wider research project “Reversing Carbon Emissions in the Geothermal Energy Industry: Template for Emission-Intensive Industries” (UOAX2211). We would also wish to thank the NZ Ministry of Business, Innovation and Employment for funding this project

ABSTRACT

In the Waiwhatu Project, we created five new kupu (words) in Te Reo (language) Māori (Indigenous peoples of Aotearoa New Zealand) relating to geothermal. This search for shared understanding was born out of difficulties experienced when trying to source meaningful relevant words in Te Reo Māori to define scientific terms used in geothermal research and development.

This pilot project created an opportunity to understand the practice of others. We listened to scientists explain useful technical concepts, relevant to earth sciences, geothermal and volcanology, and then interpreted these through a Māori lens into a shared language, bringing Mātauranga Māori (indigenous knowledge) and western science into one space. One of the new kupu is *waiwhatu* for geothermal, which means fluid from the core (heart of the Earth), not fresh water, but fluid woven through the inside of the Earth to the surface.

We share the process for developing, testing and sharing the new kupu. Seven learnings from using the Waiwhatu model were:

i. Embrace multiple world views
ii. Don’t rush
iii. Choose the right people
iv. Everyone must be a learner
v. No one owns the words
vi. Value outcomes, not outputs
vii. Be the leader you wish to see in the world

The true test going forward will be in the uptake and use of the words and concepts outside of our project team—that is when language truly exists in the world.

TUHINGA WHAKARĀPOPOTO

I te Whaimahi Waiwhatu nei, hanga ai mātou i ngā kupu hou, i ngā kupu e hāngai ana ki Te Ahi Tupua, arā, ko ngā mea ngāwhā. I ahu ake te whāinga nei i te uaua o te rapu atu i ngā kupu e tika ana mō ngā kupu pūtaiao no te ao o te rangahau me te whakawhanake i aua mea ngāwhā.

Ko tā te whaimahi tōmua nei ko te whakatuhera i te māramatanga ki ngā mahi a tangata kē. I whakarongo mātou ki ngā mātanga pūtaiao e whakamārama ana i ngā āria matua e pā ana ki ngā tikanga pūtaiao ā-nuku, ki te mātai ngāwhā, ki te mātai puia, kātahi ka whakamāori i aua āria me ngā kupu e hāngai ana ki tā tērā tuku, ki tā tērā tuku, e tūtakitaki ai te mātauranga Māori me te pūtaiao o te rātō, e kiia nei, ki te marae kotahi. Ko tētahi o aua kupu ko 'waiwhatu' – *geothermal liquid* – e mea nei ko te wai no te whatu o te ao, ehara kē i te wai māori, engari ko te wai e rangā ake nei i te whatu o Papatūānuku ki te mata o te whenua.

Ko tā mātou ko te whākī i ngā tikanga o te whakawhanake, o te whakamātautau, o te tohatoha i aua kupu hou. E whitu ngā akoranga matua i puta ake i te tauira Waiwhatu nei:

i. Kia tuhera ki ngā tirohanga rere kē o te ao
ii. Kei whakateretere
iii. Whirihia ngā tāngata e tika ana
iv. Me huri ngā tāngata katoa hei ākonga
v. Ehara nō tētahi te mana o ngā kupu, engari no te kupu ake
vi. Uaratia atu ngā putanga i ngā whakaputanga
vii. Kia rite te tangata ki te kaiārahi e tika ana mo te ao

Ko te tino putanga mō ngā tau e whai nei, ko te mau me te kōrero i aua kupu nei me ngā āria e hāngai ana i waho atu o tō mātou kapa—kātahi ka tūturu te noho o te reo i tēnei ao.

1. Tīmatanga kōrero | Introduction

Whaowhia te kete o te mātauranga
Fill the basket of knowledge

1.1 Māori and geothermal resources in New Zealand

Geothermal activity is found all over the world, and each culture has responded to it in their own ways. Aotearoa's central North Island hosts more than twenty world-class high temperature geothermal systems, making it one of the globally rare places where widespread geothermal development is economically viable and technically feasible. Geothermal energy is a critical component of New Zealand's future renewable energy portfolio as it transitions to a low-carbon economy.

Māori, have a recognized and powerful constitutional role in New Zealand society, and a critical and increasing role in the national economy, including future geothermal development (Blair et al., 2018; 2024; Climo et al., 2022). As landowners, investors and kaitiaki (guardians of natural resources), Māori will determine the use of geothermal resources and make influential decisions in how they are developed. The long-term nature of such projects requires a multigenerational approach to resource management, which aligns with Māori values and worldview.

In New Zealand, geothermal use is regulated through the Resource Management Act (1991) and is considered primarily as a water take (i.e. volume of fluid per day), unlike many other countries that provide for geothermal exploration, development and production under mining permits (Blair et al., 2018). Developers in New Zealand can seek and obtain geothermal consents for fluid take; however, to obtain land access, and access to geothermal resources beneath the land, developers must have permission of the landowner(s). This permitting framework provides for landowners to negotiate commercially beneficial agreements (Blair et al., 2018). Most geothermal fields have a commercial arrangement with a Māori-owned entity in the form of, (for example), ownership, fuel supply agreements, royalties and lease agreements (Climo et al., 2022).

Yet, geothermal research still has low representation of, and participation by, Māori. One of the barriers is an inadequate understanding of Mātauranga Māori within the broader geothermal science community; it is our hope that this paper will add to the growing understanding and discussion in this area. A glossary of Māori terms is included at the end of the paper.

1.2 Embracing different knowledge systems make for better science

Western science systems have a strongly defined structure and methodology for excellence. Whilst the focus is increased knowledge, in practice, alternative knowledge systems are often deemed inferior. This is demonstrated by the need for validation of indigenous knowledge using Western scientific knowledge or criteria, assumed to be the gold standard (de Beer, 2022). We should *"not … try to validate indigenous knowledge utilizing the processes of science, but rather to enhance appreciation and respect for the richness of indigenous knowledge and its merit."* (de Beer, 2022)

Therefore, work that seeks to grow indigenous knowledge, whilst not actively discouraged, often fails to be prioritized when funds are limited. And in research, funds are always limited.

However, if the true nature of science excellence is the pursuit of understanding, and that an idea or concept becomes accepted when it is challenged over time and still maintains, the ability to apply an indigenous knowledge lens to Western scientific thinking will surely increase the robustness of scientific ideas, concepts and understanding. *"Challenges to our general knowledge of the world around us are equally challenges to our scientific knowledge."* (McCain, 2016)

1.3 Māori language and geothermal research

Improved connection between Te Ao Māori ki te ao rangahau (the world of Māori to the world of research) was actively sought out in the *Geothermal: The Next Generation* (GNG; Chambefort et al., 2019; GNS Science, 2020) program. This New Zealand Government-funded research program (2019-2024) was established to explore and understand Aotearoa's supercritical geothermal resources, by going hotter and deeper into the Earth than drilled before (>4 km, >400°C).

GNG had an extensive technical workplan, encompassing geophysical, geological, geochemical investigations as well as numerical modelling. In tandem with the geoscience, the program also aimed to reduce non-technical barriers to the adoption of geothermal technologies, including overcoming regulatory hurdles and formation of an engaged stakeholder community. A specific goal was to facilitate more culturally responsive, inclusive and effective approaches for undertaking geothermal research and resource development.

Three key elements in its engagement approach (Climo et al., 2023) were:

i. Māori-first Engagement: interweaving knowledge systems and a multigenerational approach to resource management;

ii. Strategic Partnering: involving others to expand the impact for, and beyond, the science activities; and

iii. Authentic Communication: curating information and being open and honest about the unknowns.

Due to the long lead in times for the development and adoption of technologies and utilization of supercritical resources, and the increasing influence of Māori for legal and social license to operate with respect to natural resource management, Māori were a key stakeholder of this research program. The goal was to engage with Māori in a manner that provides future leaders and decision makers with the relevant insights to enable informed decision making for these projects.

External ‘push’ of scientific information in ways more palatable for Māori wasn’t the focus; often scientists look to educate others to understand their scientific concepts and views. Instead, focus was on broadening and growing the GNG science team’s thinking through exposure to a knowledge system different from their own.

1.4 The need for new language in geothermal

Science is often hard to relate to for non-scientists, as scientists use discipline-specific language, and concepts aren’t easily aligned to the natural knowledge systems of mātauranga (knowledge). Similarly, scientists find it hard to understand and relate to Māori concepts and thinking.

A search for shared understanding was born out of difficulties experienced when trying to source meaningful relevant words in Te Reo Māori to define scientific terms used in geothermal research. While there are traditional Māori terms relating to geothermal systems, the development of geothermal science has resulted in the borrowing or coinage of vocabulary internationally to keep pace. This needs to be matched in Te Reo Māori.

Many geothermal terms used are from specific languages, such as lahar from Javanese, pāhoehoe and a'ā from Hawai'ian, geyser from Icelandic 'geysir' and lava from Italian. Using English words as the basis for translation is also difficult – words driven by English often make no sense in Te Reo Māori. Instead, words and concepts are often cobbled together with literal translations for parts of words. For example, ngawha means hot spring, but is commonly used to replace the word geothermal.

Language is a fundamental tool to share knowledge, and a key barrier limiting effective engagement with Māori. Thus, the ‘Waiwhatu Project’ was developed to improve communication. It is important to note that our goal was to create new language for expression and use within Aotearoa New Zealand, not overseas. There is no expectation that the Māori words created will replace existing global terms for key scientific concepts.

2. The Waiwhatu Project

I orea te tuatara ka patu ki waho
A problem is solved by continuing to find solutions

The Waiwhatu model was developed through a pilot project, designed to take people on the journey of mutual understanding and collaboration through the development of shared language tools.

2.1 Project Goals

The project had two objectives:

1. Create five terms and basic concepts in Te Reo Māori that were meaningful and relevant.
2. Spread and use the new terms in the wider Aotearoa New Zealand geothermal community.

2.2 Team

The project team balanced a range of ages, genders, skills and experience:

1. Uenuku Fairhall (Ngāti Rangiwewehi, Waitaha): An expert Te Reo Māori linguist and fluent speaker who holds the underlying concepts of Te Ao Māori, including whakapapa, mātauranga, noa and tapu.
2. Aroha Campbell (Ngāti Tahu): A kaitiaki consultant who has deep experience navigating geothermal developments and Te Ao Māori.
3. Corey Rehua (Te Arawa, Tainui, Mātaatua): An early career Māori researcher and engineer, with a broad range of interests, who is on a reo journey.
4. Paul Siratovich: A senior scientist (geologist) who understands core geothermal concepts and terminology who is on a Te Ao Māori journey.
5. Andy Blair: A strong communicator, with a background in science and is comfortable in Te Ao Māori, who can help translate the concepts.

2.3 Methods

Selection of concepts/terms

A longlist of ideas was shortened by selecting five of the most common science words used when speaking about and describing geothermal energy and earth processes. These would be the ‘anchor’ words in sentences that other terms relate to.

The shortlist of terms selected were: geothermal fluid, magma, lava, reservoir, and enthalpy.

We deliberately chose common words (more likely to be used) but some are also hard to understand. For example, reservoir and enthalpy are hard concepts to grasp but are used a lot in geothermal research and industry.

Developing shared language

For each selected concept/term the following process was undertaken:

1. Scientific Concept

Scientists explained the technical concept, relevant to earth sciences, geothermal and volcanology. This included the genesis of the word/concept i.e., where it came from and why (including for example, the Latin basis for components of each word).

2. Word Use

The use of each term/concept was discussed. Examples of questions asked included:

- How is/will the word be applied in sentences?
- Does it have negative or positive connotations?
- When should (and shouldn't) the word be used?
- Who uses it?
- How does it work with other words?
- How is the word used within the science/geothermal community?
- How is the word commonly used in a lay context? e.g. the general public would call a geothermal surface feature a 'hot spring'.

3. Interpretation through a Māori Lens

The team discussed the concepts and interpreted them through a Māori lens, i.e. how the natural process of formation (e.g. reservoir, lava, etc) is thought about in Te Ao Māori. Examples of questions asked included:

- How is a reservoir made?
- What are the components?
- How do they behave and interact with the surroundings?

4. Kupu hou (new words)

A few Te Reo Māori kupu were proposed and the spelling and pronunciation clarified. These were tested against other words currently in use.

- How does the word sound? Is it pleasing to say? Does it sound good?
- Does the word flow in a sentence - spoken in Te Reo Māori and in English?
- Can it be used interchangeably in both English and Te Reo Māori sentences with ease?
- Is there an emotive response, and if so, what does it emote and is that consistent with the kupu?

Both the English and Te Reo Māori versions were defined and put into example sentences and the team practiced using the different sentences. The kupu were also informally tested on the Waiwhatu Project team's contacts.

3. Ngā Kupu Hou | New Words

Whāia te mātauranga hei oranga mō koutou
Seek after learning for the sake of your wellbeing

Table 1: The new kupu and their definitions.

Magma: Tokarewa [toh-car-reh-wah]	
Definition	Magma – Extremely hot molten or semi-molten rock that exists exclusively underground. **toka** - rock; **rewa** - to melt, to become liquid.
Example sentence	A surprise **tokarewa** pocket was found in Iceland during deep drilling project. He mea ohorere te kite iho i te pūkoro **tokarewa** i Tiorangi i te wiringa iho ki raro rawa.
Lava: Rangitoto [rung-ee-taw-taw]	
Definition	Lava – Molten rock that has been erupted at the surface of the earth, magma that has now become lava. **Rangitoto** - black lava, scoria; said to be the blood from Tamatekapua's nose.
Example sentence	Scientists use the term **tokarewa** for molten rock that is underground and **rangitoto** for molten rock that breaks through the Earth's surface. Whakamahi ai ngā mātanga pūtaiao i te kupu tokarewa hei tohu i ngā toka kua rewa i raro i te whenua, ā, ko te kupu **'rangitoto'** ina pākaru ake te **tokarewa** ki runga i te mata o te whenua.
Geothermal fluid: Waiwhatu [why-fuh-too]	
Definition	Geothermal fluid - The liquid present inside a geothermal reservoir that can flow to the surface naturally or through wells. Geothermal fluid is the energy carrier that allows the extraction and utilization of heat from the core of the earth. **Wai** - liquid, oil, etc; **whatu** - stone, core.
Example sentence	**Waiwhatu** is a hot and concentrated saline solution, having circulated through the very hot rocks of geothermal areas and are enriched with minerals. He mehanga kurutai kukū wera te **waiwhatu**, na te rērere haere i waenga i ngā toka wera rawa o ngā wāhi ahitupua, ā, nā reira hoki i kīkī ai i ngā kohuke.
Reservoir: Māpuna [mah-poo-nah]	
Definition	Reservoir - The section of a geothermal field below ground that is so hot and permeable that fluid can be economically extracted for the production of fluid and heat. This contains: (1) an aquifer or fracture network containing hot fluid, (2) a path through which cold water can flow to recharge the system or an input of magmatic fluid and (3) a source of heat. **Māpuna** - to well up, to form a pool.
Example sentence	The resource is not the power station on the surface but the **māpuna** in the subsurface. They are a treasure. Ehara te wharehiko i te rawa no runga i te mata o te whenua, engari ko te **māpuna** waiwhatu kē o raro iho. He tāonga ērā.
Enthalpy: Ngaohū [ng-ow-who]	
Definition	Enthalpy - the sum of the internal energy and the product of the pressure and volume of a thermodynamic system **Ngao** - strength, energy; **hū** - still, at rest
Example sentence	The specific **ngaohū** of geothermal liquid depends primarily on temperature. Hāngai ai te **ngaohū** ake o te waiwhatu ki te paemahana.

4. Kōkiritia ngā kupu hou | Sharing the new words

Mā mua ka kite a muri, mā muri ka ora a mua
Those who lead give sight to those who follow, those who follow give life to those who lead

Early Testing

July 2022 — A group of Māori postgraduate students, all ancestrally connected to the Central North Island of Aotearoa New Zealand, attended Reykjavik University's Iceland School of Energy for a 3-week Summer School course on Sustainability and Energy Systems. This was an opportunity for the group to test the kupu, as they were constantly being spoken to about geothermal, they had good Te Reo fluency and they were in a foreign country so could think about how others used the terms. Their overall assessment was:

"In the end, we all collectively agreed that these kupu do effectively support bridging the gap between science and Te Ao Māori."

Launch

November 2022 — Delivery of project report to GNG program team.

February 2023 — Corey Ruha, a member of the Waiwhatu Project team and Ngā Tauira o Rūaumoko, presented the project and shared the new kupu at the IAVCEI (International Association of Volcanology and Chemistry of the Earth's Interior) Scientific Assembly (Ko Rūaumoko e Ngunguru Nei) in Rotorua, New Zealand.

March 2023 — The kupu were shared using the GNG website and social media channels. This included the words, definitions, sentence examples, and accompanying audio files.

April 2023 — The New Zealand Geothermal Association shared the kupu and the Waiwhatu Project information (via a link to the GNG website) to their members through their monthly newsletter.

June 2023 — Engagement with GNS Science to share the kupu (GNS Science is a research institute with geothermal as one of its focus areas and was the lead organization for the GNG program).

July 2023 — To coincide with Geothermal Week, GNS Science posted one kupu per day to their social media channels. This was shared by other groups and was picked up by New Zealand news media.

5. Ngā Whakaaro | Lessons & Learnings

He waka eke noa
A canoe which we are all in with no exception
[we're all in this together]

This endeavor to develop shared language is not unique, and it may be a suitable test case and example for other areas and undertakings. As such, below are seven learnings gained from using the Waiwhatu model.

5.1 Embrace multiple world views

Learning a language is also learning a new culture and discovering new ways of seeing the world. Developing shared language is not the place to contest the relative validity of Western Science and Indigenous Knowledge systems, rather, it is an opportunity to build relationships, seek personal growth, to share understanding, and for innovation.

Whilst English is impacting the evolvement of the Māori language, it was important to be conscious of the need to protect, but not stifle, the scientific understanding as well as the linguistic integrity of either language. For example, English and Te Reo have different language structures – how a word is used in a sentence is different.

The process of looking at scientific concepts through a different lens helped us to know the concepts better, to be more thoughtful than just using the existing terms. For example, a question about how geothermal reservoir formed sparked a discussion about the parallels with a pregnant belly. We moved from a 2D/3D understanding of geothermal terms and levelled up our understanding, bringing in richness through adding time, values and beliefs.

We did not seek to rationalize nor to justify geothermal development in developing the new kupu. It was important that the new kupu did not reinforce a positive or negative association. There is no 'right' and 'wrong'. There is no universal truth – the team did not have to all come to one agreed position. This meant the team had to overcome their own biases, embrace the emotive response to the concepts, and explore the philosophical relationship between humans and the natural environment.

5.2 Don't rush

Learning a language, and developing shared language, is not just having an intellectual discussion about the translation. It's about becoming part of another culture. Don't try to translate. Instead, seek the essence of the relevant scientific terminology by discussing concepts and their deeper meanings.

It's better to focus on taking time to develop less words/concepts in depth, than rushing through many words lightly. We took time to explore, discuss and iterate. We didn't settle for the first 'close-enough' word. Proposed kupu were left alone to percolate and be tested by the group over weeks and months before coming back together to share thoughts and feedback.

5.3 Choose the right people

Ensure the team is diverse. Having a range of ages, genders and experience meant richer conversations and perspectives influenced the development of shared language.

Deduce who the best candidates are to model the language and improve exposure. For example, those who understand the geothermal science, communicate well, and have influence.

It was important to select team members that were predisposed to embracing new ways of working. They had to be willing to try to understand the science. They had to be willing to try to understand indigenous knowledge. Many people may say they're interested, and be genuinely interested, but when selecting team members, look for evidence of interest i.e. judge them on their actions and behavior. What have they done to lean into those interests already? For example, are they scientists who are taking language lessons, and trying to use the second language in their daily lives? Curiosity and commitment are key.

5.4 Everyone must be a learner

Learning a language is an act of bravery and vulnerability. It is important to create a safe space where team members can say something 'wrong' and make mistakes – a prerequisite part of learning a language! No-one can be defensive or protective; ego and pride must be put aside. There should be no hierarchy in the team, with everyone's mana (authority) mutually respected. Everyone in the team is both teacher and student, gaining new knowledge.

This high-trust environment allows team members to challenge each other on definitions, explanations and deeper meanings. Having non-specialist team members is critical – it pushes the 'experts' for a better explanation of something they intrinsically understand. The discourse discussion is more important than the words. The team iterates and optimizes until the shared meaning is reached. This will include open questions, and lots of seeking clarification. Many times, our team built an ideological visual picture of each concept, and then much of the discussion was spent clarifying with each other if they saw the same thing.

Consider colonization and personal histories in the relationships being formed within the team. This is not an academic exercise. If necessary, spend time recording the rules of engagement or how to deal with each other, at the start.

5.5 No one owns the words

It was important to choose Māori kupu that were not already in use or already associated with a particular region, dialect or place. The new words need to be usable across Aotearoa New Zealand without any perceived prior 'ownership' or expectation on their use.

Likewise, the new words are not 'owned' by the creators. Language is common to all who use it, and is a social, not individual act. Te Reo Māori is an ever-evolving language, and the true test of these kupu will be how widely they are used by others outside the test group. If the new words are not adopted, don't be afraid to go back and change them, or to adopt what becomes common use.

5.6 Value outcomes, not outputs

The true value of this work is not the new words – these are outputs, and short-term thinking. Some, especially those who are driven by financial measures of success, may perceive that creating five new words is not good value for money (i.e. because time (money) is required to do this well).

The value in this work is in the long-term outcomes: A proven process that works. Opening lines of communication and inviting diverse perspectives. The start of acceptance within New Zealand's geothermal research and industry that there is another way to view geothermal resources. Supporting Māori stakeholders to feel more included in the geothermal industry. It can be useful to start by asking the questions: *What is this worth to you? What is it worth to the wider industry and community at large?*

5.7 Be the leader you want to see in the world

Individuals are on a personal journey, and many people are not ready for work that decolonizes research and welcomes indigenous voices into 'science' discussions. It challenges the infrastructures that they have built their careers and thinking frameworks on. This means some people can't appreciate the problems and are unable to see the vision. We had this experience.

In order to realize the project, we had to put significant effort into convincing others that this work was important, including self-funding some of the time required. However, once the kupu were developed and shared (and a tangible product was available), many questioners (sceptics) became supporters and the work is now being extended. Adoption of the kupu brings credibility, and credibility converts the sceptics.

If you think developing shared language is important, then you are the right person to move it forward. Leading this work isn't about expertise, rank, titles or your role within an organization. Don't wait. Believe in yourselves and the project. You don't need permission.

6. Ā Mua | Next Steps

Ka mua, ka muri
Walking backwards into the future
[look to the past to inform the future]

This project has been extended and continues under the leadership of the Māori Strategy team at GNS Science, under a new name: Waiwhatu-Arawhata. Arawhata means "bridge", recognizing that the next stage of this journey is transitional. Their goal is to use and refine the Waiwhatu methodology in a workflow that sees more development of shared language.

Through their efforts, in June 2024 the Waiwhatu kupu was officially accepted in Te Aka (Māori dictionary) through a submission to Te Taura Whiri i Te Reo Māori (the Māori Language Commission).

Planned future initiatives (2024-2026) include:

- Promotion of the existing kupu at Geothermal Week 2024
- Develop ten more kupu, and launching them by mid 2025

- Presentations at conferences and workshops
- Delivery of an outreach event to socialise the new terms with Māori geothermal communities

7. Whakamutunga | Conclusion

Whāia e koe te iti kahurangi, ki te tūohu koe, me he maunga teitei
Pursue excellence – should you stumble, let it be to a lofty mountain

The Waiwhatu model was successful in demonstrating an effective methodology for developing shared language and the pilot project produced five new kupu. This approach is a reproducible and not limited to use in Aotearoa New Zealand.

Developing shared language is an opportunity to build relationships, seek personal growth, to share understanding, and for innovation. The discourse and discussion are more important than the words.

Our hope is that the geothermal community becomes a welcoming place for indigenous peoples to meaningfully engage, participate and lead discussions, debate and direction for future research and industrial developments.

Ngā mihi | Acknowledgements

Ehara taku toa i te toa takitahi, engari kē he toa takitini
My success should not be bestowed onto me alone,
it was not individual success but the success of a collective

The authors acknowledge input from many people in challenging our thinking, exposing our biases and assumptions, and teaching us. We are thankful to benefit from your insights and revision of this paper. Thank you to all who shared their experience and mātauranga with us.

We are grateful for the leadership and support from Dr Isabelle Chambefort, Program Leader *Geothermal: The Next Generation*, who gave us the opportunity to do this work. We offer the Māori Strategy team at GNS Science, who are leading the Arawhata Project, our thanks for their interest and continuing effort in this space.

Funding for this project was provided by New Zealand's Ministry of Business, Innovation and Employment (MBIE, contract C05X1904) for the "*Geothermal: The Next Generation*" research programme.

Kuputaka | Glossary

Te Reo Māori Terms used in this paper.

Term	**Description**
Kaitiaki, kaitiakitanga	Guardian of natural resources and the act of guardianship; principle of intergenerational sustainability and the practices to achieve it
Kupu	Word
Māori	The Indigenous peoples of Aotearoa New Zealand
Mātauranga Māori	Knowledge, culture, values, and world view held by Māori
Noa	Ordinary, unrestricted (free from the extensions of tapu)
Tangata whenua	People of the land

Tribal Land, Renewables, Geothermal, Oil wells, Sustainability

ABSTRACT

Native American tribes have a profound cultural and spiritual connection to the land, viewing it as a sacred entity rather than a commodity for profit. This perspective has historically created tensions with industries exploiting fossil fuels. The Pawnee Nation's Rural Energy Pilot Program (REPP), initiated in January 2024 and funded by a $2.6 million USDA grant, aims to transition the community towards sustainable energy.

REPP focuses on converting decommissioned oil wells into geothermal energy sources, integrating smart sensors for energy efficiency, promoting solar gardens, and encouraging electric vehicle adoption. This initiative addresses the environmental impact of abandoned oil wells while leveraging renewable resources to support community needs. The program emphasizes community engagement through education and workshops, ensuring an inclusive transition to sustainable energy and addressing environmental justice by targeting the ecological burdens faced by marginalized communities.

The project highlights the underutilized renewable energy potential of tribal lands, aiming to rectify energy inequalities and foster community resilience. Strategic partnerships and innovative models for integrating renewable energy with existing infrastructure underscore the collaborative nature of REPP, setting a precedent for sustainable land use and energy production on tribal lands. This paper presents the Pawnee Nation's Rural Energy Pilot Program that started in January 2024.

1. Introduction

In January 2023, Pawnee Nation was awarded the Rural Energy Pilot Program also known as REPP. The Rural Energy Pilot Program, supported by the United States Department of Agriculture (USDA), represents a transformative initiative focusing on sustainable energy and community empowerment. The Rural Energy Pilot Program is a 2.6-million-dollar grant from the USDA to help transform the energy landscape of Pawnee Nation for a cleaner, more sustainable future. Pawnee Nation is partnering with Pawnee Nation College, Pawnee Nation Housing Authority, Pawnee Public Schools, Indian Electric Cooperative, University of Oklahoma, and Tribuquent Corporation. Central to the program is the conversion of oil wells into sources of renewable energy, coupled with the integrating smart sensors in homes for energy efficiency. This three-year expedition also emphasizes solar gardens, electric vehicle adoption, and community engagement through education and workshops, ensuring an equitable transition to a sustainable future. Moreover, the Pawnee Nation's project stands as a testament to environmental justice, targeting the disproportionate ecological burdens faced by marginalized communities. By emphasizing the underutilized renewable energy potential of tribal lands, which encompass a significant portion of the nation's renewable resources, the initiative aims to rectify energy inequalities and foster community resilience. The formation of the Pawnee Nation Center for Rural Innovation and Strategy (PNCRIS) represents a collaborative endeavor, comprising a Housing Authority, a Tribal College, the Tribal Nation itself, an Electric Cooperative, a State University, and a Non-profit organization. This consortium is ever-evolving, consistently broadening its network to encompass additional local partners. Figure 1 shows the main partners of the project.

2. The Significance of Land to Oklahoma Tribes

2.1. Cultural Importance

For Oklahoma tribes, the land holds profound cultural significance, intertwined with their identity, heritage, and spirituality. Tribes view the land not merely as a resource but as a sacred entity, a living relative to be respected and protected. This deep connection to the land is rooted in traditions, oral histories, and spiritual beliefs, where the landscape, flora, and fauna are integral to cultural practices and ceremonies. The Pawnee Nation, for instance, has historically revered specific sites as sacred, conducting rituals and ceremonies that honor their ancestors and the natural world. This relationship fosters a sense of stewardship, where the protection of the land is paramount, ensuring its health and vitality for future generations.

2.2. Economic Importance

Rural areas are also economically vital for tribes. These regions often encompass vast tracts of land rich in natural resources, including agricultural lands, forests, and mineral deposits. For the Pawnee Nation and many other tribes, these resources have historically provided sustenance, economic opportunities, and means of self-sufficiency. Agriculture, hunting, and fishing have been traditional livelihoods, and in recent years, there has been a shift towards exploring renewable energy resources. By harnessing the potential of geothermal energy, as proposed in the Pawnee Nation’s Rural Energy Pilot Program, tribes can diversify their economies, reduce reliance on external energy sources, and create jobs within their communities.

2.3. Environmental Importance

Environmental sustainability is a core principle for many tribes, who have long recognized the importance of maintaining ecological balance. Rural areas offer an opportunity to implement sustainable practices that align with traditional ecological knowledge. The Pawnee Nation's initiative to convert old oil wells into geothermal energy sources exemplifies this commitment. This project not only mitigates the environmental impact of abandoned oil wells but also leverages renewable energy to support community needs. The integration of smart sensors in homes for energy efficiency further illustrates a holistic approach to environmental stewardship, reducing carbon footprints and promoting sustainable living.

2.4. Pawnee National Rural Energy Pilot Project

Central to the REPP is the innovative conversion of decommissioned oil wells into sources of geothermal energy coupled with solar thermal collectors. This process not only addresses environmental concerns associated with abandoned wells but also taps into a renewable resource that aligns with the tribe’s commitment to sustainability. Complementing this initiative, the project involves the installation of smart sensors in homes to enhance energy efficiency, the development of solar gardens, and the promotion of electric vehicle adoption. These efforts collectively aim to reduce energy costs, lower greenhouse gas emissions, and create a more resilient energy infrastructure. The REPP is built on 6 Phases that will enable to validate and prove the concept, see Figure 2.

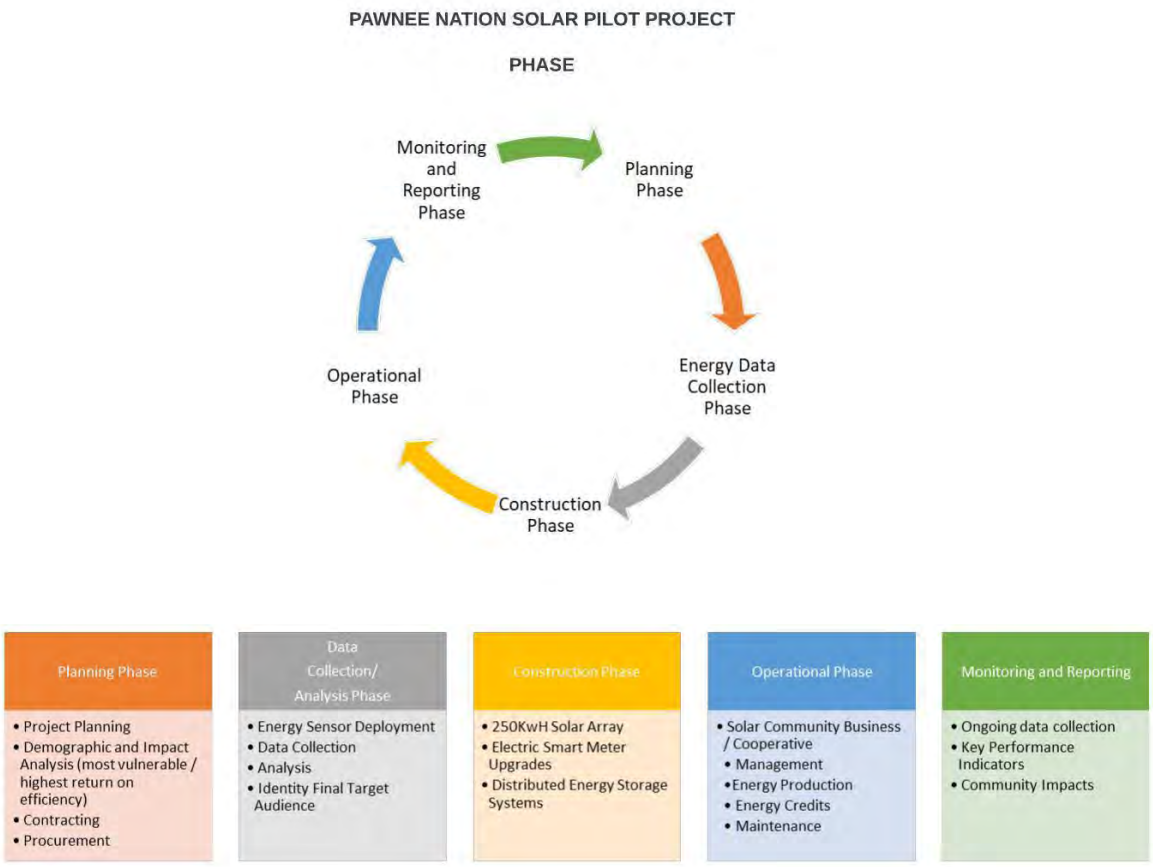

Figure 2. REPP Phases

The project also prioritizes community engagement through education and workshops, ensuring that the transition to renewable energy is equitable and inclusive. By fostering a collaborative environment, the REPP seeks to empower community members with the knowledge and skills necessary to participate in and benefit from the sustainable energy transition.

The Pawnee Nation's approach to geothermal energy is inspired by groundbreaking research into the potential synergy between heavy oil reservoirs and renewable energy sources. By adopting Enhanced Oil Recovery (EOR) techniques for eco-friendly purposes, the project pioneers the use of deep-well geothermal storage, tapping into the latent thermal energy of abandoned oil fields. This innovative approach goes beyond mere repurposing; it transforms dormant geological assets into vital resources for thermal heating, crucially supporting both residential and commercial needs and significantly advancing the Nation's food security through enhanced hydroponic greenhouse operations.

The integration of Solar Thermal Collector technologies with geothermal storage is a testament to the project's commitment to sustainability, providing a consistent energy supply and paving the way for a method that local and global communities can adopt. This harmonious blend of accumulated geothermal heat and solar innovation encapsulates the project's broader ambition toward a resilient and enduring energy transition. Figure 3 shows the main REPP components:

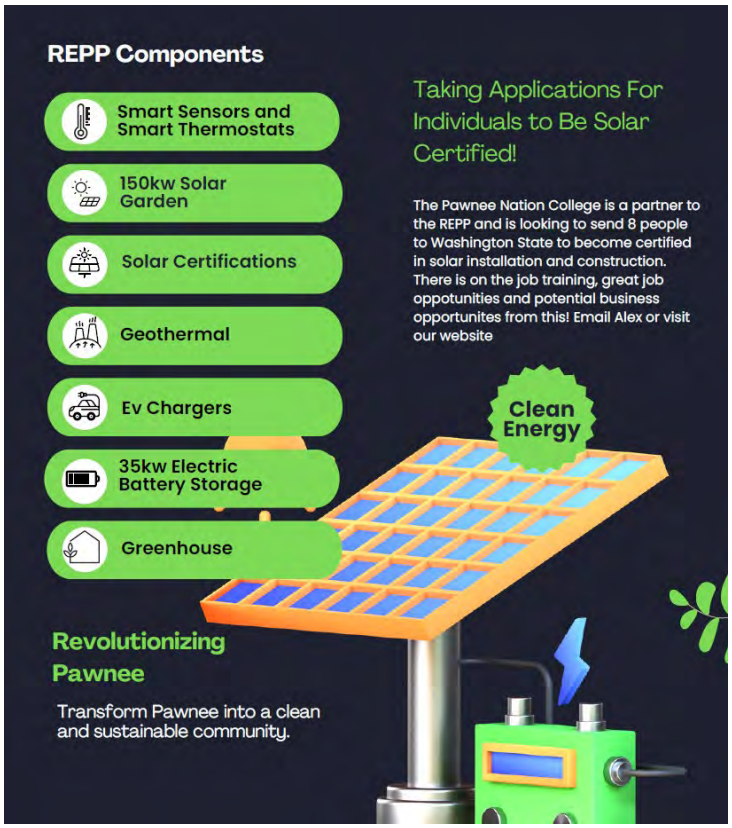

Figure 3. REPP main components

The Pawnee Nation's efforts underscore the untapped renewable energy potential lying dormant within tribal lands, representing a significant share of the nation's resources. The project seeks to correct the imbalances and inequalities in energy access, fostering a sense of resilience and empowerment within the community. Central to this endeavor is the collaborative spirit embodied by PNCRIS, which includes diverse entities such as the Housing Authority, Tribal College, Tribal Nation, Electric Cooperative, State University, and Non-profit organization. This evolving alliance ensures local governance and merges traditional wisdom with modern technological solutions.

Strategic partnerships with the Bureau of Indian Affairs (BIA) and the Bureau of Land Management (BLM) aim to develop a hybrid lease model for geothermal and oil well infrastructure. This innovative model integrates geothermal energy projects with existing oil and gas infrastructure, allowing for a seamless transition from fossil fuels to renewable energy sources on tribal lands. By re-purposing and co-managing oil well sites for geothermal energy production, this model underscores a commitment to sustainable land use and energy production. This collaboration sets a precedent that could redefine the use of tribal lands for renewable energy projects across the United States, respecting tribal sovereignty while fostering economic development and environmental stewardship.

3. The Solar to Geothermal Synergy

Oklahoma is considered to have a poor geothermal gradient to develop electrical power production. However, the thousands of wells drilled on Oklahoma lands shows consistently the availability of low-temperature sources ranging from 30 to 60°C. These sources are beneficial for heat use, especially when existing oil wells are available. While Oklahoma benefits largely of high solar intensity, our project is focusing on combining the solar heat generation with the wellbore heat storage and delivery, to provide a 24-hour constant heat output that can be used for heating and industrial heat purposes.

Some researchers (WEA, 2004) suggest that excess solar power can be stored during the day and utilized at night. As illustrated in Figure 1, part of the energy recovered at night comes from heat storage, with the remainder generated from other "backup" fossil energy sources, as proposed by Teodoriu et al. (2007) and later by Limpasurat et al. (2011). It has been demonstrated (WEA, 2004) that solar-to-thermal energy conversion technologies have an advantage over other technologies due to their unique ability to integrate with conventional heat generators in any energy-producing system, such as power plants. Figure 2 presents an example of combining a solar-to-thermal heater with thermal storage and/or a fossil fuel backup heater to produce electricity without causing stochastic perturbations in the electric grid. However, the innovative concept proposed for the REPP focuses on utilizing wellbore-stored heat for heating purposes. The proposed solar array will generate heat for immediate use during the day, while the excess heat will be injected into selected oil wells for storage.

Although the REPP does not currently focus on the potential for oil recovery, this may remain a future option if oil is still needed during the energy transition to secure national energy demands.

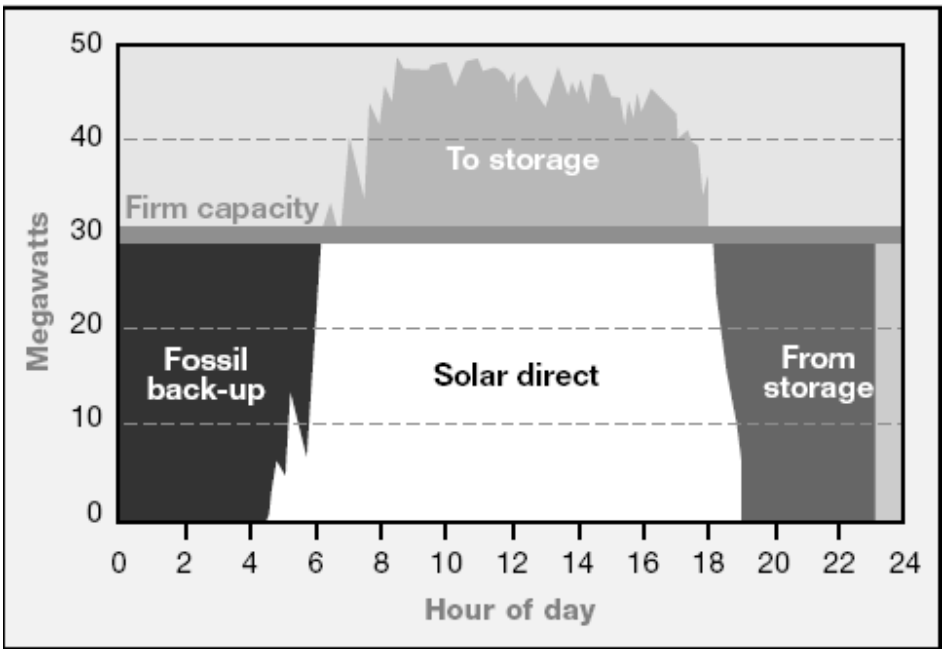

Fig. 4. Solar energy available in 24 hours (WEA, 2004)

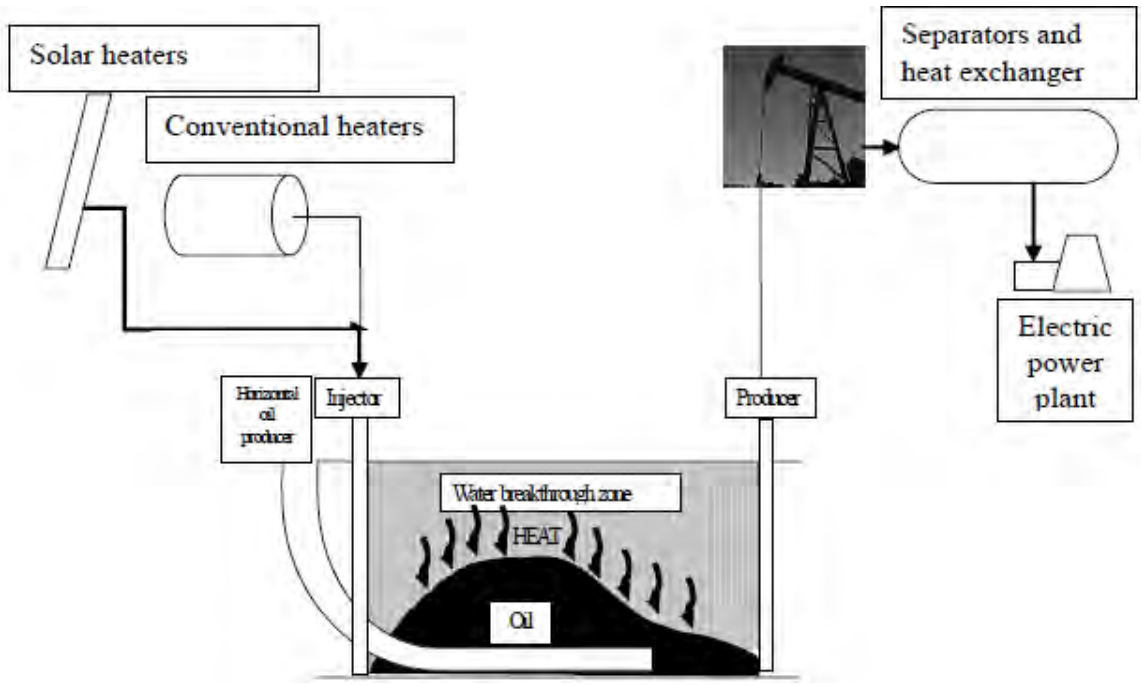

Fig. 5. Schematic of the EOR with electric power-producing process

Why does using old wells matter?

Through the REPP we will be changing the energy landscape of Pawnee in multiple ways. One of these ways is by converting old oil and gas wells into geothermal wells, giving new life to idle and orphaned wells.

Typically, the life cycle of the oil and gas well starts with drilling and ends when the well is deemed to be no longer economically viable. Initially, the well is drilled and cased. The drilling process creates a hole to the targeted formation, and then the casing is run to protect freshwater zones and achieve zonal isolation. Some formations need to be stimulated as well, or other tools need to be used in the well, this is called completing the well. Once you have access to the hydrocarbons, the well is then put on production, and you can begin producing the fluids and gases in the reservoir. Once you have recovered all the oil and gas possible and re-stimulating won't produce enough hydrocarbons to make financial sense, the well is then idled for future use, plugged and abandoned (P&A), or if the operator goes out of business and doesn't have the means to P&A the well, and the well has no known operator, orphaned. Sometimes wells are kept suspended, meaning they are not producing but also not set yet for P&A. Our current project is focusing on the latter.

Instead of permanently abandoning these wells, we can give them a new lease on life by converting them to geothermal wells. Pawnee has 3 idled wells near their greenhouse and administrative buildings that would be great candidates to heat these buildings during the winter by storing heat in the formation during the summer and extracting it during winter. Our goal at REPP is to bring

a cleaner and more sustainable future to Pawnee Nation and the surrounding areas, and with geothermal heating and other energy sources we are bringing to the table, our goal will be achieved.

As part of the community commitment, a team of students from the University of Oklahoma has taken the opportunity to investigate possible solutions for wellbore completion under various scenarios and costs associated with it. Figure 6 shows the final proposed well completion for the selected wellbore. The main task here was to investigate if a single well could provide an adequate flow rate and temperature for the project. The small production casing size and wellbore limitations have shown that the proposed solution using 2 7/8" tuning for production and annulus for injection may be the bottleneck to achieving higher flow rates, especially for phase two of the current REPP when the solar-thermal array and surface hot water pipeline network may be expanded. Currently, the team is also considering the option of using several adjacent wells to expand the geothermal flow rate potential. This new solution will allow us to expand our geothermal storage similarly as shown in Figure 5, but without electricity production, since we aim for direct heat use. As mentioned, the oil recovery from the reservoir may remain as an alternative to quickly recover the investment costs and once oil is depleted the system will remain a true geothermal heat storage solution for the long term.

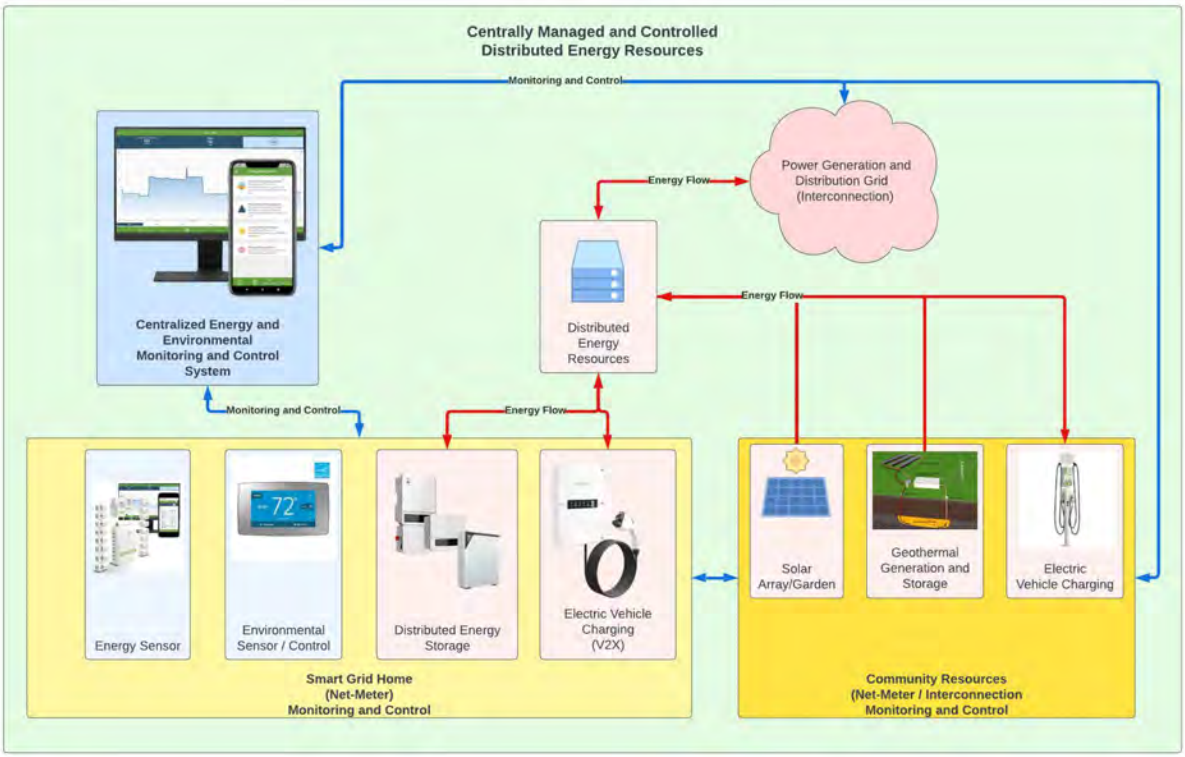

Figure. 8. REPP concept and implementation

4. Conclusions

This project, although small in scale, demonstrates that the most important element of success is the early involvement of the locals in the project phases. Community engagement and workshops were the key to understanding the priorities and needs of rural communities.

We also demonstrated that when geothermal potential is low, a synergy between solar thermal array and geothermal can improve economics and provide continuous heat.

The project also shows the complexity of implementing renewables in rural areas, hence only through prioritization the success of these projects can be achieved. Although we are the beginning of the project, we hope to further improve renewables adoption by emphasizing the need of energy efficiency and efficient use of electricity through smart sensors and usage monitoring.

Acknowledgment

We also acknowledge the generous support from the United States Department of Agriculture (USDA), whose $2.6 million grant made this transformative initiative possible. The guidance and expertise provided by the Bureau of Indian Affairs (BIA) and the Bureau of Land Management

(BLM) have been invaluable in developing the hybrid lease model for geothermal and oil well infrastructure.

The authors would like to extend their deepest gratitude to the Pawnee Nation for their visionary leadership and unwavering commitment to sustainable development, which has been instrumental in the success of the Pawnee Nation's Rural Energy Pilot Program. Special thanks to the Pawnee Nation College, Pawnee Nation Housing Authority, Pawnee Public Schools, Indian Electric Cooperative, and Tribuquent Corporation for their collaborative efforts and partnership.

Our heartfelt appreciation goes to the University of Oklahoma for its substantial contributions, particularly in the research and technical support that have shaped the geothermal energy solutions presented in this project. We are also grateful to the Well Integrity Laboratory at the University of Oklahoma for providing access to their unique cement repository and database, which has been crucial for the project's wellbore completion studies. The dedication and hard work of the students from the University of Oklahoma in investigating and developing wellbore completion solutions under various scenarios are deeply appreciated.

Finally, we extend our gratitude to the community members of the Pawnee Nation for their active participation and support in the project's educational and engagement initiatives. This project is a testament to the power of collaboration, traditional wisdom, and modern technology working hand-in-hand to create a sustainable future.

ABSTRACT

The Hawaiʻi Groundwater and Geothermal Resources Center (HGGRC) engaged with the Lānaʻi Island's community and land management company, Pūlama Lānaʻi, when conducting geothermal and groundwater research. Lānaʻi Island holds blind geothermal resources–the geothermal resources are deep below the surface. Lānaʻi Island will likely undergo substantial development in the near future, which will place additional demands on its freshwater supply and renewable energy resources. More knowledge of Lānaʻi's water supply, source, and quality will be needed. For the Hawaiʻi Play Fairway project, HGGRC deepened an existing water well on Lānaʻi, collected data, and engaged with the Lānaʻi community and Pūlama Lānaʻi. This drilling project is the first deep-drill geothermal research project in the Hawaiian Islands outside of Hawaiʻi Island. HGGRC shared its research with community members in three community meetings and gave them a tour of the drilling site. HGGRC coordinated its geophysical surveys with Pūlama Lānaʻi's archeology division. Local high schoolers contributed to the research as paid interns. HGGRC disseminated its research through peer-reviewed publications, presentations, datasets and a blog with drilling updates. HGGRC's research benefited the Lānaʻi community: the research increased the knowledge of Lānaʻi's water supply and enabled the community to consider geothermal as a renewable energy source. HGGRC aimed to empower the Lānaʻi community, so it can contribute to and benefit from the research and can effectively manage the island's groundwater and geothermal resources for continued sustainable livelihood and development.

1. Introduction

Even with Hawaiʻi's volcanic origins, much of Hawaiʻi's geothermal resources remains unknown (Lautze, 2022). The State of Hawaiʻi is producing geothermal electric power from only one geothermal system: the Kīlauea East Rift Zone (KERZ) on Hawaiʻi Island (Lautze et al., 2017a). Beyond KERZ, Hawaiʻi's geothermal resources are blind–their manifestations, such as hot springs

and steam vents, do not appear on the ground surface because the heated water flows far below (Lautze, 2022). Historically, not a lot of research has been done on the blind resources in the rest of the state; very few deep (~2 km) wells were made for Hawai‘i’s geothermal exploration (Lautze, 2022).

As the State’s leader in earth sciences research, the University of Hawai‘i (UH) conducted the State’s comprehensive statewide geothermal resource assessments and determined that all of the major Hawaiian Islands likely hold geothermal resources. For Hawai‘i’s second assessment, a UH research unit, the Hawai‘i Groundwater and Geothermal Resources Center (HGGRC), produced the Hawai‘i Play Fairway project. From 2014 to 2021, this $2.3 million project accomplished many firsts for Hawai‘i geothermal:

- Hawai‘i’s first comprehensive statewide geothermal resource assessment in over three decades (Lautze et al., 2017a)
- First mathematical application to Hawai‘i’s geothermal resource probability (Ito et al., 2017)
- First deep-drill geothermal research project in the Hawaiian Islands outside of Hawai‘i Island–on Lāna‘i Island (Lautze et al., 2024)

Because of Hawai‘i’s abundance of geothermal resources and the need for more affordable firm renewable energy, HGGRC encourages the State of Hawai‘i to expand geothermal energy use beyond Hawai‘i Island and to other major Hawaiian Islands. Any resource found on Hawai‘i’s older volcanoes will hold temperatures more compatible with binary power generation rather than flash-steam generation. Binary power generation will have significantly less impacts and lower visibility in the community.

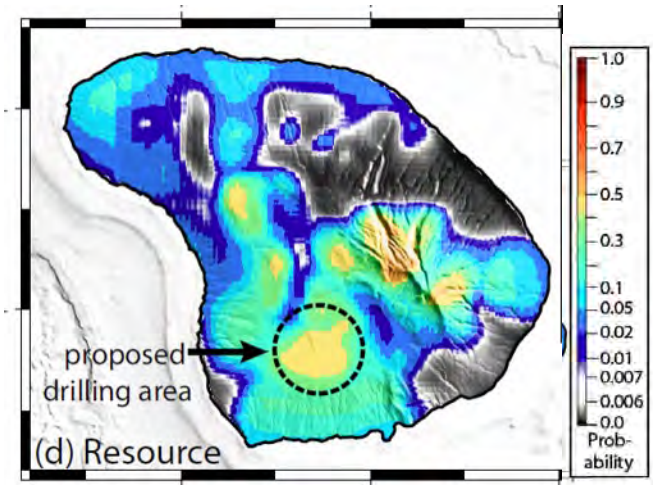

Figure 1: A map of the Lāna‘i Island with the areas colored by local probabilities of a geothermal resource. The color bar on the right shows how the geothermal probabilities are mapped on Lāna‘i. The circle of short dashed lines delineates the proposed drilling area (Lautze et al., 2020).

Throughout the Play Fairway project, HGGRC collected data (Lautze et al., 2017a), developed new simulations for subsurface heat across the Hawaiian Islands (Ito et al., 2017), ranked areas for exploration (Lautze et al., 2017b), and performed on-the-ground experiments (Lautze et al., 2020). HGGRC analyzed data for gravity, resistivity, and groundwater temperature to determine which locations held resources at an accessible depth and considered the costs and logistics for drilling

at each location (Lautze et al., 2020). Ultimately, for deep-drilling geothermal exploration, the project chose Pālāwai Basin, Lānaʻi Island–geologically the caldera region of Lānaʻi volcano (Lautze et al., 2024). Because research should benefit the community, HGGRC incorporated community engagement throughout the entire drilling project on Lānaʻi.

2. Understanding the Lānaʻi Island

Basaltic lava flows from a single shield volcano formed a dome-shaped island–the Lānaʻi Island (Stearns et al., 1940). A three-and-a-half-mile caldera–the Pālāwai Basin–formed during a collapse of the southwest and northwest rift zones and a subsidence at their intersection (Stearns et al., 1940).

Lānaʻi is one of the more arid of the Hawaiian Islands. In the rain-shadow of Maui, Lānaʻi receives very limited rainfall–only 400 to 800 mm of rainfall annually on average (Giambelluca et al., 2013). As a result, most of Lānaʻi's nearshore areas hold very limited basal freshwater aquifers.

During the 1920s, pineapples covered the Pālāwai Basin as part of the world's largest single pineapple plantation. Under James Dole's Hawaiian Pineapple Company, pineapple cultivation became Lānaʻi's main industry, and Lānaʻi earned the nickname the "Pineapple Island" (County of Maui, 2016). For decades afterwards, the pineapple served as Hawaiʻi's major cash crop and a symbol of Hawaiʻi (Hawkins, 2011; County of Maui, 2016).

Today, pineapple is no longer commercially grown on Lānaʻi, and wild grass now covers the Pālāwai Basin (County of Maui, 2016). Lānaʻi's economy now focuses on tourism (County of Maui, 2016). Entrepreneur Larry Ellison owns about 98% of Lānaʻi; the State, County of Maui, and other private landowners own the remaining 2% (County of Maui, 2016). Lānaʻi City operates as Lānaʻi's commercial center and home to 99 percent of the island's population (County of Maui, 2016). Lānaʻi Island will likely undergo substantial development in the near future (Maui County, 2016), which will place additional demands on its water supply.

3. HGGRC's Research on Lānaʻi Island

The current model for groundwater in Hawaiʻi is generalized and not specific to the individual island systems–including Lānaʻi's (Lautze, 2018). A lot about Lānaʻi's groundwater system is unknown–including the groundwater's storage and transport throughout the island (Lautze, 2018). At present, Lānaʻi Island has had minimal efforts to characterize the relationship between its geologic history and structure and its water resources–the U.S. Geological Survey still lists the 1940 work of Stearns as Lānaʻi's primary study of water resources there (Lautze, 2018; Stearns et al., 1940).

HGGRC's research explores the geologic structures in Hawaiian volcanoes and how those structures influence groundwater storage and flow. On the Lānaʻi Island, Pālāwai Basin holds high-level brackish water, a unique feature in the Hawaiian islands (Lautze, 2018). The water's origin remains unknown (Lautze, 2018). As Pālāwai Basin is a remnant caldera, geologically similar locations exist around the state (Lautze, 2018). Hence, this research will inform groundwater management across the state (Lautze, 2018).

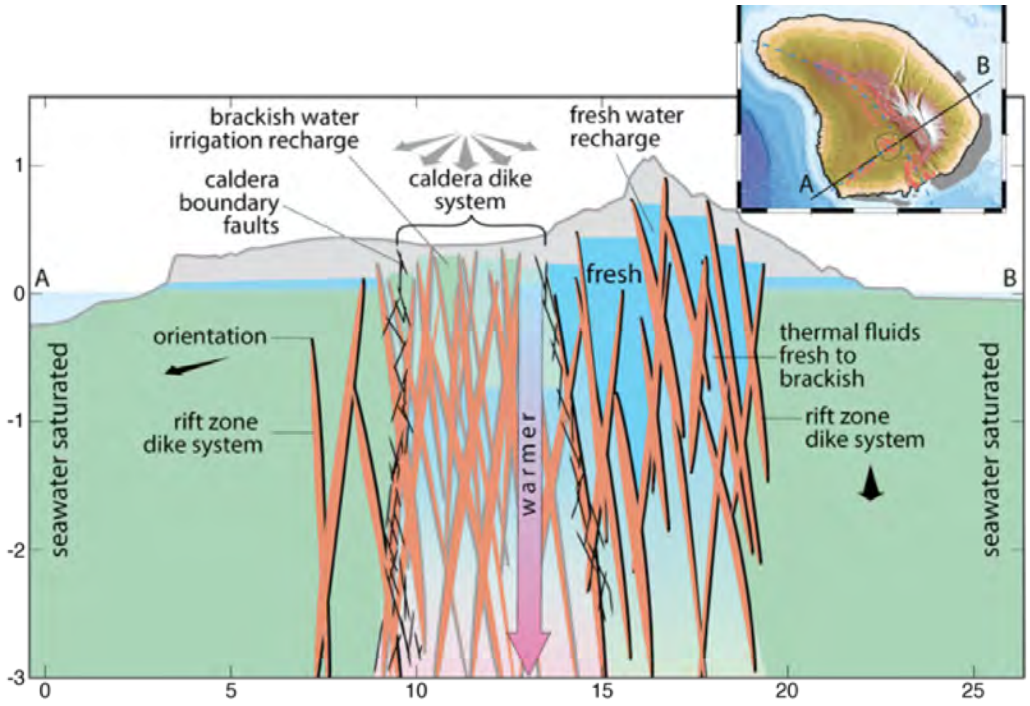

Figure 2: Conceptual model of Lāna‘i’s hydrology along cross-section AB (inset top right). Red hatches are relatively impermeable dikes; black hatches are caldera boundary faults. We theorized the presence of three aquifers: a thin basal low-level aquifer at the coast; a warm brackish high-level aquifer within the Pālāwai Basin; and a cold, fresh higher-level aquifer within the rift zone. The temperature data from Lāna‘i Well 10 indicate that the water within the Pālāwai Basin likely will get warmer and fresher with depth (Lautze et al., 2024).

Figure 3: A panorama of the drill site in Pālāwai Basin. At the work site are shipping containers, a work station for core processing, and a drilling rig, which deepened an existing water well from a depth of ~427 to ~1,057 meters (1,400 to 3,467 feet). The island's highest ridge rises in the background.

By drilling a 4-inch-diameter hole into Pālāwai Basin, HGGRC conducted “slim hole” drilling, using bits less than 7 inches wide, to descend more than a kilometer down. During the drilling, HGGRC collected a drill core–a continuous sample of rock collected from the ground. Currently, HGGRC is analyzing the drill core, which is hundreds of feet long and several inches thick. Analyzing the core will yield information on how minerals and water are distributed underground–

including the brackish water found at elevation in Pālāwai Basin–and Lāna‘i’s hydrologic and volcanic history and geologic structures (Lautze, 2018).

Outside of Kīlauea’s summit and East Rift Zone, Hawai‘i’s geothermal resources are blind. That is, their manifestations, such as hot springs and steam vents, do not appear on the ground surface because the heated water flows far below. Historically, little work had gone into exploring blind resources over the rest of the state. By drilling on Lāna‘i, HGGRC conducted the first deep-drill geothermal research project in the Hawaiian Islands outside of Hawai‘i Island (Lautze et al., 2024).

4. Planning with Pūlama Lāna‘i

The land management company of Lāna‘i, Pūlama Lāna‘i, has supported developing Lāna‘i’s groundwater and geothermal resources. HGGRC provided reports and information to Pūlama Lāna‘i and discussed Lāna‘i’s groundwater management and fresh water resource assessment. Before the drilling, Dr. Lautze gave a talk on Lāna‘i Island’s hydrology to Pūlama Lāna‘i. Furthermore, Pūlama Lāna‘i assisted HGGRC when it produced an Environmental Assessment for the Hawai‘i State Office of Environmental Quality Control (Lautze, 2018).

Prior environmental work and land use of the drilling location reduced the drilling project’s regulatory requirements (Lautze, 2018). According to a regulatory review, Pūlama Lāna‘i already did extensive environmental, cultural, and land use documentation for much of the island (Lautze, 2018). Furthermore, because a pineapple plantation operated in the area for several decades, the area poses little likelihood of hosting threatened or endangered plants or animals (Lautze, 2018).

Pūlama Lāna‘i offered two deep wells for HGGRC to deepen from ~305 m (>1000'). After conducting video and deviation logging of the wells, HGGRC determined that it could deepen Lāna‘i Wells 9 and 10. HGGRC chose Lāna‘i Well 10 because of reports of unconsolidated material at the bottom of Well 9, its proximity to residential areas of Lāna‘i City, and its location closer to the dominant source of cold rainfall recharge.

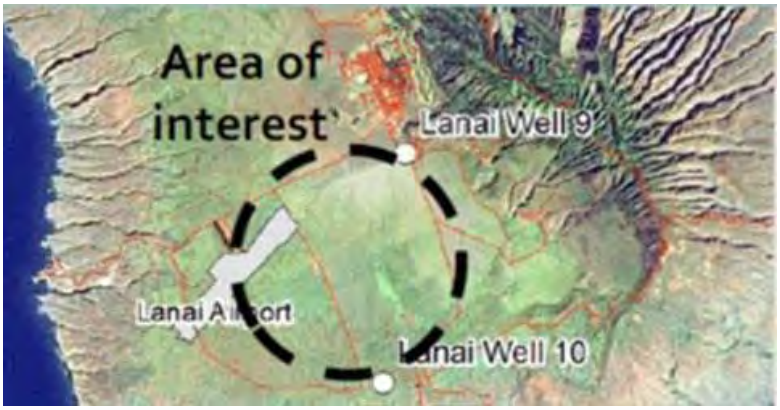

Figure 4: A satellite image of the Pālāwai Basin. The circle of dashed lines delineates the area of interest for research. On the edges of the circle: Lāna‘i Airport on the left, Lāna‘i Well 9 on the top right (just below Lāna‘i City), and Lāna‘i Well 10–the well that the project deepened–on the bottom right.

5. Community Meetings

Throughout the course of the drilling project, HGGRC shared updates with the Lāna‘i community in three community meetings organized by Pūlama Lāna‘i:

Before drilling–September 10, 2018: Senior researchers Nicole Lautze and Don Thomas introduced the Lāna‘i community to the drilling project. Lāna‘i’s newspaper, Lāna‘i Today, published an article about the meeting. In the article, “Straight from the Source,” Lāna‘i Today said, “Although the presentation was technical, it was also fascinating!”

Middle of the drilling, Open House of drilling site–June 29, 2019: HGGRC invited the community to tour the Well 10 drilling site. Walking on the rocky red dirt of Pālāwai Basin, community members viewed the drilling rig, shipping containers, and drill cores. Senior researchers Nicole Lautze, Don Thomas, and Eric Haskins explained the drilling process and drill cores on display and answered questions.

Figure 5: HGGRC invited the community to the drilling open house, and Pūlama Lāna‘i produced the announcement (left image). At the drilling open house, Lāna‘i residents visited the active drill site, and researchers discussed drilling and showed the rock core and drilling fluids. Lāna‘i Today published an article about the open house (right image; Lāna‘i Today, 2019).

After self-potential survey (electrical survey) and end of project–February 27, 2023: The presentation included the following speakers and their topics:

- Nicole Lautze: Updates
- Donald Thomas: Collecting rock cores, research results, and technical information
- Eric Haskins: Collecting and processing rock cores
- Mattox Telwar: Field experience and working with Lāna‘i students

After the meeting, a community member emailed Nicole, thanking her for the presentation:

> Just wanted to thank you for coming back to us. It was very informative and helpful. I hope you all get the chance (and thus the funds!) to come back …

6. Internships

During geophysical surveys with Pūlama Lāna‘i’s archeology division, HGGRC coordinated paid internships for three students from Lāna‘i High and Elementary School. During March 2022, they measured groundwater movement below the surface. For this self-potential survey, an electrical survey of the groundwater, they coupled sensors to the ground and attached them with wire to measure the electrical current between them. The data showed whether water moved up or down and illustrated a high degree of complexity in water movement within the Pālāwai Basin. Bolós et al. (in review) incorporated the data into their research. To support this endeavor, Pūlama Lāna‘i funded this fieldwork and a postdoctoral fellowship and provided housing and a vehicle at no cost (Bolós et al., in review).

Figure 6: Three students from Lāna‘i High and Elementary School contributed to the self-potential survey. In the left image, the interns apply a wire onto the ground. In the right image, a student inserts a sensor into the ground. The collected data illustrated complex water movement within the Pālāwai Basin.

7. Sharing Knowledge

To share the gained knowledge, HGGRC produced the following:

- Lāna‘i Island Project Updates: a blog with updates on the drilling by Rock and Data Manager Eric Haskins on the HGGRC website
- Peer-reviewed publications and presentations: 9 journal articles, 2 theses, 9 conference papers, 19 conference presentations
- Shared datasets: core log photos and report, noble gas data, resistivity and density 3D models, and daily drilling reports.

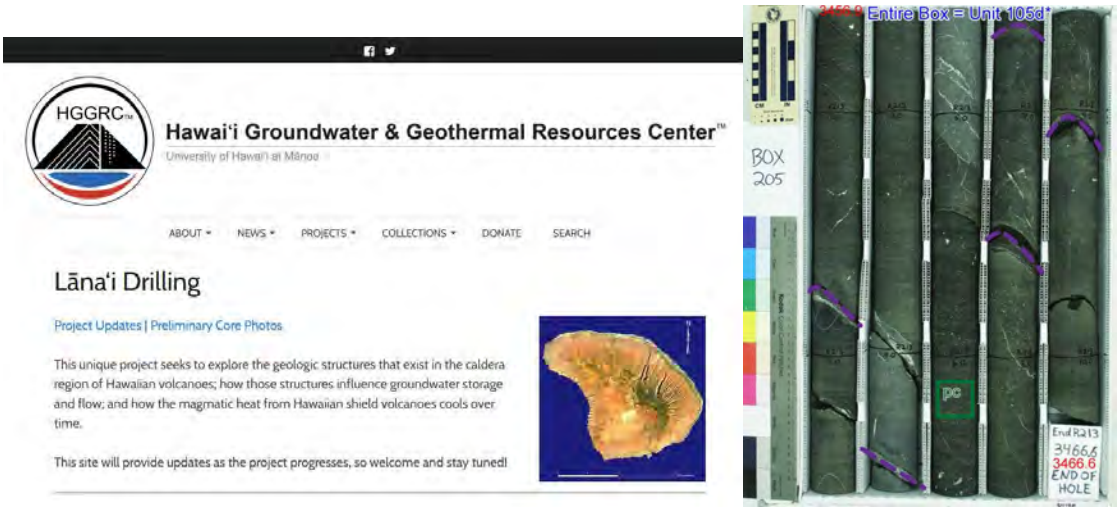

Figure 7: HGGRC's webpage for the Lāna'i drilling project (left) and the last box of cores from Rock Core Log Report: Well 10, Lāna'i Drilling Project (right, deepest cores in the well at a depth of 3,466 feet) .

8. Benefiting the Lāna'i Community

The Lāna'i community's future livelihood, self-sustainability, and development will require additional use of groundwater resources and renewable energy:

Additional water resources – Lāna'i's current water supply is restricted to Lāna'i's single aquifer (Maui County, 2016). As stated earlier, as one of the more arid of the Hawaiian Islands, Lāna'i receives very limited rainfall, and most of Lāna'i's nearshore areas hold very limited basal freshwater aquifers. Therefore, the Lāna'i community will need more knowledge of its water supply, source, and quality. Currently, HGGRC believes that as many as three aquifers store the Lāna'i Island's groundwater (Lautze et al., 2024). By informing the community, HGGRC's research will empower it to efficiently and sustainably manage Lāna'i's groundwater.

Renewable energy sources – By state law, all of the energy that Hawai'i consumes must come from renewable sources by 2045, and the Lāna'i community is still developing its renewable energy sources (Dobbyn, 2022). Two years ago, the Hawaiian Electric Industries initiated Lāna'i's largest utility-scale renewable energy project (DeJournett, 2022). Hawaiian Electric, the state's largest electricity supplier, has contracted with DG Development & Acquisition to build and maintain a solar and battery storage energy storage system (DeJournett, 2022). However, Hawaiian Electric recently paused this project because Pūlama Lāna'i planned to remove the island's two resorts off of Hawaiian Electric's grid and build a microgrid to power them by 2027 (Dobbyn, 2022). Pūlama Lāna'i planned to use solar and battery energy storage systems (Dobbyn, 2022). Because Four Seasons Lāna'i and Sensei Lāna'i currently expend 40 percent of Lāna'i's power, these plans will likely increase electricity rates for the Lāna'i community beyond the two resorts (Dobbyn, 2022).

As a potential solution, geothermal energy can serve as a cost-effective baseload renewable energy source for Lāna'i, and the results from HGGRC's drilling project indicated a potential geothermal resource on Lāna'i (Lautze et al., 2024). In Pālāwai Basin, when HGGRC drilled to a depth of ~427 to ~1,057 meters (1,400 to 3,467 feet), it measured medium-high temperature: a maximum bottom hole temperature of 66°C (151°F) and a gradient of 42°C/km (Lautze et al., 2024). In fact,

this gradient lands within a range of gradients measured in this depth range for exploration wells in the volcanically active East Rift Zone of Kīlauea Volcano (Lautze et al., 2024).

According to HGGRC's analysis, the geophysical datasets–self-potential, magnetotellurics, and gravity data–indicate a probable concealed hydrothermal system and potential magmatic plumbing reservoir beneath the Pālāwai caldera (Bolós et al., in review). As the analysis indicates, a hydrothermal upflow circulates from deep magma reservoirs beneath the central and southern Pālāwai caldera at a depth of ~2 km (Bolós et al., in review). The analysis recommends further research to confirm the geothermal resource's presence (Bolós et al., in review).

9. Conclusion

The drilling project on Lāna‘i serves as a historic milestone for Hawai‘i's geothermal research as the first deep-drill geothermal research project in the Hawaiian Islands outside of Hawai‘i Island (Lautze et al., 2024). The resulting deep-thermal information may serve as the first data on the long-term rates of cooling of the cores of Hawai‘i's volcanoes (Lautze et al., 2020). So far, the initial data analyses indicate that the Lāna‘i Island does indeed hold blind geothermal resources (Lautze et al., 2024; Bolós et al., in review). As information on blind geothermal resources in the main Hawaiian Islands is scarce, project results could direct Hawai‘i's future statewide geothermal development strategy (Lautze et al., 2024).

HGGRC's research on Lāna‘i's will inform groundwater management not only on Lāna‘i but also across the state (Lautze, 2018). The research provides new insights into Lāna‘i's hydrological cycle and will contribute to the island's future planning and siting of water supply wells (Lautze et al., 2024). Furthermore, Pālāwai Basin exemplifies a remnant caldera in the Hawaiian Islands and is similar to other remnant calderas in the Hawaiian Islands (Lautze et al., 2024; Lautze, 2018).

In the near future, the Lāna‘i community will require additional use of groundwater resources and renewable energy to ensure sustainable livelihood and development. Through its research and sharing of knowledge, HGGRC is empowering the community to better understand and manage these resources.

Acknowledgement

We thank the U.S. Department of Energy's Geothermal Technologies Office for funding and managing this project under award number DE-EE0006729 and Pūlama Lāna‘i for its generous financial and logistical support. Warm mahalo to the Lāna‘i community for welcoming us.

Geothermal Energy, Direct-Use Application, Greenhouse Heating, Osage Tribal Nation, Sustainable Development

ABSTRACT

Geothermal energy stands at the forefront of sustainable solutions, offering a renewable and environmentally friendly alternative to traditional energy sources. The Osage Tribal Nation, like many communities worldwide, recognizes the immense potential of geothermal resources in addressing energy needs while minimizing environmental impact. Utilizing geothermal energy for direct-use applications holds promise for revolutionizing agricultural practices and enhancing community resilience.

This study delves into the transformative potential of geothermal direct-use technology, focusing on its application in greenhouse heating within the Osage Tribal Nation. The greenhouse serves not only as a vital source of fresh produce but also as a symbol of cultural heritage and community sustenance. However, the challenge of providing consistent heating to sustain agricultural operations underscores the need for innovative and sustainable energy solutions.

Against this backdrop, our research endeavors to explore the geothermal landscape of the Osage Nation, employing advanced geological modeling, reservoir simulation, well planning, and economic analysis techniques. By investigating the feasibility of drilling new wells near the greenhouse and harnessing geothermal heat flow, we seek to establish a robust framework for integrating geothermal energy into the tribe's energy portfolio.

The Osage Tribal Nation's commitment to sustainable energy practices aligns with the broader goal of fostering environmental stewardship and self-sufficiency within indigenous communities. This case study serves as a blueprint for leveraging geothermal resources to address food security challenges and promote sustainable development initiatives.

1. Introduction

1.1 Overview

Geothermal energy is a growing renewable energy source that can be used worldwide. Geothermal energy is the energy harnessed from the Earth's natural heat reservoirs. Despite the recent increase in geothermal applications, geothermal energy still has one of the lowest energy usages among all renewable energy sources, accounting for less than 1% of the total utility-scale energy generation. Low geothermal energy usage can be attributed to many factors, such as a lack of awareness and acceptance of geothermal energy, low investment, and low infrastructure. Geothermal energy has multiple applications ranging from electricity generation to direct use. Direct geothermal use provides a range of possibilities, ranging from aquaculture, farming, greenhouse gas, and building heating and cooling. The significance of energy sustainability and self-reliance is deeply engrained in tribal communities around the United States. [] Through its direct-use applications, geothermal energy holds immense promise in ensuring that tribal communities are self-sufficient and have long-term sustainable energy. Direct geothermal energy applications, which encompass various aspects of one's daily life, from heating and cooling buildings to greenhouse heating and beyond, offer a valid path toward energy independence, economic development, and cultural preservation for tribal communities. This project will investigate the techno-economic feasibility of providing direct heat to a greenhouse during winter to support tribe's effort for food sovereignty.

1.2 Motivation

Many tribal communities face economic and energy challenges that affect their daily lives. The Osage Nation tribal community is one of the largest tribal communities in Oklahoma. The Osage Nation tribal community, like many other tribal communities, resides in remote and rural areas with unique energy requirements and challenges. In 2020, during the COVID-19 pandemic, the Osage Nation tribal community experienced a major breakdown in their food system. As a result, a 40,000-square-foot greenhouse was built to increase their food production capacity and increase food sovereignty in the tribal nation. However, the greenhouse is faced with a major challenge during winter, where lack of sufficient heat limits the growth of the crops. This creates a need to provide heat to the greenhouse during winter to facilitate its proper operation. Geothermal wells, through their direct-use application, are a suitable heat source for addressing the issue. The project will investigate the feasibility of drilling two geothermal wells around the greenhouse to provide direct heat during winter.

2. Study Area

2.1 Overview

Within the scope of our collaborative project focused on harnessing geothermal heat for greenhouse and building heating, this section of the report delves into the potential scenarios and challenges associated with implementing geothermal heating systems. This project will explore two scenarios where geothermal heat could be employed as a primary heating source for greenhouses and other structures if need be while also examining the challenges that may emerge during the planning, installation, and operation of such systems. By identifying and addressing these hurdles, we aim to provide valuable insights that inform the decision-making process and promote the sustainable utilization of geothermal energy for heating purposes in our chosen settings. The study area for this project will be the Osage Nation, as shown in Figure 1**.** The Osage

Nation's petrophysical, geologic, and temperature data was obtained from drilled active and inactive wells. The Osage Nation consists of 40,086 drilled wells, which include 2,495 active wells and 34,064 inactive wells. The inactive wells in the study area account for more than 84% of the total wells in the region. The inactive wells in the region provide a good data source for understanding well conditions, formations, and drilling concerns in the area. Two scenarios are investigated in this project for feasibility studies. The study area was narrowed down to a greenhouse located in the Harvest Land Farm of the Osage Nation. The Greenhouse needs heat and cooling during winter and summer respectively, leading to the decision to implement the project in that area to contribute to the community effort toward food sovereignty.

3. Scenarios Analysis

3.1 Scenario 1: Repurposing Existing Wells for Geothermal Heat

One of the scenarios under consideration in our project involves repurposing existing wells in the vicinity to extract geothermal heat. This approach holds significant promise, particularly from a cost-effectiveness perspective, as it eliminates the need to undertake the costly and resource-intensive process of drilling new wells. By leveraging these pre-existing wells, we can tap into an established infrastructure, potentially accelerating the implementation of our geothermal heating system. Figure 2 shows a visual of a potential layout consisting of three wells that the team analyzed during a trip to the site in 2023. Figure 3 also shows some relevant information about the wells located in the greenhouse neighborhood.

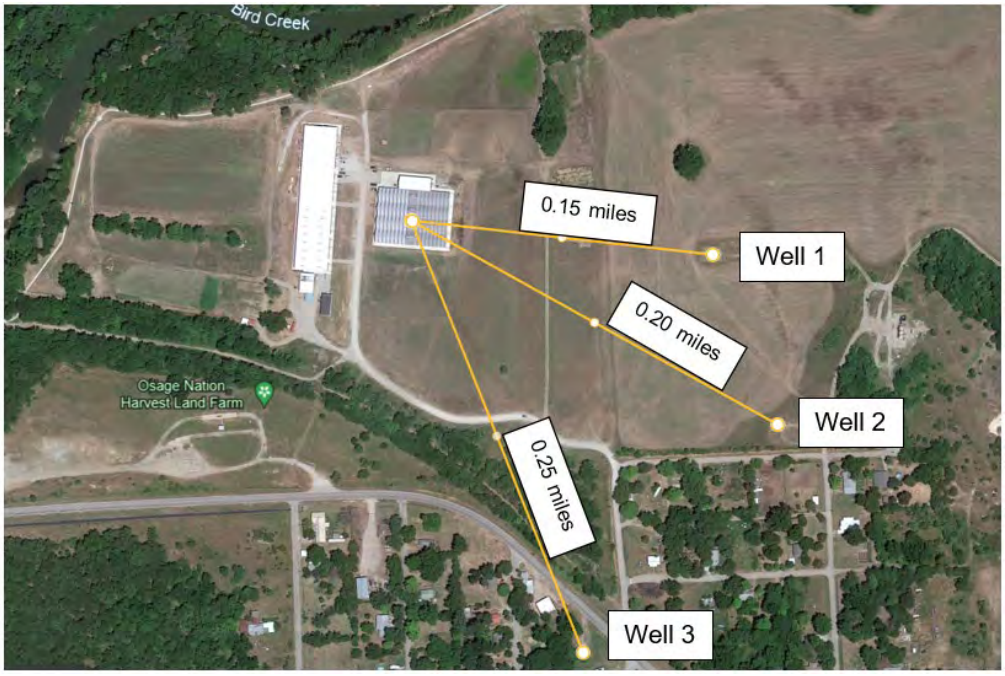

Figure 2: Visual representation of the wells around the area of study

Figure 3: Information on Well 2 design

While the location of wells with respect to the site is good, this scenario also presents a unique set of challenges that demand careful consideration. Notably, the wells in question date back to the years between 1900 and 1940, introducing potential well integrity issues. (Khankishiyev, Salehi et al.) These older wells' structural integrity and depth may not be suitable for geothermal applications, necessitating refurbishment, and potential reinforcement to meet modern standards. (Hu, Vivas et al. 2024)

Moreover, geological factors and the thermal characteristics of the existing wells need to be evaluated to ensure their suitability for geothermal heat extraction. Variability in the temperature and flow rate of the geothermal resource can impact the system's efficiency and overall performance. We must also account for potential environmental and regulatory concerns while repurposing these aged wells.

In this scenario, assessing and mitigating these challenges, including those associated with the age and integrity of the wells, will be essential in realizing the cost-effective potential of repurposing existing wells for geothermal heating, making it a worthwhile avenue to explore in our project.

3.2 Scenario 2: Drilling New Geothermal Wells

In our second scenario for geothermal heating implementation, we contemplate the construction of entirely new geothermal wells. This approach offers distinct advantages, notably the assurance of wellbore integrity and the ability to control drilling depth for optimal temperature utilization. By drilling new wells, we can ensure that the well structures are modern, robust, and designed specifically for geothermal applications. This minimizes the risk of structural issues and potential leaks often associated with older or repurposed wells. Furthermore, the flexibility to control well depth enables us to target zones with higher temperature gradients, enhancing the efficiency of our geothermal heating system. It also presents the potential to explore lower depths for geothermal cooling, offering a dual-purpose solution that caters to both heating and cooling needs.

However, this scenario also presents its share of challenges. Notably, the primary challenge concerns the substantial cost implications of drilling new geothermal wells. These expenses encompass drilling equipment, materials, labor, and the depth to be drilled, making it a potentially significant investment. A comprehensive cost-benefit analysis will be imperative to evaluate this option's financial feasibility and sustainability. Additionally, a critical concern is the presence of an aquifer beneath Osage County that provides the nation with drinkable water. If we opt for this scenario, we must design and implement robust isolation methods to ensure that our drilling activities do not interfere with or contaminate the aquifer.

Protecting this vital resource is of utmost importance and will require stringent design and monitoring protocols to mitigate any potential risks and safeguard the nation's drinking water supply. In summary, while drilling new geothermal wells offers precise control over wellbore integrity and drilling depth for optimized geothermal heating and cooling, it must be carefully evaluated in the context of the significant cost implications and the imperative need to protect the underlying aquifer, making it a scenario that requires thorough assessment and planning.

4. Geological Setting

4.1 Geological Deposition

The Osage Reservation is located in the Mid-Continent Cherokee Shelf of NE Oklahoma. The county is underlain by the strata of the Oklahoma platform that lies between two uplifts, the Ozark Dome and the Nemaha Ridge (Figure 4), that were deposited during the late Paleozoic (Cole, 1969). The near-surface bedrock in Osage County consists of a series of north-northeast striking outcrop bands of Upper Pennsylvanian to Lower Permian sedimentary sequences of interbedded shale, sandstone, and limestone, as reported by Hudson et al. (2016). The shale, sandstone, and limestone units were deposited on Mississippian to Cambrian age strata that overlie basement rock

and have a thickness of up to ~1,500 m (~5,000 ft). The subsurface beds of the Pennsylvanian age, which underlie the whole county, are similar in character to those found at the surface; they consist of alternating sandstone, shale, and limestone beds with a thicker shale section. The sedimentary strata in Osage County are shallow, resulting in shallower wells being drilled in the formation. (Cole 1970)

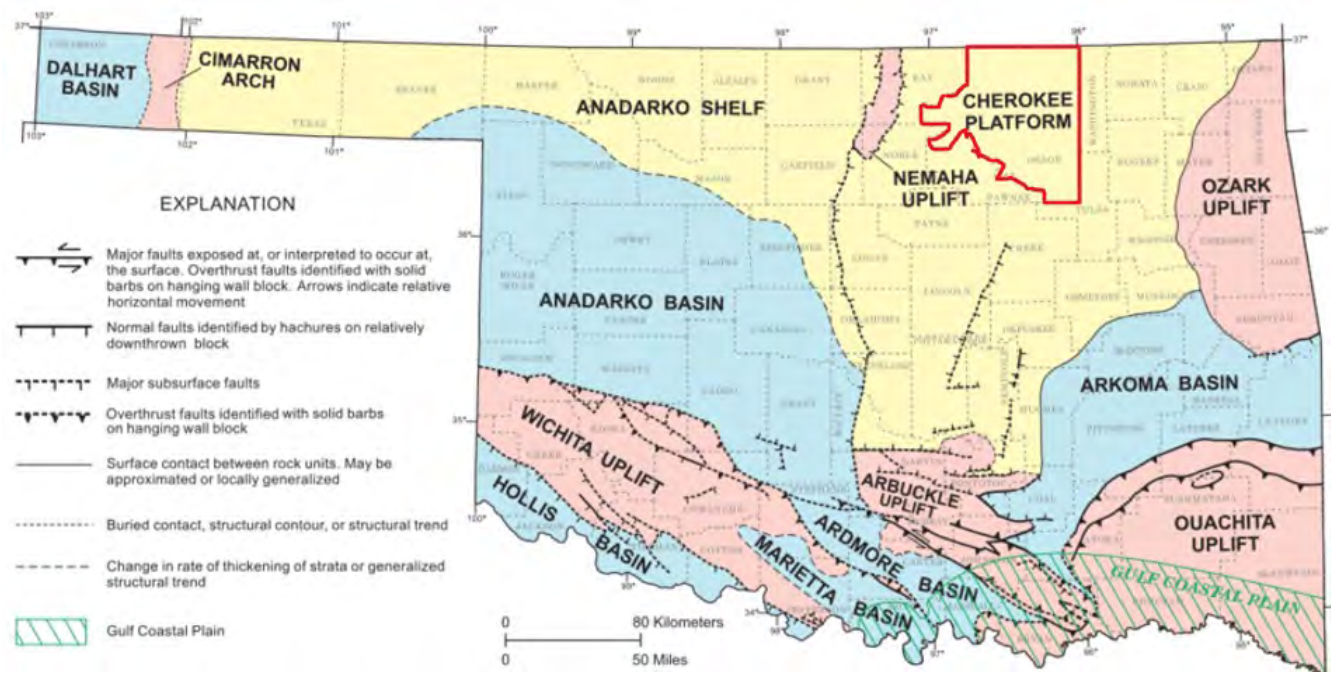

Figure 4: Geologic provinces of Oklahoma (Johnson, 2008; modified from Norhcutt and Campbell, 1995) Osage County outlined in red.

4.2 Stratigraphy

The stratigraphy of Osage County is convoluted due to the use of an informal naming system in various areas during early hydrocarbon exploration. However, the transitional sedimentary facies between the regions of central Oklahoma and southeastern Kansas are well-documented and can indicate the sedimentary facies of Osage County, as reported by Hudson et al. (2016). Despite the variation in the naming system, the rock types and their position to one another are well-documented in the region. The sedimentary rock units at the surface or shallow subsurface of Osage County are mostly interbedded sandstone, shale, and limestone sequences. Figure 5 shows the stratigraphic column for Osage County. The stratigraphic cross-section of Osage County modeled from various wells drilled in the region highlights that the primary formation in the region include Big lime, Oswego lime, Verdigris lime, Pink lime, Mississippian, Woodford shale, Simpson granite, and Arbuckle granite as shown in Figure 6. The most common reservoirs that were penetrated by these wells were all sandstone-dominated. (Vivas, Hu et al. 2023)

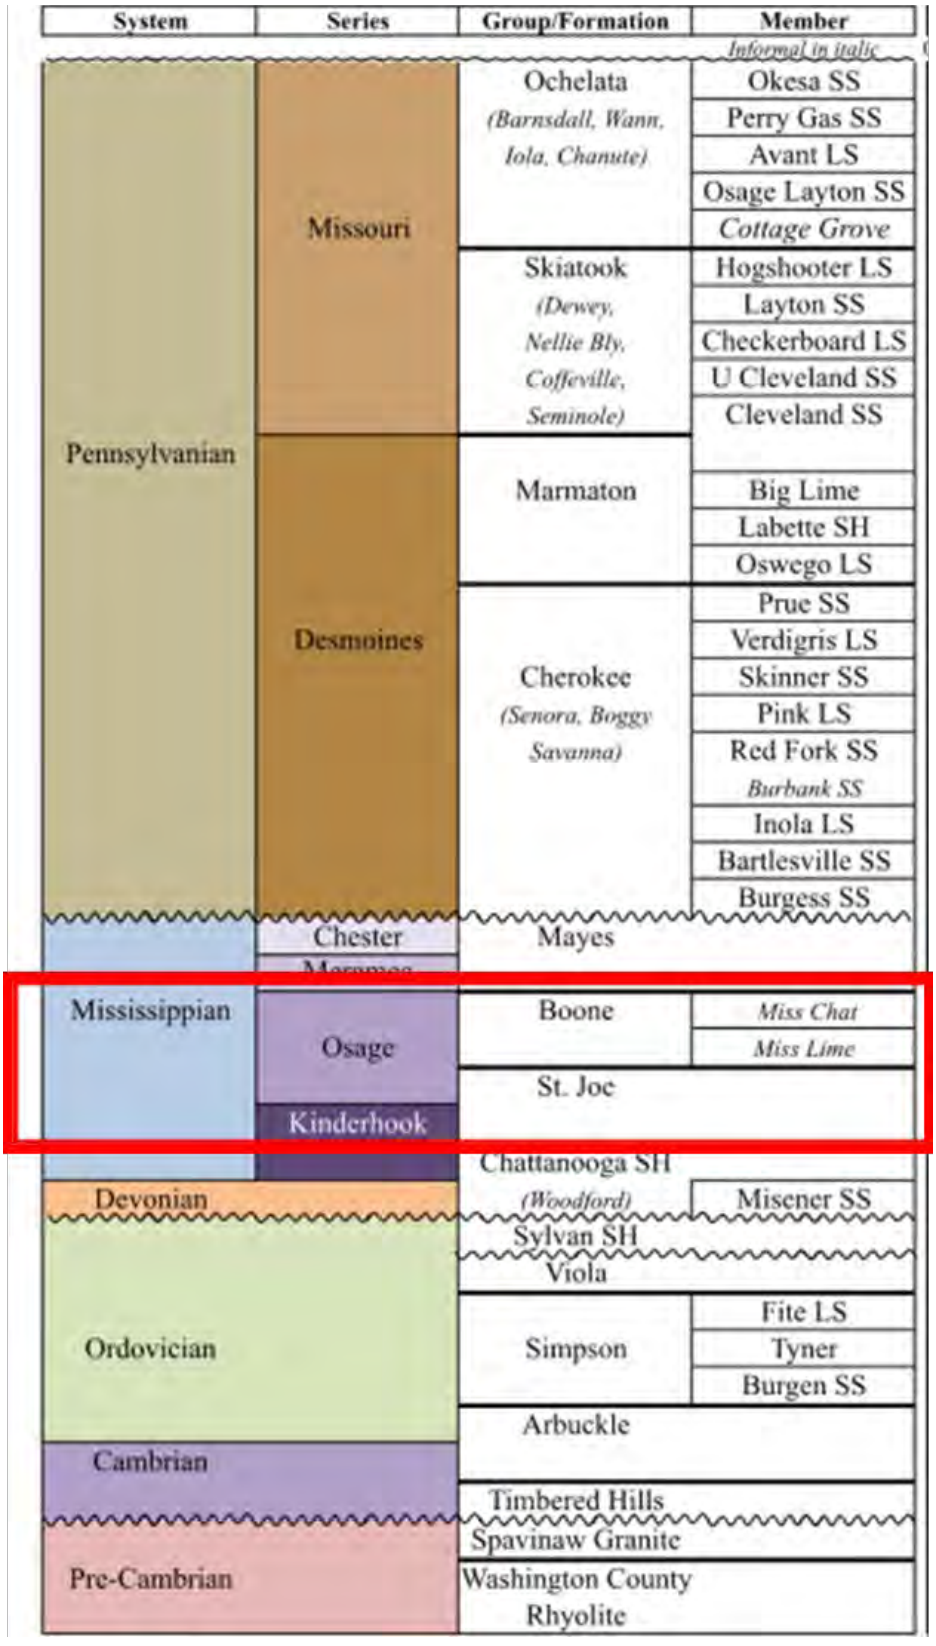

Figure 5: Stratigraphic column for Osage County

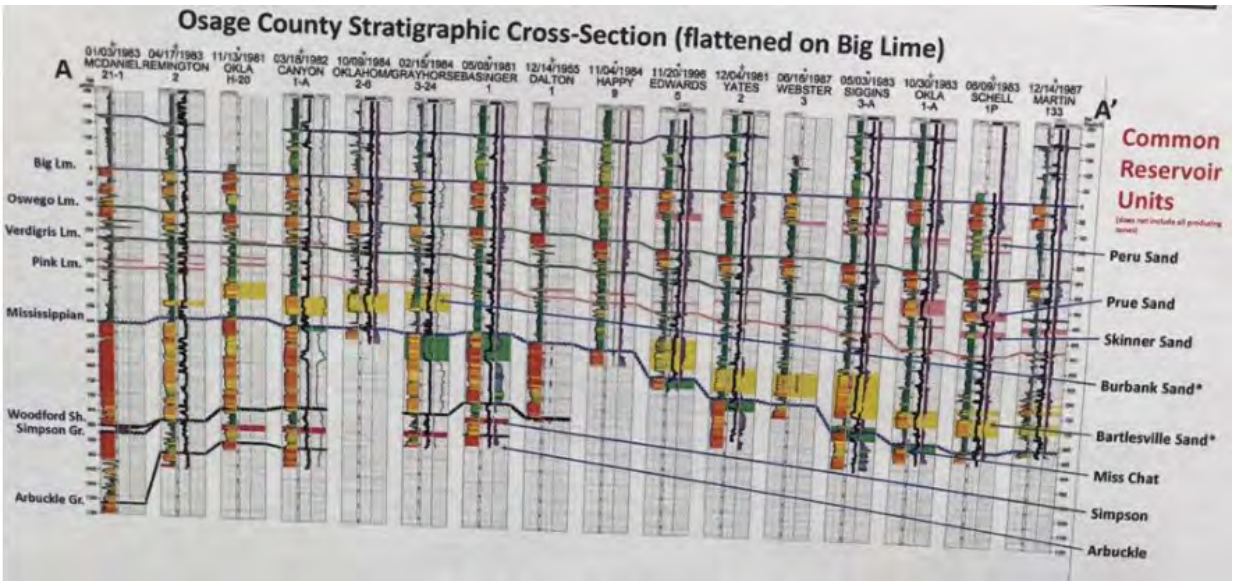

Figure 6: Osage County stratigraphic cross-section of a few wells drilled in the region. (Council)

4.3 Geological and Subsurface Modeling

Reservoir characterization and modeling encompass a comprehensive grasp of petrophysical and thermal characteristics alongside an in-depth understanding of reservoir fluids and the geothermal gradient. Beyond geological insights that aid in comprehending optimal formation facies and properties, understanding how the working fluid will flow through porous media emerges as a crucial factor in assessing the viability of geothermal applications. While geological attributes notably influence energy extraction and well stability, a profound understanding of the subsurface becomes imperative to project evaluation.

The initial phase of subsurface modeling involved digitizing raster logs obtained from the Osage Mineral Council via Petra software by S&P Global. Various logs, including gamma ray, resistivity, neutron porosity, and density porosity, were accessible from 9 wells of Briggs 1A, Briggs 2A, Briggs 3A, Edwards 5-22, Edwards 1-22, Jones 14, Jones 15. Digitizing these logs facilitated the construction of lithology models and the computation of porosity and permeability.

Following this, the Petrel model necessitated the placement of well heads. As crucial data was lacking in the raster logs, the Enverus platform and the Osage Mineral Council website were referenced to determine longitude and latitude coordinates.

Subsequently, three cross sections were generated, and corresponding correlations established. The outcomes of these processes are presented below.

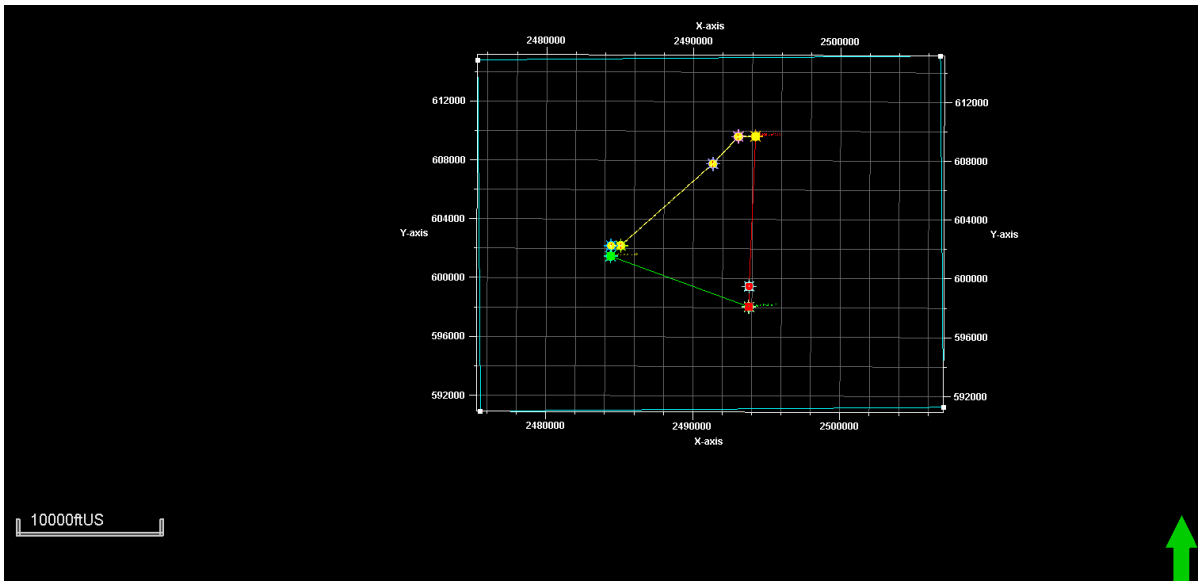

Figure 7: 2D view of cross-sections

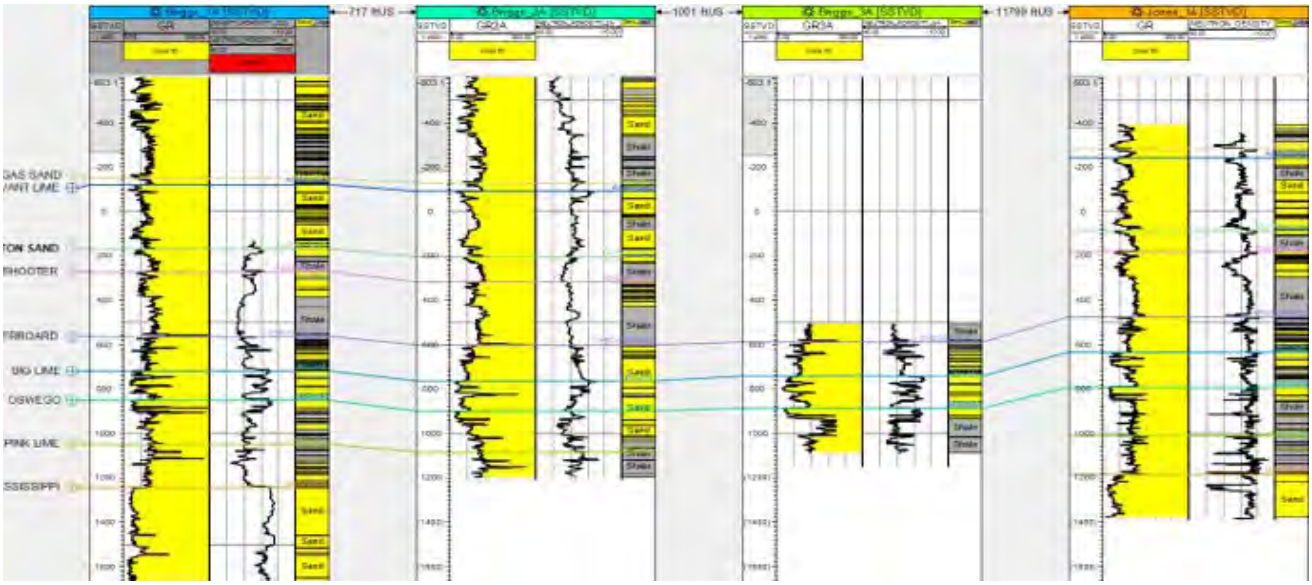

Figure 8: Well top correlations of the formation.

7 formation tops – Layton Sand, Hogshooer, Heckerboard, Big Lime, Oswego, Pink Lime, and Mississippi- were found through Enverus platform and correlated in each cross-section. Then, surfaces, horizons, and zones were created in Petrel, and the resultant 3D model is shown below.

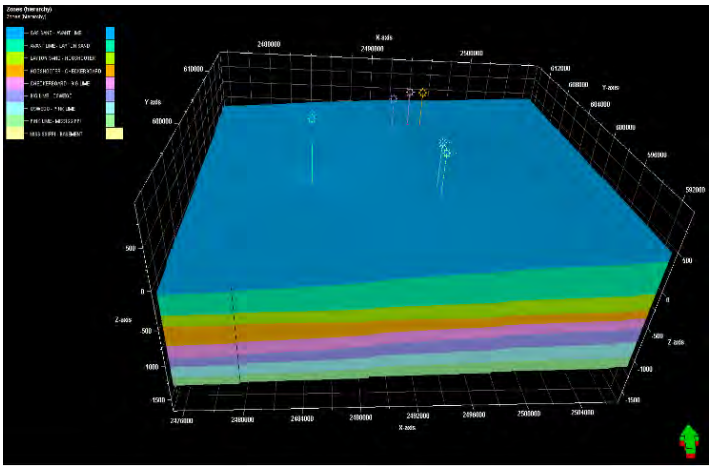

Figure 9: 3D reservoir model with all layers.

The 3D reservoir model was built using a grid that covers an area of 769,747,000 ft^2 .The thickness of the grid varies from ~1,200 ft to ~1,600 ft. A proportional layering of 20 ft was used for the model, and 100 ft x 100 ft cells were assigned to account for 12.3 million cells in the model.

For petrophysical models, the neutron-porosity raster log was readily available for 5 wells Briggs 1A, Briggs 2A, Briggs 3A, Edwards 5-22, Jones 14, and Jones 15, respectively. The Techlog software was utilized to generate porosity values from those wells. It can also be calculated from the density porosity log by the following formula:

$$PHIT = \frac{\rho_{matix} - \rho_{bulk\ volume}}{\rho_{matrix} - \rho_{fluid}} \quad (1)$$

where PHIT is the total porosity with ρ being the density of respective material.

Porosity values were upscaled, and then a 3D petrophysical porosity model was created in Petrel. Sequential Gaussian Simulation modeling was the method used. Porosity values range from 0.0010 to 0.4989, with a mean of 0.247. Too high porosity values may result from the fact that formations are shallow and there is not enough compaction and the resultant overburden stress. (Mahdaviara, Rostami et al. 2021)

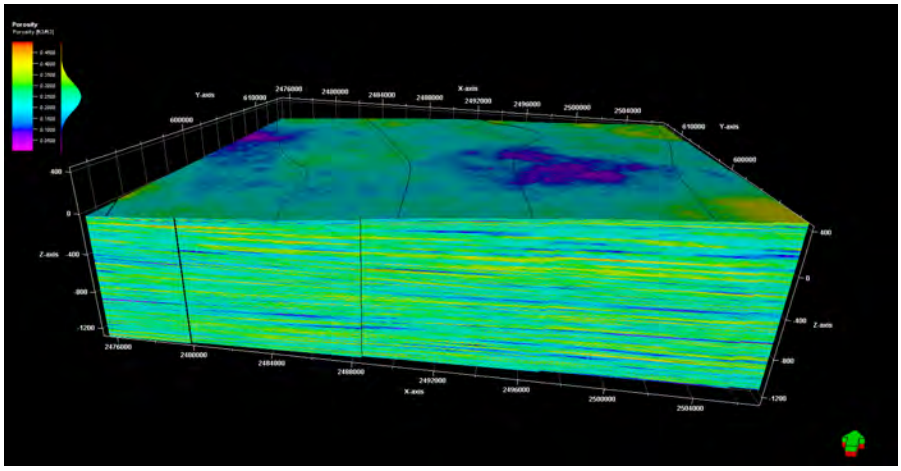

Figure 9: 3D porosity model.

Techlog used the Wyllie-Rose equation to make the correlation between porosity and permeability. Wyllie and Rose proposed a permeability correlation in an attempt to quantitatively evaluate the physical properties of reservoir rock by employing information achieved by electrical logs. They considered two independent variables of porosity and irreducible water saturation as the inputs as follows: (Sciencedirect , Sciencedirect)

$$k = \left(a \frac{\varphi^b}{S_{wirr}}\right)^c \quad (2)$$

Where a, b, c are constants, S_{wirr} is irreducible water saturation, and φ is porosity. Below is an example of how permeability values are created from porosity values. It can be seen that sandy formations' porosity and permeability values are higher than other lithologies.

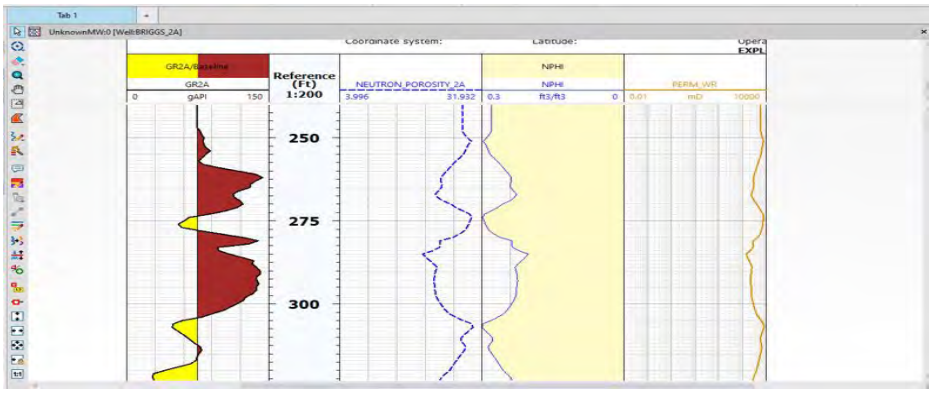

Figure 10: Techlog view of generated logs.

The model for permeability was established utilizing the permeability logs generated through Techlog software. Elevated porosity values corresponded to increased permeability values, as depicted in the permeability model. This characteristic proves advantageous for the working fluid due to its facilitated movement. However, optimizing the flow rate becomes crucial to avoid inefficient heat extraction resulting from overly swift fluid movement.

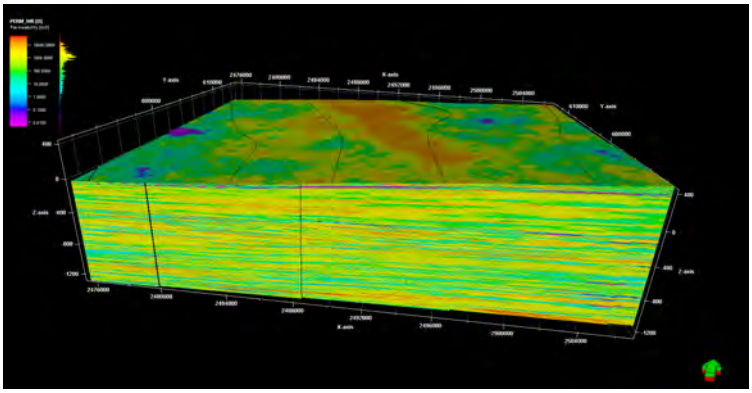

Figure 11: 3D permeability model.

Because of the model's extensive size and lengthy simulation periods, we found it necessary to limit each zone within the reservoir of interest to 10-foot layers. This adjustment significantly reduced the grid size to 7.6 million, optimizing computational efficiency. In response to the CMG model's requirements, we introduced a new zone encompassing the Mississippi-Basement zone to encompass the entirety of the reservoir. This addition was necessitated by the absence of this information in previous well logs, which is crucial because deeper regions contribute to our heat extraction. During the inclusion of this zone, we made an assumption regarding the stratigraphic continuity of permeability and porosity for seamless integration within the model's framework. This step was essential to ensure comprehensive coverage of the reservoir's subsurface characteristics and its deeper heat sources. The resultant 3D grid, porosity, and permeability models after changing layering and adding new zones are given below:

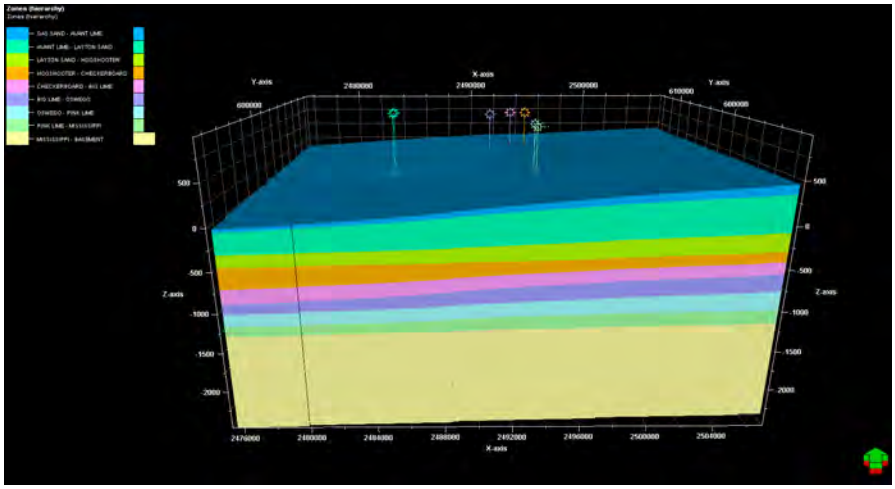

Figure 12: Final 3D reservoir model with all layers.

The final 3D reservoir model was constructed using a grid covering an area of approximately 769,747,000 square feet. The grid's thickness varies between approximately 2,456 feet and 2,800 feet. The model employed a uniform layering of 10 feet, incorporating cells measuring 100 feet by 100 feet, totaling 7.6 million cells within the model.

Permeability values, depicted in Figure 13, range from 0.0118 millidarcies to 10,000 millidarcies, with an average value of 1,660 millidarcies. Porosity values, shown in Figure 14, span from 0.0010 to 0.5, with an average of 0.25.

Visualizing petrophysical properties is valuable for evaluating and identifying the most promising oil and gas well sites within the specified area. For instance, warmer tones in the visualization highlight regions with the most favorable reservoir attributes.

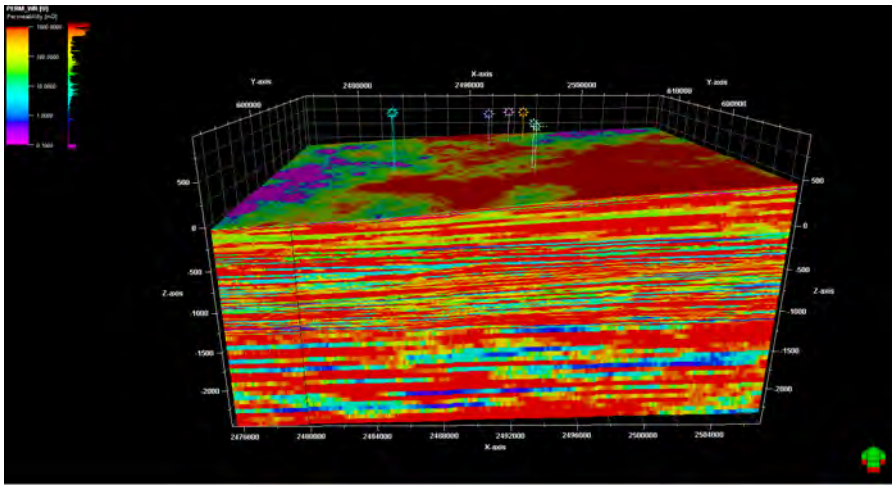

Figure 13: Final 3D permeability model.

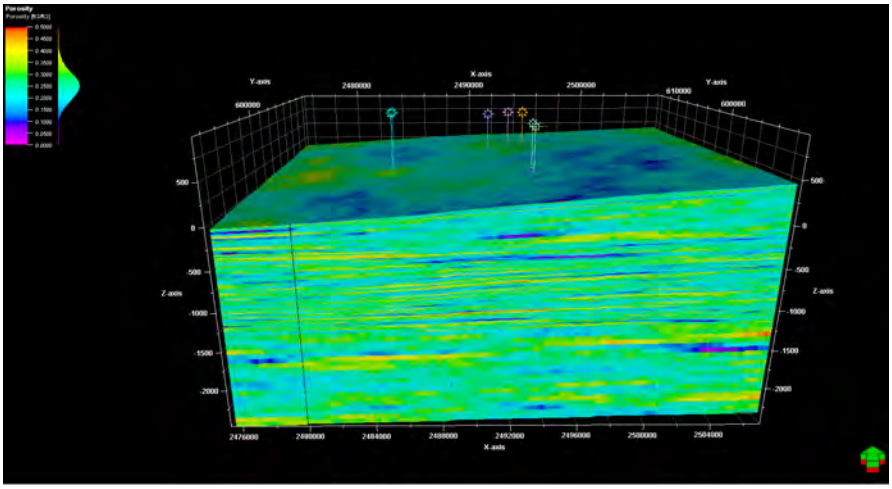

Figure 14: Final 3D porosity model.

5. Modeling

5.1 Temperature Modeling

Temperature survey logs obtained from wells drilled in the neighborhood of the greenhouse were analyzed to characterize the study area's geothermal gradient. A geothermal gradient of 0.0205 °F/ft or 37.36 ℃/km. The estimated geothermal gradient is used to model the heat potential around the greenhouse. The CMG modeling software built the temperature model, where equation 1 was applied.

$$T = 0.0205 * D + 78 \quad (3)$$

Where T represents the temperature, and D is the depth of interest.

Figure 15 shows the temperature model for a total depth of 2,020 ft. A total temperature of 118 °F can be generated from a well drilled at a depth of 2,020 ft. According to the GeoVision report of 2019, a minimum temperature of 110 °F is required for greenhouse and food processing. Therefore,

to maintain the greenhouse in the Osage Nation heated during winter, wells with a minimum depth of 2,000 ft must be drilled to produce the required heat.

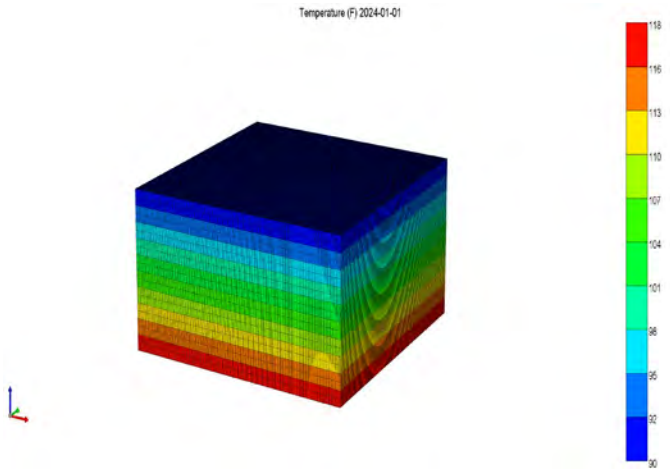

Figure 15: Temperature modeling based on the temperature surveys obtained from wells drilled in the neighborhood of the area of interest.

5.2 Reservoir Modeling and Enthalpy Production

A combination of geological and petrophysical models obtained from Petrel was exported in CMG using STARS to simulate the system's potential enthalpy production over a 20-year lifespan. Due to the excessively long computational time of the simulation, the exported model from Petrel was cropped to the study area to optimize the computational time. The simulated model included two (2) producing wells and one (1) injection well. All three (3) wells used in the simulation were drilled at a depth of 3,000 ft. As the temperature model reports, a minimum depth of 2,000 ft is enough to generate sufficient temperature to sustain a greenhouse. Figure 16 shows the simulated grid. The resources assessment was conducted for various injection rates ranging from 1,000 bbl/d to 5,000 bbl/d. The injection rate on the injection well was varied to estimate the overall enthalpy production at each rate.

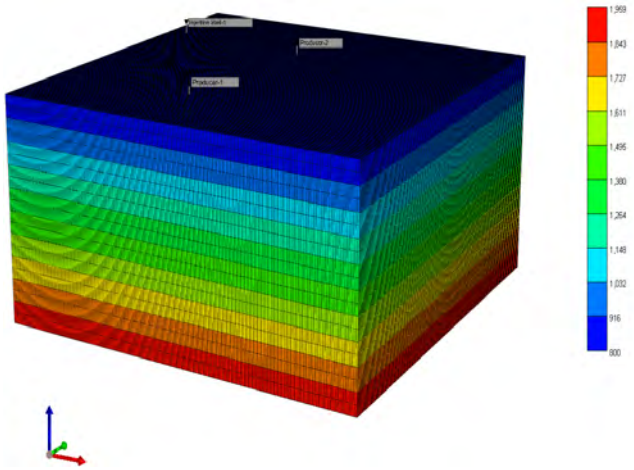

Figure 16: Reservoir model displaying the two (2) producing wells and one (1) injection well.

The cumulative enthalpy production from the producing wells is obtained for all injection rates to estimate the optimum injection rate for generating the required enthalpy needed to fulfill the heat demand for heating the greenhouse. The results of the simulation indicated that the enthalpy production range from 20 MMBTU/day for the injection rate of 1,000 bbl/d to 40 MMBTU/day for the injection rate of 5,000 bbl/d. Figure 17 shows the enthalpy production rate for all injection rates. Based on the results, an injection rate of 2,000 bbl/d is sufficient to produce the heat required for the greenhouse with a total enthalpy production of over 20 MMBTU/d. However, an injection rate of 3,000 bbl/d is chosen so that the extra energy produced can be distributed to the research laboratory and the fish farming buildings near the greenhouse, therefore optimizing the project and making it more economically attractive and beneficial to tribal communities in their pursuit for food sovereignty.

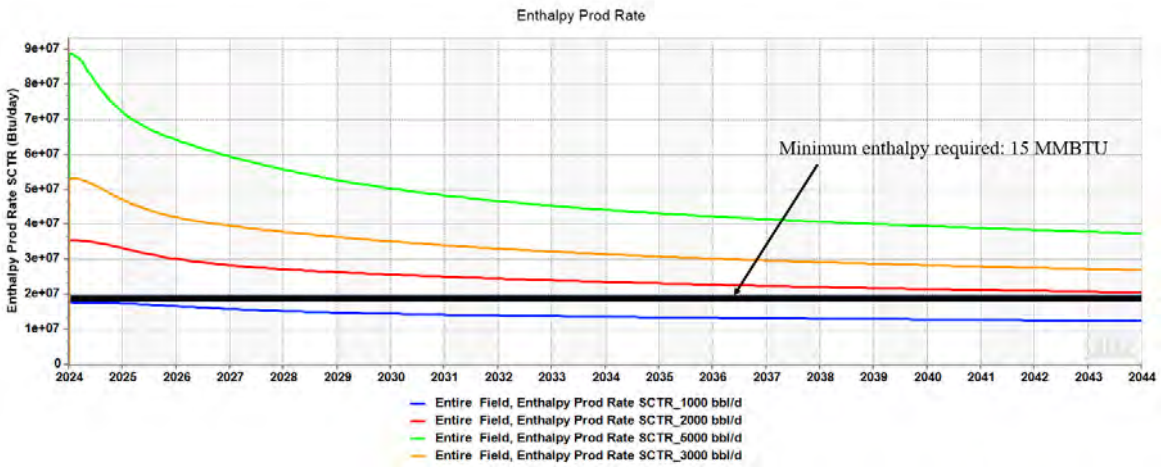

Figure 17: Enthalpy production rate for all four injections rate

Although a very detailed model comprises all the formations in the area, the reservoir model dimensions limit or inhibit the capacity to perform simulations in later stages using CMG. Therefore, it is recommended that the model be simplified without losing the details in the formation of interest. The well models can be optimized to maximize the enthalpy production and investigate the use of secondary production recovery mechanisms to maximize the enthalpy.

The temperature is one of the driving forces behind the energy production from the wells used in this project. A temperature drop analysis revealed that the entire field, which includes the two producing wells, does not exhibit major temperature loss over the 20-year lifespan of the project. A faster temperature decline is obtained when water is injected at a rate of 5,000 bbl/d. This is due to the reservoir cooling down at a faster rate since a larger volume of cooler fluid is injected into it. Figure 18 shows the temperature drop profile for four (4) injection rates over 20 years.

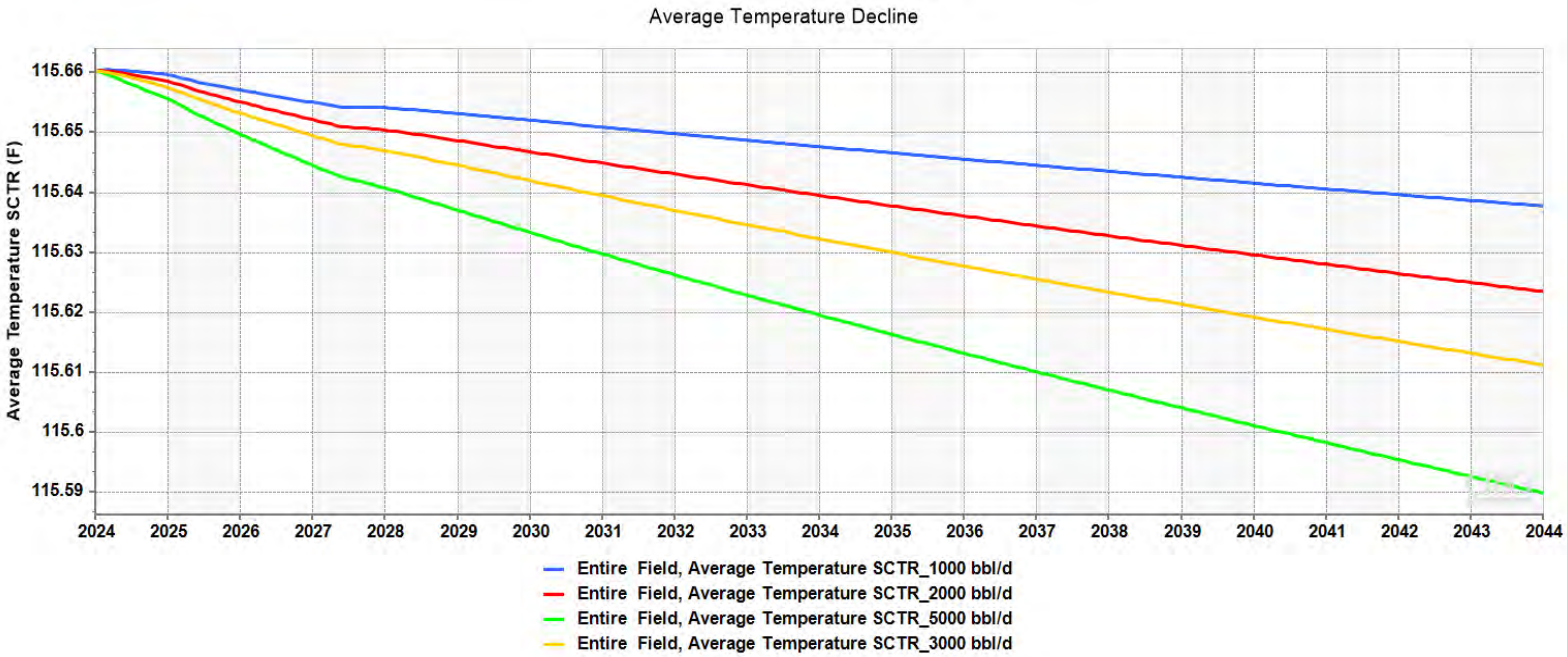

Figure 18: Temperature drop profile for the entire field over 20 years.

5.2 Pipesim Modeling

A geothermal well is modeled in Pipesim to investigate its performance in terms of pressure drop and water flowing rate in the well. The well was designed to a depth of 3,000 ft. The completion includes a surface casing set at a depth of 500 ft to seal the freshwater aquifer in the study area. The intermediate casing was set at a depth of 1,600 ft; finally, the production casing was set at a depth of 3,000 ft. A nodal analysis of the created well was conducted to estimate the well performance. Figure 19 shows the well design and the water flowing rate as a function of temperature. The water flowing rate is shown to be increasing with temperature, indicating the potential for higher steam water production at larger downhole temperatures.

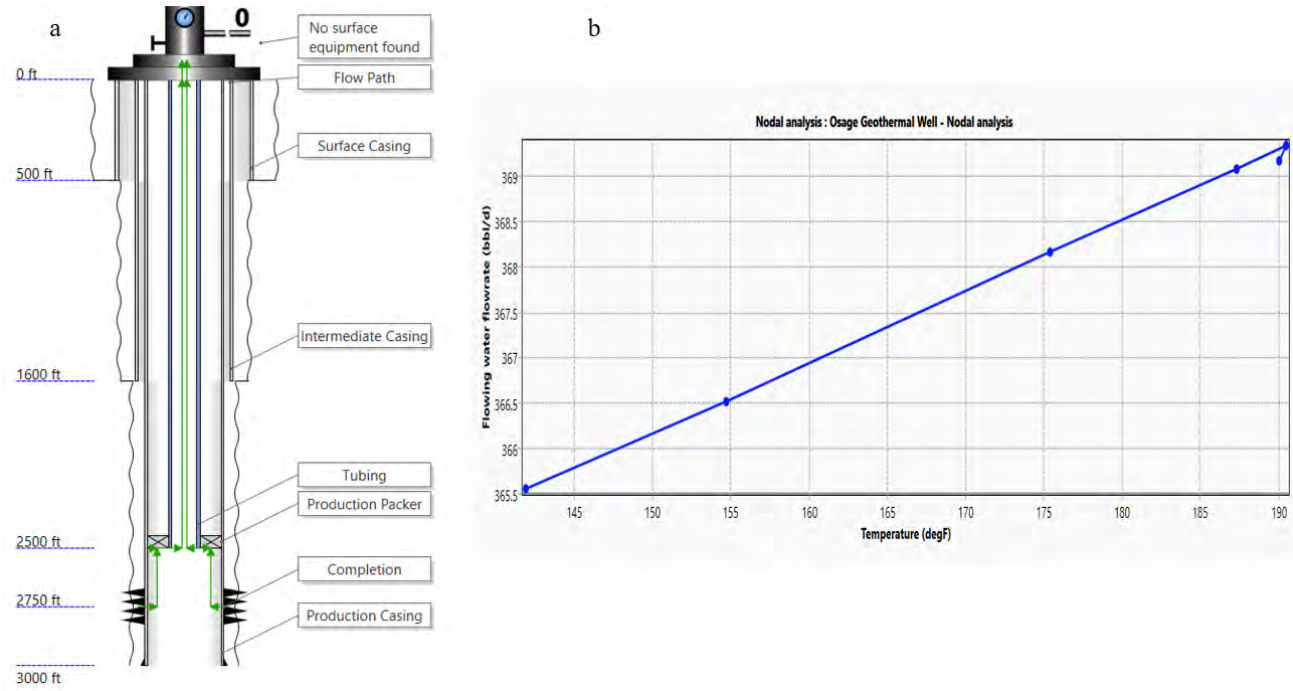

Figure 19: (a) Well design and (b) the water flowing rate as a function of temperature.

The Pipesim model was used to investigate the potential for artificial lift in the different production wells. The implementation of artificial lift will help in optimizing energy production.

6. Economic Analysis

6.1 Energy Consumption of the Greenhouse

The electricity bills for the greenhouse serve as a crucial indicator of its energy consumption trends, and a notable pattern emerges when examining the correlation between energy usage and the seasonal calendar. Figure 20 vividly illustrates a substantial surge in energy demand during the cold months, spanning from December through the beginning of March. This significant uptick in electricity consumption can be attributed to the imperative need for climate control within the greenhouse environment during winter. Maintaining an optimal and consistent climate inside becomes paramount for cultivating plants as temperatures plummet outside. Heaters, ventilation systems, and other climate control mechanisms operate at heightened capacities during these colder months, contributing to a pronounced spike in energy consumption. Consequently, the observed increase in electricity usage during this period underscores energy's critical role in sustaining a conducive environment for greenhouse cultivation when external conditions are less favorable.

Additionally, noteworthy energy consumption spikes are evident during June and July, albeit not as pronounced as during winter. These summer peaks are associated with the cooling requirements of the greenhouse, as the rising external temperatures necessitate active measures to prevent overheating. While the energy demand during these warmer months is not as steep as in winter, it underscores the dynamic nature of the greenhouse's energy needs throughout the year. These insights into seasonal energy consumption patterns lay the groundwork for evaluating how the

Osage County Geothermal Energy Project can effectively address both heating and cooling demands, providing a comprehensive understanding for the subsequent economic analysis.

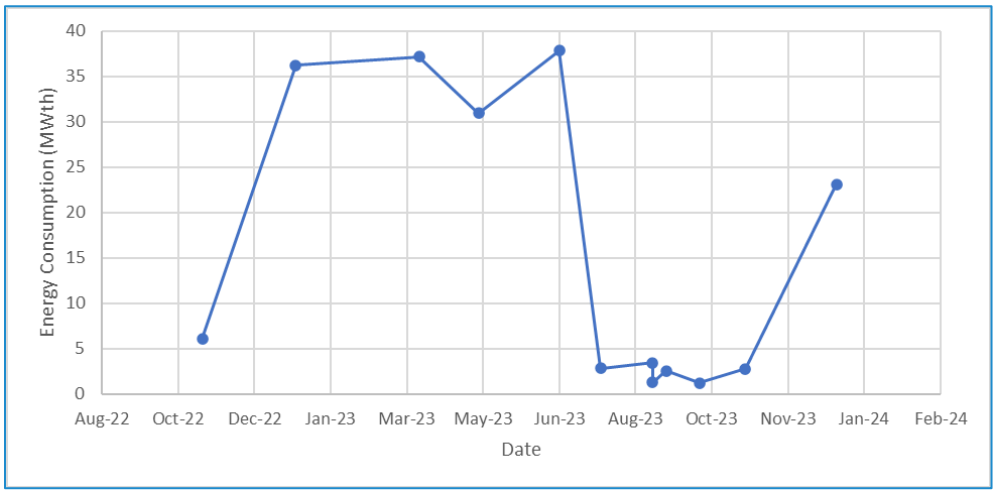

Figure 20: Energy Consumption of the Greenhouse

6.2 Levelized Cost of Energy in Oklahoma, USA

The graph depicting the price of natural gas in $/thousand cubic feet ($/Mcf) in Oklahoma, sourced from the US Energy Information Administration (2023) and covering the period from January 2021 to September 2023, unfolds a dynamic narrative of fluctuation. This variability in natural gas prices directly impacts the overall energy landscape, influencing the levelized cost of electricity (LCOE). Notably, the LCOE experiences discernible spikes, especially during the cold months, reflecting the heightened demand for heating in various sectors, including greenhouse operations.

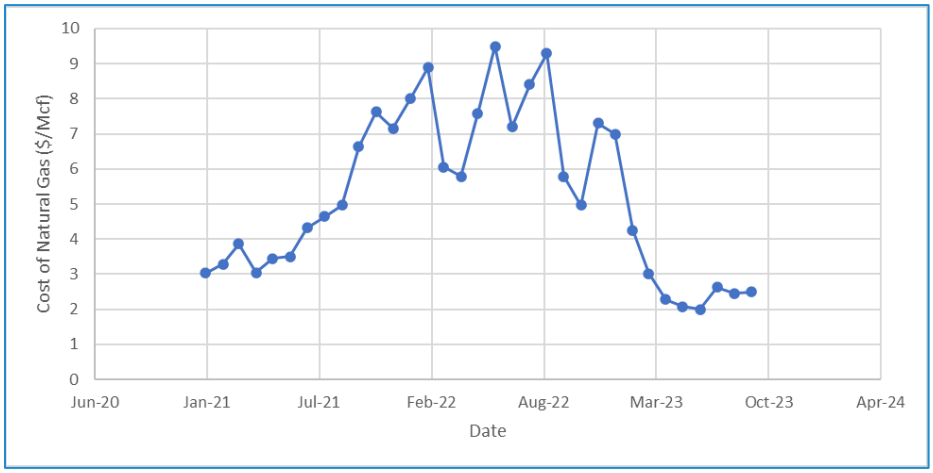

Figure 21: Natural Gas Price, eia (2023)

The reliance on natural gas as a primary driver for electricity generation introduces an element of unpredictability into the cost equation. The sporadic spikes in natural gas prices, particularly evident during colder months, pose a notable challenge when attempting to predict expenditures for the greenhouse. These fluctuations can significantly impact overall electricity costs for the greenhouse, creating an intricate environment for precise budgetary forecasts. As we navigate

through the economic analysis of the project, it becomes imperative to recognize and strategize around the inherent unpredictability in natural gas prices to establish a resilient financial foundation.

6.3 Economical Feasibility Analysis

The foundation of our economic feasibility analysis for the project rests upon the robust capabilities of GEOPHIRES v2, an open-source software by National Renewable Energy Laboratory (NREL). This advanced tool plays a pivotal role in unraveling the intricacies of the project's financial landscape, calculating a comprehensive array of techno-economic values crucial to its success. GEOPHIRES v2 goes beyond conventional analyses, encompassing key metrics such as the Levelized Cost of Heat (LCOH), Capital Expenditures (CAPEX), Operational Expenditures (OPEX), and the simulation of net heat over a specified timeframe. Furthermore, it navigates the nuanced details of reservoir pressure, temperature drop-down, and pressure losses during production, providing a holistic understanding of the geothermal system's behavior.

The utilization of GEOPHIRES v2 for our economic feasibility analysis introduces a versatile suite of calculation methods and accommodates a multitude of inputs to enhance precision. Notable among these inputs are user-provided reservoir output temperature data, with a specific focus on Direct Use as the chosen end-use of geothermal energy, as discussed in preceding chapters. The Standard Levelized Cost Model is the economic model employed for calculating the Levelized Cost of Energy.

In the meticulous breakdown of Capital Expenditures (CAPEX), the calculation encompasses Well Drilling and Completion Capital Cost and surface Plant Capital Cost, while Operational Expenditures (OPEX) amalgamate Wellfield O&M Cost, Surface Plant O&M Cost, Make-Up Water O&M Cost, and Average annual pumping costs. The analysis delves into multiple scenarios, with a standout case featuring well depths set between 3,000 to 4,000 ft. Despite slight variations in drilling and completion costs within this depth range, the resulting values for the Levelized Cost of Heat (LCOH) and net heat prove notably similar.(Clark, Harto et al. 2010)

Key parameters defining the geothermal system include a maximum reservoir temperature set at 120 F, aligning with temperature log readings. The optimal configuration for maximizing net heat at the lowest LCOH involves drilling two producing wells and one injection well, each with a production casing diameter of 7.75 inches. The injection temperature of the working fluid is set at 80 F. Furthermore, the plant's lifetime is conservatively set at 30 years to simulate changes in net heat over time. This nuanced approach ensures a comprehensive evaluation of the Osage County Geothermal Energy Project, considering various factors to enhance the accuracy and reliability of our economic projections.

6.4 CAPEX and OPEX Insights

The detailed economic breakdown provided by GEOPHIRES v2 sheds light on the comprehensive costs associated with the geothermal heat initiative. The Wellfield Cost, covering the drilling and completion of three wells, is quantified at 4.85 million dollars. Complementing this is the Surface Plant Cost, which is estimated at 9.78 million dollars. When combined, these elements contribute to a total Capital Expenditure (CAPEX) of 14.63 million dollars.

Regarding operational expenditures, the annual costs for efficient Wellfield Operation and management amount to 0.29 million dollars. Simultaneously, Surface Plant Operation & Management incurs an annual cost of 0.88 million dollars. The Make-Up Water Operation & Management Cost also contributes an annual expenditure of 0.12 million dollars. This meticulous breakdown of operating costs provides a clear understanding of the ongoing financial commitments necessary for the sustained and effective operation of the geothermal plant.

These detailed CAPEX and OPEX figures offer a comprehensive financial snapshot, essential for evaluating the economic feasibility and sustainability of the geothermal energy initiative. The meticulous accounting of costs ensures a transparent foundation for further economic analyses and decision-making processes.

6.5 LCOH and Market Competitiveness

The simulation results from GEOPHIRES v2 yield a compelling economic assessment for the direct use of geothermal resources in Osage County. The levelized cost of heat (LCOH) calculation stands impressively low at 3.7 $/MMBTU. This figure signifies the economic viability of harnessing geothermal energy for direct use and positions it as an exceptionally cost-effective alternative.

In comparison to the historical natural gas prices over the past three years, the LCOH of 3.7 $/MMBTU represents an average cost reduction of approximately 65%. This substantial cost advantage underscores the economic competitiveness of the geothermal solution, positioning it favorably within the energy landscape. This significant cost differential holds promising implications for the project's sustainability and economic success, reaffirming geothermal energy's potential as a cost-effective and environmentally friendly energy source.

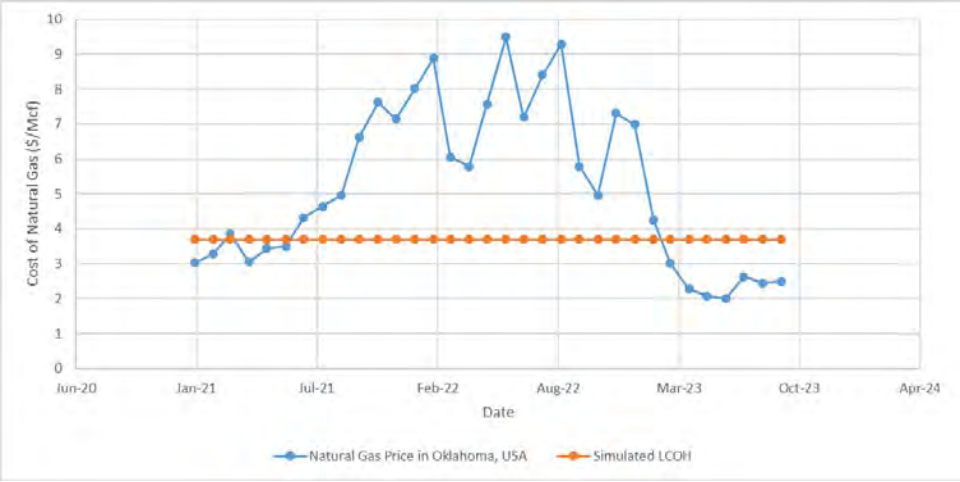

Figure 22: Calculated LCOH vs Gas Prices

6.6 Net Heat's Reliability and Adaptability

The net heat extraction from the geothermal field, as determined by the simulation using GEOPHIRES v2, reveals a robust and consistent performance. The average net heat obtained

stands at an impressive 35.20 MWth. Throughout the comprehensive 30-year simulation period, the net heat production displays a commendable range, spanning from a Minimum Net Heat Production of 32.36 MWth to a Maximum Net Heat Production of 37.97 MWth.

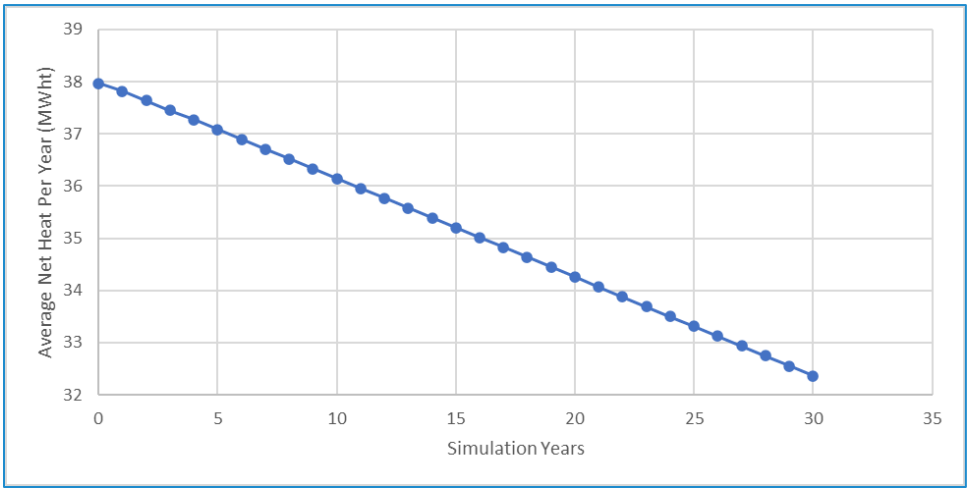

Figure 23: Simulated Net Heat Over 30 Years

The consistently obtained net heat from the geothermal plant, with its commendable average of 35.20 MWth, is sufficient for meeting thermal requirements throughout the majority of the year. This reliability underscores the robust performance and sustained output of the geothermal system. The minor setback noted during periods of massive consumption spikes suggests the plant's capacity to handle varying demands, with occasional adjustments needed during peak consumption intervals.

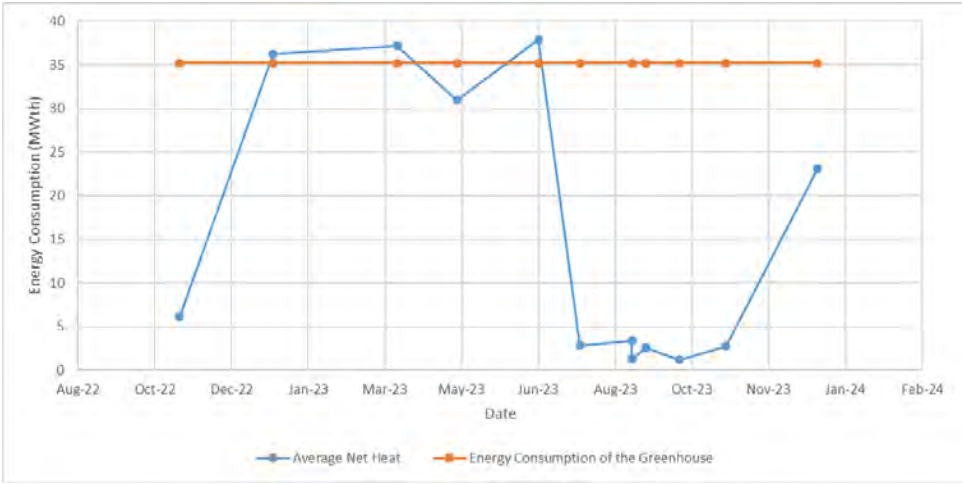

Figure 24: Simulated Net Heat vs Energy Consumption of the Greenhouse

7. Conclusion

The geothermal project within the Osage Nation represents a significant advancement in sustainable energy development, symbolizing the Osage tribe's journey toward energy sovereignty and self-sufficiency. The project's multifaceted benefits include economic stability, environmental

responsibility, and community development, establishing a standard for responsible resource utilization and renewable energy practices within Indigenous communities. This initiative serves as a testament to the Osage tribe's dedication to creating a resilient and sustainable future, showcasing the transformative power of community-driven, environmentally conscious energy projects. Specifically, an injection rate of 3000 barrels per day proved effective for heating and cooling the greenhouse. Additionally, the project achieved a levelized cost of heat of $3.7 per MMBTU, which represents a 65% reduction compared to the average energy costs in the surrounding area.

8. Recommendation

Looking ahead to the future development of the Geothermal Project in the Osage Nation, several key strategies have been outlined to enhance its effectiveness and sustainability. First, there is a push to enhance data integration by incorporating additional well logs and seismic data. This will provide a more comprehensive understanding of subsurface formations, which is crucial for refining reservoir models and improving predictive accuracy.

Secondly, there will be an ongoing effort to continuously refine these reservoir models, utilizing newly acquired data. This iterative process is designed to ensure more accurate predictions and to optimize production strategies, keeping the project efficient and effective over time.

Community engagement is also a priority. Plans are in place to establish educational programs that will inform and engage the local community about the project’s benefits and its commitment to sustainability. These initiatives aim to foster partnerships and maintain transparent communication with community members.

Moreover, thorough environmental impact assessments will be conducted regularly to mitigate any potential adverse effects on local ecosystems. Integrating sustainable practices into all project operations will be a cornerstone of these assessments, ensuring that environmental health is preserved.

Finally, there is a commitment to technological innovation. Investment in research for advancements specific to geothermal energy extraction is planned, which will include fostering collaborations for the development of novel drilling and heat extraction methods. This focus on innovation will help push the boundaries of what is currently possible in geothermal energy, making the project a leader in sustainable energy technology.

9. Acknowledgement

We would like to express our deepest gratitude to Osage Nation members, Osage Mineral Council, greenhouse staff, and our advisor for their invaluable guidance, encouragement, extensive communication, and support throughout this research. Their insights and expertise were instrumental in shaping the direction and quality of this work. We are also grateful to the University of Oklahoma for providing the resources and the DOE Collegiate team for creating this opportunity to formulate and present the project to the vast.

Geothermal, downhole tools, full-scale testing, Utah FORGE

ABSTRACT

The current demand for energy, in addition to the efforts to reduce greenhouse emissions in the United States, has increased the importance of sustainable energy than ever before. In this respect, geothermal energy has become one of the most attractive solutions due to the huge amount of untapped resources that are present in many parts of the world. It is the only source of renewable energy that is not dependent upon climate conditions and remains in operation mode 98% of the time. However, extracting geothermal energy is challenging, as most conventional downhole tools fail under high-temperature, high-pressure (HPHT) conditions. Moreover, if these tools fail during the completion or production phase, it can compromise the well integrity and jeopardize project success. Therefore, this paper provides a summary of downhole tools, such as zonal isolation tool and flow valves developed under FORGE 1 project used for geothermal purposes, that can work under HPHT conditions. In addition, schematics of completions and working procedures will be presented to show how these tools would be installed and operated in the geothermal wells. These downhole tools have been tested at HPHT conditions and will be installed in one of the FORGE (Frontier Observatory for Research in Geothermal Energy) wells.

1. Introduction

The increase in the population around the globe has led to an increment in the energy demand. Dudley (2017) estimates that by 2035, the earth's population will be around 8.8 billion. To meet the rising demand of energy, some challenges need to be addressed, such as the greenhouse effects produced by fossil fuels, which are the primary source of energy at present. Fossil flues have played an essential role during the past years; however, CO_2 emitted by burning these fossil fuels has become an accelerator for global warming. According to Crippa et al. (2022), in 2012 the CO_2 emission per person was about 4.8t.

For this reason, green alternatives such as geothermal have become more attractive, not only because they help with the reduction of the greenhouse effect but also due to the vast amount of untapped resources, availability in different parts of the world, and wide range of applications (Lund, 2000). The possible applications for geothermal energy go from small scales, like heating buildings, to larger scales, such as electric power generation (Abid et al., 2022).

One of the challenges in geothermal engineering is related to the high pressure and high temperature (HPHT) conditions in which they are found. It is estimated that most geothermal systems currently exist in a temperature range between 150 – 300 ºC (Velasquez et al., 2024, as cited by Renisch et al., 2017 and Abid et al., 2022). DiPippo (2016) mentions that approximately 50% of the geothermal budget goes towards drilling and completion due to the extreme conditions of the subsurface. Moreover, the downhole equipment must withstand extreme HPHT conditions of the geothermal wells.

For this reason, and as part of the Utah FORGE project, Welltec Inc. has designed some downhole tools capable of withstanding the extreme HPHT conditions encountered in geothermal projects. In that respect, Welltec Inc. has developed a zonal isolation tool and downhole valve for use in the Utah FORGE Field, where the downhole temperature is 175 to 225°C (Moore, 2020). These tools were tested at HPHT conditions at the University of Oklahoma. The testing temperature ranged between 240 and 320°C, whereas the pressure was about 6,000 psi. The purpose of testing the tool at temperatures higher than those encountered downhole in the Utah FORGE wells is to ensure its reliability and robustness under extreme conditions. By subjecting the tool to these elevated temperatures, we can confirm that it will perform effectively and withstand the maximum temperatures it may encounter in the wells, thereby enhancing its security and operational safety. This paper will present the results of these tests and provide a schematic of how the tools will be deployed in the Utha FORGE wells.

2. Tools description

In this section, a full description of the zonal isolation tool and flow valve will be presented to better understand the functionality of these new tools designed by Welltec.

2.1 Zonal isolation tool

The design and the cross-sectional view of the zonal isolation tool are illustrated in Figure 1. Whereas, Figure 2 shows a picture of the toll before being exposed to the HPHT test.

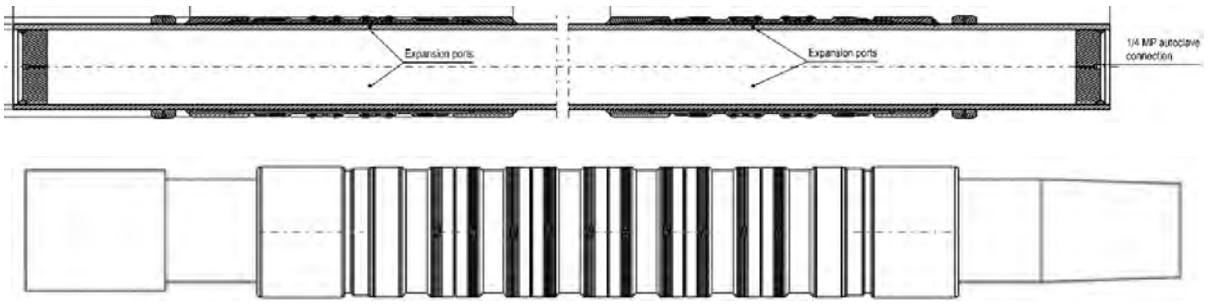

Figure 1: Design and cross-sectional view of the zonal isolation tool

Figure 2: Zonal isolation tool designed by Welltec

The zonal isolation tool is designed to expand and set at 6,000 psi (differential pressure) with the maximum run in hole ID 8.42". It has the capacity to operate at the temperature range of 60 to 260°C.

2.2 Flow Valve

The flow valve is designed to withstand 6,000 psi for burst and collapse conditions, and its operating temperature is 260 ºC. The unloading cycle is closed – open – closed, and to be able to open or close the valve, 1,500 psi of force is necessary, and the valve has to be shifted. The schematic of the flow valve is shown in Figure 3.

Figure 3: Flow valve schematic

3. HPHT test before installation

Before installing the tools in the Utha FORGE well (Well 58-32), they were tested at HPHT conditions in the facilities of the University of Oklahoma at the Well Construction Technology Center (WCTC). Both tools were tested in separate facilities but with same HPHT conditions (6,000 psi and 225 ºC).

3.1 Zonal isolation tool HPHT test

This tool was tested for three cycles (One cycle = heating to 225 ºC and cooling down). However, this paper will focus on one of the HPHT tests performed during cycle #2. Figure 5 shows the schematic of the testing setup, whereas Figure 6 shows thermometers placed in different spots of the setup to monitor the system's temperature.

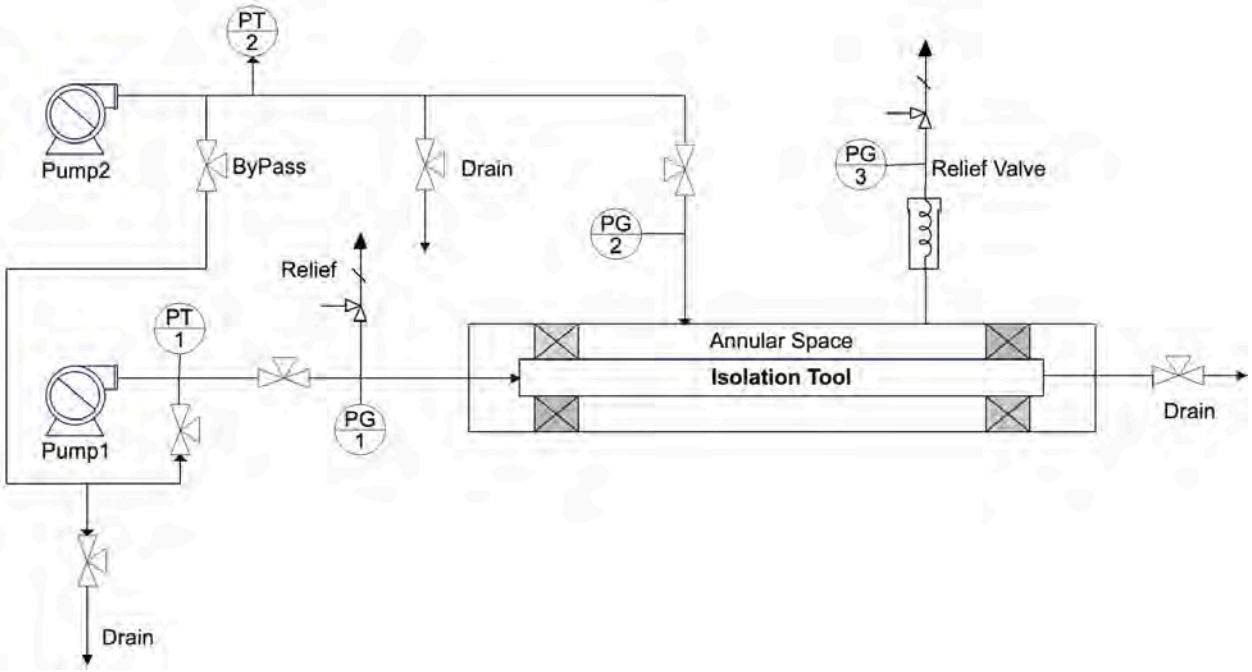

Figure 4: Schematic diagram of the long-scale testing setup

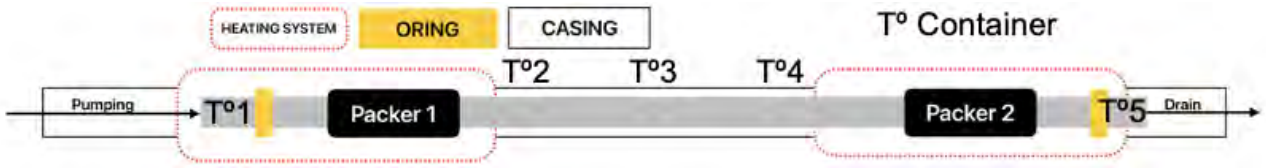

Figure 5: Thermometer placement in the system

The tool was tested for 14 days straight in cycle #2, where the temperature was kept over 225ºC during the whole cycle. Meanwhile, the pressure in the annular section and inside the tool was kept at 3,000 psi and increased to 6,000 psi three times for 1 hour to test the tool at its extreme conditions. Figure 6 presents the temperature and pressure conditions during this cycle.

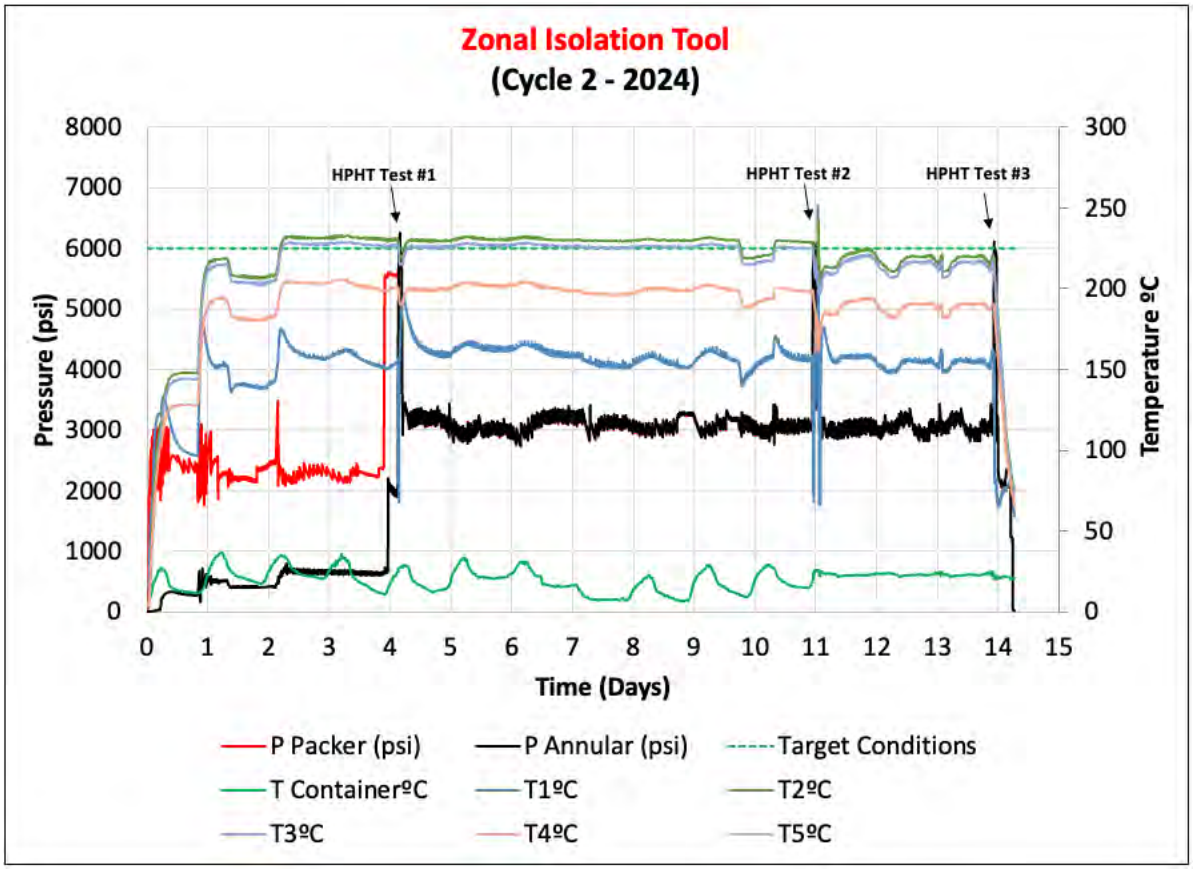

Figure 6: Cycle # 2 performed on zonal isolation tool

In Figure 7, the first HPHT performed on the zonal isolation tool is shown, where it can be seen that the pressure was able to be kept at over 6,000 psi for 1 hour, with an average leak lower than 0.2 GPM.

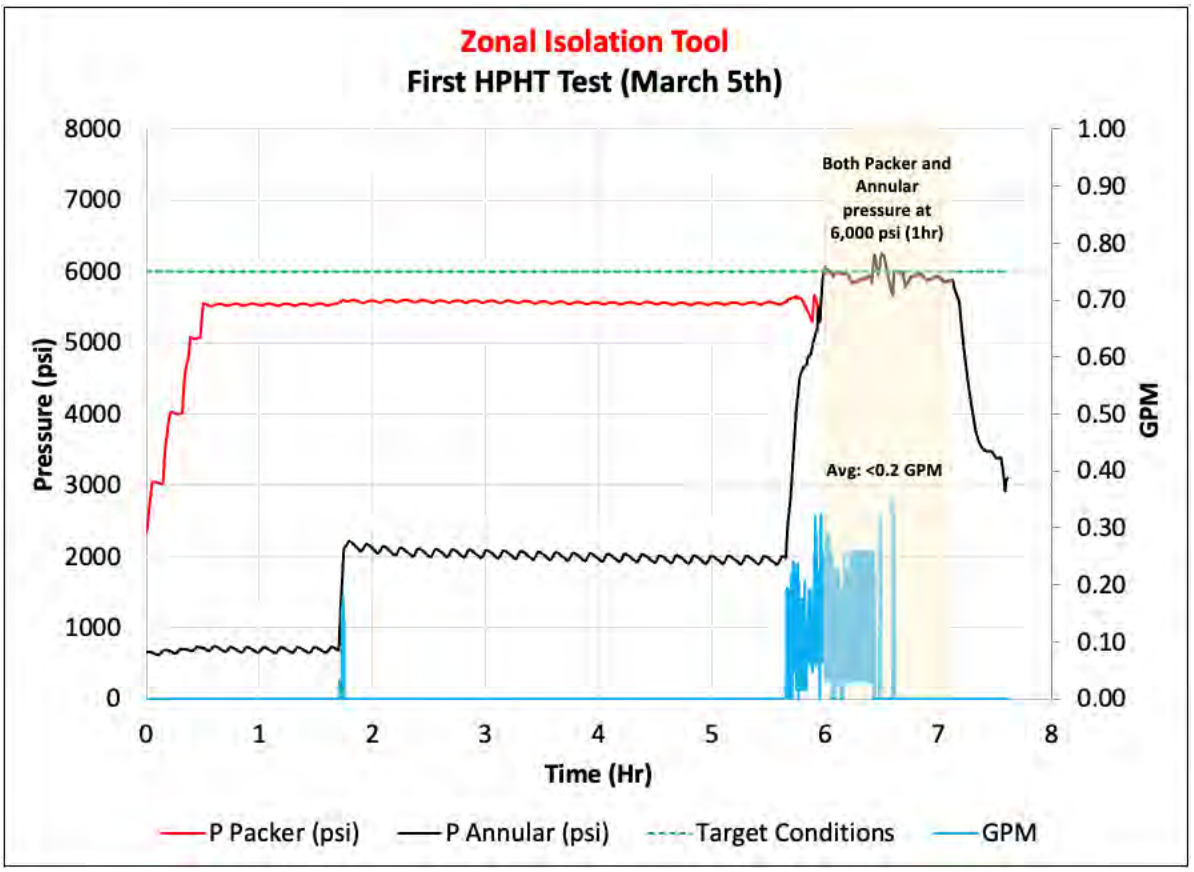

Figure 7: First HPHT test

3.2 Flow valve HPHT test

The flow valve was tested at 6,000 psi and 260 ºC for 30 minutes. Figure 8 illustrates the setup schematic, whereas Figure 9 shows the pressure and temperature behavior during the test. (Velasquez et al., 2024)

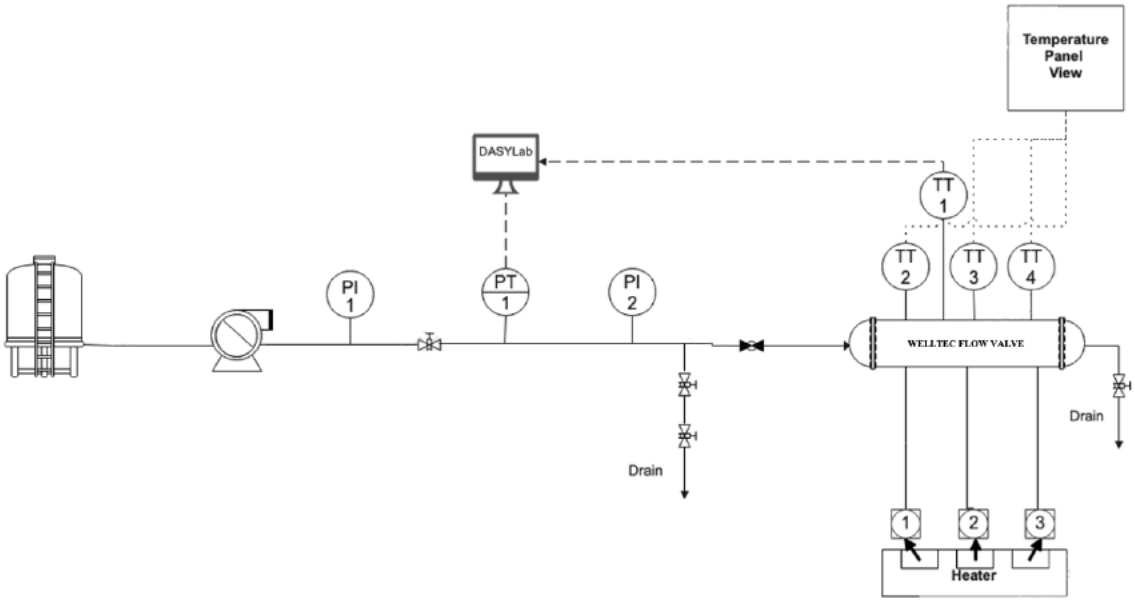

Figure 8: Flow valve testing setup (Velasquez et al., 2024)

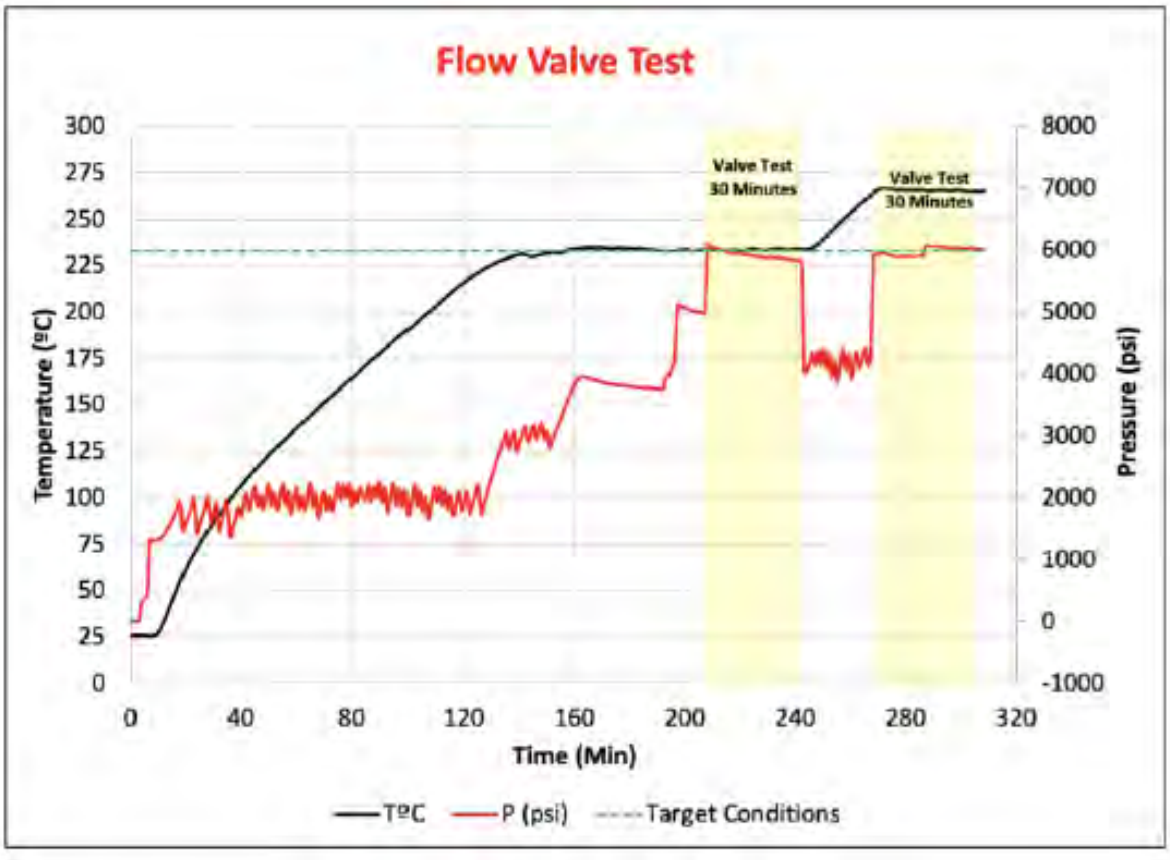

Figure 9: Flow valve HPHT test

4. Tool Installation

4.1 Well selected for installation

The tools are planned to be installed in the Well 16B(78)-32, which is one of the UTAH Forge wells. Figure 10 shows the UTAH Forge project distribution of the wells.

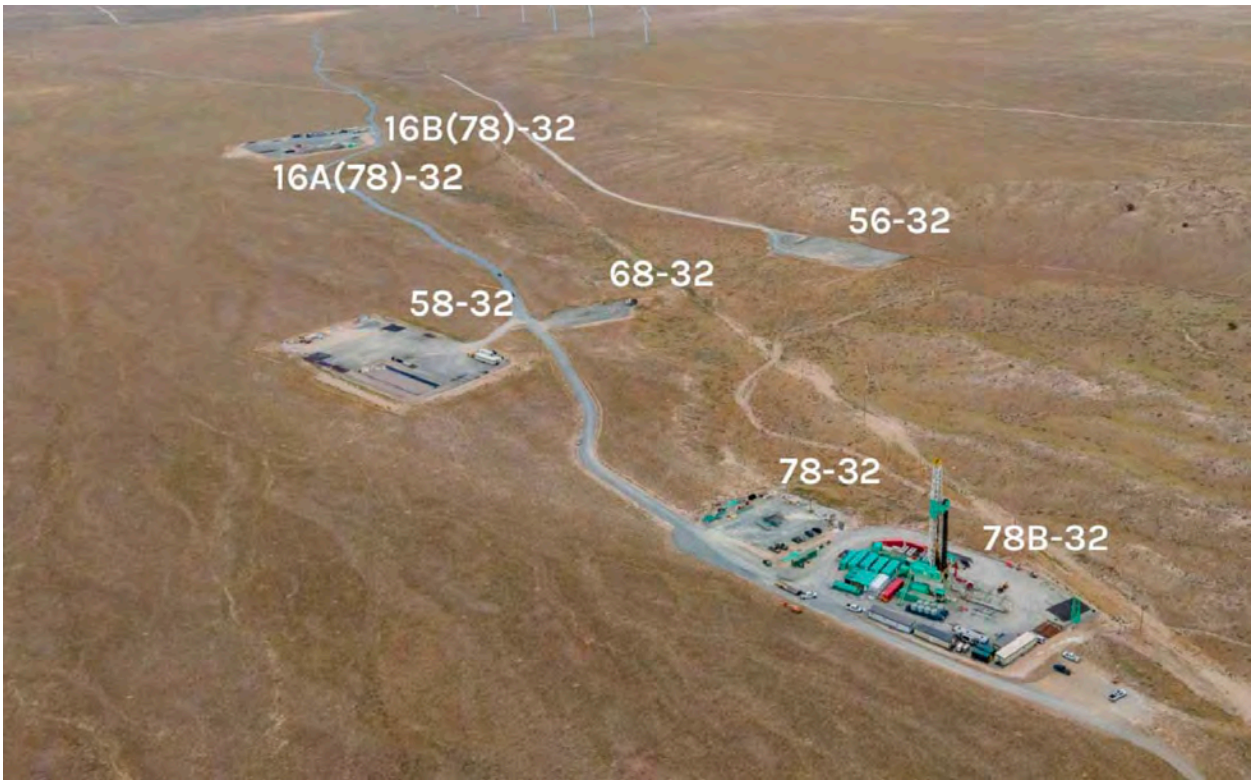

Figure 10: UTAH Forge Wells recovered from Data Dashboard by Utah FORGE (2024)

Following is the list of the wells and their description:

- Well 16B(78)-32: Production well with 10,947 ft MD
- Well 16A(78)-32: Injection well with 10,987 ft MD
- Well 58-32: Pilot well with 7,536 ft MD
- Well 68-32: Seismic monitoring well with 1,000 ft MD
- Well 56-32: Seismic monitoring well with 9,145 ft MD
- Well 78-32: Seismic monitoring well with 3,280 ft MD
- Well 78B-32: Seismic monitoring well with 9,500 ft MD

4.1.1. Well 16B(78)-32 (Production Well)

Table 1 shows the information of well 16B(78)-32, whereas Figure 11 shows a general schematic of the Well.

Table 1: Well 16B(78)-32 information (England et al., 2023)

Northing of Wellhead	13987765.96 ft (UTM 4263471.065)
Easting of Wellhead	1097907.09 ft (UTM 334642.081)
KB Elevation	5447.65 ft (confirm)
GL Elevation	5415.65 ft
Kick-off Depth	5,600 ft KB
Azimuth of Tangent	105°
Build Rate	5.5° /100 ft

TD Easting	UTM 335832.0477 LL: 38.501242, -112.882661
Total Measured Depth	10,700.97 ft
True Vertical Depth at Toe	8,262.48 ft
Horizontal Offset	4,079.22 ft

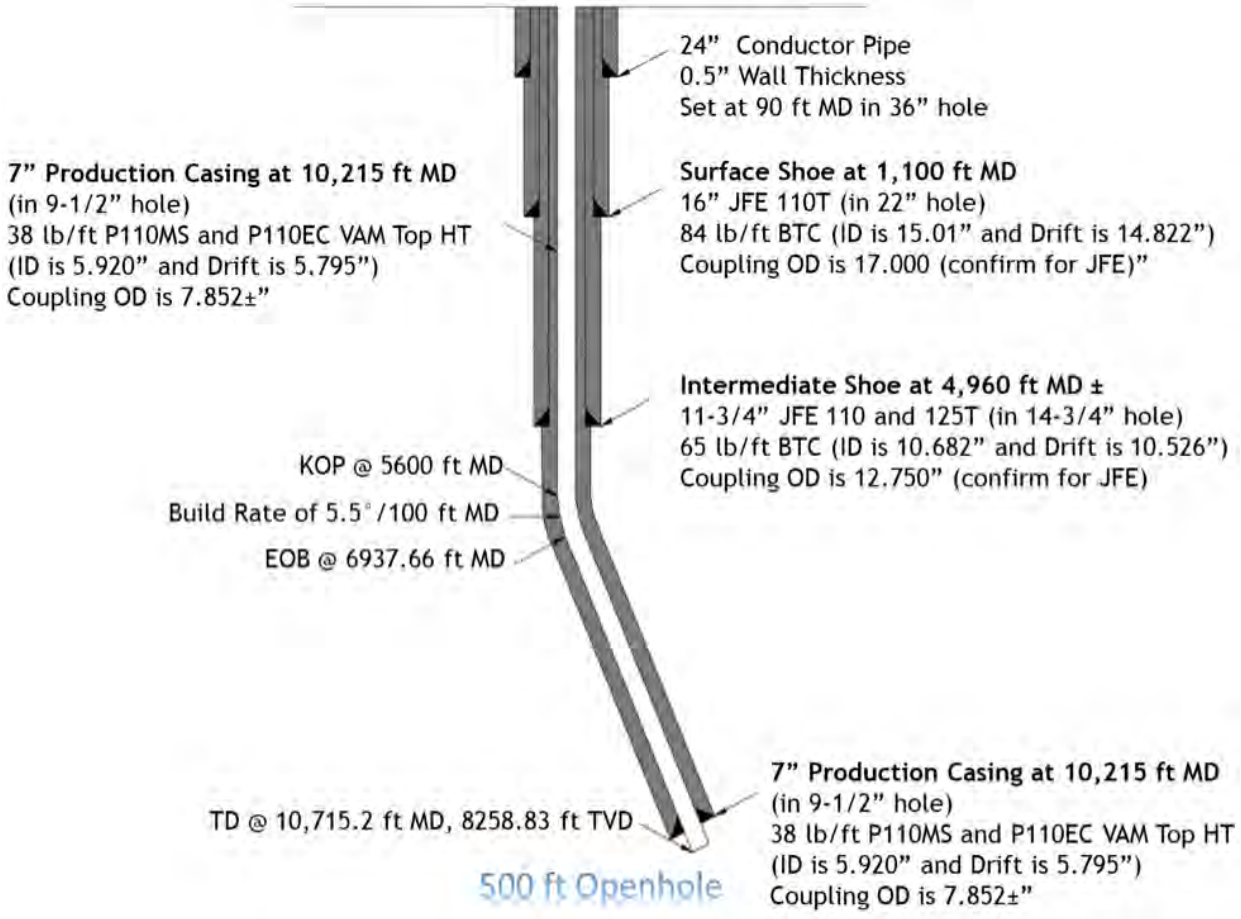

Figure 11: Schematic of Well 16B(78)-32 (Energy and Geoscience Institute, 2023)

The drilling operations for well 16B(78)-32 finished on June 20th, 2023. The main objectives, according to England et al. (2023) of this Well were:

- Develop a companion well, designated as 16B(78)-32, to align with Well 16A(78)-32, which follows a trajectory of roughly 105° with an inclination of 65° to the vertical. The primary aim is to establish a connection with Well 16A(78)-32, utilizing hydraulic fractures created in April 2022. Implement a build angle of 5.5° per 100 feet measured depth (MD) to ensure that Well 16B(78)-32 is vertically displaced from Well 16A(78)-32 by 300 feet true vertical depth (TVD).
- Drill and complete Well 16B(78)-32 to accommodate fiber optics for research programs at the University of Texas and Rice University.
- Keep the section from the 11-3/4-inch casing shoe at 4,837 feet MD to total depth at 10,947 feet MD uncased for a maximum of ten days to allow for potential open-hole stress measurements as part of the Battelle research program.
- Core the toe section of Well 16B(78)-32, specifically the final 500 feet before TD, in strategic intervals to investigate fractures, tracers, and other diagnostic materials introduced during hydraulic fracturing at the toe of Well 16A(78)-32. Allocate core sampling for geologic characterization, mechanical properties analysis, and other research and development (R&D) activities. Begin with an 8-3/4-inch core bit size and subsequently ream it out to 9-1/2-inch.
- Additionally, acquire core samples from a vertical section of the Well in granite formation for geologic characterization and mechanical properties assessments. Initially, it was planned at a depth of 4,970 to 5,030 feet MD, whereas actual coring occurred from 4,855 to 4,878 feet MD.
- Obtain multiple open hole and cased hole logs, including ultrasonic and resistivity imaging runs, a quad combo log at TD, and cement evaluation runs. Monitor for tracers and micro proppant from the stimulations at the toe of Well 16A(78)-32. Plan for production logging (PLT) suites or high-resolution temperature measurements to identify fractures communicating with Well 16A(78)-32.

4.2 Installation of tools in Utah FORGE well

Once the tools are tested individually in the University of Oklahoma's testing facilities, they will be installed in the Well 16B(78)-32 in the Utah FORGE project. The packer should seal a zone where fracturing will be performed through the flow valve. After fracturing, the same flow valve will be utilized for the production. Figure 12 shows how the isolation tool and the flow valve are installed together; it is essential to mention that multiple sets of isolation tools + flow valves will be installed in the Well. Figure 13 shows how three sets of tools (Isolation tool + flow valve) could be installed in the open-hole section of the production well. It is important to mention that at the bottom hole (8,500 ft TVD), the maximum expected temperature is 430ºF (221ºC), lower than the temperature at which the tools were tested.

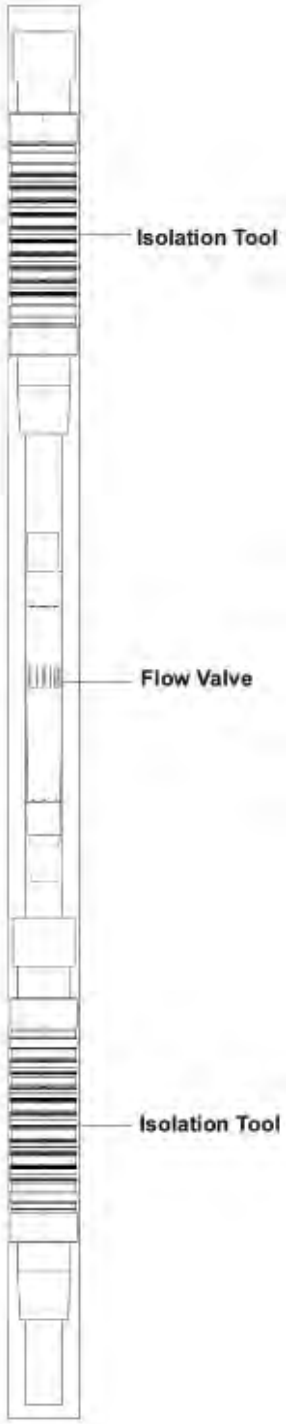

Figure 12: Isolation tool and flow valve

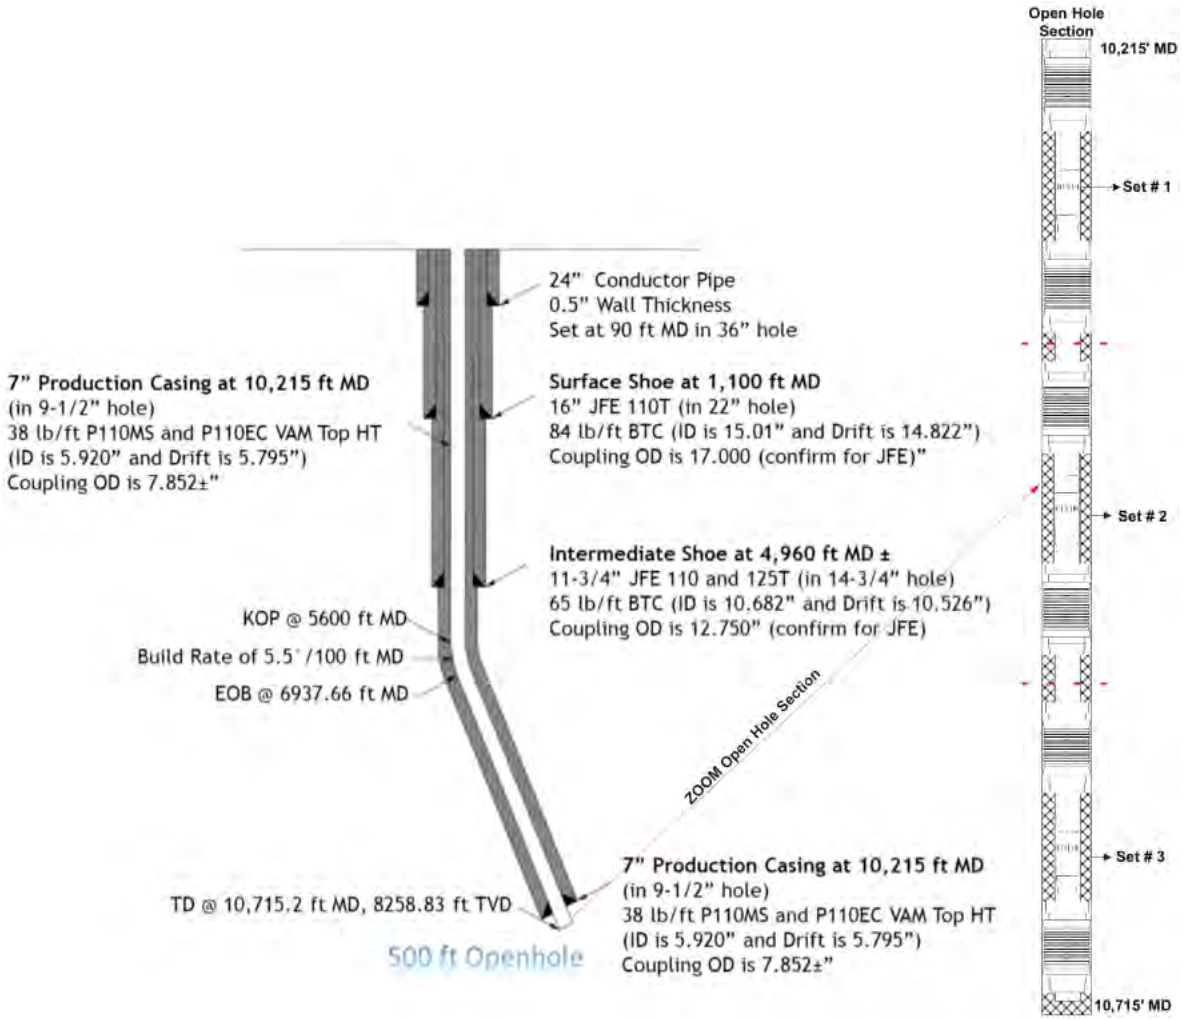

Figure 13: Set of zonal isolation tools and flow valve installed in open hole section (modified from Energy and Geoscience Institute, 2023)

5. Conclusions

From this paper, it can be concluded that the isolation tool and flow valve designed as part of the FORGE project performed satisfactorily during the HPHT tests performed at the University of Oklahoma's facilities. Therefore, these tools are ready to be installed and used in the Well 16B(78)-32 or any other available well. In addition, schematics of the deployment of the tools in this well have been presented in this paper to better understand how the tool would operate in the project. This would help to achieve the objectives set for the Utah FORGE project.

Acknowledgment

The authors of this paper would like to thank Welltec Inc., the manufacturers of the downhole tools, for the help provided in the elaboration of this paper. Additionally, the authors would like to

thank The University of Oklahoma for the facilities provided at the Well Construction Technology Center to conduct the experiments.

Enhanced Geothermal Systems, UtahFORGE, Casing Port Sleeve, Wellbore Tractors

ABSTRACT

A major technical hurdle for an economically successful Enhanced Geothermal Systems is properly balanced flow conformance to ensure equal heat harvesting from each fracture. Without flow conformance providing a near equal flow from injection to production wells, the system could "short circuit" creating a rapid cooling of produced fluid and subsequent electrical generation decline. The goal of this project is to build the tools necessary to construct and provide for a uniformly distributed flow through Enhanced Geothermal System fractures to maximize heat extraction. This research and development project is referred to as the GeoThermOPTIMAL.

This project is funded by a grant from the DOE Geothermal Technology Office through the Utah FORGE project and consists of Colorado School of Mines with partners Tejas Research & Engineering and KSWC Engineering and Mechanical with Defiant Exploration. The research team is developing two innovative devices. The first device is a casing port sleeve which will be cemented in place for multi-stage fracture stimulation and conformance control. It will be tested at geothermal conditions in experimental facilities. The second device is a downhole tractor optimized for horizontal geothermal well deployment. It will be tested at geothermal conditions in surface facilities. Both devices will be deployed and demonstrated at Utah FORGE or other geothermal sites. Finally, we are conducting mathematical modeling pertaining to the Utah FORGE rock formation flow characteristics and the near-wellbore rock breakdown processes. This paper is a summary of the project thus far.

The cemented casing port sleeves will have a port for a hydraulic fracturing stage and then controlled using the tractor to selectively close the sleeve. Any specific sleeve can be actuated for stimulation with the same size frac ball, regardless of the number of stages for fracture stimulation. Then, afterwards, the injection profile can be optimized at individual casing port sleeves to force injection fluid to move where needed to minimize thermal decline of the produced fluid. To close the casing port sleeves, the wireline wellbore tractor with flow sensors would be deployed to first detect the fluid short circuit and then engage with the sleeve and close it, removing the short circuit.

In addition to device building, mathematical analyses of recent laboratory and field data are being done. These models indicate that the current two-well, injection-production configuration (Utah FORGE and Fervo Energy's Nevada Pilot test), connected with multiple hydraulic fractures, is the most promising, practical method for extracting heat from enhanced geothermal systems. For additional heat recovery, modeling shows the current two-well system could be expanded to a three-well system consisting of one injection well and two symmetric producing wells connected with the same hydraulic fractures that emanate from the injection well. In addition, to enhance the understanding of how the casing port sleeves will behave in-situ, various levels of modeling have also been incorporated in the project to assess how the casing port sleeves enhance the Enhanced Geothermal System process. Near-wellbore breakdown processes have been modeled to determine failure behaviors as the hydraulic fractures initiate from the well.

1. Introduction

Given the success of horizontally drilled and multi-staged fractured wellbores in petroleum operations, there has been a strong interest in applying this technology for horizontally drilled and multi-stage fractured Enhanced Geothermal Systems.

The use of "perf and plug" completions has been the standard means of achieving multi-stage hydraulic fracturing. This method uses a pumped down wireline conveyed perforating gun/composite bridge plug system to a given point within the wellbore. The composite bridge plug is set inside the production casing to isolate the wellbore below the setting point in the wellbore. Then the perforating gun is withdrawn up the wellbore to a desired interval. At that point, the casing is perforated. The fracture stimulation subsequently takes place through those perforations. When a given fracturing stimulation stage is completed, another wireline conveyed perforation gun/composite bridge plug system is pumped down hole to isolate the previous frac stage; and the process starts anew. Getting perforating guns and composite bridge plugs to handle high temperatures and especially be able to be removed for production can be problematic.

There is another means of horizontally drilled and multi-staged fractured wellbore completion which is called the frac sleeve system or "port and packer". Initially casing port sleeves with closed ports are incorporated into the casing string and run into the hole with the production casing. The casing typically had external packers on the outside of the casing between the ports which would eventually expand to fill the open annulus isolating each port from each other. The use of external packers has replaced by completely cemented casing which would be more suited to geothermal operations given the heat related casing design issues. To open the port for fracture stimulation, a "frac" ball is pumped down the hole to engage the port. However, each sequential port requires larger and larger diameter tripping balls the closer to the vertical section of the hole. Depending upon the number of stages, one could run out of tripping ball sizes. In the past, after all

the stages were fracture stimulated, it was necessary to grind out each ball in each port. Today, dissolvable balls are available which eventually dissolve, opening all the stages to flow.

There has also long been a concern with horizontal and fractured Enhanced Geothermal Systems that unequal flow between the injector and producer may be a problem. This is due to varying fracture conductivities between and within each fracture stage. Conformance control is critical for the long-term success of Enhanced Geothermal System. With recent projects coming online, this issue has been shown to be indeed a problem.

This research and development project, called GeoThermOPTIMAL, was initiated to mitigate multiple frac port opening and conformance control. This project is supported by the US Department of Energy Geothermal Technology Office through the University of Utah's FORGE project. The team developing the system consists of the Colorado School of Mines, Tejas Engineering and Research, and KSWC Engineering and Mechanical with the support of Defiant Exploration.

The project consists of the development, construction, testing, and deployment of a casing sleeve port system, a wellbore tractor for sleeve manipulation, and modelling of flow and temperatures both near and far from the wellbore. Tejas Engineering and Research is responsible for the casing sleeve port system, using a patented frac sleeve developed by the Colorado School of Mines. KSWC Engineering and Mechanical along with Defiant Exploration is responsible for the wellbore tractor system. The Colorado School of Mines is responsible for the reservoir modeling as well as overall management of the project. The Principal Investigator is Dr. William Fleckenstein.

The goals of the project are to design, build, test, and demonstrate a low-cost, rapid multistage fracture stimulation device using cemented casing port sleeves. The same device can then be used for injection flow control. And second, to design, build, test, and demonstrate a geothermally suited wellbore tractor to effectively detect and manipulate the casing port sleeve to control the flow from the injector to the production well to improve heat recovery.

2. Problem with Enhanced Geothermal Systems

Enhanced Geothermal Systems are predicated on the assumption that the fluid flow from an injection well flows evenly to the production well, harvesting the heat uniformly. Augustine (2016), using original work by Gringarten et al. (1975), showed that if this doesn't happen, the Enhanced Geothermal System electrical generation capability might prematurely end due to excessive cooling. Fleckenstein et al. (2023) ran a stochastic economic analysis of an Enhanced Geothermal System and found an economically strong sensitivity to thermal decline as well as the size of the system, which drives the maximum fluid circulation rates. As shown in Figure 1, uniform spacing shows the lowest thermal decline rate whereas with variable spacing as well as variable fracture apertures, show much faster temperature declines.

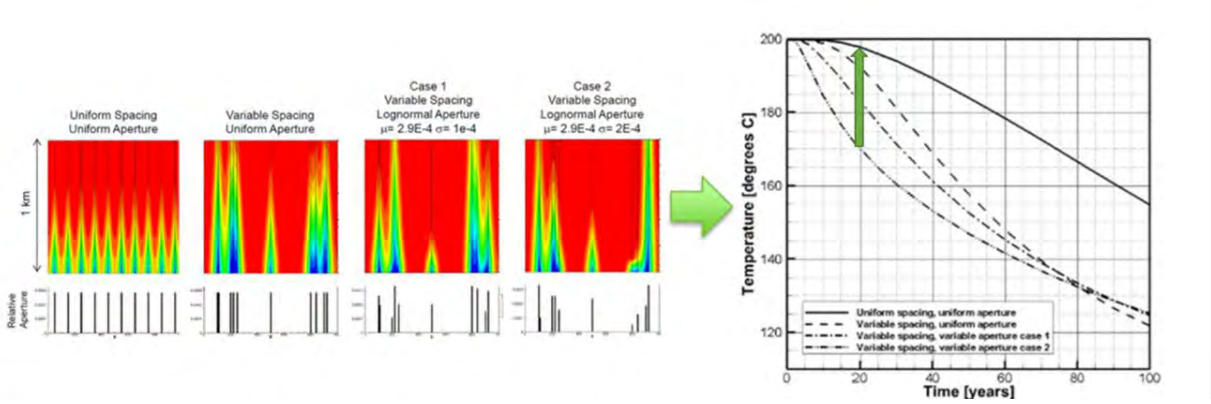

Figure 1: Augustine's (2016) Models Showing the Effect of Non-uniform Flow from the Injector to the Producer

Fleckenstein et al. (2023) shows that this thermal decline significantly impacts the return on investment.

Several key variables in addition to thermal decline impact the economics of Enhanced Geothermal System. The impacts of these variables were evaluated stochastically to determine their impacts on the economics of Enhanced Geothermal System. The three independent variables were determined to be (1) thermal decline, (2) flow rate per well, and (3) Power Purchase Agreement pricing. The thermal decline and flow rates per well are dependent on conformance control to regulate the fluid flow in system and overcome the lack of symmetry in nature. This provides uniform heat recovery and minimizes the system thermal decline.

What is needed to minimize this decline is a means to allow for any number of fracture stimulation initiation points as well to control fluid flow into the various fracture points after stimulation. The DOE, through the Utah FORGE Project, tasked the Mines/Tejas/KWSC Team to develop a casing port sleeve and wellbore tractor to accomplish these tasks. The casing port sleeve is designed to selectively open for stimulation with single sized, large diameter dissolvable balls, regardless of the number of frac stages. The wellbore tractor allows for the detection of abnormally high fluid injection rates in the wellbore and for the casing port sleeve to be closed by the tractor through manipulation of the sleeve at any time and at high bottom hole temperatures.

The casing port sleeves and tractor being developed and tested are envisioned to be demonstrated at the Utah-FORGE site but may be demonstrated at a well of opportunity depending on the funding and rig scheduling.

3. Casing Port Sleeve

The casing port sleeves are designed to catch the same size frac balls and either actuate the sleeve to open position for stimulation or release the frac ball for a downstream casing port sleeve. The catching or releasing of a frac ball depends upon the pumping flow rate. Each frac ball dropped will engage with a collet located at the far end of the casing port sleeve. However, if the flowrate is 12 barrels per minute (1.9 m^3/min) or more, the ball “pops” through the collet, creating a pressure surge that is noted at the surface and continues to travel toward the next port sleeve. When the number of pressure surges detected at the surface equals the number of casing port sleeves to be bypassed, the flowrate is dropped to about 8 barrels per minute (1.3 m^3/min). When the frac ball

catches in the collet this time, because of the slower flow rate, the pressure needed to "pop" through the collet is too low. The frac ball and collet now have enough time to travel far enough to open and lock the sliding sleeve ports and lock the ball into the collet. This is not unlike the process that a hydraulic jar uses with a metering port. Once the casing sleeve port opens, the flow diverts through the casing sleeve port with the ball acting as a sealing plug, isolating the previous frac stages from further flow. The frac balls will eventually dissolve in the heat and wellbore fluid, opening all the frac stages for injection, with no further wellbore intervention.

The casing port sleeves as shown in Figure 2 are designed for use in 7-inch (178 mm) 39 pound for foot (570 N/m) casing in a 9-1/2-inch (24.1 cm) borehole at a bottom hole temperature of 225°C (437°F). The overall length of the sleeve is 146-inches (3.7 m). The casing port sleeves have a total outside diameter of 8-3/4-inches (22.2 cm) which gives a wellbore clearance of 3/8-inch (1 cm) when centered in the borehole. This is a typical clearance for oil field casing port sleeves and has been shown effective for cementing. The casing port sleeves also have an internal clearance at the end housing or 5.95-inches (15.1 cm) which is 0.03-inches (0.76 mm) larger than the 39 pound for foot (570 N/m) casing inside diameter. A cross section of the sleeve is shown in Figure 3. The shifting sleeve itself has an internal diameter of 6.08-inches (15.4 cm). This difference in inside diameters allows for the sleeve ports to be shifted. The port flow area when open is 38 inches^2 (245 cm^2) which is a larger flow area than the casing at 27 inches^2 (174 cm^2). The collets are designed to handle a 5-3/4-inch (14.6 cm) dissolvable frac ball. A magnified drawing of the ports and shifting sleeve is shown in Figure 4.

The casing port sleeves have been designed to minimize any cement being pumped to foul the casing port sleeve mechanism. There is also a spring mechanism that engages upon opening the port. To close the casing port sleeves later, they have a specific profile that allow the wellbore tractor to be able to engage the sleeve. The tractor will "click" into the sleeve, allowing the port to be closed using the stored energy of the spring and a tug of the tractor.

Figure 2: Isometric Model of the GeoThermOPTIMAL Casing Sleeve

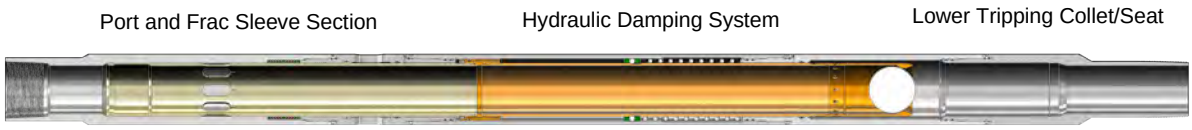

Figure 3: Cross Section of the Casing Sleeve. Note the Ball Sealer Caught in the Collet.

A prototype casing port sleeve has been built and tested for critical components/subassemblies and actuation. The collet has been tested with frac balls and has successfully passed or caught frac balls depending on flowrate. No significant wear has been noted on the collet even after multiple frac ball passage. The seals on the port shifting sleeve have been tested for seal drag friction. After various iterations, the seal drag at room and geothermal temperature regimes have been minimized around 500 pounds force (2.2 kN) for actuation.

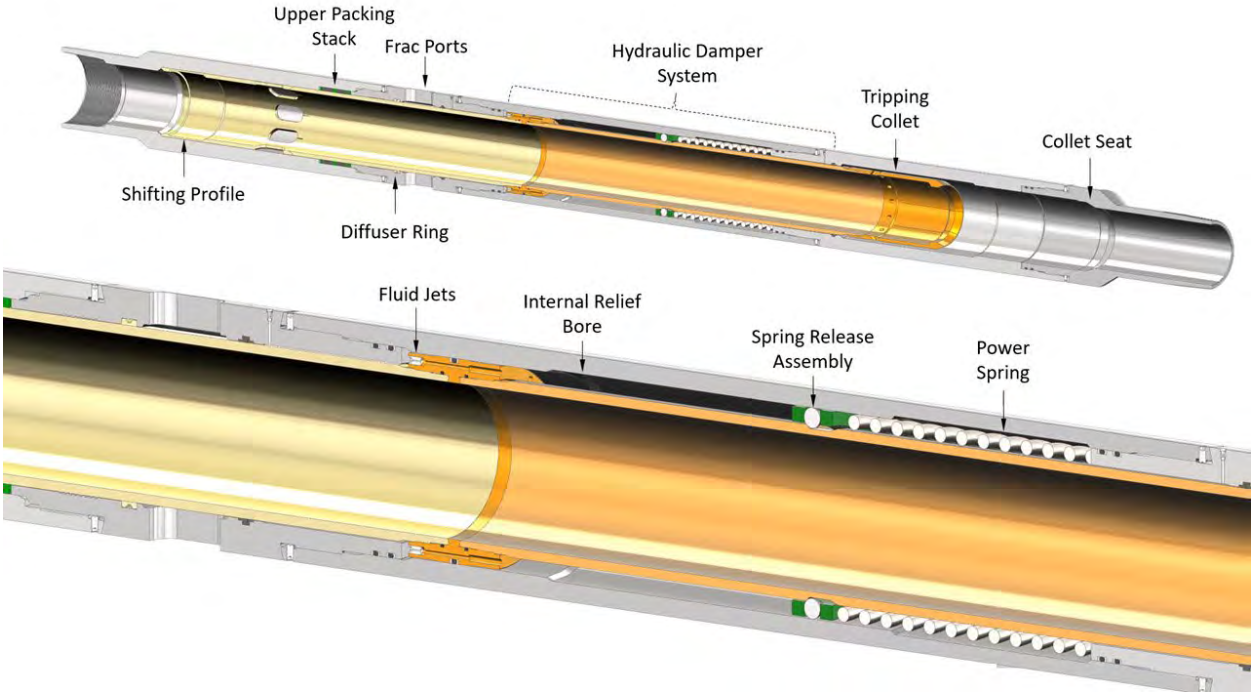

Figure 4: Magnification of Casing Sleeve Ports and Shifting Sleeve

4. High Temperature Tractor

The tractor being developed is based on an oil and gas wireline deployed wellbore tractor modified for higher geothermal temperatures. The tractor has been used for over 30 years. It will be deployed using a high temperature rated monocable. The tractor has a high temperature rated cable

head, swivel joint, a casing collar locator, high resolution temperature and pressure real time sensor package, an electromechanical wheeled tractor, and the hydraulically driven casing port sleeve control device. These are all currently being used in oil and gas operations up to 500°F (260°C). A drawing of the 44-3/4 foot (13.6 m) long tractor is shown in Figure 5**.**

The tractor has the capability to measure fluid flow around the device while injection is ongoing. Once it is determined that a given casing sleeve port is taking "too much fluid", the tractor can engage the casing port sleeve and lock it closed. This is a permanent closure with this casing port sleeve design. This shifts the fluid flow to other more productive ports.

Figure 5: Overall Drawing of the Wellbore Tractor

To protect the electronic and drive sections, these sections are encased in an insulating flask. The electronics section has 350°F (175°C) PC boards rated for continuous operation. The flask is designed to house this equipment at 440°F (225°C) for a duty cycle of 12 hours. This would be enough time to operate various casing port sleeves downhole.

The tractor drive components are modified from current oil and gas industry wellbore tractor hardware. The drive wheels engage the casing inside diameter to propel the unit up and down the casing regardless of the casing orientation. When a casing port sleeve is located, the tractor will anchor itself into the casing (Figure 6), the sleeve engagement latching mechanism (Figure 7) will make contact with the sleeve port, and a hydraulic piston (Figure 8) will latch into the sleeve and pull the port sleeve to the closed position. The position of the sleeve can be monitored from changes in hydraulic pressure. This process can be repeated for any number of casing port sleeves if the time is within the temperature duty cycle.

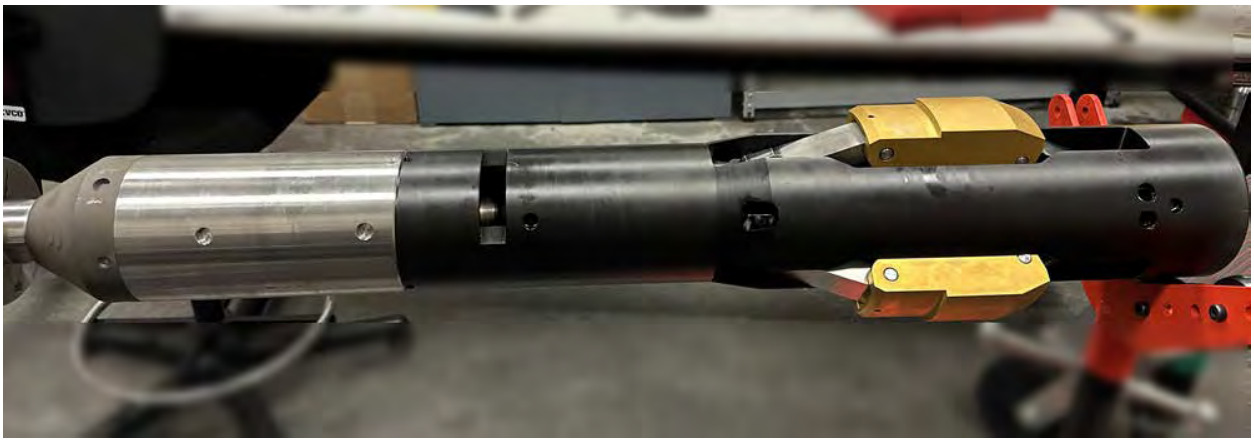

Figure 6: Wellbore Tractor Anchor Module

Figure 7: Wellbore Tractor Latching Tool

Figure 8: Wellbore Tractor Hydraulic Piston

The tractor has been design has been completed. Critical components/subassemblies for the prototype tractor system have also been tested at the component and subassembly stages, including actuation. The final system assembly and test of the tractor remains with further integration testing of the casing port sleeves and tractor at room and geothermal temperatures and pressure conditions in the surface test facility. Upon successful final assembly and integration testing at the laboratory, the system will be deployed to a field location for field trials and testing.

5. Modeling

As part of the GeoThermOPTIMAL team's integrated design efforts, multiple formation modeling efforts have been and continue to be developed. There is a system modeling effort for determining the fluid flow patterns and effectiveness over long distances. There is also a near wellbore

modeling effort to understand the fracture stimulation initiation and flow through the port and cement and into a formation. The mathematical modeling is to support device design and implementation based on assessment of the impact of reservoir stimulation results in the FORGE geothermal reservoir site in Utah as well as the reservoir stimulation and circulation effects at Fervo Energy's Project Red in Nevada. And the modeling will assist in evaluating well stimulation efficacy, effective stimulated formation permeability, and determining formation heat transfer. Furthermore, the modeling will predict induced fracture initiation and reactivation in the near fracture region. The reservoir characterization components of these mathematical models are similar to the models used in assessing unconventional oil and gas reservoirs.

The mathematical modeling includes several components and activities:

- Develop a wellbore heat transfer model to determine the temperature profile for cooling during the fracture stimulation
- Determine the needed duty cycle for the tractor electronics based on temperature thresholds of components under a variety of pumping and temperature scenarios.
- Develop a reservoir heat exchange model to determine the efficacy of heat extraction from the reservoir hot formation rock and reservoir fluid to deliver the heated water in the Enhanced Geothermal System to the power plant.
- Assess viability of the discrete fracture network and its value in quantifying formation stimulation and heat extraction from a formation
- Evaluate past tracer concentration response and diagnostic fracture injection test pressure response from field and conceptual model data to recommend future tests to quantify the efficacy of the fracture network resulting from well stimulation

1. Far-Wellbore Modeling

Earlier this year, the results of the modeling efforts was presented (Mindygaliyeva et al. 2024) pertaining to the effectiveness of fracture stimulation from two recent field test projects—the Utah FORGE field research (Figure 9) and the Blue Mountain commercial filed pilot test (Figure 10). The modeling effort began with laboratory experiments conducted on several core samples from Utah FORGE geothermal reservoir (Figure 11). These experiments were aimed to measure the key

formation parameters such matrix and fracture permeabilities and porosities.

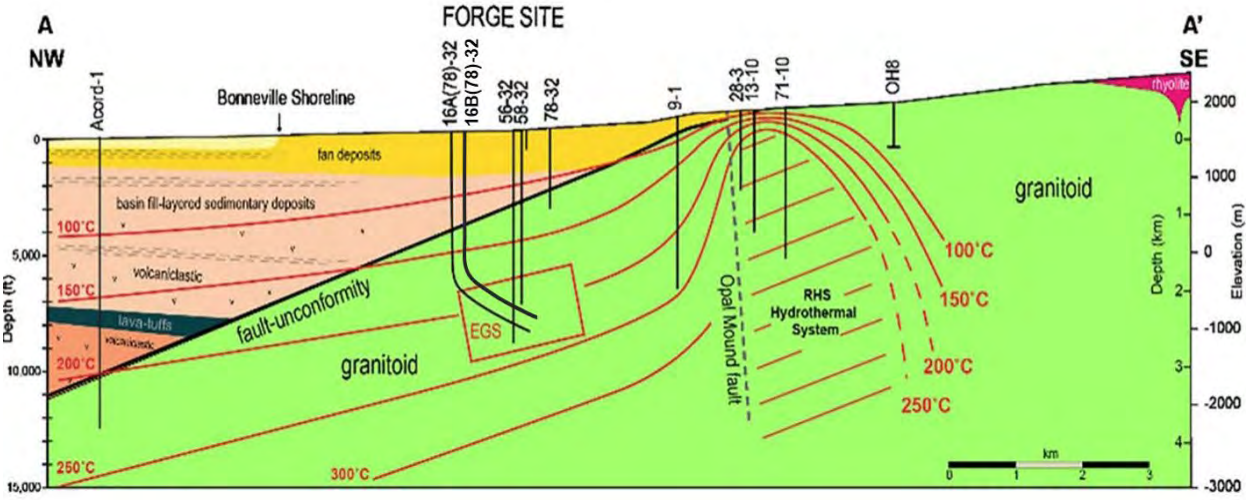

Figure 9: A cross-section of Utah FORGE site highlighting stratigraphy, structure, and thermal regimes—Enhanced Geothermal System on the left and hydrothermal on the right (Adopted from Kirby et al., 2018)

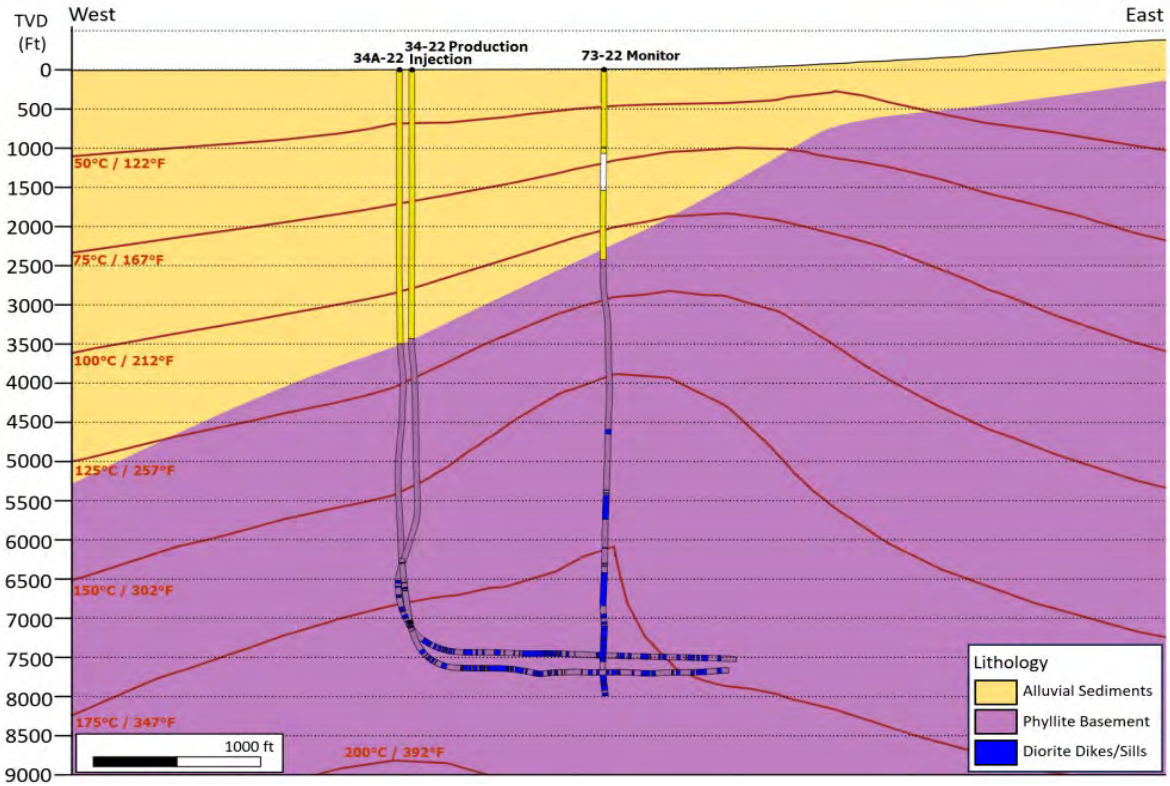

Figure 10: Project Red, the horizontal doublet, and vertical monitoring well in Blue Mountain Enhanced Geothermal System project (Norbeck and Latimer, 2023)

This data served as input for analytical and numerical modeling pertaining to the effectiveness of fracture stimulation.

The experimental results of Utah FORGE rock samples indicate that the rock matrix permeability is around 10^{-3} mD (10^{-18} m^2) and matrix porosity is approximately 1%. The analysis of artificially fractured core measurements yielded an effective fracture permeability of 1 mD (10^{-15} m^2) and the induced micro-fracture & macro-fracture porosity of 0.01%. This data served as guides for the input of analytical and numerical solutions to match field pressure falloff behavior from hydraulic fracture stages 1, 2, and 3 in FORGE (see Figures 12 and 13 for stage 1). While the team did not have any core samples from the Blue Mountain Enhanced Geothermal System wells, the team successfully applied the Utah FORGE analysis approach to some of fracture stages using the Blue Mountain pressure falloff data. This gave similar results as in Utah FORGE. At the time of this paper, the Team is in the process of analyzing the pressure falloff data from the newly implemented stages 4 through 10 of the Utah FORGE and the restimulation data from stages 1, 2, 3 of Utah FORGE.

The pressure falloff analysis technique utilizes the following equation:

$$p_{wf}\left(t_{inj}+\Delta t\right)\Big|_{x=0}-p_{ws}\left(\Delta t\right)\Big|_{x=0}=\frac{4.064\,qB\mu}{\sqrt{k_{f,eff}}\left(h\,L_f\right)}\left(\frac{1}{\left(\phi c_t\right)_{f+m}\mu}\right)^{1/2}\left(\sqrt{t_{inj}+\Delta t}-\sqrt{\Delta t}\right) \tag{1}$$

The Team used the above equation to determine formation effective permeability near the hydraulic fractures. The calculated effective permeability represents the enhanced formation permeability resulting from the hydraulic fracture placement. This permeability is calculated from the slope of:

$$p_{wf}\left(t_{inj}+\Delta t\right)\Big|_{x=0}-p_{ws}\left(\Delta t\right)\Big|_{x=0}\ \text{ vs. }\left(\sqrt{t_{inj}+\Delta t}-\sqrt{\Delta t}\right). \tag{2}$$

In addition to pressure falloff analysis, the Team developed a heat transfer and a stress calculation model to determine the efficacy of heat extraction from Enhanced Geothermal System reservoirs.

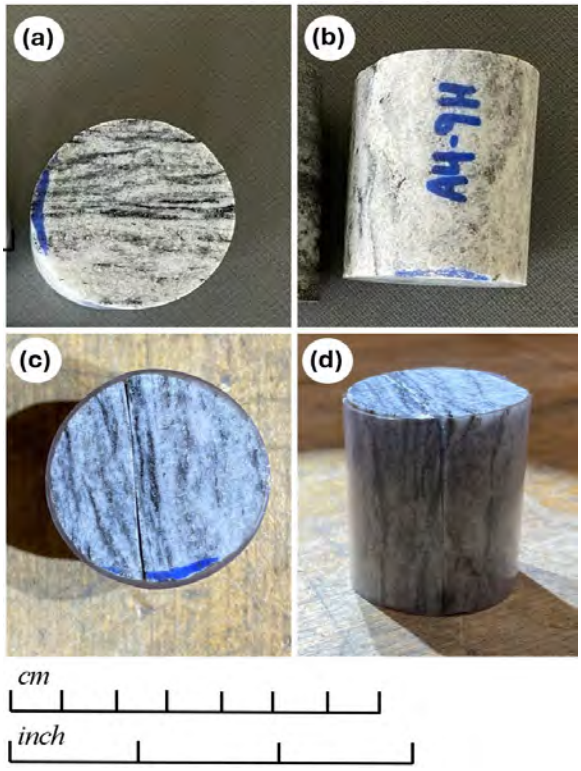

Figure 11: Horizontal core A4-9H from Utah FORGE depicted in (a) top view and (b) side view before fracturing (image scales on the bottom); (c) top view and (d) side view of core with induced fracture, wrapped with PVC tape to maintain core integrity.

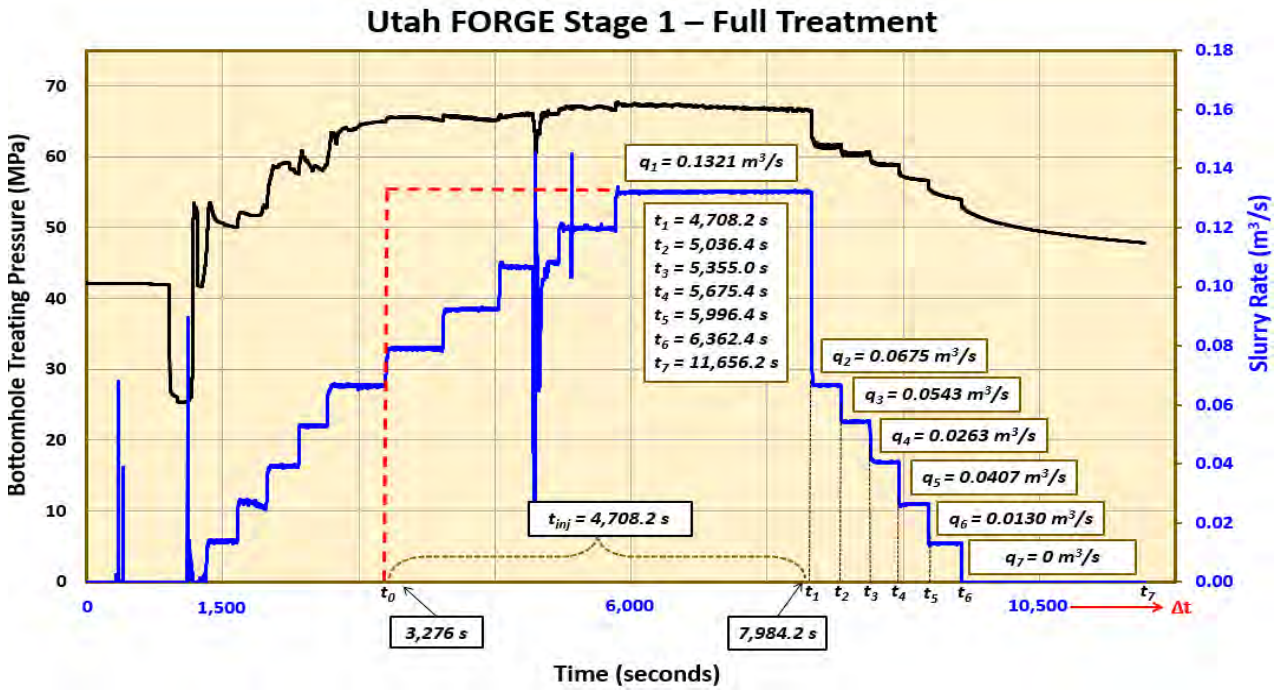

Figure 12: Stage 1 treatment data from Utah FORGE 16A(78)-32. The bottomhole treating pressure is indicated in black (MPa), while the slickwater rate is illustrated in blue (m3/s). Slickwater was pumped into a 200 ft (60.96 m) open-hole section.

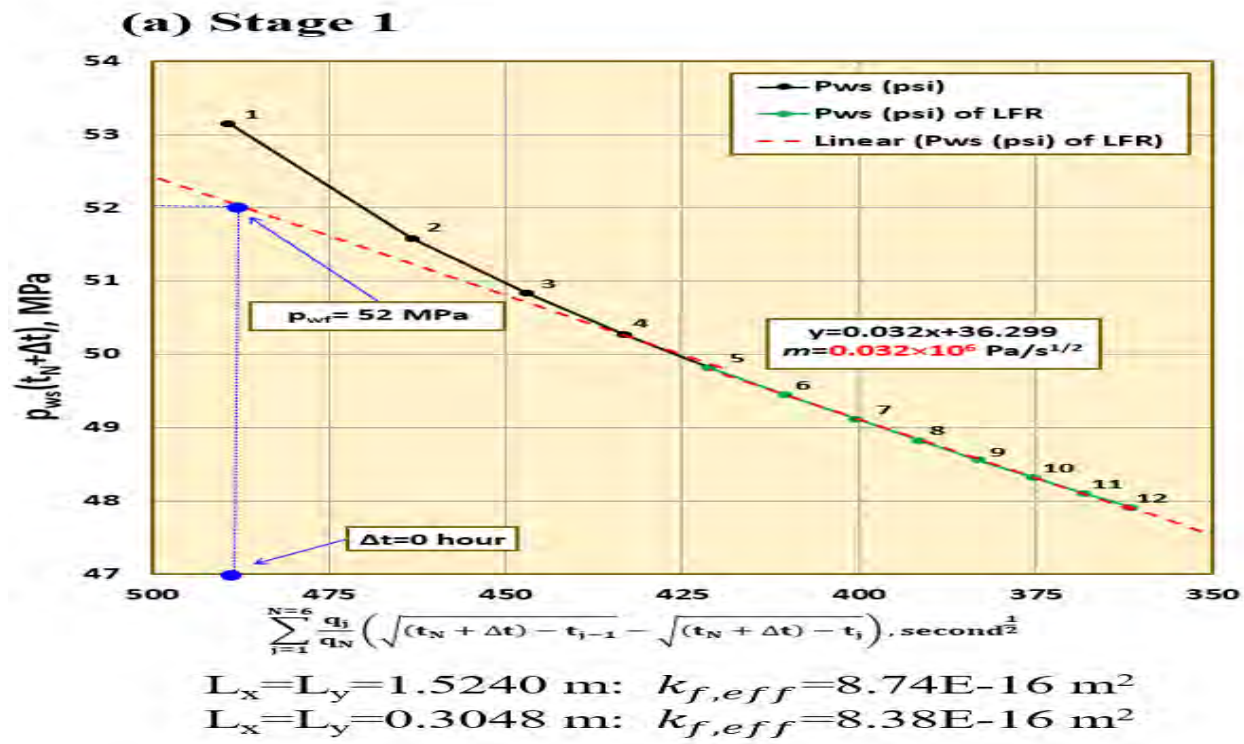

Figure 13: Shut-in bottomhole versus time for field pressure data for Utah FORGE 16A(78)-32, illustrating analytical pressure transient analysis method. The analysis of the line slope yielded the effective formation permeability ($k_{f,eff}$) for two matrix block sizes: 5 × 5 × 20 foot (1.5 × 1.5 × 6.1 m) and 1 × 1× 20 foot (0.31 × 0.31 × 6.1 m). Included are 12 data points recorded every 180 seconds.

2. Near-Wellbore Modeling

The near-wellbore model simulates fracture initiation and propagation through the casing port sleeve and into the immediate vicinity of the wellbore. The results demonstrate different fracture initiation pressures and propagation pathways depends upon the cement initial stresses, eccentricity of the cement sheath, and the location and geometry of existing fractures on the granitoid wellbore surface.

The numerical model employs the extended finite element method approach in a commercial finite element modeling software package. This allows for a detailed simulation of fracture dynamics. This approach explicitly represents the cement sheath and existing natural fractures in granite formation. The software has fully coupled pressure/deformation extended finite element elements are used to model fracture propagation and the fracturing fluid flow. Simultaneously, the deformation of the porous medium and the pore-fluid flow are modeled using coupled 'pore-pressure/deformation' continuum finite elements.

Two numerical models are being employed: a quasi-static model for cement failure and a dynamic model for hydraulic fracture propagation. The first model investigates cement sheath failure during hydraulic fracture initiation through the casing port sleeve. Several cases are being considered including fully concentric cylinders with a uniform cement thickness ring and cases of casing/wellbore eccentricity. The thinnest section of the cement ring was set at the low side of the horizontal wellbore. Additionally, three different initial stress conditions in the cement sheath are considered: zero initial stresses, intermediate compressive stresses, and hydrostatic stresses.

The second model examines hydraulic fracture initiation and propagation in the presence of pre-existing fractures, whether drilling induced or natural. Hydraulic fracturing fluid pressure is exerted through the micro-annulus formed at the casing/cement and cement/granite interfaces. In-situ stress conditions are set to match those at the Utah FORGE site, with the minimum horizontal stress aligned with the wellbore axis. The fluid injection rate in the simulation is 5 bpm (0.013 m^3/s), and the far-field boundaries are fixed.

Simulations are being conducted to study the role of initial stresses in the cement sheath and its eccentricity relative to the wellbore before hydraulic fracturing stimulation. Figure 14 illustrates the modeling results for two scenarios: one with 50% eccentricity and initially unloaded cement, and the other with a uniform cement ring and initial intermediate compressive stresses. At a depth of 8,500 feet (2,591 m), the cement cracks under the hydrostatic pressure exerted by the slick water inside the casing as soon as the casing port sleeve is opened. In the scenario with 50% eccentricity and initial compressive stresses, the pumping surface pressure needs to reach approximately 14,500 psia (100 MPa) to fracture the cement. The geometry of the fracture in both cases is radial (longitudinal).

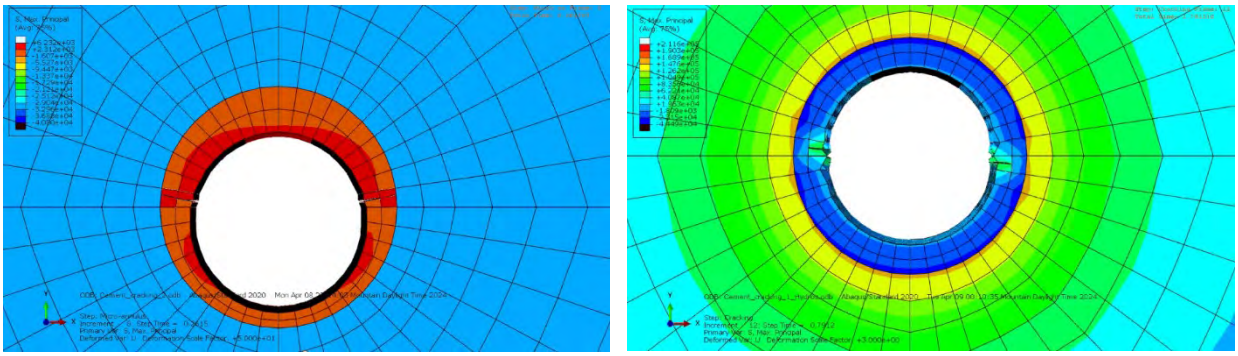

Figure 13: Left: 50% Eccentricity with Zero Initial Stresses in a Cement Sheath. Right: Concentric Cylinders with Intermediate Compressive Initial Stresses in Cement

The second fracture initiation model shown in Figure 15 examines two cases: transverse pre-existing fracture propagation and longitudinal fracture propagation. In the first case, there was a single pre-existing fracture on the side of the wellbore perpendicular to the minimum horizontal in-situ stress. Notably, the fracture grew both circumferentially and away from the wellbore in the direction of the initial crack, forming a penny-shaped, circular, planar fracture. In the case of the longitudinal fracture, it continued to grow along the wellbore axis. Simulations were run for 100 seconds at 5 bpm (0.013 m^3/s) to investigate fracture width, length, fluid pressure, and fluid leak-off into the rock. Future investigations will focus on the impact of varying injection rates and durations to understand fracture behavior under different pumping regimes and fluid properties.

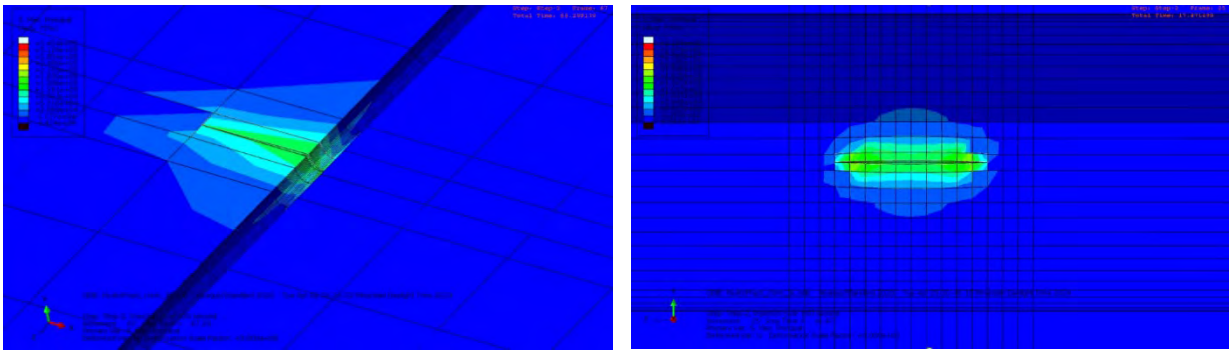

Figure 14: Left: Transverse pre-existing fracture; Right: Longitudinal pre-existing fracture

II. CONCLUSIONS AND FUTURE WORK

A casing sleeve has been designed, built and successfully tested for frac ball passage and sleeve closing at room and expected geothermal temperature and pressure conditions.

The wellbore tractor has been designed and subassemblies built. It will be fully assembled within a few months of this paper's publication and tested at room and expected geothermal temperature and pressure conditions

.

Two finite element models have been successfully developed and conducted pertaining to the Utah FORGE rock formation flow characteristics and near-wellbore rock breakdown processes. They have been used to determine the design parameters of the casing sleeve and tractor.

Finite element modeling performed on the near wellbore fracture initiation indicates that under the Utah FORGE stress and well conditions, fracture initiation occurs immediately upon port opening. This behavior occurred under a variety of sensitivities including eccentricity of the wellbore and varying cement sheath thicknesses (casing-wellbore offset).

The far finite element model was used to successfully assess the flow data from the Utah FORGE project and Fervo's 2023 Project Red pilot test.

Successful completion of this project will provide the devices needed for Enhanced Geothermal System construction using low-cost, rapid multistage fracture stimulation with cemented casing port sleeves. These same cemented casing port sleeves would then be used in conjunction with a geothermally rated wellbore tractor to control the flow of heat-carrier fluid to improve heat recovery.

Future work is being done to determine a means for throttling the injection flow rate, rather than cutting flow off in highly conductive fractures, with a goal of uniform injection in the entire reservoir.

ABSTRACT

The potential for geothermal power is significant however the reality of delivering that potential in an economic way remains extremely challenging. This is especially true with regards to well completion technologies and methodologies due to the limitations in the performance of existing equipment in well conditions up to 300°C. A critical requirement for the successful stimulation of geothermal wells is effective well isolation technology.

This paper presents the research and development of a high temperature, elastomer based isolation system, with the potential to be retrievable, that will enable controlled stimulation of an EGS reservoir. It details the test equipment design, test results and the engineering process for the development, testing and qualification of the elastomers chosen for the production packer. Focusing on reduced complexity with minimal moving parts this isolation system draws on experience gained in the oil and gas industry adapted to operate effectively at temperatures up to 300°C.

The paper will also discuss the development of the polymers and packer design to provide sufficient diametrical expansion to provide a seal and further to deliver the differential pressure performance of 6000psi required for these wells. It will also outline the qualification program to API 19OH and the results to date of a successful packer test at 225°C.

1. Introduction

Well stimulation has been used extensively in the oil and gas industry to increase production, hydrocarbon flow, from reservoir rocks. In combination with horizontal drilling to optimize reservoir contact this technique provides higher production rates and higher overall recovery. This is especially true in what have been characterized as unconventional oil and gas wells.

A key enabling technology for these wells has been the use of annular isolation systems to provide wellbore segmentation along the long horizontal well sections. These devices provide a mechanism for efficient stimulation of, now distinct, zones and also allow the possibility to shut-in zones in the event of water or gas breakthrough over the life of the well.

One of the most successful forms of annular isolation system has been the swellable packer. Due to simplicity of design and its ability to swell and seal into microvariations in the wellbore it provides a robust seal even in open hole conditions.

Enhanced Geothermal Systems (EGS) are looking to employ techniques of wellbore stimulation by hydraulic fracturing in the wells to improve overall production and to access further resources. The plan is to use annular seals to isolate sections of the wellbore so that high pressure stimulation above the fracture pressure of the reservoir formation can take place. This hydraulic fracturing creates a highly conductive flow path between the reservoir and the wellbore.

The challenge for these geothermal wells is that existing technology simply cannot perform at these extremely high temperatures. Swell rates are typically too fast to be practical and the elastomers are either too soft to hold pressure or quickly embrittle resulting in failure.

This paper will outline the development and testing of a high temperature swellable packer and critically the polymer to be used for the packer element for use in geothermal applications.

2. Design Concept

The scope of the work is to develop a temporary, wellbore packer system that will allow controlled stimulation of an EGS reservoir at temperatures from 150°C to greater than 225°C and which can hold a differential pressure of at least 6000 psi.

2.1. Specification

The full target technical specification for the system is outlined in the table below:

Table 1: Design specification

Design Temperature	Minimum temperature – 150°C (302°F) Qualification target temperature - 225°C (437°F) Push target temperature - 300°C (572°F)
Required Pressure Rating	6000 psi
Sealing Diameter & tool geometry	Hole Diameter - 12.25”

	Mandrel OD – 9.625” Element OD – 11.75 Hole Diameter – 8.5” Mandrel OD – 7” Element OD – 8.125
Swell Fluid	Brine or Fresh Water
Run in hole time	Typically complete in 6 hours
Design time to contact	12-24 hours (6 hours in and 6 hours safety to POOH)
Time to Pressure hold	As soon after 48 hours as possible
Duration of pressure hold (frac duration)	7-14 days
Subsequent degradation time to retrieval	14 days
Wellbore/swelling fluids	Fresh water – Likely injection fluid 3.5% NaCl – Alternate injection fluid salinity (Seawater) 10% NaCl – (Typical produced water salinity)

The approximate operational performance required from the system was outlined in the guidelines below:

Sequence of Events		**Time**
Run In Hole	-	0-6 Hours
Swell to contact	-	0-12 Hours
Packer set	-	12-48 Hours
Hydraulic Fracturing (packer holds 6000psi)	-	Day 2 to Day 14
Packer degrades	-	Day 15 to 28
Pull Out Of Hole	-	Day 29

The major success criteria for this design were broken down into four phases which lead to the definition of stage gates for the development.

- Controlled expansion of the elastomer within the high temperature window to achieve a realistic running diameter and run in hole time but still be able to expand to contact the wellbore.
- The ability of the elastomer to withstand temperatures between 150°C and 300°C.
- Pressure performance – The system must be able to hold a 6000psi differential pressure across it.
- The system should then be able to reduce in diameter to allow it to be retrieved from the well.

Figure 2: Swellable packer assembly

3. High Temperature Elastomer Development and Testing

A large number of different compounds and compound families were assessed in an initial review phase to find polymers that had previously shown some performance at higher temperatures. From these a short list of three elastomers was selected from three different elastomer families to ascertain their performance at the target temperatures.

Swell testing was carried out in autoclaves, as shown in Figure 3, placed inside ovens, shown in Figure 4, in order to apply a consistent heat to the entire fixture. Test pieces were manufactured as 2” x 2” x 0.5” molded test pieces bonded to a metal plate. Experience has shown that this is a reliable and accurate way to observe swell for the large number of samples required for an R&D program.

Figure 3: Flanged autoclave for high temperature plate testing

Figure 4: Oven containing autoclave for improved temperature control

3.1 Test Results and Analysis

3.1.1 Swell testing at 150°C

Detailed coupon and plate testing was carried out at 150°C and 225°C using 3 compounds from different swellable elastomer families in 3 different salinities. The compounds were designated -

42, -117 and ,155. The different fluids would give further insight into the swell performance and fluid compatibility of the elastomers.

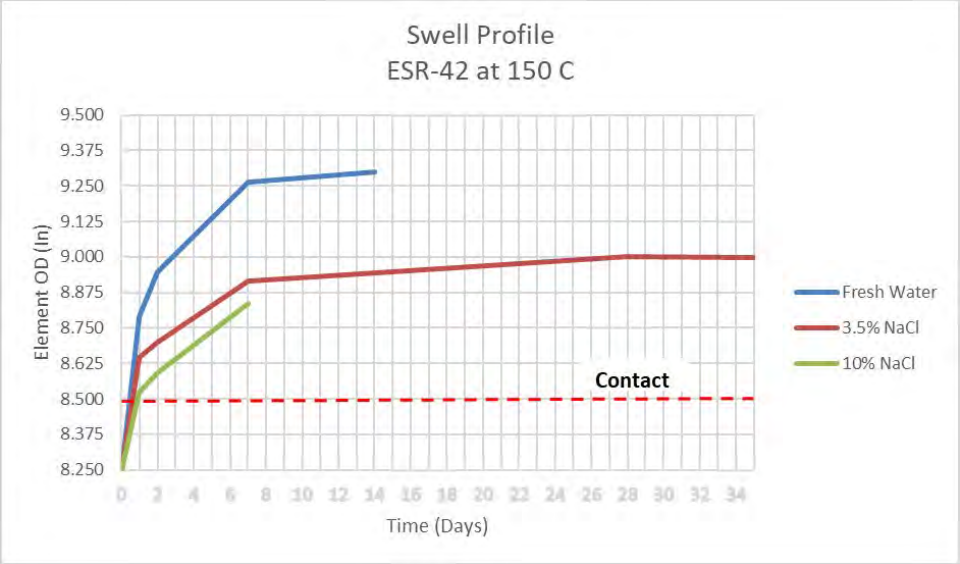

Figure 5: Swell profile of -42 at 150°C

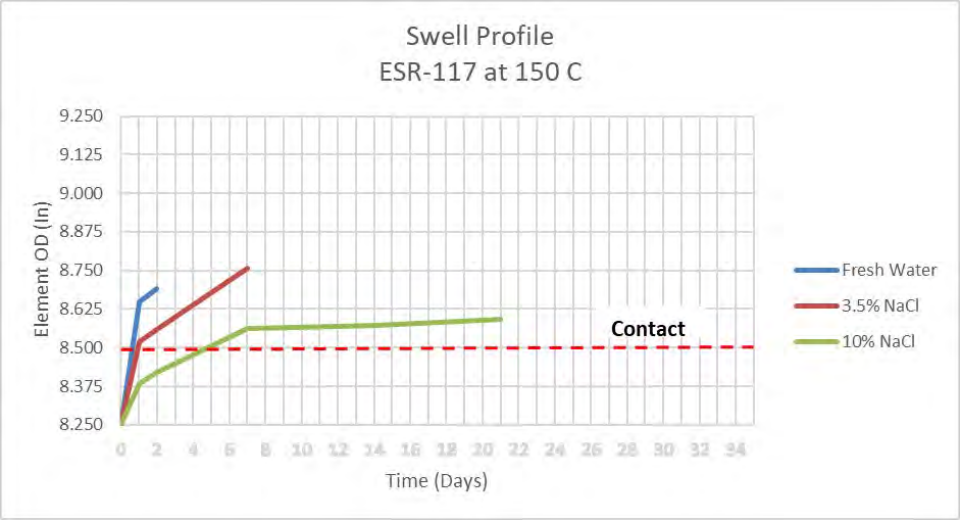

Figure 6: Swell profile of -117 at 150°C

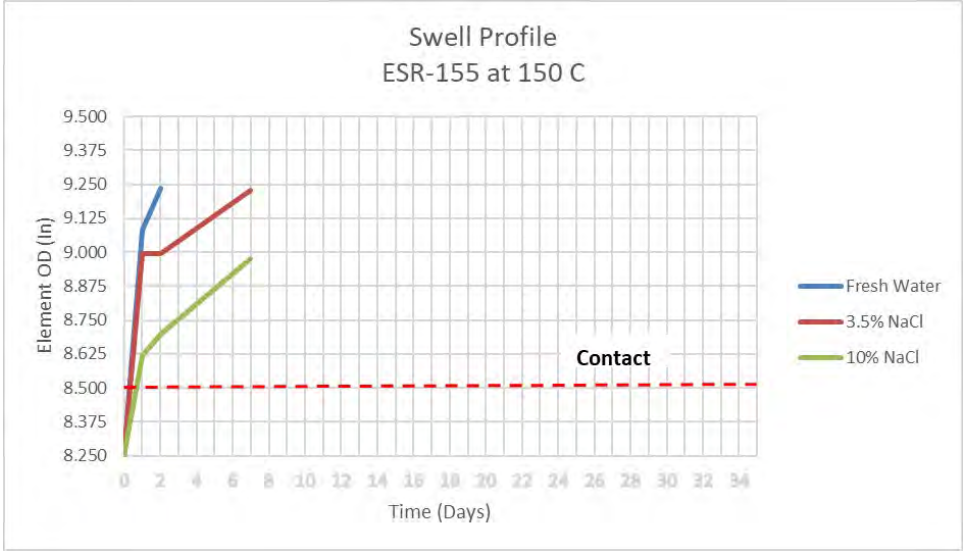

Figure 7: Swell profile of -155 at 150°C

In these graphs if the line has stopped it is because the compound swelled off the plate making further results ineffectual as the sample is no longer constrained. This is also an indication that the compound has begun to breakdown to a significant degree.

3.1.2 Analysis

It is clear from the 3 graphs that the impact of the fluid has a significant effect on the swell rate of the compounds. This is clearly shown in Figure 8:

Figure 8: Plate samples at Day 1 in Fresh water - Pictured L to R: ESR-155, ESR-42, ESR-117

The higher the salinity of the fluid the slower the rate of swell and in some respects the more controlled the swell is also.

The 3 compounds behave differently in terms of rate of swell and ultimate swell but all 3 swell to contact and beyond.

3.1.3 Swell testing at 225°C

The following graphs show the performance of the 3 original compounds in different fluids at 225°C.

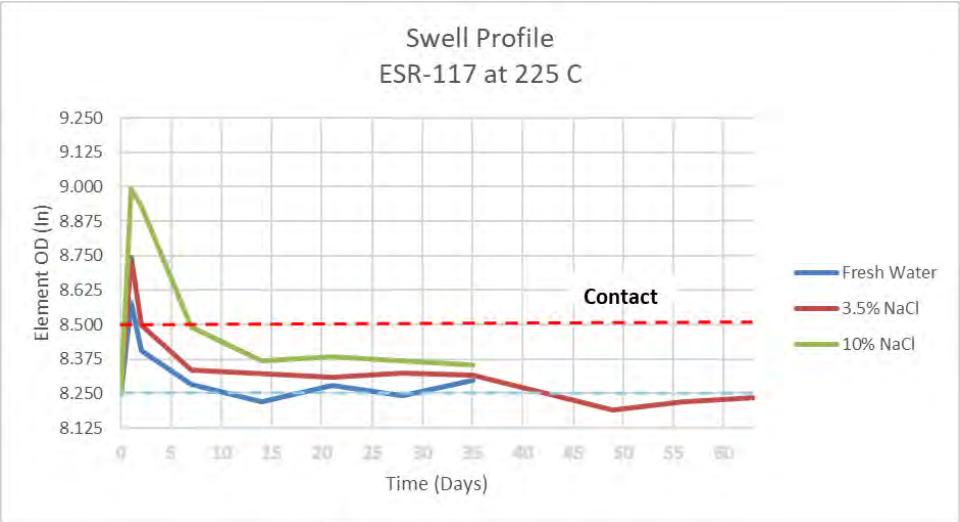

Figure 9: Swell Profile – ESR-117 at 225°C

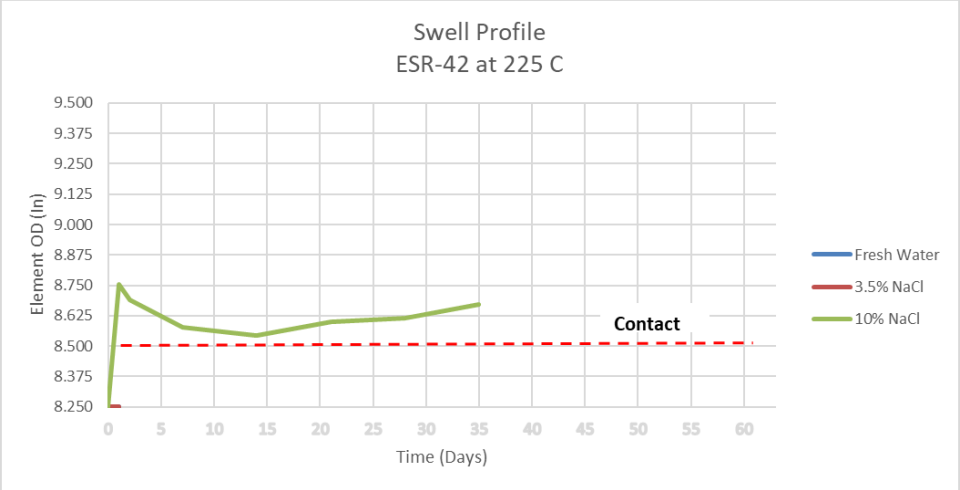

Figure 10: Swell Profile – ESR-42 at 225°C

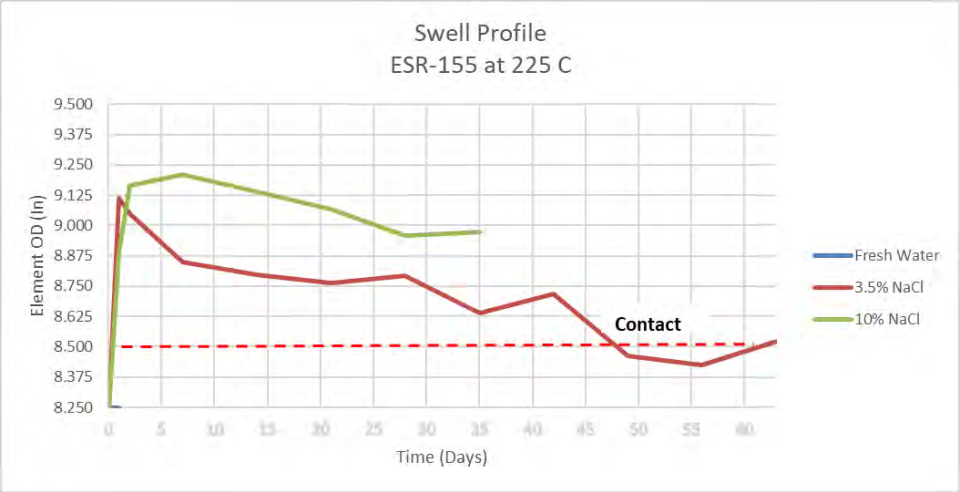

Figure 11: Swell Profile – ESR-155 at 225°C

Further variables were examined, examples of which are shown in Figures 12 and 13 below.

Figure 12: Weight loss over time - ESR-42 at 225°C

Figure 13: Change in hardness over time - ESR-42 at 225°C

3.1.4 Analysis of results at 225°C

The 10% fluid test once again shows the impact of increasing the salinity of the activation fluid. Increasing salinity slows the rate of swell. The -117 shown in Figure 9 clearly shows a very rapid swell and de-swell though definite breakdown of the compound can be observed. This is also demonstrated even more strikingly in -42 as it swelled so rapidly in freshwater and 3.5% salinity that it swelled off the plate within 24 hours. Figures 12 and 13 demonstrate an observable characteristic that the -42 compound does harden over time due to the increased temperature but rather than maintain its volume/weight this reduces over the same period.

Finally Figure 11 shows that -155 performs significantly better at this higher temperature however while the de-swell is much more controlled the swell rate, even in 10% fluid, may be too fast to be practical.

3.1.5 Conclusion and outcome of swell testing

As a result of these tests it was clear that the best performing of these compounds at the higher temperatures was -155. A decision was made to adapt this compound to provide even more controlled swelling and eventually -158 was developed. This compound was subsequently tested at 225°C in 3.5% NaCl and the results are shown in figure 14 below.

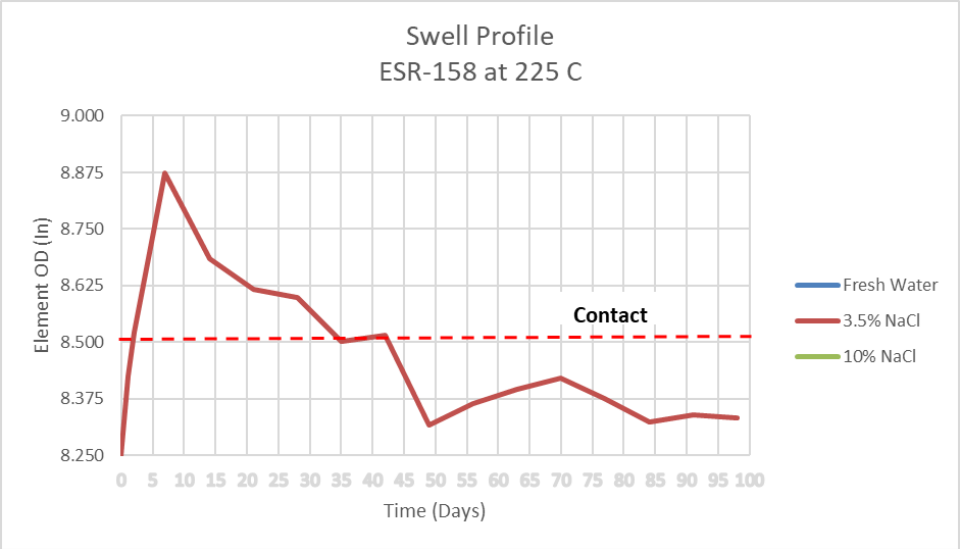

Figure 14: Swell Profile – ESR-158 at 225°C

The key points to note are:

- There is a significantly more controlled swell at this high temperature and salinity compared to previous compounds
- The compound has maintained its elasticity even after nearly 100 days at temperature
- The compound has reduced in diameter to the point it no longer contacts the target wellbore diameter.

3.1.6 Swell performance at 300°C

On the strength of this performance a decision was made to try both versions in this family of compounds at the upper project target temperature of 300°C. The graph below, figure 15, shows the performance of these two compounds at 300°C in 10% salinity.

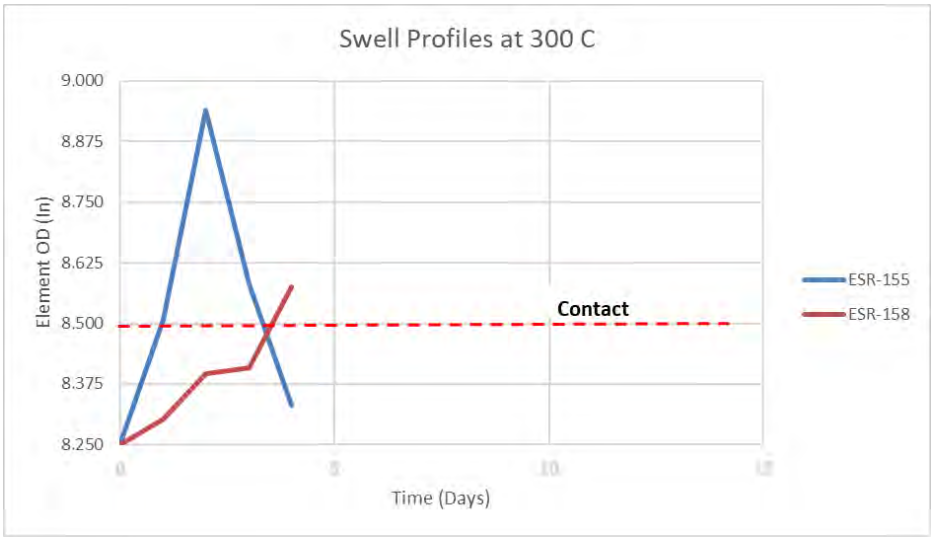

Figure 15: Plate Testing at 300°C

3.1.7 Analysis

It can be observed that ESR-155 swelled and deswelled almost back to its initial size in just 4 days. It had also hardened considerably. This temperature therefore appears to be too high for this compound to perform effectively. On the other hand, ESR-158 was continuing to swell and was still flexible. However, the extreme temperature has now caused another issue in that the rubber sample has swelled off the plate at day 4 due to failure of the bonding agent and primer. This can be seen as a crackled layer in figure 16.

Figure 16: Bonding failure during plate test at 300°C

While this result is disappointing it clearly shows the upward potential of these materials and further work will be carried out.

3.2 High temperature polymer development

The main finding regarding the polymer design for these extreme high temperature conditions has been the observation that while some of the compounds are embrittling as expected they are not remaining at their initial swell volume and are in fact shrinking back.

This can be explained by the following. Typically, in the presence of increased temperature and oxygen rubber will react one of two ways. One way is termed “chain hardening” and the other “chain scission”. Both reactions lead to a reduction in physical properties. The polymer types we are utilizing fall into the “chain hardening” category.

This condition occurs when the environment is one of increased heat and the presence of oxygen will accentuate this condition. Rubber compounds have additives called vulcanizers and accelerators that essentially form bridges between the multiple polymer chains of the raw polymer. These bridges are referred to as cross-links. This is the characteristic that contributes to the properties that the compound will have after it is cured. When exposed to increased heat “free radicals” are formed that create additional cross-links. If you can imagine, each additional cross-link pulls the polymer chains tighter as they are added. As they are pulled tighter properties

change. The material gets harder, elongation goes down, tensile may increase to a point before embrittlement. We believe these processes are responsible for the results observed in these experiments.

4. Pressure Testing

The pressure test was carried in accordance with API specification 19OH. The test was performed in the horizontal condition, which is a worst-case scenario for the element, inside a 6” bore. The test packer used was designed to utilize existing pressure test fixtures at this stage of the project while still replicating the expected rubber thickness and required radial swell as closely as possible. The 5ft element is required to hold a minimum of 2500 psi to meet the performance target. This correlates to 6000psi over the planned 12ft length of the production packer element.

4.1 Test Equipment

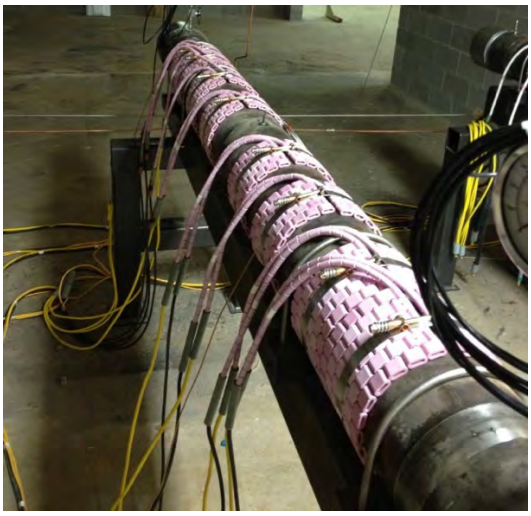

Figure 17: Pressure test fixture with heating blanket

Figure 18: Pressure test fixture with heating blanket – alternate view

4.2 Pressure Test Results

4.2.1 Pressure test at 347°F (175°C)

The graph below shows the overall performance of the packer with the build from 0psi differential all the way up to an eventual pressure hold above 3500 psi. This is in accordance with API 19OH.

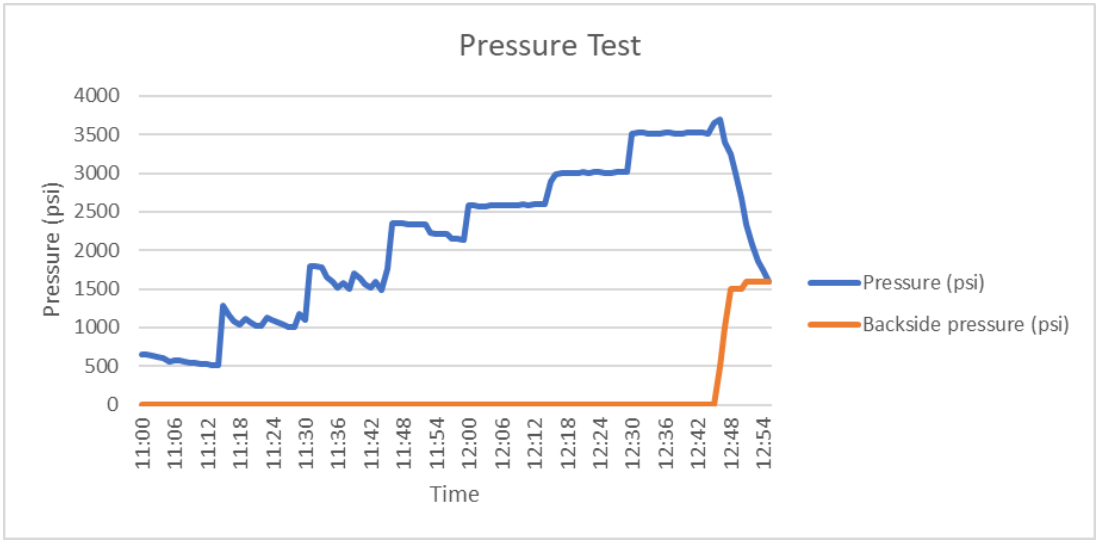

Figure 19: Differential pressure performance of 5ft packer at 347°F (175°C)

At around 3700psi pressure was observed on the back side indicating a leak. The pressure was subsequently bled off and after cooling the packer was removed from the fixture. Figure 5 below shows the packer in situ in the test fixture after the test and shows that there was little to no extrusion of the element past the end rings.

Figure 20: End view of the packer in the test fixture – no visible rubber extrusion

When viewing the full packer outside of the fixture the packer is in good condition, with surface marks from being forced out of the pipe bore in the swelled condition. There is a short section, less than 18”long, of rubber that has broken away down to an OD equivalent to the end ring diameter at the low pressure end. This is typical of observed swellable packer failures at standard oil and gas operating temperatures.

Figure 21: Packer after removal from the test fixture showing typical damage at the low pressure end.

4.2.1 Pressure test at 437°F (225°C)

The graph below shows the overall performance of the packer with the build from 0psi differential all the way up to an eventual pressure hold above 2500 psi. This is in accordance with API Spec 19OH.

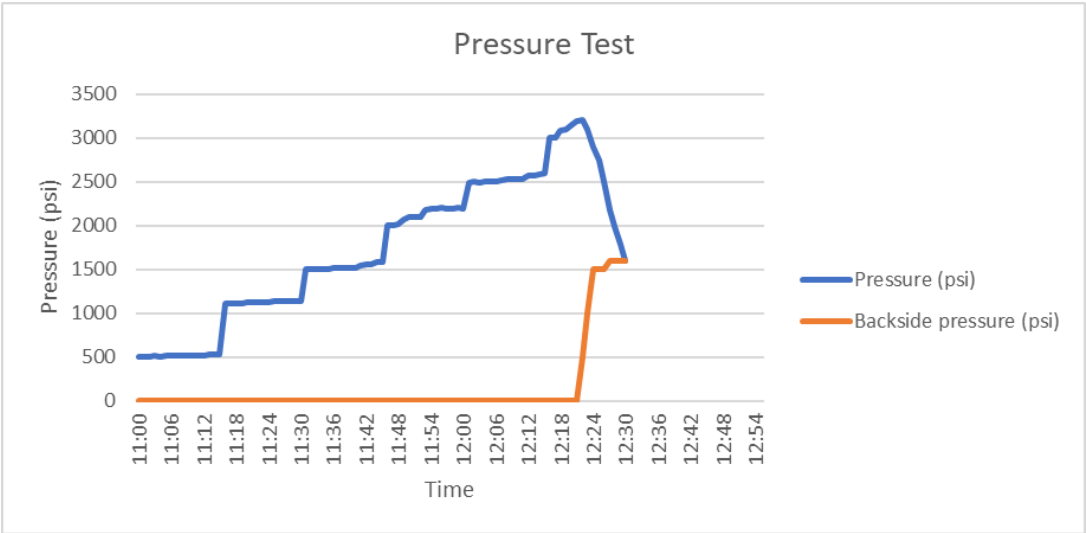

Figure 22: Differential pressure performance of 5ft packer at 437°F (225°C)

At around 3200psi pressure was observed on the back side indicating a leak. The pressure was subsequently bled off and after cooling the packer was removed from the fixture. It was observed that there was little to no extrusion of the element past the end rings.

5. Conclusion

The development work completed on the elastomer compounds has yielded an elastomer that can swell in a controlled manner at temperatures in excess of 225°C. Furthermore, it remains pliable and fit for purpose long after it's design life.

The packers performed well, demonstrating high pressure performance of 3500psi over a 5ft element at 175°C and then above 2500psi at 225°C. Despite some damage to the low pressure end of the element, overall it looked in good condition and would still continue to hold pressure albeit at a lower value. The rubber compound itself was also in good condition with no signs of hardening.

Overall these results provide evidence that this high temperature swellable isolation tool will provide effective annular isolation in geothermal wells.

Integration Well Construction, Value to Reduce Overall West Java Geothermal Development Cost

Gatra Kusuma, Doddy Darmawan, Ridha Budi Nugraha, Komang Wisnu, Hargi, Timora

Star Energy Geothermal-SLB

Keywords

geothermal drilling, optimization, cost reduction, performance drilling, cost, drilling

ABSTRACT

Geothermal drilling presents unique challenges which including harsh environments, fractured formations, and dynamic operations. These challenges are imperative to address as global interest in green energy escalates. Consequently, the development of geothermal assets remains aggressive and necessitating innovative solutions to overcome drilling complexities.

The demanding drilling conditions require substantial effort, energy, and strategic thinking. Slow penetration rates, short bit life, and equipment damage are the common issues. Understanding and mitigating these technical challenges are essential to minimize risks and enhance economic viability.

Experience and knowledge from the oil and gas industry as a common are invaluable in navigating drilling challenges. While some strategies may prove effective but others lead to inflated costs. Tailoring drilling methodologies and systems for the unique geothermal environment is paramount to optimizing drilling projects and controlling expenses.

Addressing uncertainty, mitigating risks, and enhancing efficiency are primary objectives in geothermal drilling. A structured approach across planning, execution, and post-drilling phases is crucial. By integrating workflows and methodologies, leveraging drilling expertise, and fostering continuous improvement so operational costs can be reduced significantly.

This paper underscores the value of integrated management and drilling advisory in improving performance and reducing costs. Over three years Geothermal Project in West Java, Indonesia, 70-75% reduction in well cost per meter resulted in multimillion-dollar savings through knowledge management and accelerated learning.

1. Introduction

There has been a steep increased in drilling activity over the past years in search of geothermal energy. As the search for new energy, the operators will increasingly start drilling campaign with more challenging trajectories to achieve their goals. Drilling in this environment will present an additional risks, technical challenges and huge economic impact. In fact, geothermal drilling is a

unique operation where drilling in reservoir section under loss circulation can cause bad hole cleaning meanwhile is a good sign of the potential reservoir in the other side. Historical data on previous campaigns shows significant portion of time while handling stuck pipe event and the remedial work process thus become the sources of downtime and cost. New approaches need to be introduced to this industrial climate to pursue efficient and effective geothermal drilling operations.

The new approach starts with integrate the existing resources. The integration come up with the main goal to improve service quality. The idea is to improve process by having all service requirement, increase response time to potential problems before they occur and finally cost reduction. Facing a challenging environment requires integration of every interrelated element. Real-time monitoring program able to provide timely intervention, catch various adverse possibilities and provide solution assistance. The proposed solution is to define operational workflows that utilize data and information integration to make improvements in each phase: planning, implementation, evaluation phase. Discussion of the operational framework and background and the role of technology to support operational performance will be described in this paper.

2. Problem and Challenge

The risk of geothermal drilling will turn into a problem and become non-productive time (NPT) which can extend drilling time if not prevented and mitigated properly. Increasing the drilling process will directly increase well costs due to additional material, mud, drill bits, and other geological obstacles in reaching the target reservoir depth.

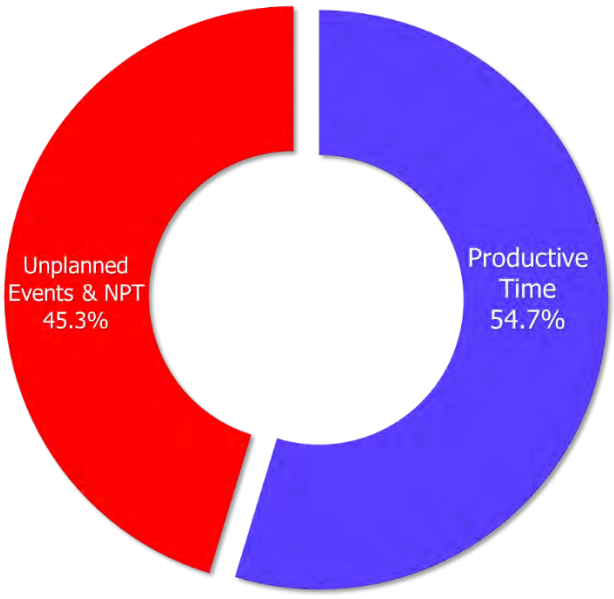

Figure 1: Drilling Time Distribution on Previous Campaign

As can be seen in Figure 1 Drilling Time Distribution, Unplanned events and Non-Productive Time (NPT) during drilling process takes 45.3% of the total time in the whole process. The large

portion of NPT is a result of uncertain drilling conditions being categorized as unplanned event. The uncertain changes in the drilling environment make the decision-making process very dynamic due to frequent changes to the initial plan. Making fast and precise decisions in this dynamic process certainly requires good and valid information from the field to the stakeholder or decision makers.

The time used during the drilling process is analyzed and broken down on each process such as drilling, tripping, casing, cementing, logging and others to see how much time is spent. Knowing which processes take up the largest portion of time, so ineffective on this process will result in significant additional costs. These problems can be derived from potential risks such as Low ROP, Stuck Pipe, Loss Circulation and Flat time issue. These four things are factors that cause company losses that need to be addressed.

The main idea of this research is the need to improve operation model and overcome the negative impact. The modeling system start to interrupt or stop the NPT as quickly as possible and reduce the potential risk and make the right decision to make the process more effective.

2.1 Hard and Abrasive Formation

The hardness and abrasiveness of geothermal formations exert a significant influence on numerous factors. Issues such as slow instantaneous penetration rate (ROP) and equipment damage commonly arise due to the characteristics of geothermal rocks. The decrease in penetration rate will give an impact on both the time and well costs. Equipment damage can halt the drilling process, necessitating equipment replacement. Junk in hole could be happen if damaged equipment was left in the hole and for sure can lead to further complications, prolonging the process and consuming additional resources, including money, time, and energy required for remedial actions.

Figure 2: Drilling Bit Condition, Left: Pre-Run and Right: Post-Run

As depicted in Figure 2 Drilling Bit Condition, the differences of actual drilling bit before-after use are clearly visible. Bit/tool failure causes a decrease in ROP and ultimately stop drilling

operation to POOH for checking and/or changing BHA. Overcoming these challenges has proven to be very challenging, especially in geothermal drilling environments where such conditions exist. Although many efforts have been made to mitigate this problem, the expected results are still not optimal. Therefore, further evaluation is essential, which includes mathematical modeling through simulation results and empirical research based on historical data.

2.2 Stuck pipe and Hole Problems

Many challenges encountered during the drilling process hampered the operator's ability to effectively achieve its objectives. This is shown in Figure 3, Previous Campaign Drilling Curves, where the various patterns appear in drilling performance, both in terms of inclination and final depth results. Highlighting the various issues encountered during drilling, the differences in the time and depth across several wells depicted in the curves are evidence of inconsistent performance.

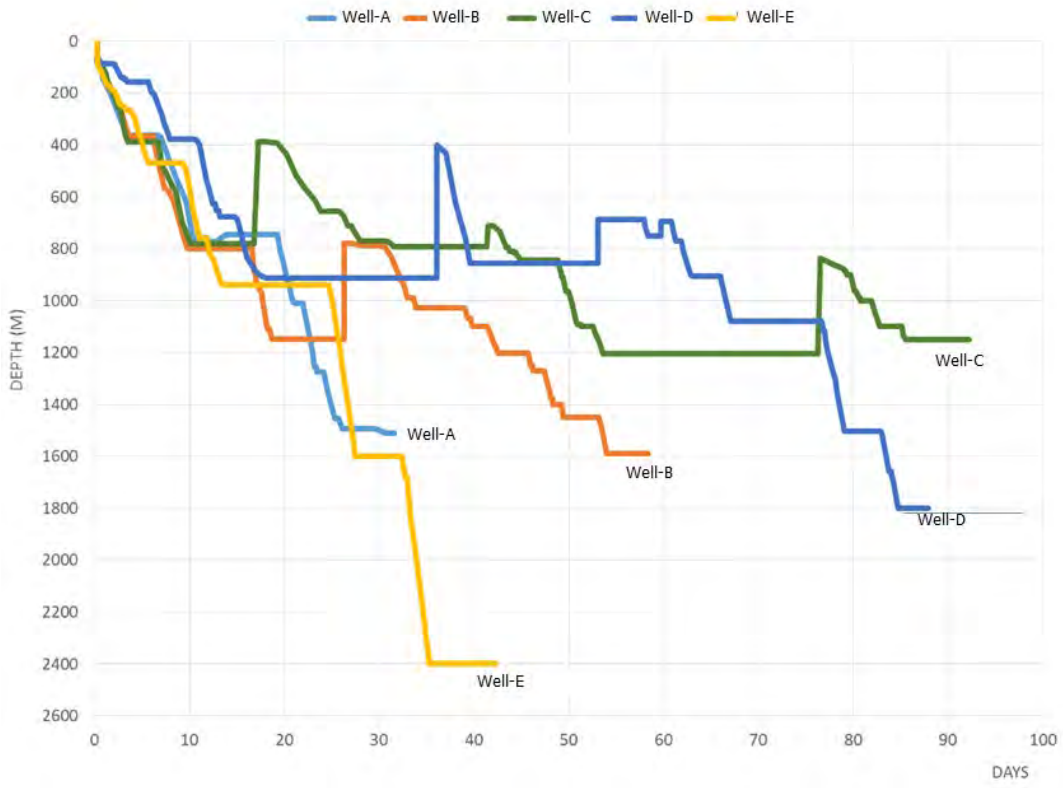

Figure 3: Previous Campaign Drilling Curve

As explained earlier, the significant prevalence of issues arising from uncertain drilling conditions resulted in long time consumption and Non-Productive Time (NPT) during the drilling process, which was classified as unplanned event. For example, the orange curve representing Well-E displays the most prominent and deepest curve among all wells, indicating an obvious deviation from the performance of other wells. None of the wells achieved the inclination and depth as Well-

E did, misalignment between objective and actual achievement. This distinction underscores the need to explore the factors that contribute to the phenomenon and form the basis for designing a strategy.

2.3 Drilling in Total Lost Circulation

Loss circulation is one of the other critical risks which is associated with geothermal drilling. The formation characteristics consist of fracture propagation which is subsequent to lost circulation. It results in significant mud loss and extremely challenging to cure the losses by using stop loss materials (LCM) or even cement plug job. This challenge is further compounded maintaining wellbore stability in formations with micro-network fractures poses considerable challenges during drilling. The drilling fluid penetrate into fractures, fails to equilibrate the pore pressure with the mud pressure and leads the fluid level to drop. Therefore, cuttings-induced pack-off over the Bottom Hole Assembly (BHA) can be happen during making up new connection due to insufficient annular pressure when the pumps is off. This scenario has been observed repeatedly when drilling fluid fails to suspend cuttings, ultimately culminating in a stuck pipe event.

2.4 Prolonged Flat Time

Essentially, well construction encompasses two main phases which are drilling activity(on bottom) and activity where no advancement occurs in hole depth (flat time). As previously mentioned, flat time activities encompass various operations which significantly contributing to the overall time allocation such as pipe tripping, casing and liner installations, cementing, BOP job, wellhead handling, pressure testing, and completions. The failure on these activities will impact to time and cost directly.

Another critical aspect of well construction which occurs during flat times is characterized by substantial the “unseen" loss time. As evidenced in the previous discussion by the Drilling Curves in Figure 3, some wells exhibit long flat periods, depicted by horizontal lines indicating no increase in depth over time. Consequently, any issues arising during these activities can prolong the average time required to condition the well. Rig performance, meticulous planning, comprehensive preparation, and clarity in low-level instructions are paramount in optimizing flat time activities.

3. Solution

The implementation of a comprehensive strategy and extensive consultation with technical experts from service providers to optimize resources, technology and workforce in the last 4 years has had a very significant impact on the drilling process across the system. The primary objective is to tackle drilling challenges, address issues with loss circulation and implement best practices to ensure geothermal drilling process are safe, efficient, and cost-effective. Therefore, this solution enables drilling operations to run smoothly without any obstacles and effectively solves existing problems.

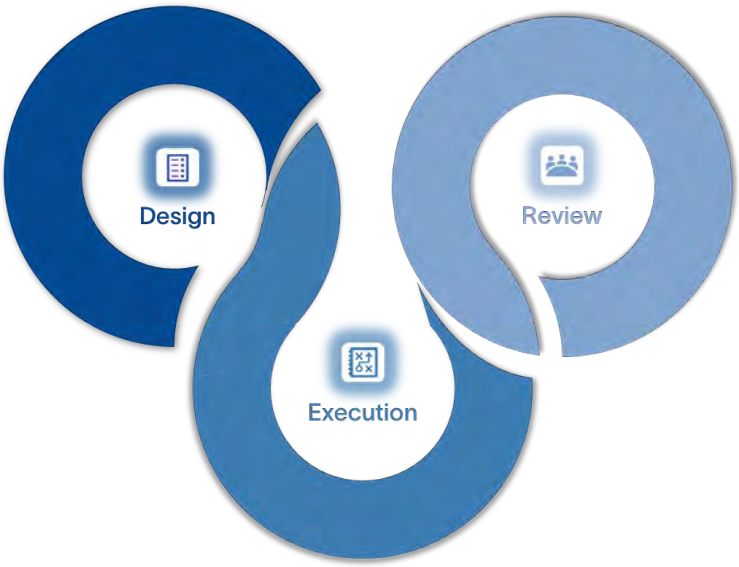

Figure 4: Improvement Cycle

The improvement initiatives encompass three fundamental phases: design, execution, and review, detailed in Figure 4. Each phase yields substantial information and data crucial for developing strategies and bridging operational gaps. In the design stage, the process begins with establishing a Risk Register to proactively identify potential issues. Subsequently, potential problem scenarios are modeled for the subject well using data from offset and similar wells in term of geological prognosis, accompanied by comprehensive solutions and lessons learned. Further analysis will refine initial best practices to uncover opportunities for enhancement and improvement.

Once the strategy and program are finalized in the designing stage, real-time monitoring of all operations will ensure the program adherence and support advisory/remedial plan for any deviations caused by unforeseen challenges. Specifically, the proposed solutions for mitigating loss circulation, hole instability issues led to stuck pipe and optimizing drilling processes empower operators to minimize risks, enhance performance, and achieve safer operation.

4. Managing the Challenges

The implementation of technology solutions and integration strategies has been proven to provide increased cognitive capabilities in improvement cycle and provide significant progress in drilling operations.

Figure 5: Managing the Challenges

The achievement is underpinned by five core pillars: Key Performance Indicators (KPIs), Historical Performance analysis, Performance Improvement plans, Implementation Strategy, and Performance Lookback as shown in Figure5. This discussion will elucidate how optimizing each of these critical components has contributed to this remarkable progress.

4.1 Key Performance Index

To improve the overall efficiency of asset investment, the focus is on assessing and achieving well productivity. This involves strategically selecting the existing locations with tiny space, optimizing resource usage and concerning environmental impact. Collaboration among function plays a crucial role in enhancing collective capabilities for achieving more economical drilling costs in geothermal operations. Integrating resources and expertise, operators can leverage knowledge and technology to streamline processes and reduce operational expenses.

Table 1 Drilling Well Objectives

Objectives	Information
Value Based Well Objective (VBWO)	Maintain well control at all times.
	Meet or exceed P50 initial expected steam rate at commercial wellhead pressure
	Meet or exceed project economic of positive NPV
	Complete well hook-up one month after flow test and put the well on-line right after well hook-up commissioning.
	Complete the well within AFE days and budget.
	Characterize the well as per plan i.e. completion test, flow test, geological data
	Flow test within five days on availability of SIMOPS permission otherwise after rig move
Health, Safety, & Environment (HSE)	No LTI'S (lost time injuries).
	No environmental incidents, spills and minimum environment impact.
	No major or catastrophic service quality incident.
	Incident and injury free operation (IIFO) .

The core of this collaborative approach is the Effort to improve drilling efficiency and minimize environmental impacts. As depicted in Table 1, Key Performance Index are translated into specific objectives for each well drilling activity. Through collaborative initiatives, operators can explore innovative drilling techniques and technologies that enhance operational efficiency while prioritizing sustainability. This collective effort not only facilitates cost-effective geothermal resource development, but also promotes responsible natural resource management. Aligning strategies and leveraging collaborative strengths, operators can pave the way for continued growth in geothermal energy production, while driving economic benefits and environmental sustainability.

4.2 Historical Performance and Performance Lookback

In the domain of drilling operations, data derived from offset wells plays a pivotal role as a foundational reference throughout the stages of design and implementation. This dataset offers critical insights into a spectrum of parameters that influence over drilling conditions. These insights play a critical role in early identification of potential challenges, such as the risk of loss of circulation or drilling damage, which can significantly impact operational efficiency and safety. Moreover, the data helps in developing effective responses to unforeseen issues that may arise during operations, such as managing cuttings during pipe landing and casing operations, and

addressing downtime for repairs, such as the installation of Blowout Preventer (BOP) connections and reaming activities.

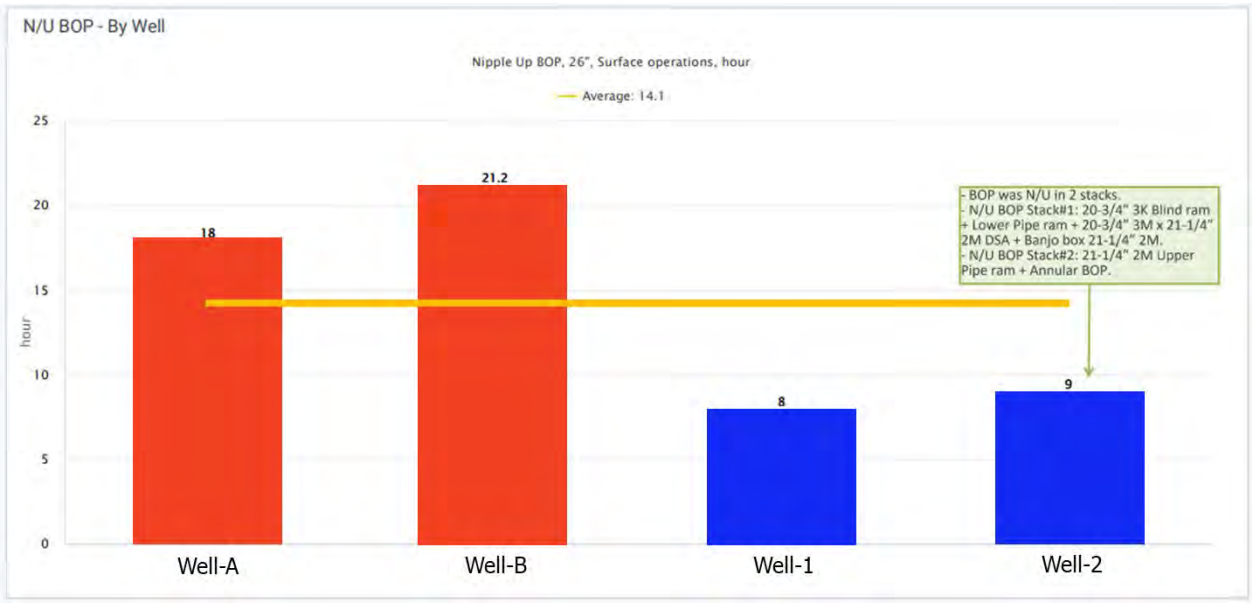

Figure 6: Improvement of N/U BOP

Leveraging the offset well data allows drilling engineers to proactively anticipate issue and develop solutions that mitigate risks while optimizing operational outcomes, as illustrated in Figure 6 which highlights improvements in process efficiency. Through effective utilization of historical data, engineering decision-making processes, streamline operations, and enforcing safety protocols. This proactive approach ensures that drilling activities proceed smoothly, minimizing disruptions and maximizing productivity. Ultimately, integrating comprehensive data analysis from offset wells plays a crucial role in achieving operational excellence and resilience in the dynamic field of drilling operations.

4.3 Performance Improvement Plan and Implementation

Engineering and operational integration initiate strategic interventions using precise principles and methodologies by following the thorough completing comprehensive identification and measurement processes outlined earlier. These actions are addressing inefficiencies and unlocking opportunities for enhancing performance. In response to identified operational shortcomings and instances of downtime, comprehensive strategies have been meticulously formulated to bolster drilling performance across all operational domains. Then these initiatives encompass a comprehensive approach that integrates process improvement, technology integration, and procedure optimization. Thus, the holistic strategy aims to maximize operational efficiency and minimize disruption, addressing both immediate and intermediate time frames.

4.3.1 Immediate Within 6 Month

In the realm of drilling operations, the data from offset wells serves as invaluable reference throughout both the design and execution stages. These datasets provide crucial insights into various parameters that influence drilling conditions. By analyzing how these parameters behaved in past operations, engineers gain a clearer understanding of expected outcomes and potential challenges. This historical data is particularly critical during monitoring phase, where real-time data is consistently benchmarked against established standards from offset wells. This comparison enables Real-time Decision Center (RTDC) engineers to promptly identify and evaluate any deviations or anomalies occurring at depth, as depicted in Figure 7 which illustrates deviations in well trajectory. Through continuous comparison and real-time monitoring, early detection of deviations allows for swift decision-making regarding necessary solutions. These insights facilitate proactive adjustments, ensuring operational continuity and minimizing risks associated with unforeseen drilling conditions.

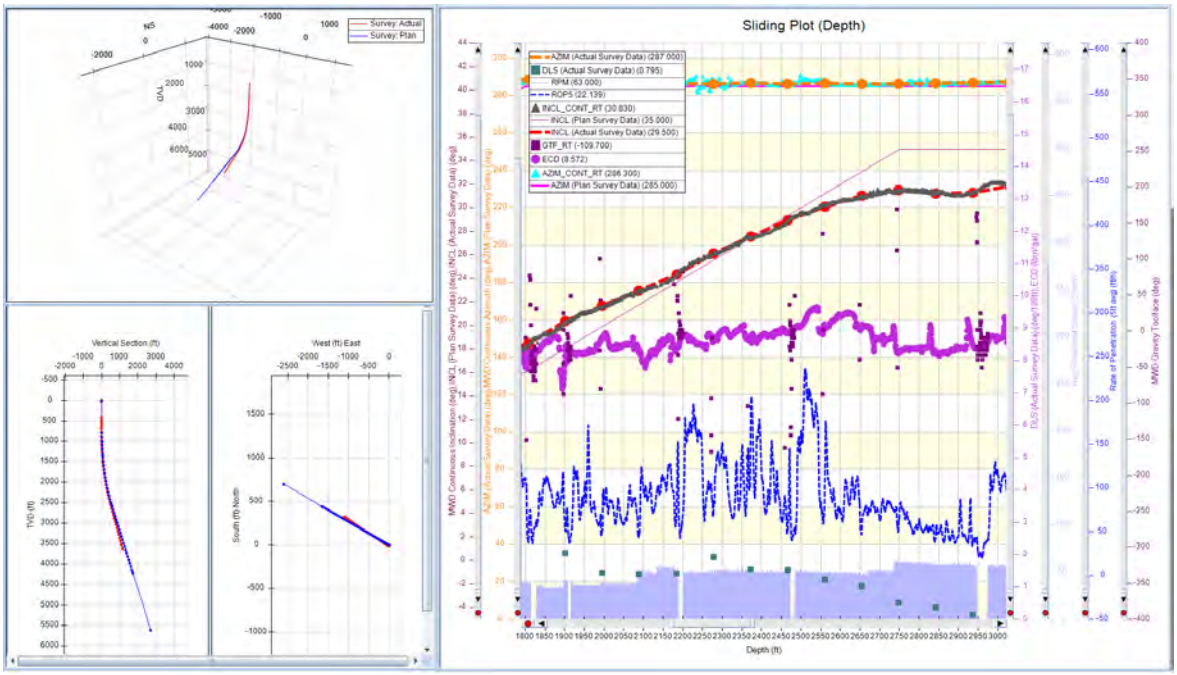

Figure 7: Real-Time Trajectory Monitoring

This visual representation not only facilitates rapid identification of anomalies but also enhances the precision of decision-making processes. Engineers can promptly correlate the parameter trends, diagnose any discrepancies and take appropriate corrective measures. This proactive approach not only enhances operational efficiency but also reduces potential downtime and optimizes resource utilization. The monitoring plot derived from real-time data as shown in Figure 7 provides a clear visualization of trajectory adjustments and their feasibility. Assessing the likelihood of achieving desired trajectories and identifying potential challenges could expedite decision-making throughout drilling operations. Leveraging insights from offset well data empowers engineers to effectively navigate complexities and uphold stringent standards of safety, efficiency, and performance in geothermal operations. This integrated approach ensures that operational objectives are met with precision while minimizing risks and maximizing operational success.

4.3.2 Intermediate 1 – 2 Years

The development of the improvement strategy are introduced to stakeholders and higher-level management, ensuring the alignment with organizational objectives and project goals. This involves comprehensive communication and detailed presentations that methodically outline the potential impact and benefits strategies. This collaborative effort aims to cultivate a shared understanding and commitment among all stakeholders, setting the stage for seamless execution by the project implementation team. Translating these strategies into actionable steps, the teams are well-positioned to implement effective solutions that not only address current inefficiencies but also establish a pathway towards sustained operational excellence in drilling operations.

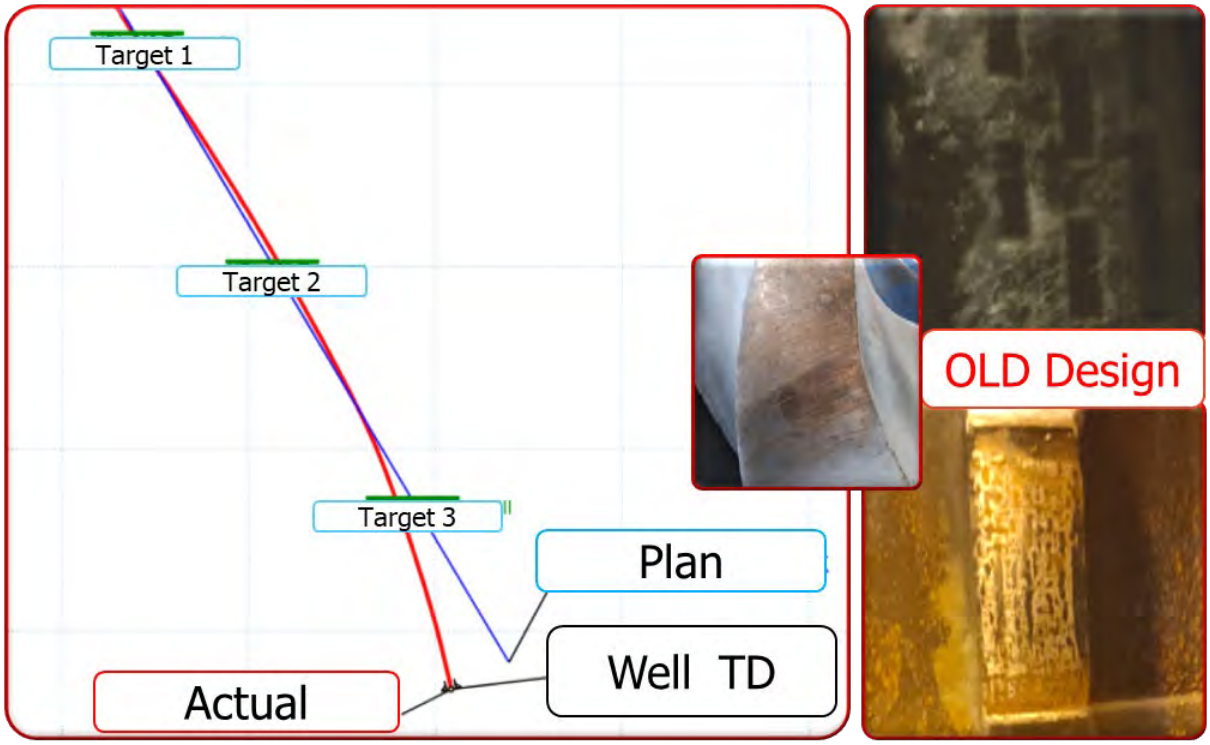

Figure 8: Equipment Deformation and Consequence

Several important factors are taken into account to optimize performance and reduce risk when designing a well. Anticipating subsurface hazards is critical and time consuming as it involves a thorough geological and geophysical assessment to identify potential challenges such as unbalanced formation pressure, lost circulation, or hard and abrasive formations. The impact of subsurface issues can be seen in figure 8 as a result of a worn stabilizer causing a near-miss incident to miss the target.

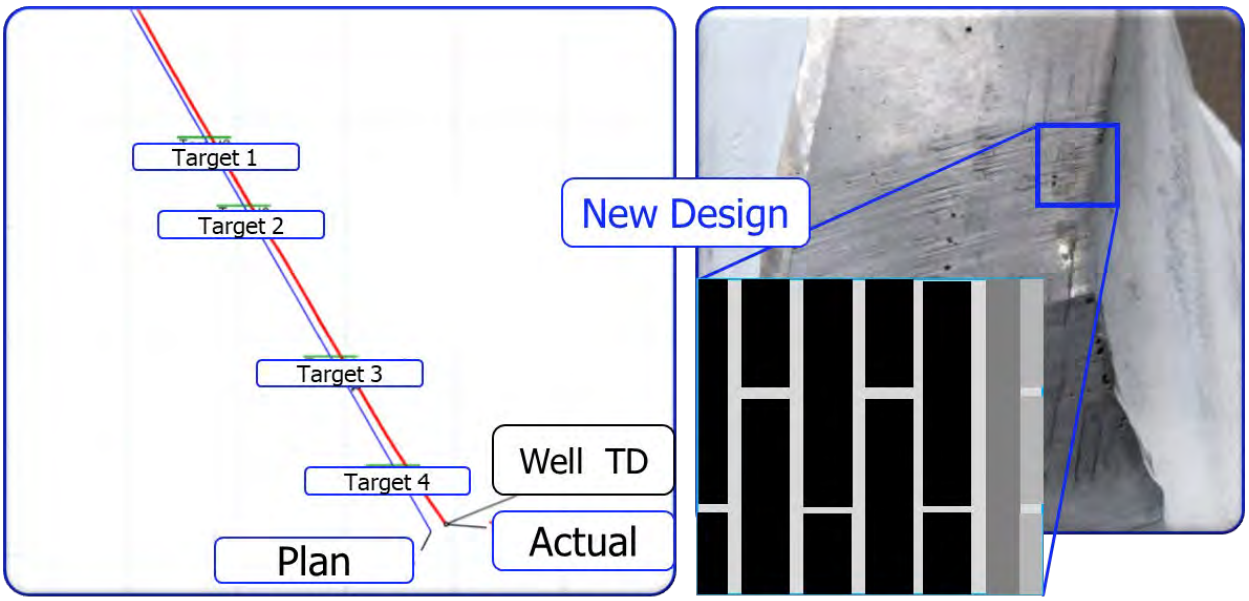

Figure 9: Quality Assurance through Innovative Design

Improvements have been made with studies on depth, formation hardness, and well trajectory requirements to ensure quality service assurance. Increasing drilling efficiency involves adapting equipment protection designs for abrasive formations and implementing advanced drilling techniques, which contribute to increasing penetration rates and guaranteeing the quality of services provided as shown in Figure 9. Additionally, selecting appropriate drilling equipment protection plays a vital role in preventing drilling problems, ensuring robust equipment no drop tendency is shown and all targets are hit without any exception in term of efficient drilling operations.

In conclusion, integrating these advanced strategies and technologies into drilling operations not only improves immediate efficiency but also lays the groundwork for long-term success. By focusing on meticulous planning, stakeholder alignment, and leveraging cutting-edge technologies, drilling teams can navigate challenges effectively, achieve operational excellence, and uphold high standards of safety and performance in geothermal and other drilling operations.

5. Result

Building up a strong organizational capability is crucial for achieving continuous improvement in drilling operations. This entails leveraging advanced technologies such as real-time monitoring systems and enhancing cognitive skills. Efforts are also focused on enhancing overall asset investment efficiency through the assessment and drilling of complex wells aimed at increasing productivity.

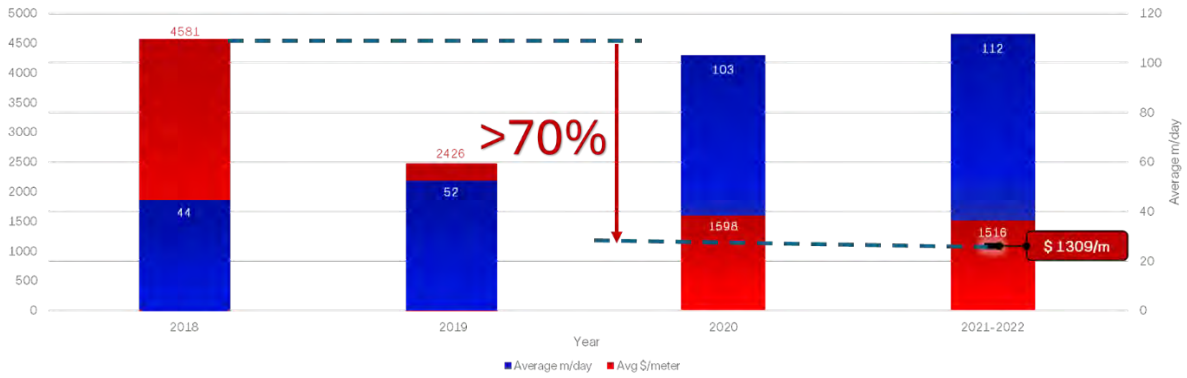

Figure 10: Reduction in Well Cost per Meter

These initiatives embody a holistic approach to optimizing operational efficiency, reducing expenses, and ensuring long-term sustainability in geothermal drilling practices. This is exemplified by the fastest and most cost-effective drilling of geothermal wells in Indonesia over the past five years, as depicted in Figure 10. The learning curve and improvements achieved in this campaign are clearly shown, with drilling costs per meter decreasing by 70-75% and drilling speed increasing. Collaborative efforts among operators further enhance capabilities, aiming to achieve more cost-effective drilling operations in future geothermal developments.

Acknowledgement

This successful implementation of systems, technology, and integration by Star Energy Geothermal demonstrates that Integrated Well Construction is a viable solution for the entire geothermal industry. The author extends sincere gratitude to Star Energy Geothermal for their invaluable support of this research. We are grateful for their permission to publish this paper and commend their dedication to advancing sustainable geothermal drilling. Special thanks are also due to the field and office personnel, including SEG and SLB crews, wellsite supervisors, and workshop personnel, whose contributions were instrumental in achieving this success.

Alkali-Activated Gibbsite Cement for Use in CO_2-rich Geothermal Wells

Tatiana Pyatina, Toshifumi Sugama

Brookhaven National Laboratory

Keywords

Geothermal wells, carbon storage, cementitious materials for supercritical wells, carbonation resistant materials, ductile well cement

ABSTRACT

In this study calcium-free (and nearly Ca-free), aluminum-based cement was hydrothermally synthesized from sodium metasilicate (SMS) alkali-activated gibbsite, characterized, and evaluated for applications in supercritical and high-temperature (HT) CO_2-rich geothermal wells. Hydrous ZrO_2, silica flour, calcium aluminate cement (CAC), and microcarbon fibers (MCF) were used for matrix reinforcement. The hydrothermal synthesis was performed by autoclaving SMS-activated gibbsite at 300^{o}C for 24 hours followed by exposures for 30 days in supercritical water (scH_2O) at 400^{o}C or 9 months in deep geothermal Newberry well at 325-350^{o}C. Changes in thermal stability, porosity, mechanical properties caused by changes in phase compositions and phase transitions were evaluated. The absence of calcium in its composition allowed this cement to avoid carbonation under the HT geothermal well conditions and to preserve its mechanical properties, including high ductility. Differences in phase compositions observed under laboratory supercritical and well conditions are discussed.

1. Introduction

Deep and hot geothermal wells can provide several advantages, including an increased power output and a possibility of critical minerals recovery (Asanuma et al., 2012, 2015; Bonneville et al., 2018; Garrison et al., 2020; Muraoka et al., 2014; Petty et al., 2021; Reinsch et al., 2017). However, requirements for materials used for construction and operation of such wells are very stringent. While the life span of some materials used in well construction is limited by days and months, cements that provide zonal isolation, casing corrosion protection, well structure support, preventing annual pressure buildup, are expected to survive for many years for the well to support operations of a power plant. These functions of cementitious materials must be fulfilled under the environments that are difficult for them to withstand (H_2S and/or CO_2 rich with high Total Dissolved Solids hydrothermal environments). Moreover, with the high well temperatures all the

degradation reactions accelerate dramatically. The decalcification of Ordinary Portland Cement (OPC) under acidic conditions has been known for a long time (Biczok, 1967). Decalcification under high temperatures may cause OPC-based formulations to lose their mechanical properties in CO_2-rich environments in a short time. Previous tests of cement samples exposure in HT Newberry well showed that commonly used OPC/silica HT cement formulation lost its mechanical properties in 9 months when exposed to the well environment (Pyatina et al., 2024). Severe samples carbonation was believed to lead to the loss of its performance. On the other hand, the strength of calcium-aluminate-based cement samples increased, while their porosity decreased during the 9-month period of their exposure in Newberry well. The extent of carbonation of these samples correlated with the calcium content, where higher carbonation was seen for samples with higher calcium (Pyatina et al., 2023, 2024; Pyatina & Sugama, 2024). The persistence and even improvement of the properties for these formulations was linked to the presence of aluminum that did not show formation of carbonated minerals under the high -CO_2 well conditions.

In this paper we report the results of well exposure tests for aluminum-based, calcium-free cementitious materials (or materials with low-calcium content), alkali-activated gibbsite cement (AGC). The materials were originally tested under laboratory supercritical conditions (Pyatina & Sugama, 2023; Sugama & Pyatina, 2022) and later exposed in Newberry well. The aluminum-based material is interesting as a standalone cementitious system that meets cement requirements for geothermal wells (specifically, strength of above 1000 psi) while being highly flexible, but also as a part of other possible formulations with mineral compositions including aluminum, which are stable under HT geothermal well conditions. Most of the geological phases that survive in such environments are aluminum-rich and calcium poor, which is very different from the currently used cementing solutions historically created for above the ground constructions. Investigation of aluminum-based cementitious composite lays a groundwork for design of new geothermal materials.

2. Materials and methods

2.1 Materials

Aluminum hydroxide, an EMPLURA® hydragillite powder with a bulk density of ~90 g/100 mL and particle size < 150 μm for 90% of the material, was obtained from Sigma Aldrich. Zirconium (IV) hydroxide as hydrous zirconium oxide, $ZrO_2.nH_2O$ (Zr), was also obtained from Sigma Aldrich.

Calcium–aluminate cement (CAC), Secar #80, was used in this study. It was supplied by Imerys. The X-ray powder diffraction (XRD) data showed that the crystalline compounds of #80 CAC were the following three principal phases: calcium monoaluminate ($CaO{\cdot}Al_2O_3$, CA), calcium dialuminate ($CaO{\cdot}2Al_2O_3$, CA_2), and corundum (α-Al_2O_3).

SMS (Na_2SiO_3), an alkali-activator powder of 93% purity with particle sizes of 0.23 to 0.85 mm, trade named “MetsoBeads 2048,” was supplied by the PQ Corporation. It had a 50.5/46.6 Na_2O/SiO_2 weight ratio.

Some formulations were modified with 10% by weight of dry blend carbon microfibers (MCF, AGM-94) derived from a polyacrylonitrile precursor supplied by Asbury Graphite Mills, Inc. They were 7–9 microns in diameter and 100–200 microns in length. These fibers are stable at

temperatures up to 600°C. Earlier application of these fibers was shown to improve the ductility and cement–carbon steel bond of HT cement samples, which commonly decrease with longer HT curing times in laboratory tests (Pyatina & Sugama, 2015). They were used to improve the mechanical properties of the tested composites and to evaluate fibers' long-term chemical and thermal stability in field tests.

2.2 Cement Formulations and Samples Preparation

The compositions (in mass percent) of cement samples discussed in this paper are given in Table 1. Cement slurries were prepared by dry-blending all components, hand-mixing them with water amount that allowed to obtain comparable self-leveling properties and poring them into glass tubes (18 × 150 mm). The glass tubes were left at room temperature for 12 h. Then samples were exposed to an 85°C environment with a relative humidity of 99.9% for another 12 h. Finally, they were autoclaved at 300°C for 12 more hours in a non-stirred Parr Reactor 4622. After the 300°C autoclaving, each tube was cut into 3 cylinders of ~40 mm each, and the solidified cement samples were removed from the glass before their shipment to the wellsite for well-exposure tests or conducting mechanical properties tests.

Table 1. Compositions of AGC samples exposed in Newberry well in mass percent. The concentrations of SMS, MCF, and Zr are given in mass percent by the total mass of ($Al(OH)_3$, CAC#80, and SiO_2).

Sample name	$Al(OH)_3$	CAC#80	SiO_2	SMS	MCF	Zr	Water
AGC/MCF	60	-	40	5	10	-	51.6
AGC/Zr/MCF	60	-	40	5	10	10	51.6
AGC/CAC#80	50	10	40	5	-	-	44
AGC/CAC#80/MCF	50	10	40	5	10	-	51.6

2.3 Exposure Tools and Exposure Conditions

Detailed information on exposure tools and well conditions can be found elsewhere (Pyatina et al., 2023, 2024). The Exposure tools were fabricated from stainless steel to host cylindrical samples. They had open slots for sample exposure to the well environment and side plates for centralized placement in the well.

According to earlier well service data, the bottom hole temperature of the well where the sample baskets were released was ~325-350°C (communications with AltaRock). Information on the pressure at the bottom of the well was not available; the pressure at the depth of about 1.6 km was nearly 14 MPa. If a constant pressure gradient is assumed between 1.6 and 3.0 km, the bottom hole pressure can be estimated to be ~26 MPa.

Geochemical analysis from flow testing of this well by Geologica performed in 2008 showed that a non-condensable gas, identified as being >99% CO_2, was coming from a geological source (hydrothermal or magmatic).

2.4 Sample Analyses

The percent of water-fillable porosity of the well-exposed samples was determined using the following formula: $(W_{wet} - W_{dry})/V \times 100$, where W_{wet} is the weight of water-saturated samples and W_{dry} is the weight of a sample dried for at least 4 days in a vacuum oven at 60 °C until the weight of the sample was constant, and V is the volume of the sample.

JEOL 7600 F (Pleasanton, CA, USA) scanning electron microscope image analysis coupled with energy dispersive X-ray (EDX) elemental composition measurements on freshly broken surfaces was employed for morphological analyses and phase identifications.

TGA/DTA (heating rate of 20°C/min in a N_2 flow, ~10 mg sample weight, model Q50, TA Instruments) and X-ray diffraction measurements (40 kV, 40 mA copper anode X-ray tube, Rigaku Smartlab) were used for sample characterization. The PDF-4/Minerals 2023 database of the International Center for Diffraction Data (ICDD) was used for the analysis of XRD patterns. The background was subtracted from all the XRD patterns before their analyses.

The uniaxial compressive strength, Young's modulus, and compressive toughness were determined using the Electromechanical Instron System Model 5967. The measurements were performed on unconfined, dry samples after the water-fillable porosity determinations. The instrument had a 30 kN load capacity, and the measurements were performed at a 1.25 cm/min loading rate. The measurements were used to obtain the comparative performance of different formulations without focusing on absolute values. The mechanical properties and percent of water-fillable porosity of the reference samples after the 300°C autoclaving were measured in the same manner. The compressive toughness was computed from the area under the compressive stress–strain curve.

3. Results

3.1 Unconfined Mechanical Properties and Water-Fillable Porosity

Compressive strength and Youngs modulus of 300°C-autoclaved and 9-month well exposed samples are shown in Figure 1. All the samples survived the 9-month exposure tests with only minor changes in strength and modulus. The strength slightly decreased for AGC/MCF samples with and without Zr (~12% strength decreased), persisted for the AGC/CAC sample and increased for AGC/CAC/MCF sample (~40% increase). The changes in the modulus mirrored those of the compressive strength with the modulus after the exposure remaining in the desirable moderate range around 1000 MPa (145 kpsi) for all the formulations except the AGC/Zr/MCF one where the value of the modulus declined to 600 MPa (87 kpsi). Such moderate values of the modulus even after the long well exposure are uncommon for cementitious composites and indicate that ductility of the systems can persist in an HT well.

Interestingly the toughness of all the tested formulations noticeably improved after the exposure. Toughness is a combination of strength and ductility and is a very desirable property for geothermal cements. Because of the high ductility of these formulations their average toughness was relatively high even before the exposure tests despite their moderate strength (0.29 $N*mm/mm^3$). It further increased by stunning ~240% after the exposure reaching 0.97 $N*mm/mm^3$ (Figure 2).

The high ductility of these formulations is partially due to their relatively high porosity of about 50%. Porosity of the samples after exposure decreased by nearly 6% with the largest decrease experienced by the AGC/CAC/MCF sample. The porosity of that formulation dropped to ~48%.

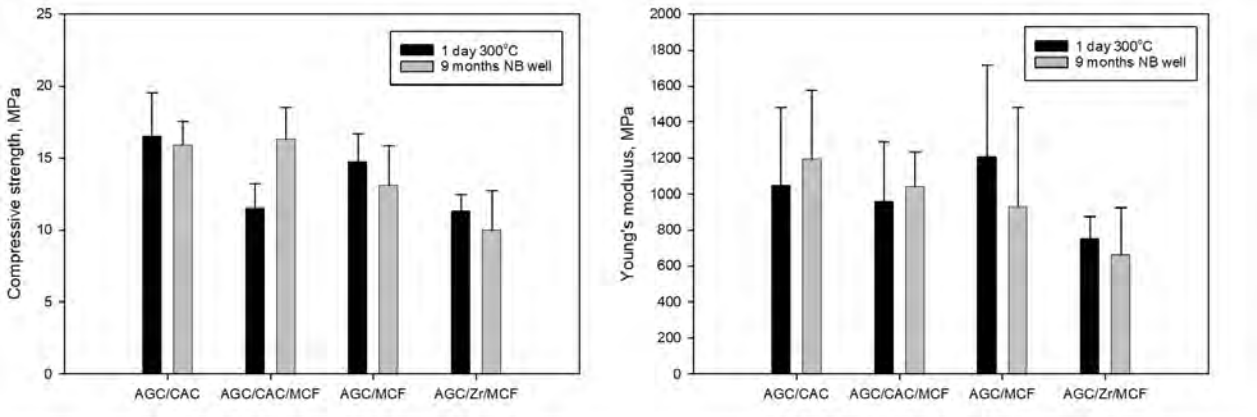

Figure 1: Compressive strength and Youngs's modulus of 300ºC autoclaved and 9-month well exposed samples.

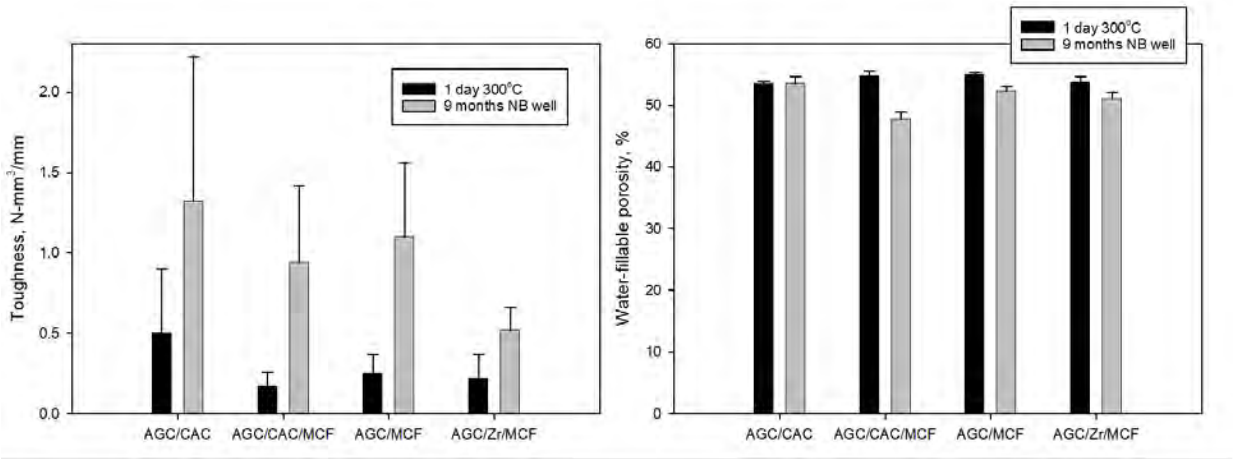

Figure 2: Compressive toughness and water-fillable porosity of 300ºC autoclaved and 9-month well exposed samples.

Noticeably, increase in compressive strength and porosity decrease after the 9-month exposure did not compromise high ductility of these formulations.

AGC and AGC/Zr formulations were tested under supercritical conditions earlier (Pyatina & Sugama, 2023). They both showed decreased strength (~20% decrease) and increased porosity (~10%) after 30 days under supercritical water. These performance differences could be partially attributed to the difference in exposure times (months of supercritical conditions were not feasible in the laboratory tests). It could also be the effect of the well fluid environment, which was not pure water as in the laboratory tests. CMF used in the case of the field-exposed samples and absent in the laboratory supercritical tests are chemically inert and could not change samples' compositions. To better understand mechanical behavior of these formulations phase analyses were undertaken to elucidate compositional changes in the well-exposed samples.

3.2 Phase Compositions

3.2.1 Crystalline phase compositions

The crystalline phase compositions of the tested samples are shown in Figure 3. There is no difference between the patterns of the samples with and without MCF and Zr. In fact, albite was the major phase in all three samples. In the case of AGC with CAC albite/anorthite formed (ICDD number 04-024-2151). Most of the other high-intensity peaks were attributed to paragonite and halloysite (ICDD numbers 04-014-7680 and 00-058-2031). Since the patterns of these two phases strongly overlap it is difficult to conclude whether both or only one of them was present in the samples. All samples showed some silica peaks and the samples with CAC also had small peaks of HT zeolite analcime commonly reported in the alkali-activated formulations with CAC. It was also observed in another alkali-activated formulation of CAC after the 9-month Newberry well exposure (Pyatina et al., 2024). In nature albite can undergo metasomatic replacement by sodium-rich nepheline and sodalite (Drüppel & Wirth, 2018). Some nepheline was also discovered in the samples after the 9-month exposure (ICDD number 00-019-1176). Paragonite is generally stable at these temperatures and if it breaks, it forms albite and corundum (Chatterjee, 1970). Thus, the formation of albite, nepheline, and paragonite was consistent with the samples' compositions and the expected formation of HT minerals under the well conditions. The sample modified with Zr, contained vlasovite mineral (ICDD number 04-016-5105) suggesting some reactivity of added Zr over the exposure period.

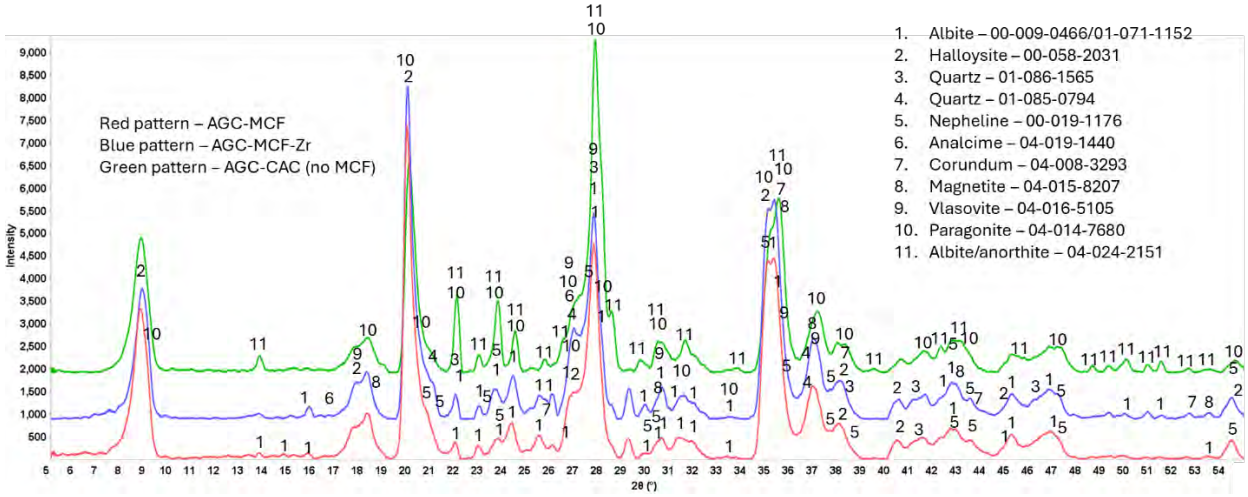

Figure 3: Crystalline phase compositions of the three tested AGC formulations after the exposure in Newberry well for 9 months.

Interestingly, crystalline boehmite was not detected in any of the samples. Aluminum was reacting with silicon with formation of albite and paragonite in these samples with a silica source. Likewise, the initially formed boehmite disappeared in other highly alkaline formulations after the 9 months in the well (Pyatina et al., 2024). The only formulation where boehmite persisted had noticeably lower pH of the slurries (calcium phosphate cement). Boehmite transition to gamma aluminum hydroxide during thermal shock tests was observed in our previous work with alkaline-activated calcium-aluminate/fly ash F blend (Sugama & Pyatina, 2018).Boehmite is not necessarily the most desirable binding phase, it is compressible due to its layered structure with hydrogen bonds. But it is carbonation resistant and provides high material ductility. Nevertheless, although crystalline

boehmite was not detected in the AGC samples, all the phases present in them resisted the carbonation that compromised OPC/silica formulation mechanical properties. This was reflected in the absence of crystalline carbonate peaks in the XRD patterns.

For the samples cured under supercritical conditions for 30 days boehmite, paragonite, as well as small amounts of analcime were detected. On the other hand, the end member of the feldspar mineral series, albite, or its decomposition product nepheline were not detected. These differences in the compositions suggest that mechanical properties of the samples can be explained by shorter curing time under supercritical conditions, so that the expected final phase compositions of the samples with boehmite transforming into albite in reactions with silicon were not reached.

3.2.2 Thermogravimetric analysis

The results of thermogravimetric and differential thermogravimetric analyses for AGC/CAC and AGC/MCF samples are shown in Figure 4. The major weight loss event for both samples occurred between ~450 and 650°C (3.9 and 3.6% respectively for AGC/CAC and AGC/MCF). This range corresponds to the decomposition of boehmite or its polymorph diaspore. However, XRD patterns did not contain peaks of crystalline boehmite. So, the likely contributors to that weight loss are halloysite, which dehydroxylates to metahalloysite ~530-590°C and albite that decomposes at ~650°C (Feng et al., 2012). The AGC/CAC sample also had a small weight loss between ~270°C and 500°C (a shoulder). Zeolite, analcime, decomposes in that temperature range (Cruciani, 2006).

The weight loss above ~700°C corresponds to the decomposition of CMF. It was also observed in the AGC/CAC/MCF sample, the decomposition pattern of which was otherwise identical to that of AGC/CAC sample. The decomposition pattern of AGC/MCF/Zr sample was identical to that of AGC/MCF.

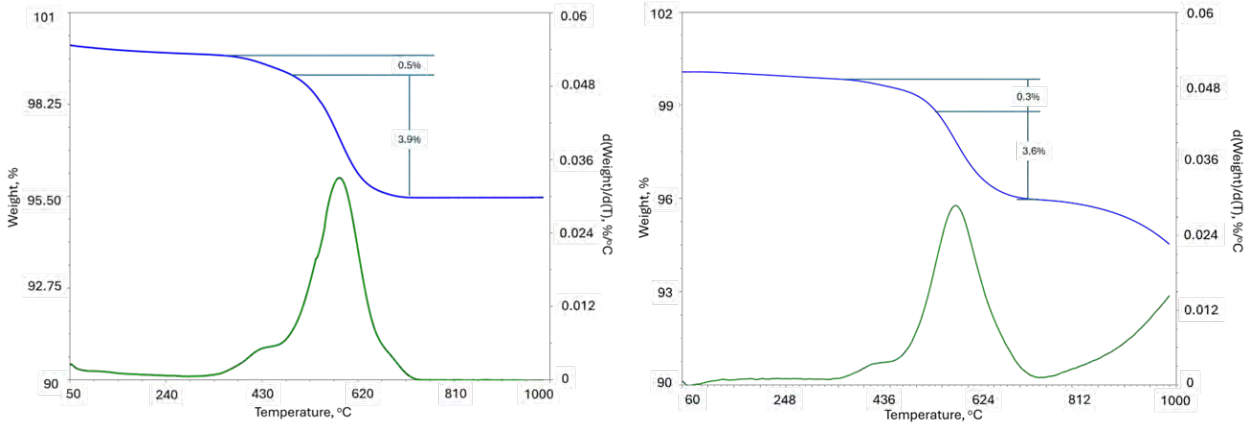

Figure 4: Thermogravimetric and differential thermogravimetric analyses of the AGC/CAC (left) and AGC/MCF (right) 9-month well exposed samples.

3.2.3 Morphologies of the exposed samples

Figure 5 shows photomicrographs and elemental compositions of typical sites of AGC/CAC samples exposed for 9 months in Newberry well. A flaky crystals morphology and elemental

compositions of sodium deficient paragonite can be seen in locations 1 and 3. Smaller denser crystals with the typical albite/anorthite composition are seen in location 2.

Figure 6: Photomicrographs and elemental compositions of AGC/MCF 9-month well exposed sample.

Figure 6 shows photomicrographs and elemental compositions of typical sites of AGC/MCF well-exposed samples. Intact MCF can be seen in the lower magnification photomicrograph on the left. The fibers survived the 9-month exposure without any visible damage. The tubular crystals have a composition of halloysite, however, albite that has similar elemental composition can also

crystallize as tubulars or flat and bladed crystals (site 2) (Christidis, 2011). Crystals in site 3 have flake-like morphology and elemental composition of paragonite.

The morphological features of the other 2 tested formulations were like the ones shown for AGC/CAC/MCF and AGC/MCF/Zr samples, with intact MCF, and crystals of paragonite and albite dominating samples' morphologies.

In summary, the morphological data agreed with the XRD results confirming presence of albite, paragonite and, possibly, halloysite. Also, in agreement with the XRD results boehmite crystals were not detected in the samples.

4. Discussion

Alkali-activated gibbsite based cementitious blends that are of interest as standalone systems or parts of other cementitious materials have some very attractive properties for EGS, including low or no calcium, providing its high carbonation resistance, and very high ductility, essential for applications in wells with frequent thermo-mechanical stresses. Their relatively high porosity can accommodate internal interstitial water expansion during the rapid well heating by the HT geothermal fluids. Tested under supercritical conditions (up to 30 days) and Newberry well (up to 9 months) they showed somewhat different changes of properties, with the strength decrease and porosity increase in the first case and varied strength response that depended on the formulation but without any significant strength decrease and porosity mostly decreasing in Newberry tests. Importantly, unlike most of the cementitious composites that experienced stiffening after longer exposures to high-temperature conditions gibbsite cement increased its toughness on average by 240% after the 9-month exposure to 325-350^{o}C Newberry well environments without any significant increase in stiffness. High cement ductility ensures a large safety operational envelope of cements decreasing the probability of cement failure under the thermal shock conditions typical for geothermal wells (Meng et al., 2024). The fact that gibbsite cement does not stiffen after 9 months of HT exposure is remarkable. Currently, the general strive for well integrity is to increase ductility or/and allow some casing movement during the stresses of the systems exposed to supercritical conditions (Thorbjornsson & Kaldal, 2021). The flexibility of the casing allows avoiding metal breakage under large thermal stresses. However, movements of the cemented casing will necessarily break the cement sheath if cement ductility and the magnitude of the casing movements are mismatched. Cement ductility can be increased by foaming it or adding fibers. However, for the large thermal stresses foam may not be appropriate, since gas expansion during heating will damage foam cement that is generally noticeably weaker than regular cement formulations and is unlikely to be able to withstand large gas expansion. For these reasons, AGC's remarkable ductility is very attractive for wells under large thermal stresses. This property of AGC can be seen in Figure 7 that compares stress-strain curves of phosphate-based cement, OPC/silica formulation and AGC after a day of 300^{o}C curing. While currently used OPC- and phosphate-based formulations reach high stress before the fracture, their abrupt fracture is typical for brittle materials. The AGC formulation, on the other hand, exhibits very ductile behavior with a long displacement tail under compression.

Under elevated temperatures AGC formulations undergo some phase transitions that take time. Incomplete phase transitions under the shorter period of supercritical exposures can account for the difference in mechanical properties of the samples cured at 400^{o}C and those exposed in Newberry well. Longer curing times causing boehmite decomposition, aluminum reactions with

silica with formation of paragonite and albite were observed in the field exposed samples. Small nepheline peaks in these samples suggest a possibility of further albite transition into nepheline or nepheline formation from aluminum from decomposing boehmite. Clay minerals, formed as the decomposition products of feldspars by water saturated with carbon dioxide in nature, and found in the AGC after the well exposure tests, including paragonite and halloysite, ensure consistent performance of this blend and its carbonation resistance. The tubular and flaky morphologies of the samples can explain their high toughness and low stiffness.

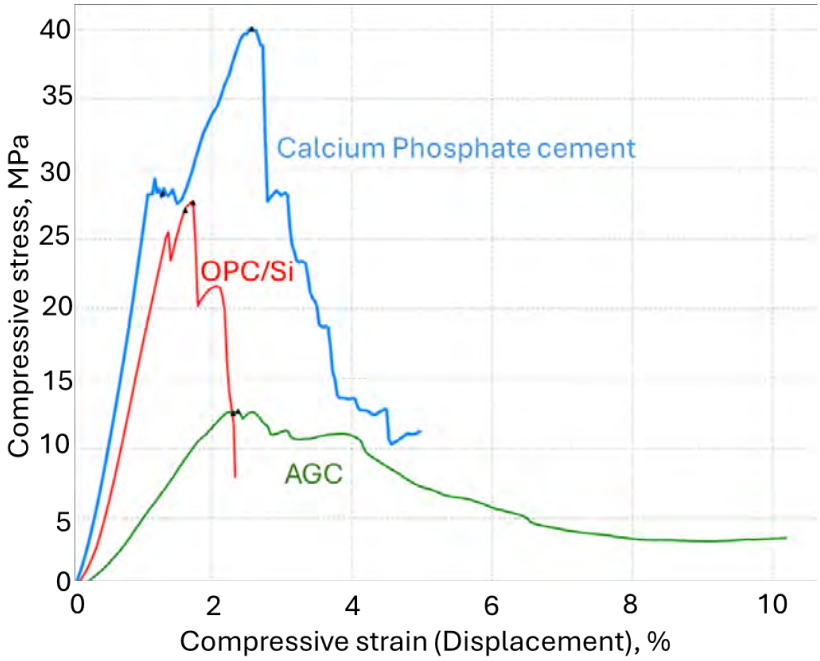

Figure 7: Comparison of typical stress-strain compressive curves for OPC/silica, phosphate cement, and AGC formulations after a day of curing at 300°C.

Nevertheless, whether AGC with its high porosity and very low stiffness can withstand large thermal shocks and provide good corrosion protection of the metal casing remains to be seen. Good metal-cement bond and low cement permeability are necessary in addition to the resistance to acidic environments for the metal protection in EGS. Higher porosity cements that are great to accommodate thermal shock conditions (e.g. foam cements) are generally less favorable for metal corrosion protection.

5. Conclusions

AGC is an attractive material for EGS applications due to its high toughness and great carbonation resistance. The results of supercritical and field exposure tests showed that AGC meets geothermal well strength criteria, with the mechanical properties and cement ductility persisting after long-term (9-month) exposure to high-temperature, high-carbonate concentration conditions in a geothermal well. The phase transitions taking place in the cement over long periods at high temperature result in boehmite reactions with silica forming paragonite, halloysite, albite, nepheline mineral phases. Boehmite persisted during shorter (30-day) exposures to supercritical conditions in laboratory experiments. Further AGC modifications may be needed to decrease its porosity, currently nearing 50%, and to ensure its ability to provide good steel corrosion protection.

Comparative Analysis of Casing-Cement Interfacial Bonding Shear Strength Using Class G and Class H Cement at Room and Elevated Temperatures

Kayode Sanni, Jorge Andres Alvarez Escobar, Khizar Abid, Catalin Teodoriu

University of Oklahoma

Keywords

Interfacial Bonding Shear Strength, Unconfined Compressive Strength, Geothermal well, Elevated Temperature Curing

ABSTRACT

Geothermal energy is an important sustainable energy source and demands uncompromising well integrity for environmental protection and operational efficiency. Central to this integrity is the cement sheath that provides critical zonal isolation throughout a well's lifecycle. However, the integrity of wellbores is often compromised by debonding at the casing-cement and cement-formation interfaces, leading to potential fluid leakage and environmental hazards. Therefore, this study aims to elucidate the impact of cement class (Class G and H) on the interfacial bonding shear strength (IBSS) of casing-cement at both room and elevated temperatures (75°C). To simulate the field condition, the cement slurry was poured in the annulus space of cylindrical pipes that were placed one inside the other. Then the cement was cured in the room and elevated temperature for 1 and 3 days. After this, the shear stress analysis was conducted on the inner casing with the help of a hydraulic press. Moreover, the unconfined compressive strength (UCS) test was conducted on the Class G and H cement cubes to obtain additional information on mechanical strength. The findings underscore the significance of curing duration and temperature on cement's mechanical properties. Class H cement demonstrated an average IBSS of 339psi at room temperature and 218psi at elevated temperatures after 3 days of curing, with UCS measurements of 27 and 45MPa, respectively. In contrast, Class G cement performed better, with 3 days room temperature cured sample having the IBSS values of 310psi and 268psi at elevated temperatures, alongside UCS values of 22MPa and 46MPa, respectively. The study also revealed that 1-day cured samples had lower values of IBSS and UCS across all settings, highlighting the critical nature of the curing process. Notably, the research indicates a general trend: as temperatures increase, IBSS decreases, whereas UCS tends to rise, suggesting a complex interplay between thermal exposure and cement matrix integrity.

1. Introduction

With the increasing energy demand and the global push towards renewable energy, the pursuit of clean and unconventional energy sources has become highly desirable (Okoroafor et al., 2022).

Geothermal energy, in particular, plays a crucial role as a sustainable and clean energy source (Srivastava & Teodoriu, 2018). Its versatility enables its application in various sectors, including agriculture, heating, and electricity generation, making it invaluable for many countries. One of the primary advantages of geothermal energy over other renewable sources is its independence from meteorological conditions, allowing it to be utilized in any location with a suitable geothermal gradient (Abid et al., 2022; Vargas et al., 2022). At present, the United States is a leader in geothermal power generation. In 2020, the US produced nearly 17 billion kWh of electricity from geothermal resources, accounting for approximately 0.4% of the nation's total electricity consumption (Administration, 2022).

In geothermal wells, cement plays a crucial role by providing zonal isolation, sealing unwanted formations, plugging thief zones, supporting casing, protecting it from corrosion, and plugging wells (Rincon et al., 2022). Loss of zonal isolation can cause the leakage of the subsurface fluid to the surface, which can lead to sustained casing pressure (SCP) that can compromise the integrity of the well (Celia et al., 2005). One common leakage pathway for formation/reservoir fluids is along the interfaces within the well, such as the cement-casing interface or the cement-formation interface. The bonding of cement to these interfaces is typically measured in terms of shear bond strength or hydraulic strength. Shear bond strength is defined as the force needed to initiate casing movement within the cement sheath or displacement of the cement from the wellbore. Hydraulic strength refers to the bond between the casing and cement, or the cement and formation, that prevents fluid flow. Although shear bond strength and hydraulic bond strength are distinct measures, their values often fall within the same order of magnitude. Studies by (Carter & Evans, 1964; Evans & Carter, 1962) found a correlation between compressive strength and shear bond strength, but no correlation between compressive strength and hydraulic bond strength is present. Current official guidelines and field practices use cement's bulk compressive or tensile strength as the target value to determine if the cement will effectively seal the annulus. While the bulk properties can be suitable for predicting leakage through the cement matrix, they do not necessarily indicate sufficient bonding to different phases.

Among the various properties of cement, the Unconfined Compressive Strength (UCS) is identified as the most critical parameter for annular sealants exposed to high-pressure high-temperature (HPHT) conditions (Bosma et al., 1999). Throughout the well's lifecycle, the cement sheath endures varying pressures and loads from formation pore pressure, casing hydrostatic pressure due to drilling mud, thermal loads from temperature fluctuations of the fluids, and periodic loads from operations such as workovers, well tests, stimulations, and hydrocarbon production (Abid et al., 2022). The compressive strength of the cement is influenced by the homogeneity of the cement matrix, its composition, loading rate, and the geometry of the tested sample (Gul, 2016). The cement composition is tailored to specific downhole conditions, while matrix homogeneity depends on the mixing strategy and slurry design. Additionally, variations in loading rate, as well as the shape and size of the specimen, can lead to different results from the same batch of mixed cement samples.

Oil well cement is classified into eight types (Class A to H) based on factors such as depth, temperature, pressure, and sulfate resistance (Abid et al., 2023). Various additives can be

incorporated into the cement to modify its properties according to the specific downhole conditions. The most commonly used cements in geothermal wells are Class G and H (Abid et al., 2015). Cement is manufactured from argillaceous and calcareous rocks, which are dried, broken into pieces, and mixed in precise proportions. This mixture is then subjected to pyroprocessing in a kiln at temperatures ranging from 1426 to 1540 °C. The resulting clinker is ground and blended with gypsum to produce Portland cement (Ichim et al., 2018).

Cementing operation in geothermal, oil, and gas wells is critical for ensuring well integrity. Many geothermal wells feature open-hole completions, yet they also include sections where the casing is cemented to the formation. With the increasing demand for geothermal energy, deeper wells necessitate a high-quality cementing job. Cement integrity in these extreme environments, where temperatures can reach up to 400 °C, relies on its physical, chemical, thermal, and mechanical properties. A study by (Davies et al., 2014) revealed that nearly 380,000 wells in the US, UK, Norway, China, Holland, and Canada experienced well integrity issues due to cement failure. Thermal loading on the cement sheath between the casing and formation can lead to shrinkage and expansion, resulting in stress redistribution and jeopardizing well integrity (Therond et al., 2016; Zhang & Wang, 2017).

This research focues on the bond strength between two types of cement (Class G and H) and different steel casing materials. The shear bond is measured to study the maximum force that the pipe can exert before the bonding fails. In addition, the mechanical properties of the cement are studied by unconfined compressive strength (UCS) testing.

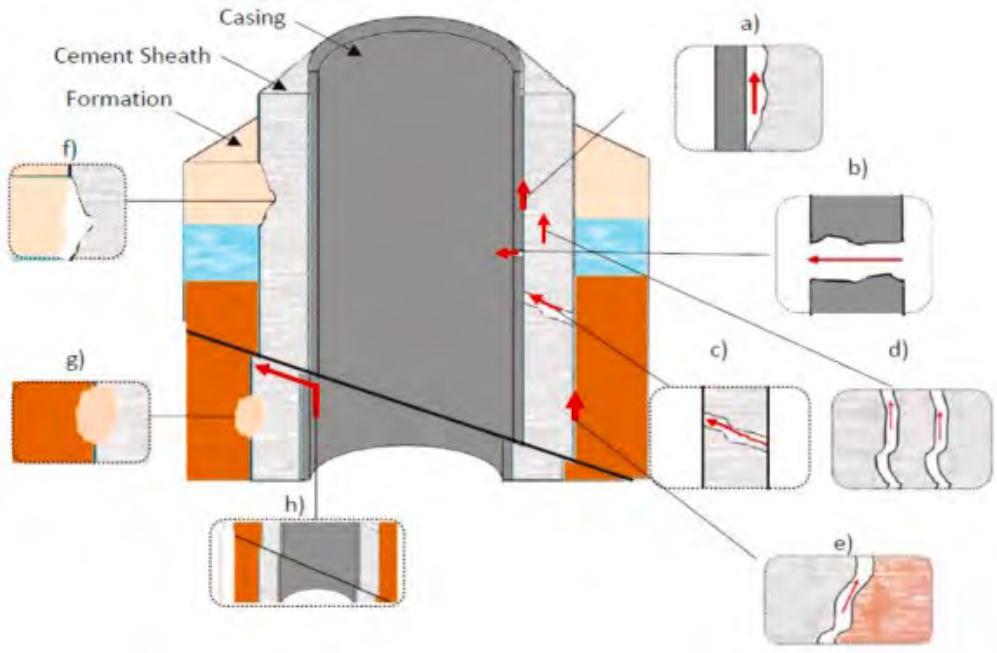

Figure 1: Possible leakage pathways in a cased wellbore (Wu et al., 2020)

2. Experimental Procedure

2.1 Materials

Two different class of well cement were used for testing: API Class G and H. The Class G Well Cement—Grade MSR (Moderate Sulfate Resistant) was obtained from Mountain Cement Company, and the Class H Well Cement was obtained from Central Plains Cement Company. Table 1 provides the chemical and physical analysis of both cement classes. Deionized water was used for the mixing of the cement. Table 2 tabulated the mix design of cement slurries.

Table 1A: Chemical and Physical Analysis of Class G Cement

CHEMICAL ANALYSIS		**Test Result**
Item	**Specification Limit**	**Class G**
MgO (%)	6.0 max	1.0
SO_3 (%)	3.0 max	3.0
Loss on ignition (%)	3.0 max	1.5
Insoluble Residue	0.75 max	0.41
C_3S (%)	48 min – 58 max	58
C_3A (%)	8 max	6

API Schedule 5: mins to 100bc	90 min – 120 max	112

Table 2: Mix designs of slurries used in our experiments.

Cement Type	Mass of Cement (grams)	Mass of Water (grams)	Water to cement ratio (by weight)
Class G	792.72	348.53	0.44
Class H	860.26	326.90	0.38

Three steel pipes were used in the bond strength measurements for each cement formulation and temperature. Table 3 shows the pipe dimensions used for the experiment. All the pipe samples were washed and cleaned with acetone.

Table 3: Pipe types and their dimension

Sample ID	Pipe OD (mm)	Pipe Thickness (mm)	Pipe Roughness (μ-in)
TSO16	73.82	5.63	36.92
TSO17	73.94	5.65	35.52
TSO18	73.89	5.61	37.17

2.2 Testing and analysis methods

For each sample, which includes the inner pipe and the outer casing, 900 ml of cement was prepared. Right after mixing, the cement was poured into one cube mold to assess unconfined compressive strength (UCS) and conduct ultrasonic pulse velocity (UPV) measurements. The remaining cement was then slowly poured into the annular space between the inner and outer pipe, and distilled water was added to the remaining annular space, after which the samples were placed in a water bath, as shown in Figure 2.

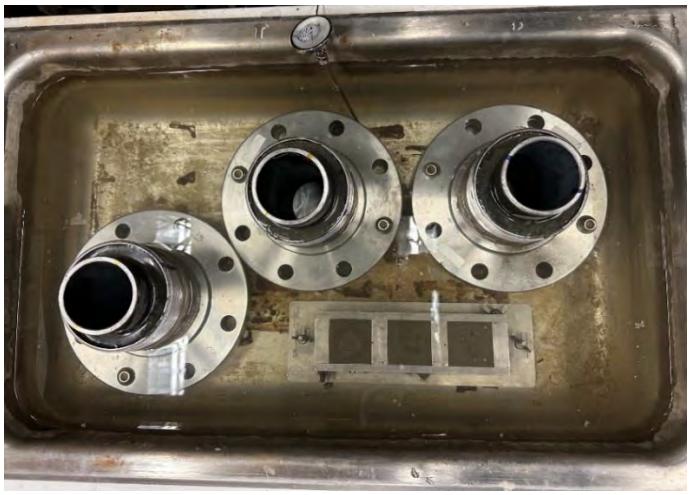

Figure 2: Experimental set up in water bath

To prepare the cement slurries, the Cement Constant Speed Blender manufactured by OFITE Testing Equipment, Inc. was used. This blender is a bottom-driven, blade-type mixer designed in accordance with API RP 10B-2 standards.

The mixing of cement and water was done in accordance with API standard 10-B (API). In this practice, cement is added to water in 15 seconds while the mixer's motor is at 4,000 rpm. Then, mixing is continued for 35 seconds at 12,000 rpm.

2.3 Interfacial Bonding Shear Strength

A shear bond is defined as the bond that mechanically supports a pipe in the hole. It is determined by measuring the force required to initiate pipe movement in a cement sheath. This force, when divided by the cement-casing contact surface area, yields the shear bond in psi (Carter & Evans, 1964).

A 2 7/8” OD steel casing pipe was placed in a 4-inch ID Casing pipe. The 4-inch ID was used to simulate the wellbore. Figure 3 shows the setup schematic used to create the bonding between casing and cement for shear bond strength measurements. Figure 4 shows the actual mold assembly used for the shear debonding test. The slurry is poured through the annulus between the outer casing and the inner casing, and on top of the slurry, free water is spread. For the elevated temperature tests, the water bath was set to 75°C and ambient pressure for curing duration of 1 and 3 days. The temperature was diligently maintained within a range of ±2°C, except briefly when fresh water was introduced into the bath, causing a temporary drop in temperature of 5-8°C. It is noteworthy that all tests adhered to the same procedural standards. After curing, it is necessary to gradually drop the temperature to avoid introducing thermal stresses to the system.

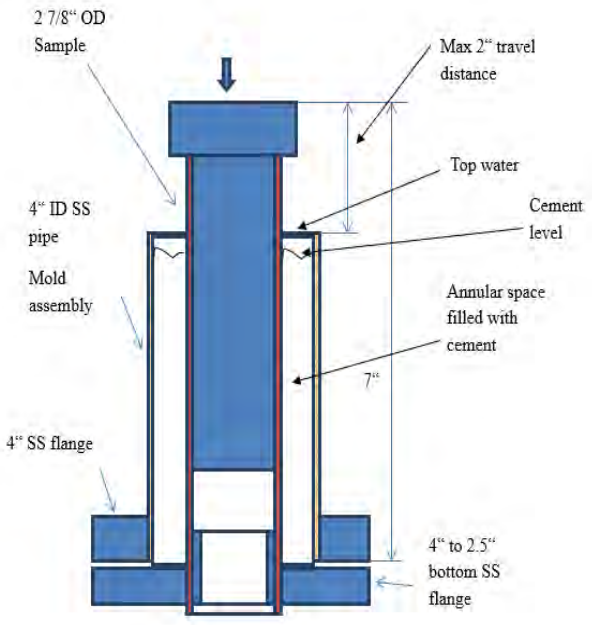

Figure 3: Schematic of the Mold assembly for the shear bond testing.

Figure 4: Mold assembly for the shear bond testing

A hydraulic press machine (Figure 5) was used to apply force on the inner casing until the point where debonding occurred. The loading rate of the machine was 1000psi/min. Using DasyLab Software, the displacement of the inner casing and the corresponding force in attaining the displacement were recorded every 0.1 seconds. After the debonding occurred, which is notable with a loud sound, the inner casing was further pushed through the cement sheath by an extra 40mm to ascertain that the debonding had occurred. After this, the entire cement sheath and the inner casing were pushed out with the help of the hydraulic press. The interfacial Bonding Shear Strength was calculated by knowing the volume of the cement in the annulus. For the shear bond strength calculation, the peak in the corresponding Force-distance plots was used to measure the force required to break the bond and move the casing sample. Combined with the known interface between the cement and casing, the shear bond strength was calculated by dividing the force by the interfacial area.

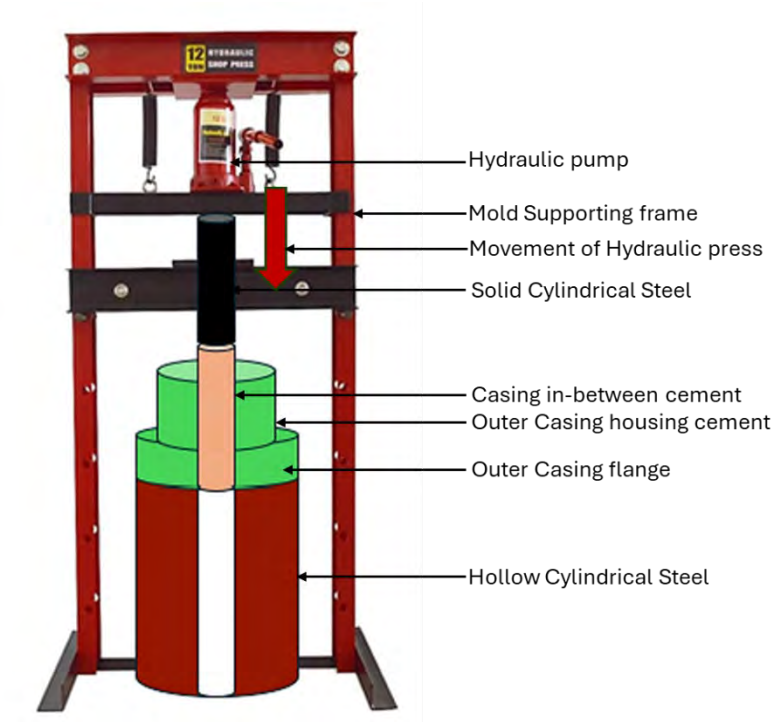

Figure 5: Hydraulic Bond Shear Testing Machine Frame

2.4 Unconfined Compressive Strength

In this study, two-inch cube molds, as shown in Figure 6, was used for the UCS test as directed by the API standards. As per the recommendations outlined in API RP 10B-2, these molds must be watertight, and the contact surfaces must be coated with a release agent, such as grease. The blended cement slurry was carefully poured into the molds until the slurry filled up the mold's depth.

Figure 6. Two-Inch Cube Molds

Prior to completely filling each sample mold, a puddling rod was employed to prevent the formation of air bubbles within the cement cubes. Subsequently, the molds were positioned in a curing bath. The samples underwent curing at atmospheric pressure, with the water bath temperature maintained at approximately 24°C (74°F). The cement samples remained in this water

bath until the testing phase. In terms of room temperature, there was a minor variation of about ±2°C.

API RP 10B-2 prescribes the testing of cubes with an edge length of 50.8 mm (2 inches). Following the removal of the cured cement cubes from the molds, the specimen dimensions were assessed using a digital calibrated caliper. The length and width of the cubes were measured at specific points, as depicted in Figure 7. This meticulous measurement process ensured strict compliance with the recommended dimensions and allowed for calculating the area required to determine compressive strength. It is worth noting that the edge length of the tested cubes consistently remained within 5% of the API recommended value, demonstrating adherence to the specified standards.

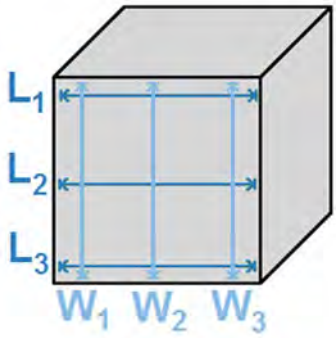

Figure 7: Cement Cube and Measurement Sites (L – length, W – width)

In contemporary practice, compressive strength can be assessed using two methods: a destructive approach (crush test) and a non-destructive approach (ultrasonic pulse velocity). Both techniques were employed to facilitate a comparison of their accuracy and the results they yield.

For the measurement of the UCS through destructive testing, the CM-2500 compression testing machine (depicted in Figure 8) manufactured by Test Mark Industries was utilized. This machine has an accuracy of ±0.5% (Test Mark Industries, 2015). The device applies a uniaxial load to the cement cube, measuring the force required to induce a permanent deformation in the cube. Subsequently, the compressive strength is automatically calculated by dividing the load by the measured surface area.

Figure 8:. Crush Test Device (Test Mark Industries, 2015)

The non-destructive method employed for determining compressive strength is ultrasonic pulse velocity (UPV) testing. These non-destructive measurements were conducted using the Pundit Lab+ device manufactured by Proceq SA (as shown in Figure 9). The process involved calibrating the measurement device using a special calibration rod. After the calibration, the transducers are placed on two opposite ends of the cement cube. To enhance the contact between the transducer and the cement cubes and ensure accurate results, a couplant was applied to the two ultrasonic pulse transducers (proceq, 2017).

This method measures the time required for the ultrasonic pulse to travel from the transmitter to the receiver. The velocity is automatically calculated using the cube's known edge length. For this particular study, the pulse was transmitted at 250 kHz. The testing device has an accuracy of ±0.1µs (PCTE, 2017).

Figure 9. UPV Measurement Device (proceq, 2017)

3. Result and Discussions

3.1 Interfacial Bonding Shear Strength

The bar chart in Figure 10 displays the Interfacial Bonding Shear Strength (IBSS) of Class G cement composites measured in psi under two different conditions: Room Temperature and Elevated Temperature (75°C), at two different time intervals (1 day and 3 days). The IBSS is higher at Elevated Temperature compared to Room Temperature after 1 day, indicating that the bonding strength of the cement composites improves with higher temperatures over this short duration. After 3 days, the IBSS at Room Temperature is higher than at Elevated Temperature. This suggests that over a longer period, the bonding strength of the cement composites improves more at Room Temperature than at Elevated Temperature. Moreover, as the hydration of the cement is accelerated at elevated temperatures and the cement matrix consolidates faster, sufficient time is not provided for the cement to get properly bonded with the casing interface (Teodoriu et al., 2019) due to which a decrease in the IBSS at elevated temperatures was noted. As noted by Teodoriu et al. (2019) the magnitude of IBSS for class H cements is lower than Class G, which is also visible in this paper. The results indicate a shift in the performance of Class G cement composites over time, with room temperature conditions becoming more favorable for bonding strength as time progresses.

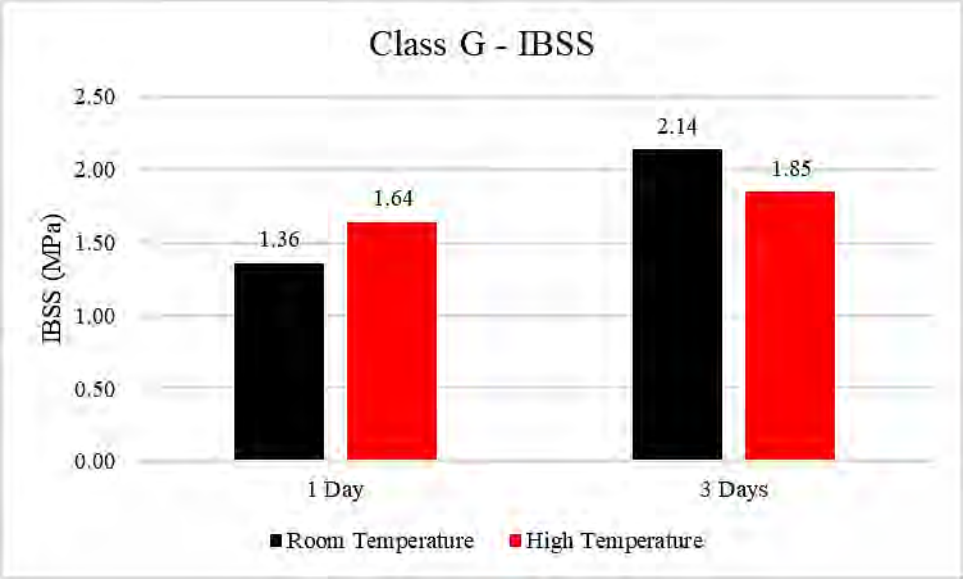

Figure 10: Interfacial Bonding Shear Strength of Class G at room and high temperatures.

The bar chart in Figure 11 illustrates the Interfacial Bonding Shear Strength (IBSS) of Class H cement composites at 1 and 3 days of curing at room and elevated temperature. The IBSS at Room Temperature is much higher than at Elevated Temperature after 1 day, indicating that the bonding strength of Class H cement composites is better at Room Temperature initially. After 3 days, the IBSS at Room Temperature remains higher than at Elevated Temperature. Although the bonding strength at High Temperature improves over time, it does not reach the level observed at Room Temperature. These results indicate that Class H cement composites perform better in terms of bonding strength at Room Temperature both initially and over time compared to Elevated Temperature.

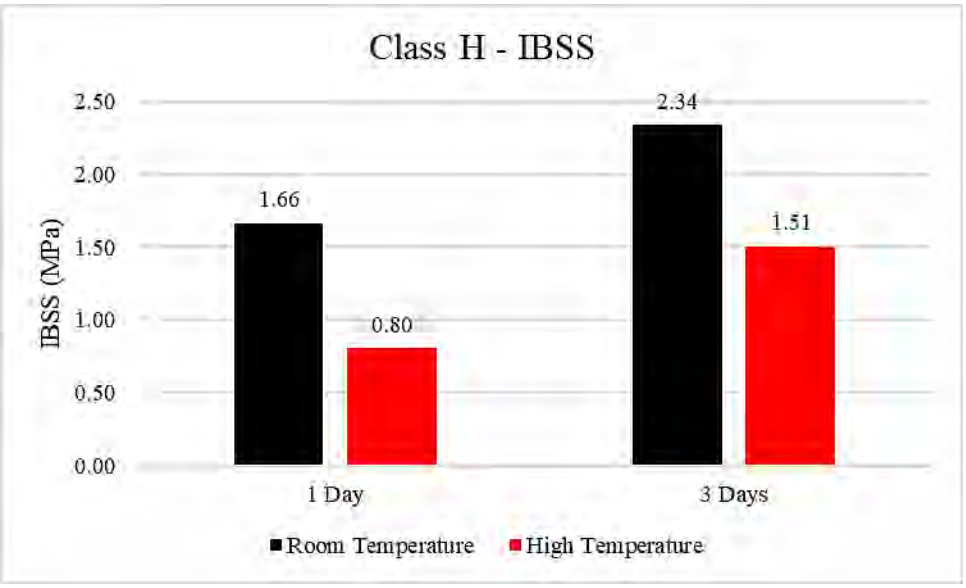

Figure 11: Interfacial Bonding Shear Strength of Class H at room and high temperatures.

From the above, it can be observed that for a one-day curing duration, Class G cement performs better at high temperatures compared to Class H, while Class H cement has a higher bonding strength at room temperature than Class G. After three days, both Class G and H cement show improved IBSS at room temperature over time. Class G performs better than Class H at high temperatures initially but not for three days of curing.

3.2 Unconfined Compressive Strength

The bar chart in Figure 12 displays the Unconfined Compressive Strength (UCS) of Class G cement composites measured in MPa under two different conditions: Room and Elevated Temperature, at two different time intervals (1 day and 3 days). The UCS at Elevated Temperature is substantially greater than at Room Temperature after 1 day, indicating that the compressive strength of Class G cement composites improves significantly when subjected to high temperatures in the short term. After 3 days, the UCS continues to be higher at Elevated Temperature compared to Room Temperature. The UCS of the sample cured at Room Temperature at day three was almost double the UCS of day one. Meanwhile, a slight increase in UCS was recorded for the elevated temperature sample on day 3. While there is an increase in compressive strength at both temperatures over time, the strength at High Temperature remains markedly higher.

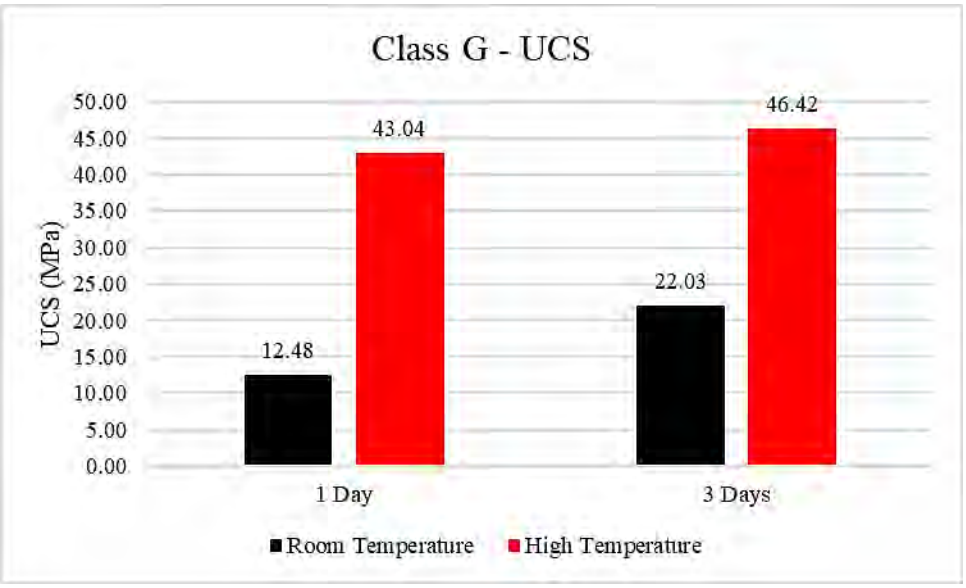

Figure 12: Unconfined Compressive Strength of Class G at room and high temperatures.

Figure 13 shows the Unconfined Compressive Strength (UCS) of Class H cement composites, measured in MPa, under Room Temperature and Elevated Temperature conditions, at 1-day and 3-day intervals. The UCS values at Elevated Temperature are markedly higher than those at Room Temperature after just 1 day, demonstrating a significant short-term enhancement in compressive strength for Class H cement composites when exposed to high temperatures. After 3 days, the UCS continues to be higher at High Temperature compared to Room Temperature. Although compressive strength increases over time at both temperatures, the strength at Elevated Temperature consistently remains significantly higher.

As seen from the above figures, the UCS of Class G and H samples at elevated temperatures, irrespective of the curing days, was higher than that of the Room Temperature samples but an expected behavior. This is because the rate of hydration accelerates at high temperatures, so the matrix of the cement solidifies faster and gains higher UCS strength.

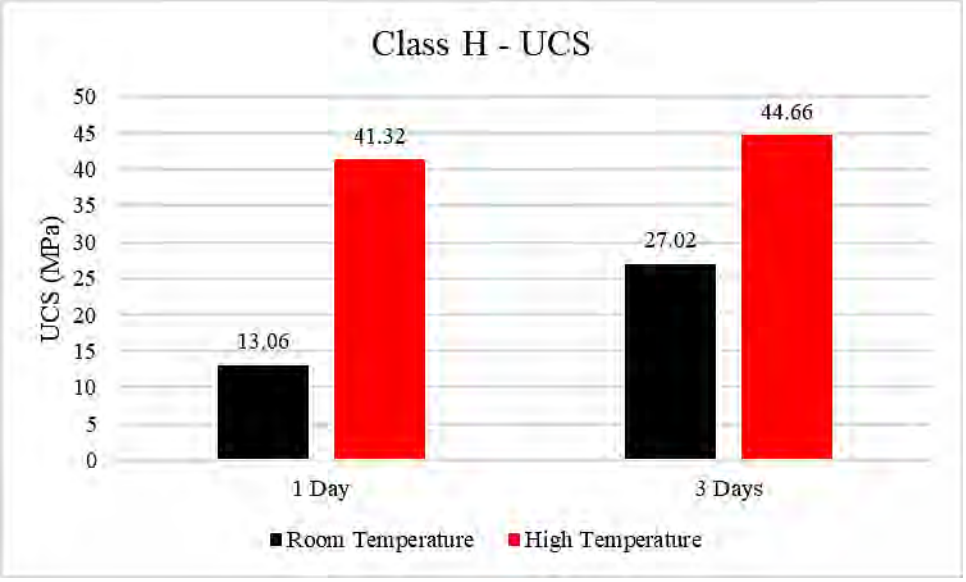

Figure 13: Unconfined Compressive Strength of Class G at room and high temperatures.

4. Conclusions

For geothermal applications where high temperatures are expected, Class G Cement might be the better choice due to its superior initial bonding strength at high temperatures. It ensures a strong initial set, which is critical for geothermal well integrity. Although the performance decreases slightly over time, it remains robust.

However, if the environment involves fluctuating temperatures and extended periods at lower temperatures, Class H Cement might be advantageous due to its superior long-term bonding strength at room temperature. Class H Cement could be considered at the well's surface and intermediate casing section.

The performance at elevated temperatures and over time is crucial for geothermal applications where high temperatures are prevalent. Class G Cement demonstrates a marginally higher initial UCS at high temperatures and maintains this strength over time, making it a good choice for environments where immediate high strength is essential. Class H Cement, while slightly lower in initial high-temperature UCS compared to Class G, still provides strong performance and better long-term UCS at room temperature, suggesting versatility in varying temperature conditions.

Considering these factors, Class G Cement is likely the better choice for geothermal applications focusing on high UCS and IBSS at elevated temperatures.

Acknowledgement

We would like to thank TENARIS for their financial and technical support. Our heartfelt appreciation goes to the University of Oklahoma for its substantial contributions, particularly in the research and technical support that is presented in this paper. We are also grateful to the Well Integrity Laboratory at the University of Oklahoma for providing access to their unique cement repository and database. The dedication and hard work of the students from the University of Oklahoma in investigating and developing the cement repository are deeply appreciated.
