Thermal and Well Flow Performance of Closed-Loop Geothermal in the Wattenberg Area

Dayo Akindipe, Abra Gold, Geoffrey Kiptoo Mibei, Adam Ketchum and Koenraad Beckers

National Renewable Energy Laboratory

Keywords

Closed-loop geothermal, slender body theory, Wattenberg anomaly, techno-economic analysis

ABSTRACT

Closed-loop geothermal systems provide an alternative to resource-constrained hydrothermal systems and stimulation-intensive enhanced geothermal systems. In this work, we apply the slender-body theory (SBT) model, to simulate the well flow and heat transfer performance of U-loop well designs in the Wattenberg area of the Denver-Julesburg Basin. Three U-loop well patterns are investigated, including a single-, double-, and multi-lateral design. The subsurface within the area of interest is characterized by deep, hot (> 200°C) igneous/metamorphic basement rock underlying multiple sedimentary formations. The lateral section(s) of the U-loop lie(s) within a target depth of 6 km, where temperatures are estimated to approach 300°C. As a base case, conduction-only heat transfer is investigated through simulations with the SBT model within U-loops with open-hole laterals that exchange heat directly with the hot, dry rock using water as a working fluid. The utilization of supercritical CO_2 as a heat transfer fluid is also considered. For each scenario, the system performance in terms of annual heat production and temperature profile over a 20-year project lifetime are assessed. Also, the levelized costs of heat and electricity (LCOH and LCOE) are determined using a top-down techno-economic analysis model. The results show that the performance- and cost-optimized U-loop design is one having an injection-production well spacing of 1,000 meters with ten 50-meter-spaced laterals that traverse a subsurface system with a temperature gradient of 60°C/km. By injecting 20°C-water at a rate of 60 kg/s through this loop, an average heat production of 19 MW_{th} (i.e., 2.2 MW_e net plant output) can be achieved, resulting in an LCOE and LCOH of \$136/MWh_e and \$1.53/GJ, respectively, over a 20-year project life.

1. Introduction

A first-of-a-kind geothermal drilling project in Colorado, titled the Geothermal Limitless Approach to Drilling Efficiencies (GLADE), has been funded by the Geothermal Technologies Office (GTO) of the U.S. Department of Energy (DOE). The project aims to significantly improve

drilling rates by combining proven and novel drilling technology and analytics to safely drill twin high-temperature wells in the Wattenberg area of the Denver-Julesburg (D-J or Denver) Basin (Figure 1). The D-J Basin is a structural basin with a large asymmetric syncline comprising Paleozoic, Mesozoic, and Cenozoic sedimentary rock layers underlain by a Precambrian basement with igneous and metamorphic lithology (Curtis, 1988). The local vertical depth to the basement is expected to be in the range ~3,000 to ~3,800 m (Porro et al., 2012). A representative cross section along the line A-A' of Figure 1 is shown in Figure 2. The sedimentary layers are dominated by subaerial deposits, with minimal carbonates (Abbott & Noe, 2004). Oil and gas production occurs from several formations in the basin, including the Pierre shale, lower Cretaceous formations, and the Lyons sandstone (Nelson & Santus, 2011; Crowell et al., 2012). Using aeromagnetic surveys and cross-correlation with exposed bedrocks in the Front Range, Sims et al. (2001) interpreted bedrocks through Colorado and established that, for the study area, the expected basement lithology consists of either Paleoproterozoic gneiss or Paleoproterozoic granite (Sims et al., 2001).

The Greater Wattenberg area is associated with a thermal anomaly characterized by higher geothermal gradients than the surrounding area (Weimer, 1996). The youngest rocks observed are predominantly sedimentary, devoid of indications of recent volcanism. The heat source for the observed anomalous geothermal gradients is not well understood, because the deepest wells in the Denver Basin penetrate only to about 2,700 m in depth (Higley & Cox, 2007). The complex structure in the deep basin (reverse faults associated with brittle deformation and basin buckling), underlain by conductive minerals in the basement rock are factors that could concentrate heat in the region. This model for anomalous heat flow in a sedimentary basin is consistent with geothermal "play types" that develop in the foreland basin of a conduction-dominated orogenic belts (Moeck, 2014; Davalos-Elizondo et al., 2023). Thermal replenishment has been hypothesized to be supported by either deep-seated magmatic intrusions, an upflow zone of a deep hot water system facilitated by faults, or a deep conductive zone created by mineralization of highly conductive minerals associated with the Colorado Mineral Belt (Eaton, 2023). Geological data from planned deep wells may help shed light on heat and fluid sources in the Wattenberg area.

Using bottom hole measurement data from 6,181 oil and gas wells drilled in the area, Lacazette et al. (2024) developed isotherms around the major hot spot in the Wattenberg area. Their map revealed a thermal gradient between 40°C/km and 60°C/km in the hot spot (Lacazette et al., 2024). The target vertical depth of the proposed twin wells is on the order of 6.1 km, significantly surpassing the Phanerozoic sedimentary layers and into the Precambrian basement. There, it is anticipated that temperatures at the target depth could be between 240°C and 360°C. At these temperatures the thermal energy from the subsurface could be primarily harnessed for geothermal power with next-generation geothermal technologies, including closed-loop geothermal (CLG) and enhanced geothermal systems (EGS). With a CLG/EGS development in a conduction-only reservoir, heat extraction typically proceeds faster than natural replenishment rates, resulting in a long-term decline of reservoir and production temperature (Fox et al., 2013). Heat transfer in low-thermal conductivity basement rocks, such as those in the Wattenberg area, is presumed to proceed at slow rates requiring significant time for thermal replenishment in the target reservoir after depletion.

In this work, we apply the slender-body theory (SBT) model to simulate the well flow and heat transfer performance of possible closed-loop (U-loop) well designs drilled in the Wattenberg area

of the Denver Basin. Three U-loop designs are investigated, including a (a) single-lateral, (b) double-lateral, and (c) multi-lateral design. We have also compared the performance of both water and carbon dioxide (CO_2) as working fluids for the closed-loop heat transfer process. Finally, we determine and compare the cost of each design option to determine the most feasible design for electricity generation and heating applications.

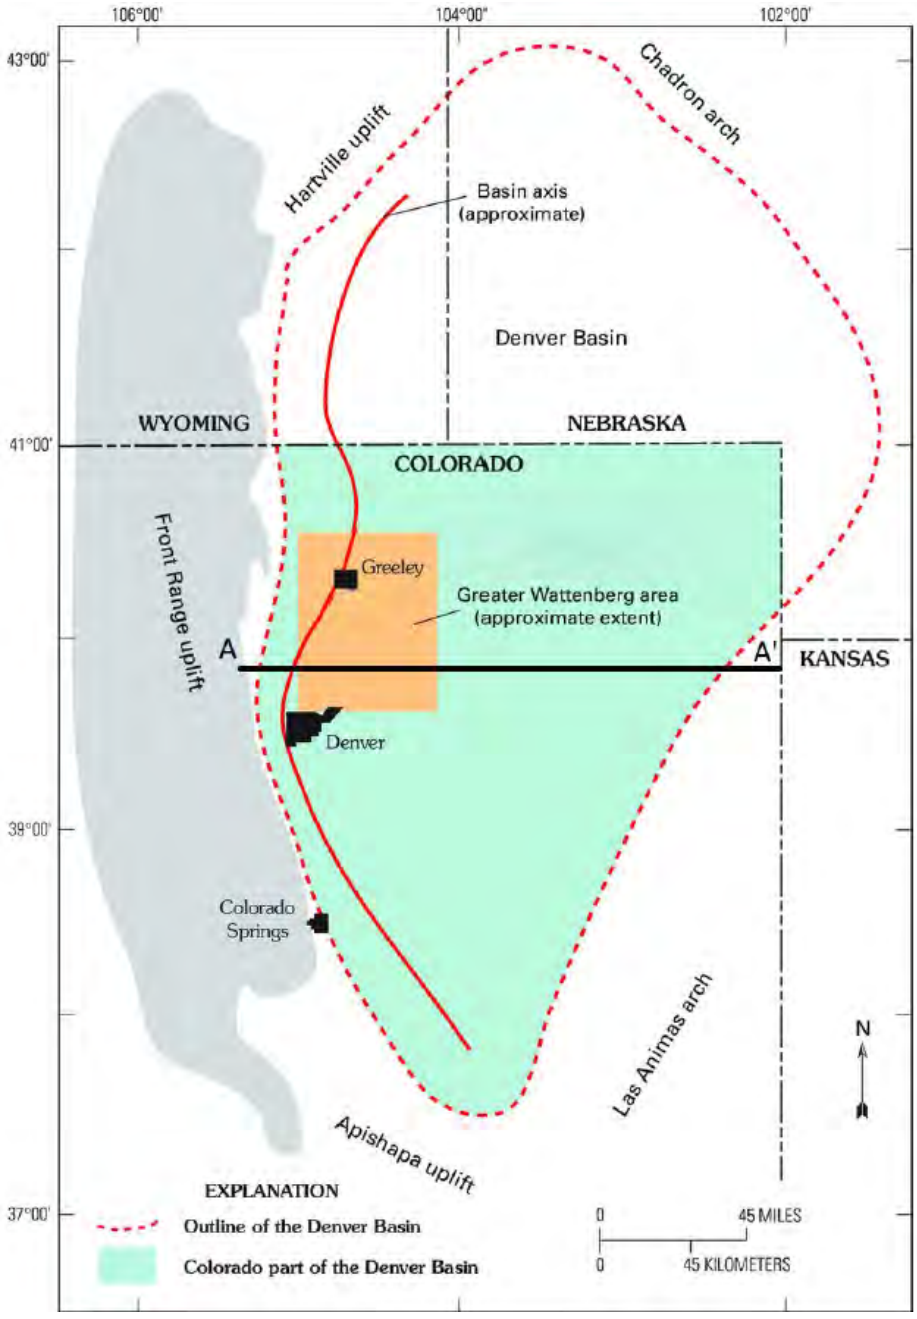

Figure 1: Greater Wattenberg area (orange rectangle) in the Denver Basin (approximate extent shown with red dashed line). The A-A' cross section is shown in Figure 2. The figure was modified from Roberts (2007).

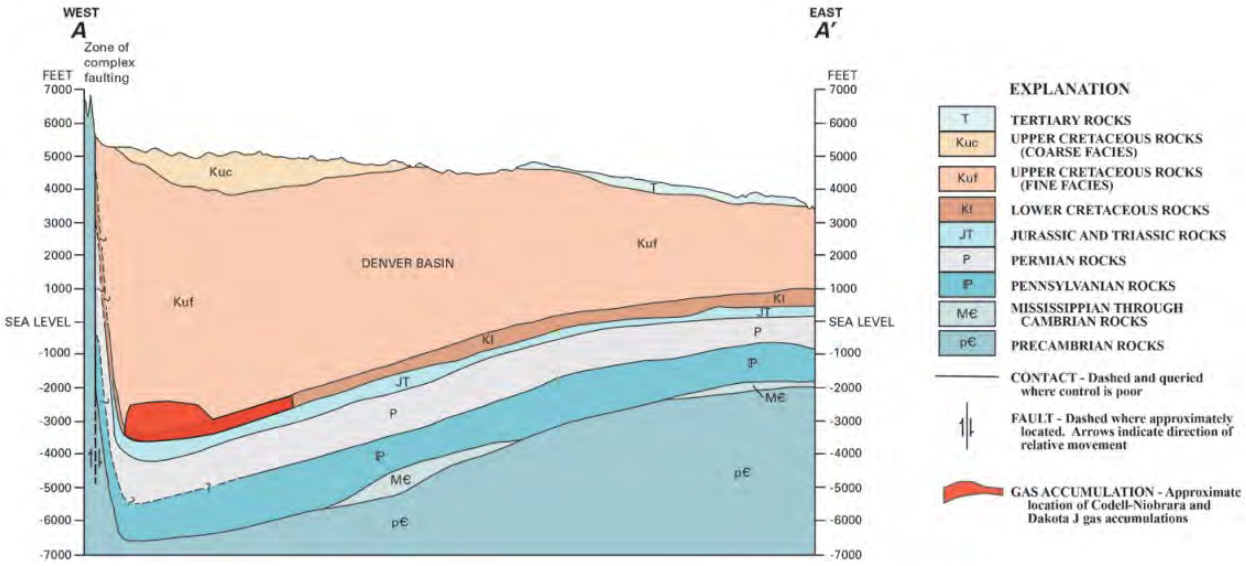

Figure 2: Representative cross section for the Denver Basin along the line A-A' in Figure 1. The Denver Basin is a large asymmetric syncline with a deepest point about 3,900 m below surface. The figure is from Nelson and Santus (2011).

2. Slender Body Theory (SBT) Modeling for Closed-Loop Well Designs

The SBT model is a MATLAB-based tool used for wellbore simulation that effectively models heat exchange, fluid profiles, and pressure profiles for closed-loop geothermal systems without high computational demand (Beckers & Johnston, 2022). By asymptotically matching a three-dimensional infinite cylinder to a one-dimensional finite line source, the model solves for temperature and pressure at each tubing element along the wellbore that is undergoing conductive heat transfer with the rock. Further information about the theory and the model implementation is found in (Beckers et al., 2015; Beckers & Johnston, 2022). The SBT is applicable to this study because the vertical distance covered by the loop is so large that the vertical and lateral geometry can be approximated as a slender, one-dimensional track. Therefore, we have applied this model to simulate the effects of altering different wellbore geometric parameters, reservoir fluid properties, and material and flow conditions in a closed-loop geothermal system to determine an optimal design from a standard base case within a conductive subsurface domain.

2.1 Closed-Loop Wellbore Geometry

We have designed twin wells based on a synthetic wellbore trajectory. The system envisioned consists of two parallel wells with a total vertical depth of 6.1 km and connected at the bottom by one or multiple laterals, depending on the investigated scenario. It is important to state that the designed well patterns are not representative of the actual well plan for the GLADE project, which is still under development.

2.1.1 Base Case

First, we implemented a base case scenario in the SBT tool, with the geometry shown in Figure 3. Both injection and productions wells have a straight vertical section down to a depth of 3,100 m,

followed by an inclined section with an angle of 12 degrees down to a vertical depth of about 6.1 km. The base case geometric properties are as described below:

- Two laterals were simulated in the Y-dimension between the production and injection wells at depth.
- Injection and production wells reached a vertical depth of 6.1 km.
- The vertical injection and production wellbore radius was 0.108 m (radius = 4.25 in; diameter = 8.5 in) and was uniform in both wells.
- The lateral wellbore radius was 0.108 m (radius = 4.25 in; diameter = 8.5 in).
- The pipe internal wall roughness was 1×10^{-6} m.
- The lateral length horizontally connecting the injection and production wells was 100 m in the Y-dimension.
- The distance between laterals was 25 m in the X-dimension.

In this and other simulation cases, all wellbores (injection, production, and laterals) along the heat exchanger path were assumed to be open hole with a negligible rock permeability at the well-formation interface. Conduction-only heat transfer between the rock and fluid was simulated, and all simulations were run on a basis of a 20-year operational lifetime. The well designs do not account for wellbore curvature; consequently, laterals are 90 degrees from the vertical direction. Going from 90 degrees to actual curvature would only slightly change total heat exchanger length (and heat transfer area). Therefore, having no curvature is expected to have negligible effect on heat extraction.

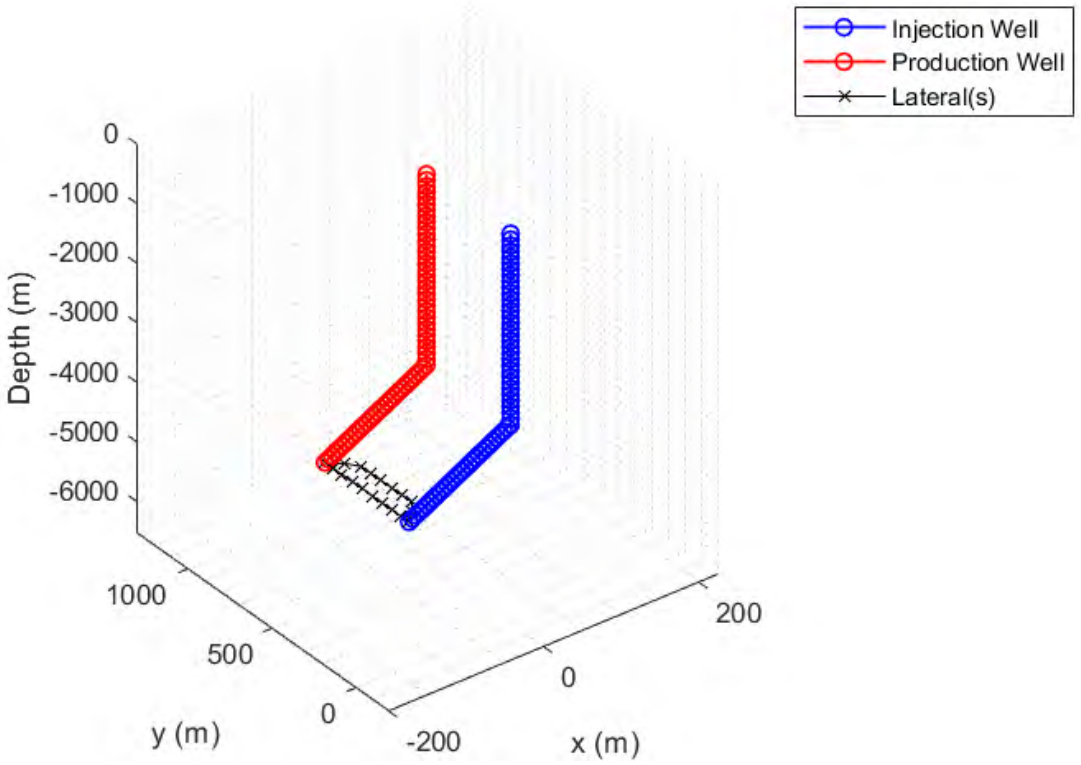

Figure 3: Well geometry schematic for the base case scenario showing the well track notated by colored circles as described in the legend on the right. Lateral length in the Y-dimension has been exaggerated to 500 m for visualization purposes (the original base case lateral length in the Y-dimension is 100 m).

2.1.2 Other Simulation Scenarios

Beyond the base case, we ran multiple simulation scenarios by varying the input parameters relating to the (a) well geometry, (b) flow boundary conditions, and (c) rock and fluid materials to determine the effect of parameter variability on the heat production from the closed-loop system. Table 1 shows the 15 scenarios and the input parameters that were varied in each simulation.

Table 1: The 15 simulation scenarios that were investigated in this work.

Simulation Scenarios	Number of laterals	Lateral spacing (X-direction), m	Well spacing (Y-direction), m	Injection rate, kg/s	Injection temp., °C	Thermal Gradient, °C /km	Rock type	Working fluid
Scenario A (Base case)	2	25	100	40	20	50	Granite	Water
Scenario B	1	25	100	40	20	50	Granite	Water
Scenario C	10	25	100	40	20	50	Granite	Water
Scenario D	2	10	100	40	20	50	Granite	Water
Scenario E	2	50	100	40	20	50	Granite	Water
Scenario F	2	25	500	40	20	50	Granite	Water
Scenario G	2	25	1000	40	20	50	Granite	Water
Scenario H	2	25	100	20	20	50	Granite	Water
Scenario I	2	25	100	60	20	50	Granite	Water
Scenario J	2	25	100	40	40	50	Granite	Water
Scenario K	2	25	100	40	60	50	Granite	Water
Scenario L	2	25	100	40	20	40	Granite	Water
Scenario M	2	25	100	40	20	60	Granite	Water
Scenario N	2	25	100	40	20	50	Gneiss	Water
Scenario O	2	25	100	40	20	50	Granite	CO_2

2.2 Fluid and Rock Thermophysical Properties

We simulated water and CO_2 as working fluids. Variable fluid properties were employed, allowing pressure and temperature to affect the density, specific heat capacity, thermal conductivity, and dynamic viscosity of both fluids. Granite and gneiss (Table 2) were used in two simulated cases. It is noteworthy that the subsurface geology in the study area is not homogeneous. There is a high uncertainty in the lithology of the basement rock in the Wattenberg area due to the unavailability of well data at the target depth. To account for the effect of the overburden sedimentary lithology, we have used the same depth-scaled averages for the rock properties and considered only one representative lithology (i.e., granite or gneiss) for the reservoir rock.

Table 2: Thermophysical properties of the two rock types studied in this work.

Lithology	Density, kgm^{-3}	Heat capacity, $Jkg^{-1}K^{-1}$	Thermal Conductivity, $Wm^{-1}K^{-1}$
Gneiss	2,570	1,080	2.9
Granite	2,540	1,185	3.1

3. System Performance

The base case is the control scenario. This case simulated a production and injection well that was 6.1 km deep with a 0.108-m radius. Two laterals were simulated that connected the production and injection wells. These laterals were approximately 100-m long and spaced approximately 25 m apart (Figure 3). Granite was the reservoir rock, and a constant ground surface temperature was selected at 20°C. The results of the base case simulation presented in Table 3 reveal an average production temperature, final temperature, and heat production of 56.1°C, 53.3°C, and 6 MW_{th}, respectively. In the remainder of this section, we probe the effect of well geometry, boundary conditions, and rock and fluid characteristics on the system performance.

Table 3: Output variables of average temperature, final temperature, and heat production for the 15 scenarios after a 20-year simulation.

Simulation Scenarios	Avg. Production Temperature, °C	Final Temperature, °C	Avg. Heat Production, MW_{th}
Scenario A (Base case)	56.1	53.3	6.00
Scenario B	55.4	52.7	5.88
Scenario C	64.7	60.8	7.44
Scenario D	55.4	52.7	5.90
Scenario E	56.3	53.5	6.03
Scenario F	59.7	56.6	6.61
Scenario G	64.3	60.6	7.38
Scenario H	83.0	78.9	5.26
Scenario I	45.3	43.3	6.27
Scenario J	71.2	68.9	5.21
Scenario K	86.4	84.4	4.42
Scenario L	48.9	46.7	4.80
Scenario M	63.3	60.0	7.21
Scenario N	54.0	51.4	5.70
Scenario O	68.2	64.7	4.40

3.1 Effect of U-Loop Geometry

3.1.1 Number of Laterals

The number of laterals in the U-loop varied from one, two (base case), and 10 laterals. All other geometry specifications, boundary conditions, and material properties were as in the base case. The general heat production and output temperature trend is an initial high heat production rate (and temperature) followed by a steep decline within the first few weeks of production towards a steady state. This is typical for closed-loop systems with a single (constant) flow rate. It is apparent that 10 laterals offer an elevated average heat production over 20 years (7.44 MW_{th}) compared to both single and double laterals (5.88 and 6.0 MW_{th}, respectively; Figure 4). Scenario C with 10 laterals also results in an elevated outlet temperature compared to Scenarios A and B.

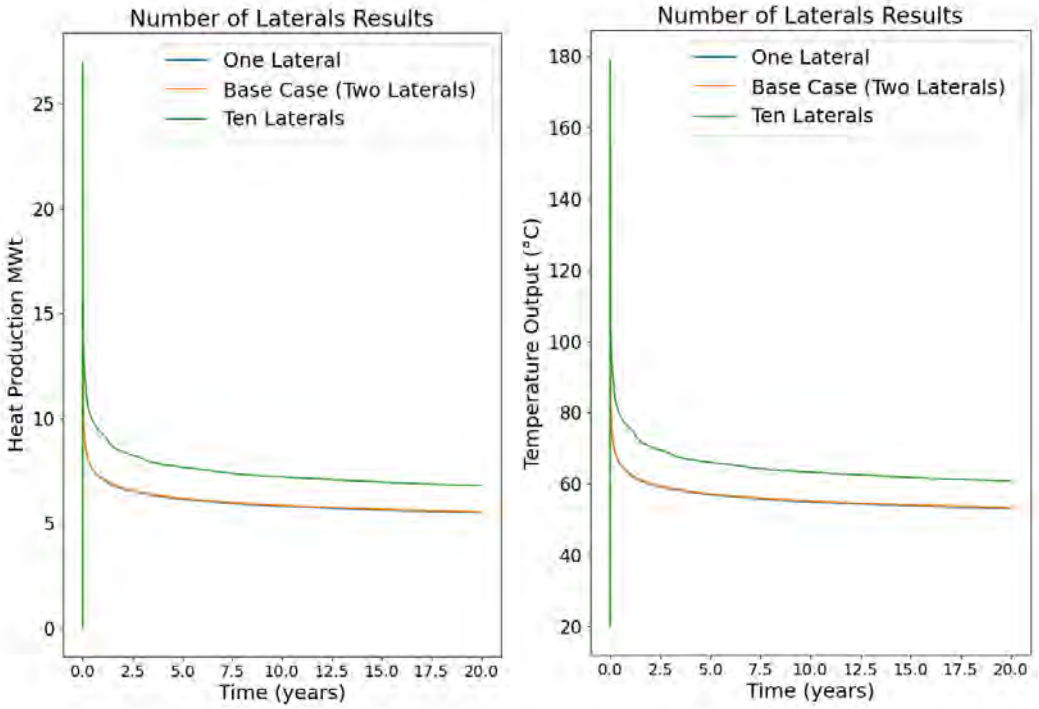

Figure 4: Heat production (MW_{th}) and temperature (°C) output over 20 years for one, two, and 10 laterals. The one- and two-lateral cases overlap due to similar heat production and output temperatures.

3.1.2 Lateral Spacing

Next, 10-m, 25-m (base case), and 50-m lateral spacings in the X-direction were simulated. All other geometry specifications, boundary conditions, and material properties were base case. Simulation results showed that a larger spacing in the X-direction between the laterals increases the outlet temperature by less than 1°C and the average heat production by less than 150 kW (Table 3). This is because, for this well design, thermal interference between laterals is minimal above the 10-m spacing. Therefore, a lateral spacing of 25 m was used as the default to minimize losses due to interference between the laterals.

3.1.3 Well Spacing

The spacing between the injection and production well in the Y-direction was modified from 100 m (base case) to 500 m and 1,000 m in Scenarios F and G, respectively. All other geometry specifications, boundary conditions, and material properties were base case. Extending the well spacing in the Y-direction between the injection and production wells yields an elevated heat production and outlet temperature output (Figure 5).

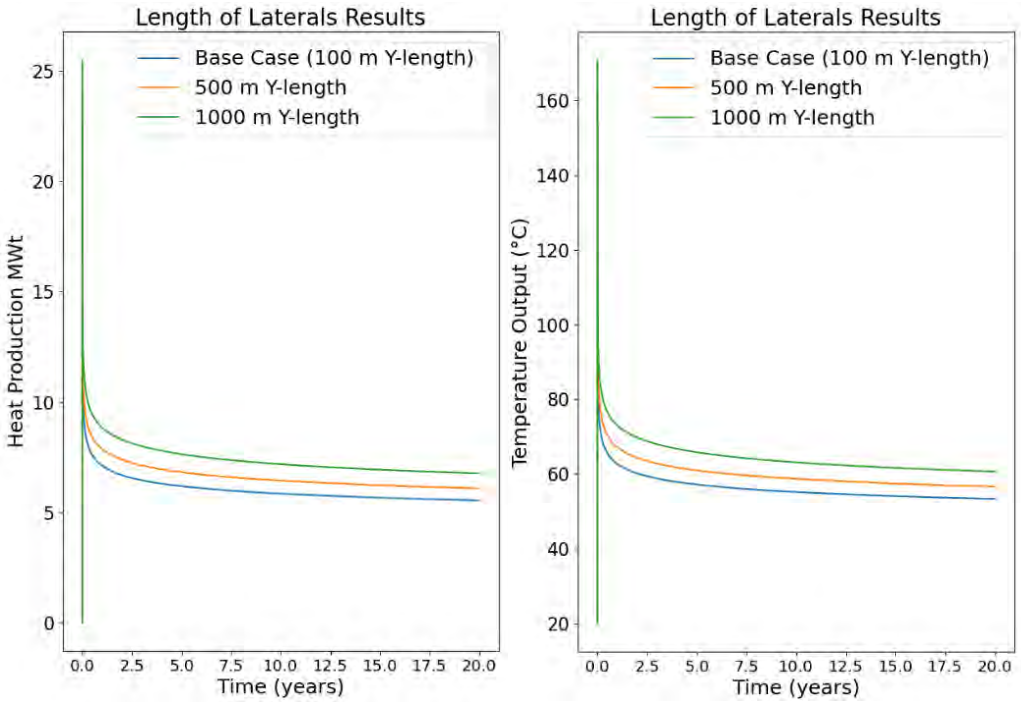

Figure 5: Heat production (MW_{th}) and temperature (°C) output over 20 years for 100-m, 500-m, and 1,000-m length laterals.

3.2 Effect of Boundary Conditions

3.2.1 Injection Rate

The system performance for multiple injection rates of 20 kg/s (Scenario H), 40 kg/s (base case), and 60 kg/s (Scenario I) were compared. All other geometry specifications, boundary conditions, and material properties were the same as the base case. Lower injection rates facilitated lower heat production over time compared to higher injection rate (Figure 6). The opposite trend was observed for outlet temperatures, where lower injection rate had higher output temperature compared to higher injection rates. This is in line with previous observations by Beckers et al. (2022), who reported that decreasing flow rate will decrease heat output, but increase outlet temperature in both co-axial and U-loop systems. This is because the reduction in mass flow is more significant than the slight rise in temperature (due to longer residence time) resulting in a combined effect of lower heat production. This observation suggests that a lower injection rate allows for better outlet temperature control and would benefit applications that need to meet this requirement. For systems that aim to maximize power output, a higher flow rate is necessary.

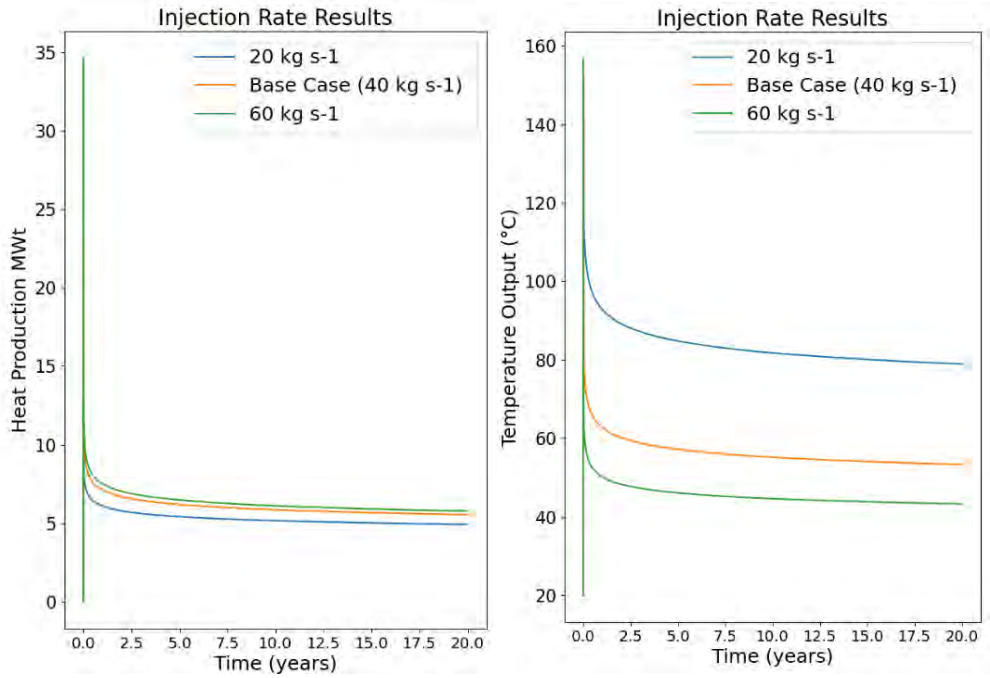

Figure 6: Heat production (MW_{th}) and temperature (°C) output over 20 years for injection rates of 20, 40, and 60 kg/s.

3.2.2 Injection Temperature

To understand the effect of the injection temperature on system performance, we ran simulations for Scenario J (injection temperature = 40°C) and Scenario K (injection temperature = 60°C). The results were compared to the base case with an injection temperature of 20°C. As shown in Figure 7, the higher injection temperatures were characterized by a lower heat production over the project life. The resulting average heat production was 5.21 MW_{th} and 4.42 MW_{th} for Scenario J and Scenario K, respectively. On the other hand, higher injection rates enabled a higher production temperature (Figure 7). Similar to results reported in prior work, increasing injection temperature results in a reduction in the extractable energy (a function of the difference between the reservoir temperature and the injection temperature), which in turn result in a lower heat production (Beckers et al., 2022).

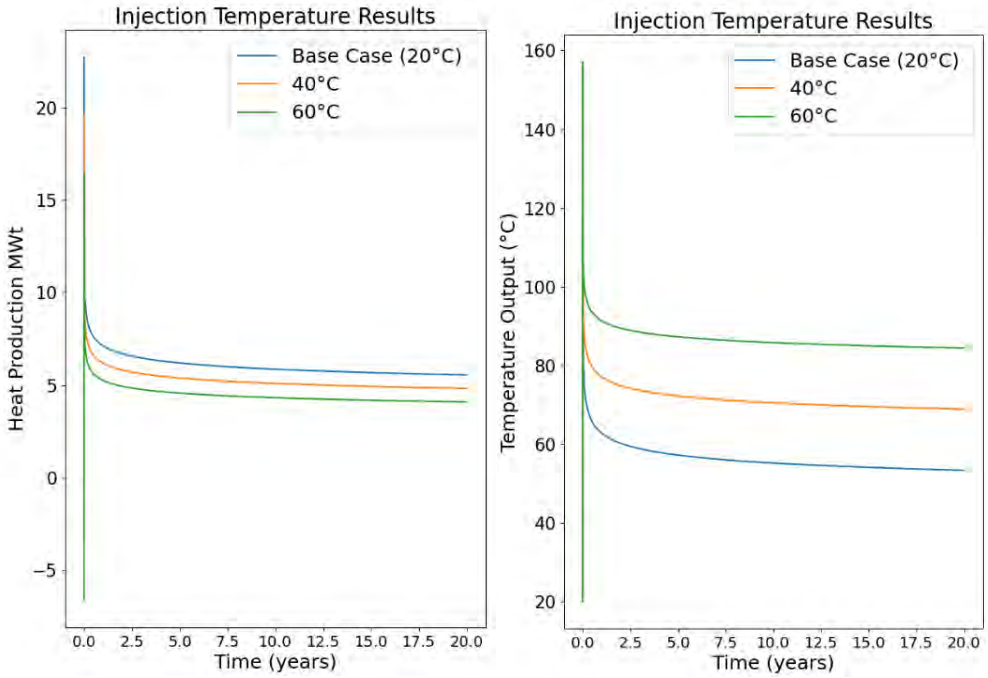

Figure 7: Heat production (MW_{th}) and temperature (°C) output over 20 years for inlet temperatures of 20°C, 40°C, and 60°C.

3.2.3 Geothermal Gradient

Variations of the subsurface geothermal gradient were employed as 40°C/km (Scenario L), 50°C/km (base case), and 60°C/km (Scenario M). All other geometry specifications, boundary conditions, and material properties were base case. Overall, it is apparent that higher heat production and outlet temperature throughout the project life are directly correlated to the magnitude of the geothermal gradient (Figure 8).

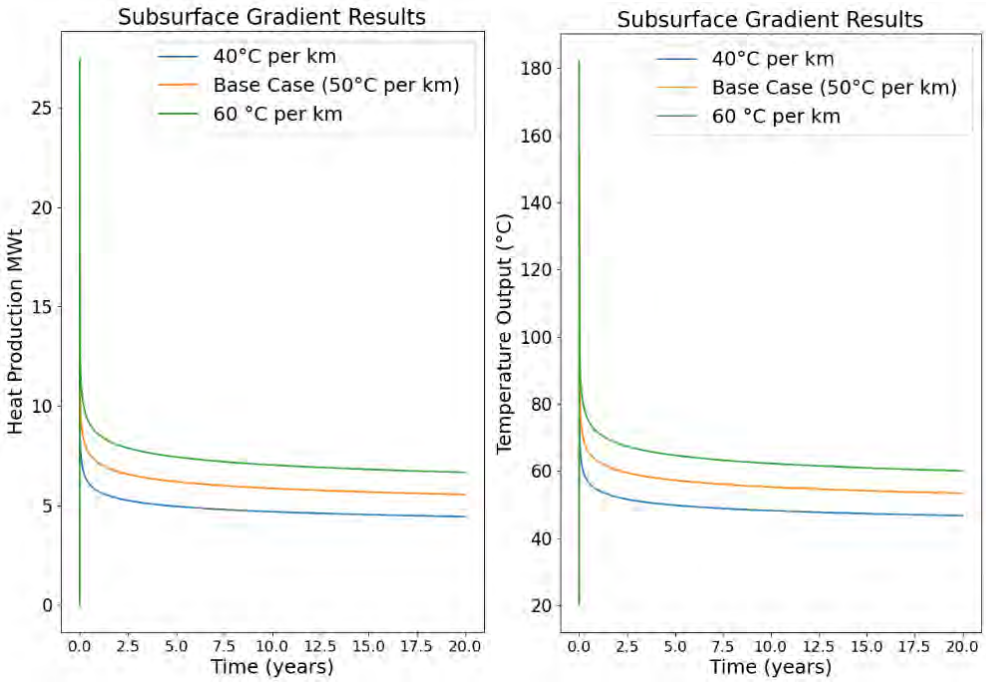

Figure 8: Heat production (MW_{th}) and temperature (°C) output over 20 years for 40°C/km, 50°C/km, and 60°C/km.

3.3 Effect of Rock and Fluid Types

3.3.1 Rock Type

To understand and quantify the uncertainty in the lithology of the basement rock and its effect on thermal performance, we completed simulations for the two end cases, i.e., the base case with granite and Scenario N with gneiss. The results in Table 3 show that a gneiss basement lithology results in lower output temperature and heat production over the project life. This arises from a combination of a higher thermal conductivity and heat capacity for the same volume of granite compared to gneiss.

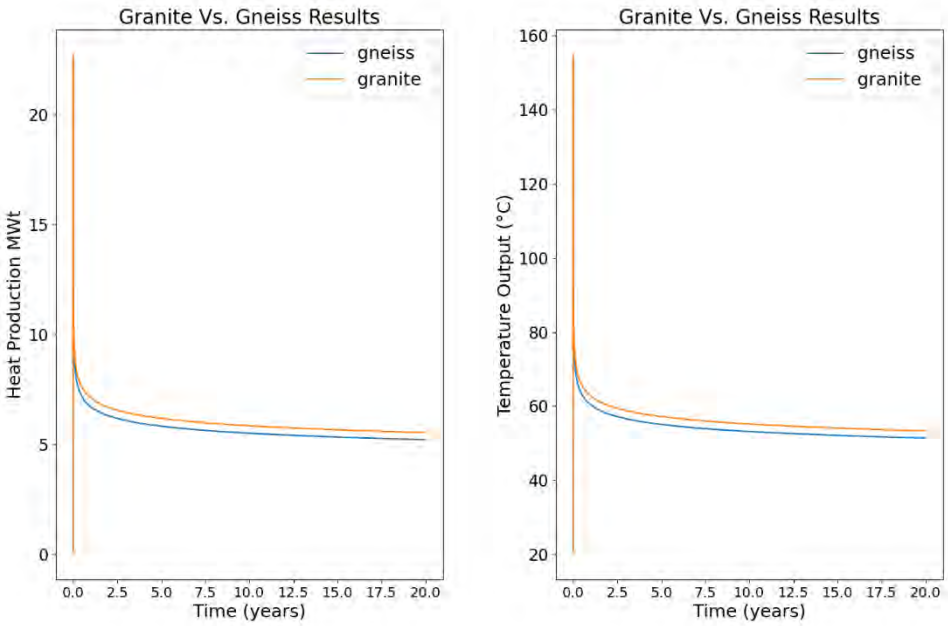

Figure 9: Heat production (MW_{th}) and temperature (°C) output over 20 years for gneiss versus granite.

3.3.2 Working Fluid

The thermal property and composition of the working fluid in a closed-loop system are important factors that influence performance. In this study, water and CO_2 were compared. At a constant injection wellhead pressure of 100 bar, the CO_2 is supercritical within the closed loop system as it traverses the reservoir domain and the production well. As displayed in Figure 10, the average production temperature for a CO_2-based U-loop was elevated compared to water, yet the opposite was evident for average heat production. Water shows an elevated average heat production (6.0 MW_{th}) compared to CO_2 (4.4 MW_{th}). The higher heat production is mainly due to the higher specific heat capacity of water compared to CO_2 (4.2 versus 0.84 J kg^{-1} K^{-1}). However, the higher outlet temperatures for CO_2 arises from the lower rate of reservoir thermal depletion (due to less heat extracted).

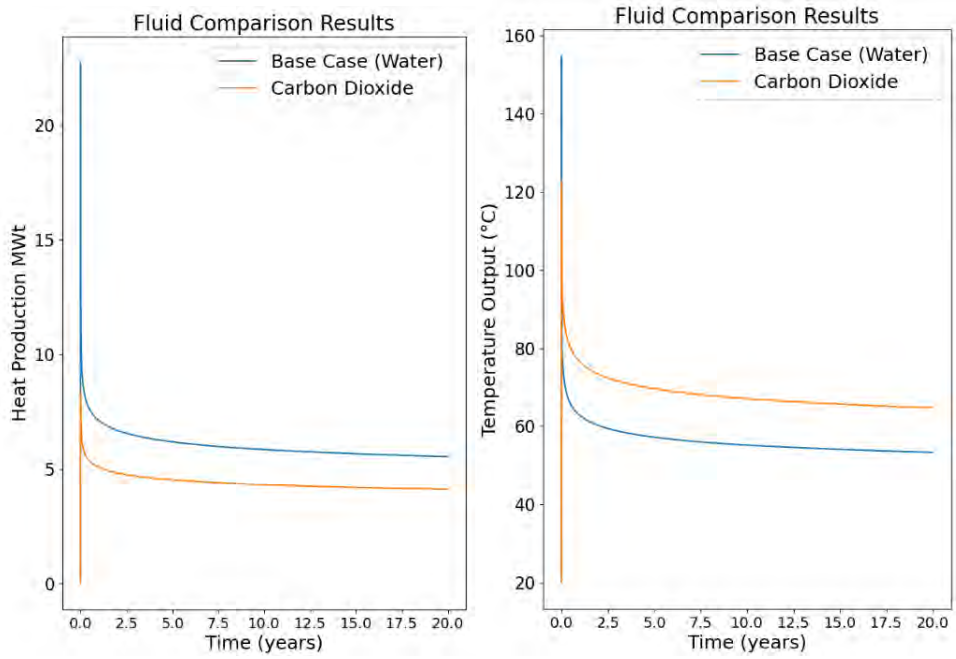

Figure 10: Heat production (MW_{th}) and temperature (°C) output over 20 years for CO_2 and water.

3.4 Optimal Well Design

An optimal well design scenario for both heat production and outlet temperature maximization has been developed based on the observed parameters and their effects over a 20-year lifetime. This scenario includes a production and injection well that was 6.1 km deep with a 0.108-m radius. Connecting the two wells are 10 laterals with radii of 0.108 m, 50-m spacing between each of the ten laterals in the X-dimension, and a well spacing of 1,000 m in the Y-dimension (Figure 11). To maximize heat production, the injection temperature is held constant at 20°C, with a constant injection rate of 60 kg/s, and flow divided evenly over the 10 laterals. The reservoir rock is granite, with an average thermal conductivity of 3.1 W m^{-1} K^{-1}, average heat capacity of 1,185 J kg^{-1} K^{-1}, and a density of 2,540 kg m^{-3}. A constant ground surface temperature was selected at 20°C and the geothermal gradient through the subsurface was 60°C/km. Water was the utilized working fluid. The pressure at the injection wellhead was 100 bar. Outputs of the system are summarized in Table 4. The trends in heat production and outlet temperature over time are summarized and compared to the base case in Figure 12. It is important to highlight that this is the performance-optimized design. The techno-economic feasibility of drilling and developing such a system is discussed in Section 4.

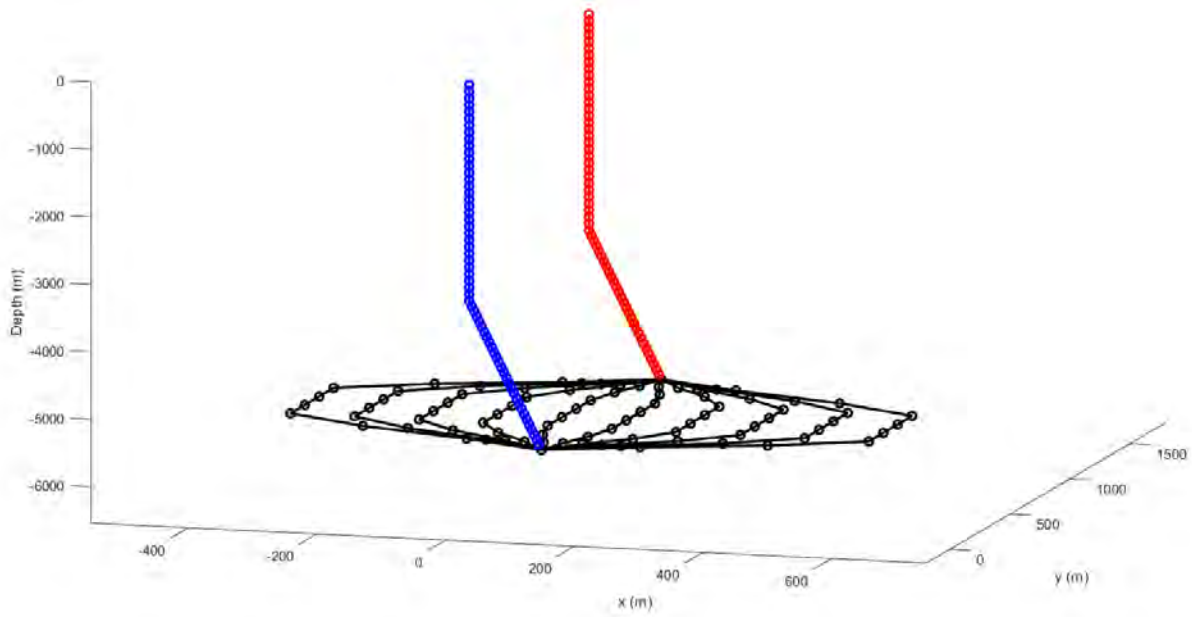

Figure 11: Optimized geometry schematic developed from observed outputs of prior scenarios.

Table 4: Inputs and outputs parameters for the optimized heat production case scenario for water after a 20-year simulation.

Parameter	**Unit**	**Value**
Input		
Injection Rate	kg/s	60
Injection Temperature	°C	20
Geothermal Gradient	°C/km	60
Number of laterals		10
Lateral Length	m	1000
Well Spacing	m	50
Rock Type		Granite
Output		
Average outlet temperature	°C	95.7
Average heat production	MW_{th}	19
Final temperature	°C	88.8

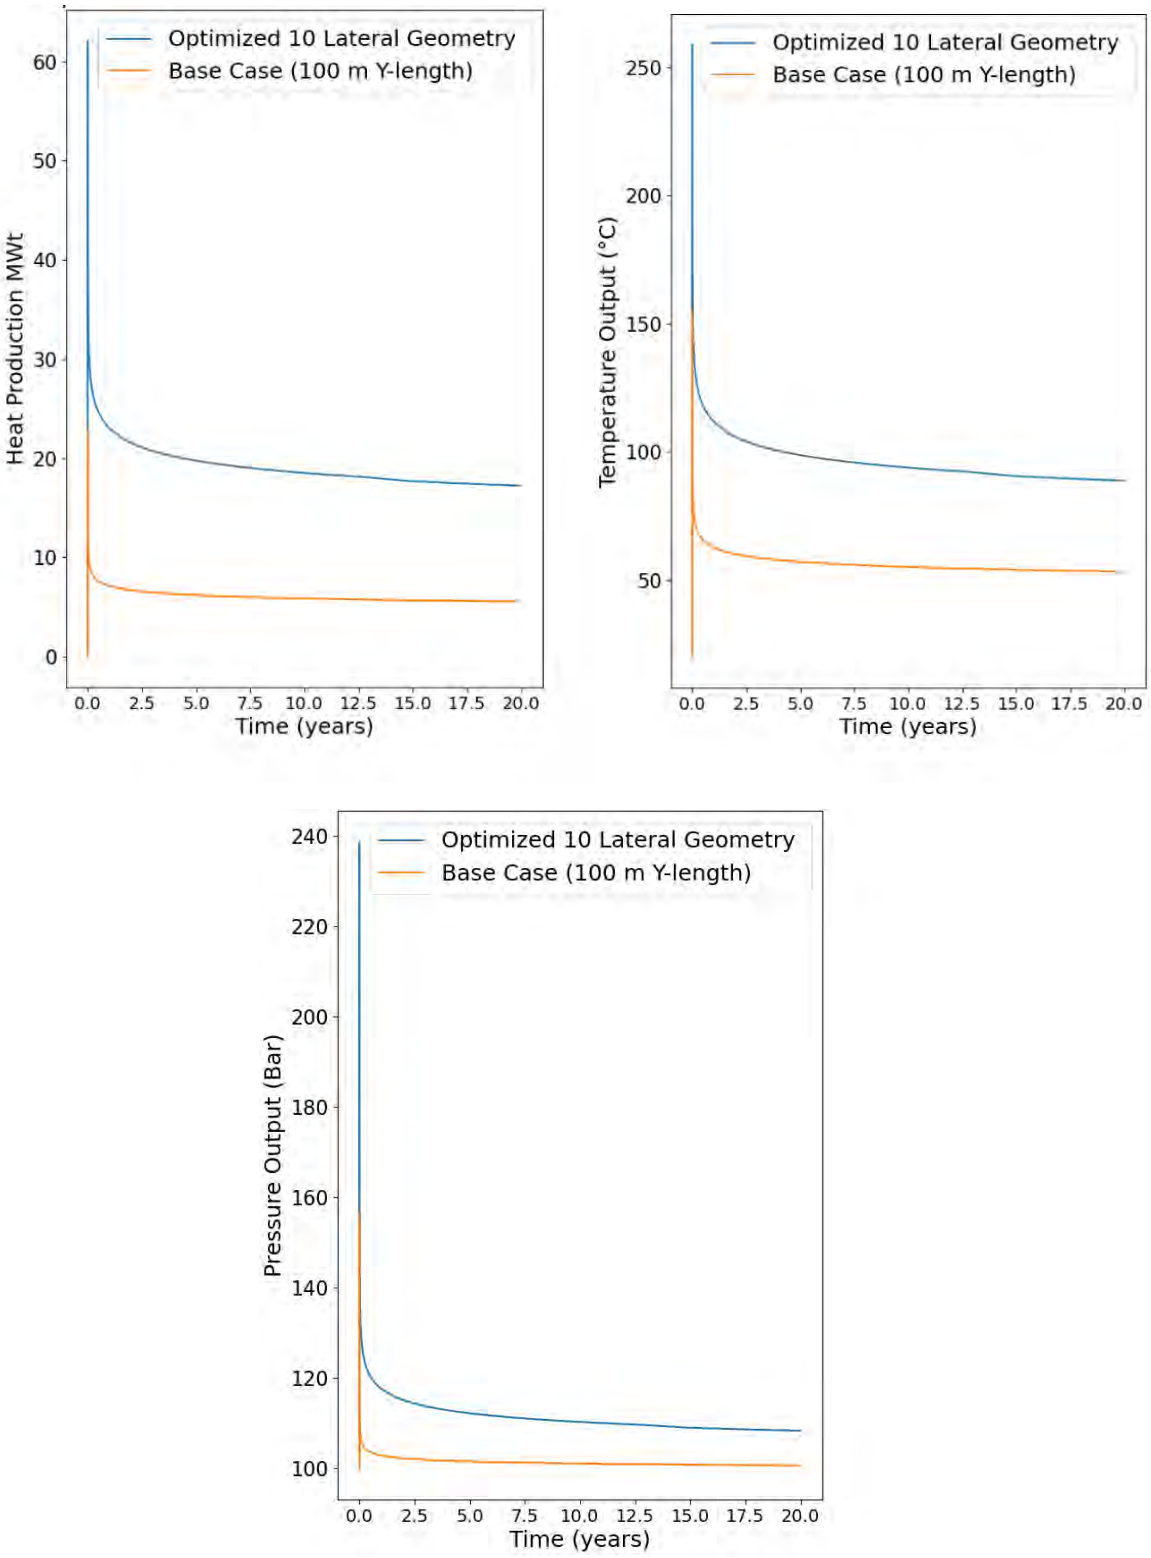

Figure 12. Optimized versus base case heat production, temperature output, and outlet pressure over 20 years for maximized heat production.

4. Techno-Economic Assessment

We have developed a simplified techno-economic assessment (TEA) model to estimate the lifecycle costs of the performance-optimized U-loop system. The TEA is a top-down Excel-based model that estimates the capital cost, operation and maintenance (O&M) costs, and the levelized costs of energy (electricity or heat). The input assumptions used in the model are listed in Table 5. These assumptions cover unit costs for the surface plant (for electricity generation only) installation and directional drilling. The model does not include the cost of project financing and does not account for tax credits or other incentives that can improve project economics.

Table 5: Input assumptions for parameters in the TEA model.

Parameters	**Baseline Value**	**Parameter Variability**	**References**
Power conversion factor, %	12%	10-15%	Beckers and Johnston (2022)
Plant availability, %	95%	-	Beckers and Johnston (2022)
Lateral cost per meter, $/m	600	400-800	Beckers and Johnston (2022)
Vertical cost per well, $	7,500,000	-	Beckers and Johnston (2022)
Power plant installation cost, $/kW	2,500	-	Beckers and Johnston (2022)
Heat exchanger cost, $	1,250,000	-	Beckers and Johnston (2022)
O&M as percent of capital cost, %	1.5% (electricity) 1% (heat)	-	Beckers and Johnston (2022)
Plant lifetime, yr.	20	-	
Discount rate, %	7%	5-9%	Beckers and Johnston (2022)

To determine the performance- and cost-optimized system, we executed the TEA model using the baseline input assumptions (Column 2 in Table 5) and the optimal values of the U-loop design parameters identified in Section 3 and listed in Table 4. The resulting levelized cost of electricity (LCOE) and levelized cost of heat (LCOH) were \$136/MWh$_e$ and \$1.53/GJ, respectively. Additionally, to account for uncertainty in the TEA parameters we considered six other optimal cases with variability in power plant conversion factor, lateral drilling cost, and discount rate. The results are shown in Table 6. These show that the LCOE can be further improved with higher efficiency power conversion systems while the LCOH benefits from lower discount rates. Drilling costs are important for both electricity and heating use cases with a larger degree of impact in the heating case.

Table 6: Output from the TEA modeling for both electricity and heating use cases for the optimal closed-loop design.

Parameter	Unit	Optimal I	Optimal II	Optimal III	Optimal IV	Optimal V	Optimal VI	Optimal VII
Power Conversion Factor	%	12	10	15	12	12	12	12
Lateral Cost per m	$/m	600	600	600	400	800	600	600
Discount Rate	%	7	7	7	7	7	5	9
Plant power output (electric)	kW_e	2,166	1,805	2,708	2,166	2,166	2,166	2,166

4. Conclusion

In this paper, we have implemented the SBT model to investigate the thermal profiles and well production performance of a U-loop well drilled into the Wattenberg area of the Denver-Julesburg Basin. A scenario-based assessment of the effect of input variables, categories as the well geometry, boundary conditions, and rock and fluid properties, on heat transfer and well production performance was implemented. This model-enabled assessment revealed that a U-loop design characterized by an injection to production well spacing of 1,000 m with ten 50-m-spaced laterals that traverse a conductive subsurface system with a temperature gradient of 60°C/km maximizes thermal energy production. Specifically, injecting 20°C-water at a rate of 60 kg/s through the optimized U-loop, an average heat production of 19 MW_{th} (i.e., 2.2 MW_e net plant output) was achieved, resulting in an LCOE and LCOH of \$136/MWh_e and \$1.53/GJ, respectively.

Keywords

Flexible geothermal; Techno-economics; Unconventional systems

ABSTRACT

Flexible geothermal operations could boost project returns through the allocation of improved power purchase agreements and/or exploitation of power price arbitrage opportunities. In this study, we investigated the techno-economic feasibility of variable flow rate control and time-of-day pricing in closed-loop geothermal systems. We considered U-shaped multilateral system configurations and modeled a variety of technical system parameters. These designs were simulated using a slender-body theory (SBT) model for transient heat transfer and fluid flow. This subsurface model was integrated into the flexible geothermal economic model (FGEM) tool to evaluate the overall flexible geothermal system techno-economics. Future hourly ambient temperature conditions were based on the Sup3rCC dataset. Published datasets were used for future hourly wholesale electricity prices. We analyzed four operating strategies: 1) baseload operation, 2) seasonal dispatch (high flow rate during summer and nominal flow rate during the rest of the year), 3) net generation maximization by varying flow rate to maximize net power output, and 4) revenue maximization by varying flow rate to maximize revenue. We ran all four scenarios for a multiloop configuration with 12 lateral passes, 7-km vertical depth and 87-km total drilling length. Furthermore, we assumed a 60°C/km geothermal gradient and ambient temperature and wholesale electricity prices for New Mexico as a typical state location. The nominal flow rate was set to 80 kg/s. When considering drilling costs of $1,000/m and a discount rate of 7%, the generation maximization scenario resulted in the lowest levelized cost of electricity (LCOE) of ~$150/MWh. When considering project return on investment (ROI), defined as lifetime net income divided by upfront capital costs, all flexible operation scenarios performed better than the base case scenario. The highest ROI of 80% was obtained with the revenue maximization scenario. With drilling costs of $200/m and a discount rate of 5%, the generation maximization scenario resulted in LCOE of $49/MWh.

1. Introduction

1.1 Closed-Loop Geothermal Systems

Closed-loop geothermal systems, sometimes referred to as advanced geothermal systems or next-generation geothermal systems, are proposed to use a heat transfer fluid circulating in a closed-loop configuration through a co-axial ("pipe-in-pipe") or U-loop-type subsurface heat exchanger to produce reservoir heat to the surface, as seen in Figure 1. The heat transfer fluid does not penetrate the rock but stays within the heat exchanger. These systems have recently received significant attention and investment, with several companies proposing to develop and commercialize this technological concept. Postulated benefits include not requiring reservoir permeability, limited need for exploration, easier handling of heat transfer fluid (e.g., clean water) at the surface, and relatively easy design and prediction of production temperatures. A key challenge is the limited thermal performance in conduction-only systems, requiring deep and hot reservoirs and/or extremely long drilling lengths to produce multi-megawatt power systems.

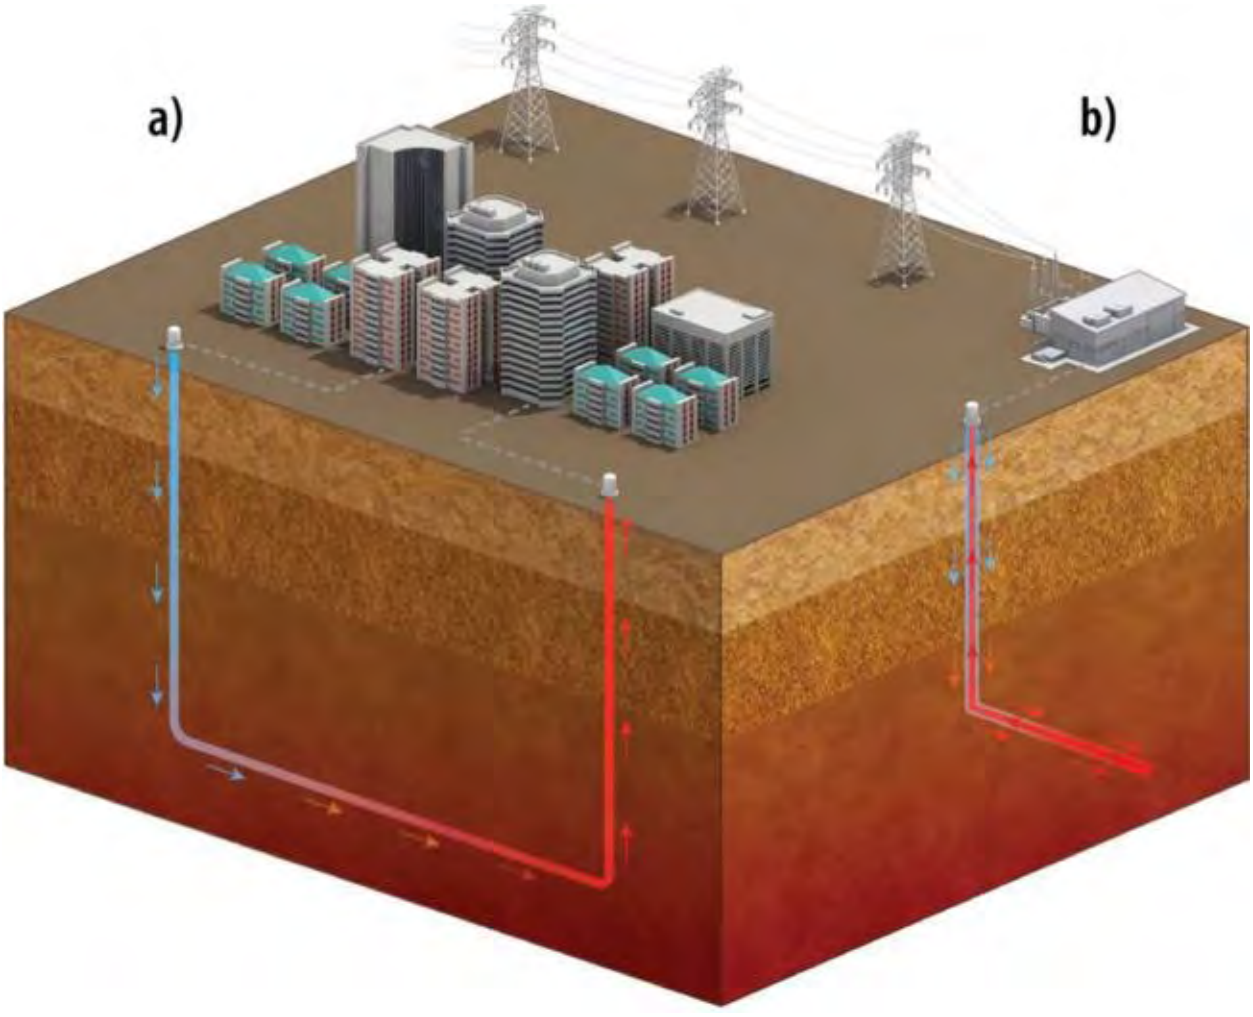

Figure 1.: Conceptual diagram of two types of closed-loop geothermal: (a) U-loop and (b) co-axial.

Various studies have been conducted to investigate the techno-economic performance of closed-loop geothermal systems. Beckers et al. (2022) studied levelized cost of heat and electricity for several co-axial and U-loop designs for a range of subsurface and operation conditions (i.e., different injection temperatures, flow rates, heat transfer fluids, depths, and geothermal gradients). Beckers and Johnston (2022) studied the performance of a multiloop design for a low- and high-geothermal gradient scenario, which forms the basis of subsurface design in this paper. Multiple studies were undertaken by the closed-loop geothermal working group (CLGWG), a U.S. Department of Energy (DOE)-funded multilaboratory and university research effort investigating the performance of various closed-loop geothermal systems. These studies include a general feasibility study by White et al. (2023); developing a database of precalculated reservoir simulations of multiple closed-loop designs (Beckers et al. 2023) used in a web-based closed-loop geothermal simulation tool—the GeoCluster tool (CLGWG 2023); investigating the heat transfer performance of closed-loop geothermal systems with thermally conductive enhancements (Beckers et al. 2024); and assessing the impact of convection on the performance of closed-loop systems (Hakes et al. 2024).

1.2 Flexible Geothermal Operations

Geothermal power has emerged as a key contender in the transition toward a greener and more resilient energy landscape, given its ability to provide consistent “baseload” power: a constant, reliable, and steady supply of electricity always (Tester et al. 2021). Geothermal power is often operated under power purchase agreements (PPAs), where an operator typically earns a fixed nominal price per energy unit generated (Moradpoor et al. 2023). By signing PPAs, geothermal operators limit revenue uncertainties associated with trading in the open and volatile electricity market, especially in decarbonized grids that are significantly penetrated by intermittent resources, e.g., solar and wind (Aljubran and Horne 2023a). On the other hand, load-serving entities often sign geothermal PPAs because they come with continuous power availability, high capacity factors, long lifespans and stability, and environmental benefits.

However, the high penetration of intermittent resources caused an increase in the value for dispatchable geothermal generation that would fill in the diurnal and seasonal gaps. Researchers and engineers worldwide have used various strategies to achieve dispatchable geothermal operations. Considering both economic viability and technical factors is essential to achieve dispatchable operations. Aljubran and Horne (2024a) categorize these operations into four main types: wellhead throttling, steam vent-off, turbine bypass, and storage. Considering conventional geothermal systems hybridized with lithium-ion battery units in a highly volatile electricity market (e.g., California), researchers found diurnal flexible operations resulted in up to 28% improvement in project profitability per unit energy generated (Aljubran and Horne 2023a). Whereas adding battery units involves significant upfront costs, another study considered wellhead throttling and turbine bypassing in enhanced geothermal systems and concluded an additional 11% of geothermal power can be realized across the United States through flexible operations (Aljubran and Horne 2024b). Other efforts investigated the value of hydrogen coproduction as a means of flexible geothermal operations in New Zealand to alleviate the hydropower supply uncertainty associated with the frequent droughts (Marsh et al. 2023).

1.3. Problem Statement

Past studies on the techno-economic performance of closed-loop geothermal systems generally focus on baseload operation with constant flow rate and injection temperature of the heat transfer fluid, a constant ambient temperature, and a constant PPA price. In this project, we investigated the techno-economic performance of flexible closed-loop geothermal operation. For example, operating a closed-loop geothermal system in a load-following capacity ("dispatchable geothermal") may allow boosting power output at times of high electricity prices and obtain a better PPA price. Lowering the flow rate during times of low electricity prices may allow the rock temperature to partially recover thermally, which may increase the longevity of the system. In this project, we investigated net present value and LCOE for flexible operation of a closed-loop system under various scenarios.

2. Methodology

2.1 System Design

We selected a multiloop design for the subsurface closed-loop system in this project, based on a previous study by Beckers and Johnston (2022). This design assumes 12 lateral passes with total vertical depth of 7 km and total drilling length of about 87 km, as seen in Figure 2. The spacing between the laterals is 500 m. We considered the scenario with a geothermal gradient of 60°C/km. The nominal flow rate is 80 kg/s, corresponding to an average production temperature of approximately 210°C.

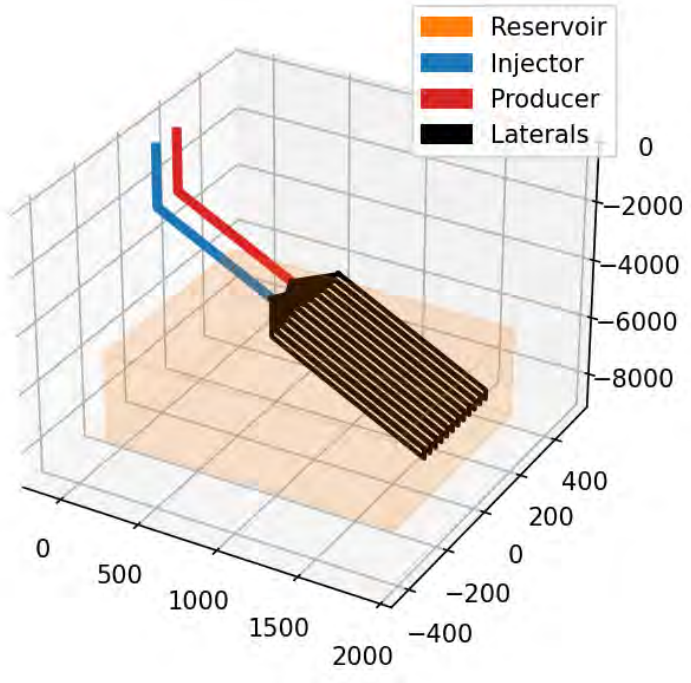

Figure 2: Subsurface configuration of the multiloop system.

2.2 Slender-Body Theory Model

We simulated the closed-loop subsurface heat extraction with the slender-body theory (SBT) model for transient heat conduction, developed by Beckers et al. (2015; 2022). The SBT model is a computationally fast heat transfer model using analytical equations (Green's functions) to simulate heat transfer between the heat exchanger and surrounding rock, requiring only a one-dimensional spatial discretization of the exchanger instead of a full three-dimensional domain discretization with traditional numerical simulators. A double integration (over space and time) is still required to simulate the impact of all past heat exchange at every element; however, simplifications in time and space domains are implemented in the SBT model to speed up that step, as seen in Figure 3. The SBT model can simulate only reservoir heat conduction with constant reservoir thermophysical properties but allows for varying fluid injection temperature and flow rate. As part of this study, a Python version of the SBT model has been coupled with FGEM and set up to simulate hourly heat extraction over the system lifetime.

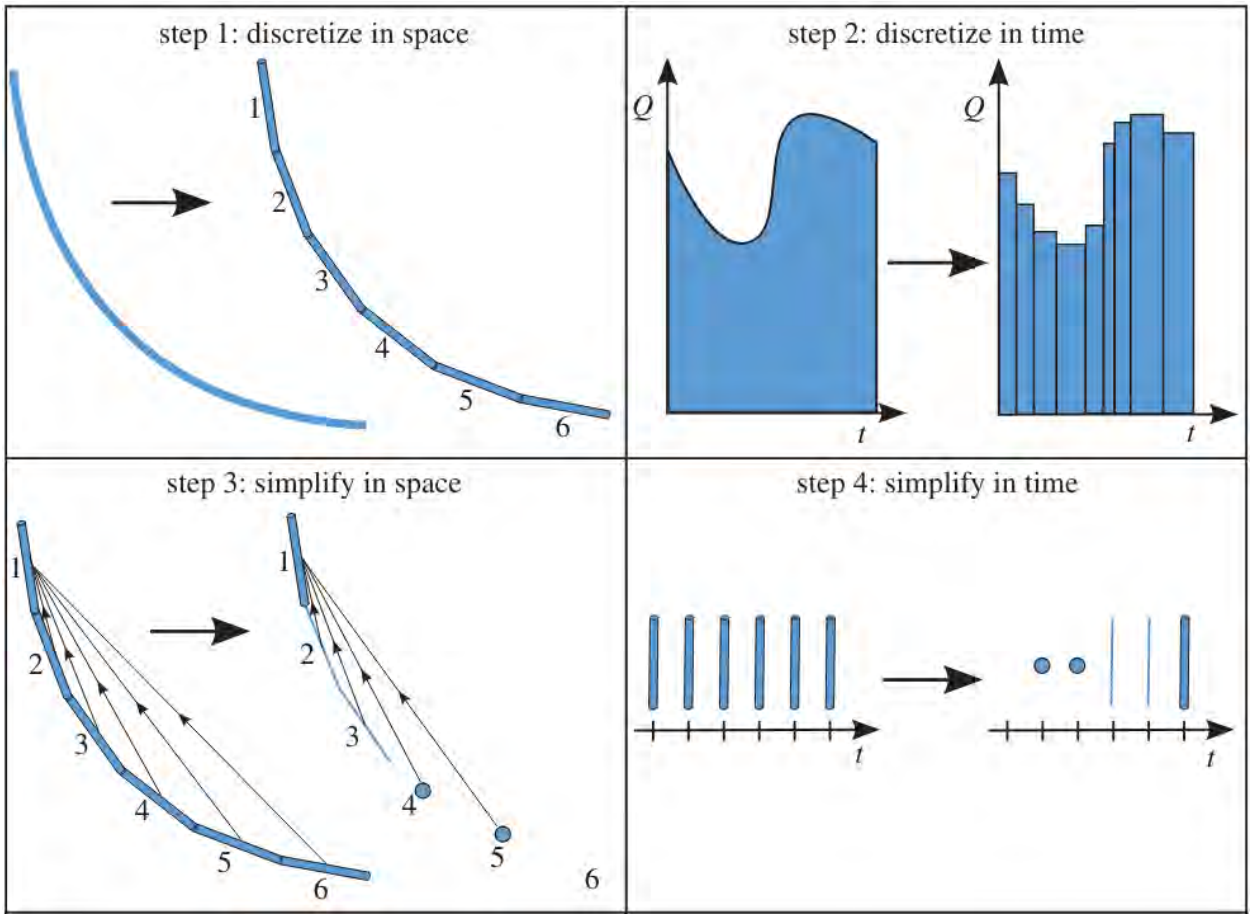

Figure 3: SBT model represents numerical implementation of using Green's functions to simulate heat transfer between fluid in heat exchanger and surrounding rock. The heat exchanger is discretized in space with "pipe elements," allowing the use of analytical equations (i.e., point source, line source, cylindrical source) to rapidly calculate heat exchange.

2.3 Binary Power Plants

There exist several types of power plants, such as dry steam, single-and multi-flash steam, organic Rankine cycle (ORC) or binary cycle plants, and combined cycle power plants (DiPippo 2012). Other than one triple-flash plant constructed in 2011, all geothermal capacity additions across the United States from 2000 through 2020 have been binary plants (Robins et al. 2021). Several key factors have driven this dominating trend. An ORC plant can operate efficiently with low-enthalpy geothermal resources; hence, it is suitable for a larger number of geothermal resources (Kagel et al. 2005). Binary power plants are closed systems, which minimizes emissions and environmental impact, unlike flash plants, which could release toxic and greenhouse gases such as hydrogen sulfide and carbon dioxide (Bonalumi et al. 2017). This is key for complying with increasingly strict environmental regulations and meeting increasing demand for clean energy. In addition, binary plants are modular and scalable, allowing incremental capacity additions and easier adaptation to varying resource conditions (DiPippo 1999). Thus, the research of this study focused on the use of ORC power plants.

Practically, power plants never operate under fixed conditions, where ambient temperature fluctuates, production temperature declines, and geofluid mass flow rate is adjusted. Thus, power output would be overestimated if a plant were assumed to always operate under on-design conditions. Hence, it is necessary to model and optimize power plants for off-design conditions. In this study, an ORC power plant was modeled and optimized across operating conditions to accommodate the variable operational settings over the geothermal project lifetime.

Seen in Figures 4 and 5, the main components of an air-cooled geothermal subcritical ORC binary power plant are the turbine, generator, condenser, feed pump, preheater, and evaporator. Three fluids are involved in the heat exchange process: geofluid, working fluid, and air. The geofluid is produced at point (a) under the wellhead pressure and temperature, then passes through the evaporator to the design pinch-point conditions at point (b) and finally through the preheater to exit at reinjection conditions at point (c) to the injection well. The high-pressure, vaporized working fluid enters the turbine at point (1) and expands through the turbine, converting thermal energy into mechanical energy, which drives the power generator. The low-pressure vapor exits the turbine at point (2) and enters the condenser, where it releases its remaining heat as a two-phase fluid at point (g) and eventually exits at point (3). The fluid is then pumped through point (4) to the preheater where it is heated to the saturation point (5) and eventually evaporated (and superheated, if needed) to point (1), completing the ORC cycle. Air is used to cool the working fluid in the condenser, entering at ambient conditions at point (x), through the condenser pinch-point conditions at point (f), and exiting at a higher temperature at point (y). The thermodynamic processes of the working fluid are shown in the pressure-enthalpy diagram of Figure 5. The system components were analyzed based on established thermodynamic laws most often used for refrigeration and air conditioning cycles (DiPippo 2012). The cycle thermal efficiency was estimated based on the first law of thermodynamics whereas net power output was then computed by subtracting the parasitic losses because of working fluid pumping and air fan cooling from the gross power generation.

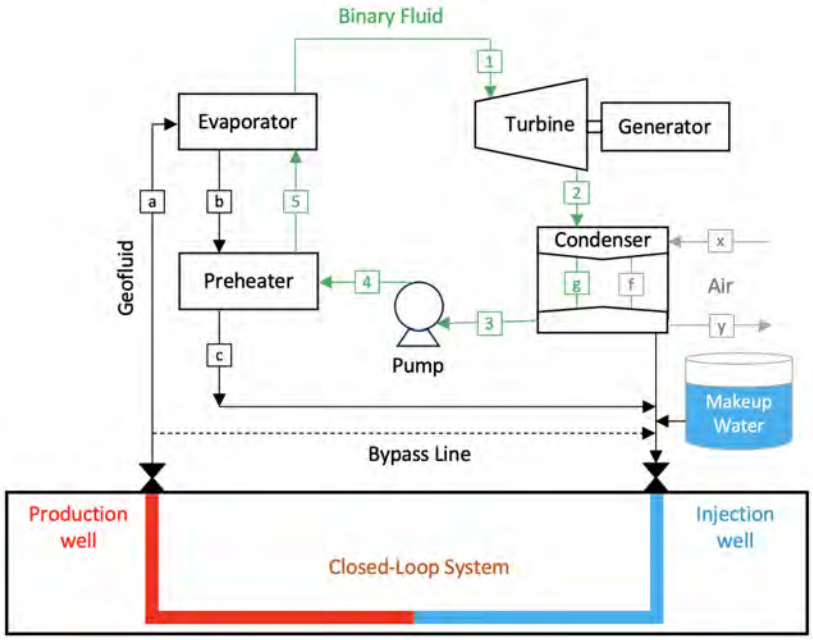

Figure 4: Schematic of the ORC binary power plant model components with emphasis on the flow paths of the geofluid (black), binary fluid (green), and cooling air (gray).

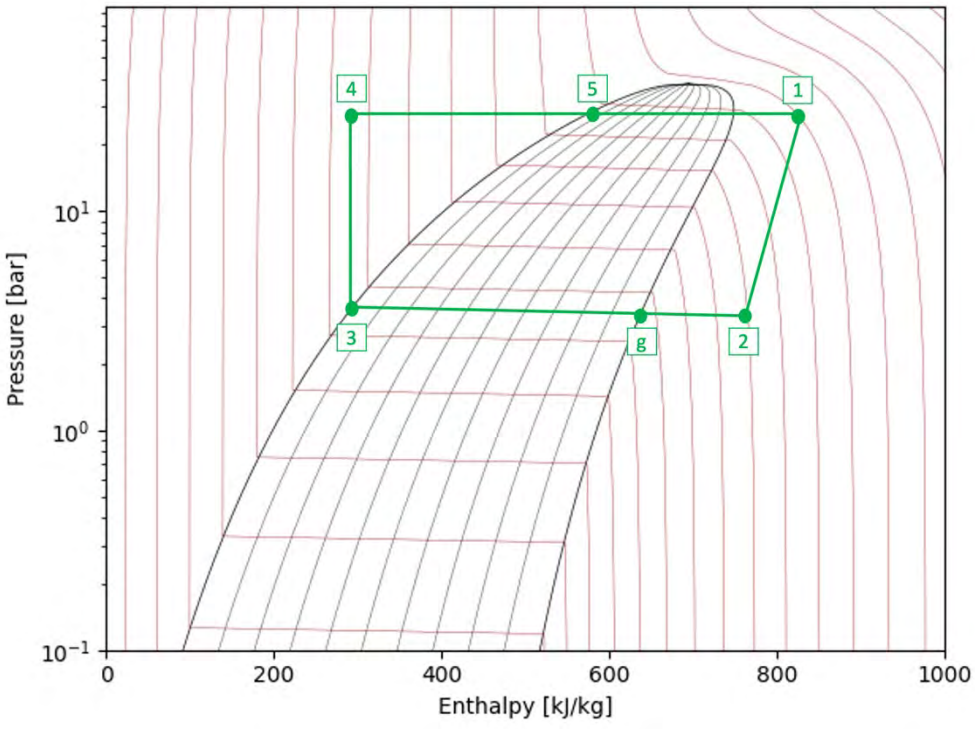

Figure 5: Example binary fluid pressure-enthalpy diagram with fluid undergoing heat-to-electricity-conversion cycle corresponding to Figure 4.

The proposed model was used in an optimization framework to design power plants optimally. Usual parameters were set across simulations, with butane as the binary working fluid, reinjection temperature of 60°C, heat exchanger pinch-point of 5.8°C, and condenser pinch-point of 3.0°C

(DiPippo 2012). The optimization objective was to maximize net power output by controlling the turbine inlet temperature, inlet pressure, and outlet pressure. Bound constraints were set to ensure subcritical conditions while allowing superheating of the working fluid, positive system pressure differential to prevent moisture from contaminating the working fluid, and operational conditions below the working fluid critical pressure. Inequality constraints were set to guarantee mass and energy balance across fluid cycles, a minimum of 2-bar positive differential pressure across the turbine, pinch-point constraints, no temperature profile crossing within the heat exchanger train and condenser, and 95% working fluid vapor quality at the turbine outlet. Adaptive particle swarm optimization (Zhan et al. 2009) was used to optimize this single-objective problem. The resulting operational conditions and power output represent the optimal on-design power plant performance. In addition, the on-design preheater, evaporator, and condenser surfaces areas were computed accordingly.

This model was developed in Python and verified by comparing against two air-cooled geothermal ORC binary power plants developed using the IPSEpro software (Beckers et al. 2022) with a similar power plant configuration. Both validation scenarios involved geofluid mass flow rate of 80 kg/s, ambient temperature of 15°C, and reinjection temperature of 60°C. The first verification scenario was based on a low-enthalpy geothermal resource producing saturated liquid at 125°C, with propane as a working fluid. Compared to the IPSEpro model net power output of 2.25 MWe, the proposed Python model yielded 2.30 MWe (2.2% difference). The second verification scenario was based on a high-enthalpy geothermal resource producing saturated liquid at 210°C, with butane as a working fluid. Compared to the IPSEpro model net power output of 8.40 MWe, the proposed Python model yielded 8.82 MWe (4.9% difference). Hence, it was concluded the proposed model was suitable to evaluate power output performance across scenarios.

The on-design ORC power plant modeling and optimization framework was then compared to the GEOPHIRES power plant correlations, a geothermal techno-economics simulator (Beckers and McCabe 2019). The GEOPHIRES expressed the net power output and reinjection temperature as functions of the geofluid production temperature and ambient temperature alone, with no correspondence to the geofluid flow rate. They also assumed the most optimal power output across an array of working fluids. In addition, these correlations were limited to production temperatures of 100–200°C, ambient temperature of 5–25°C. As seen in Figure 6, using a fixed ambient temperature of 15°C and mass flow rate of 80 kg/s, the proposed air-cooled ORC power plant model was used to evaluate the optimal on-design net specific power output across various combinations of geofluid production temperature and binary working fluids. Note how the results closely matched the on-design GEOPHIRES ORC power plant correlations between 100°C and 200°C with small differences attributed to the use of liquid water cooling and recuperator in the GEOPHIRES correlations. Most importantly, extrapolating the GEOPHIRES correlations beyond their design range of 100–200°C resulted in significantly overestimating the net power output. This on-design comparison further verified and emphasized the necessity for using the proposed ORC power plant model and optimization framework.

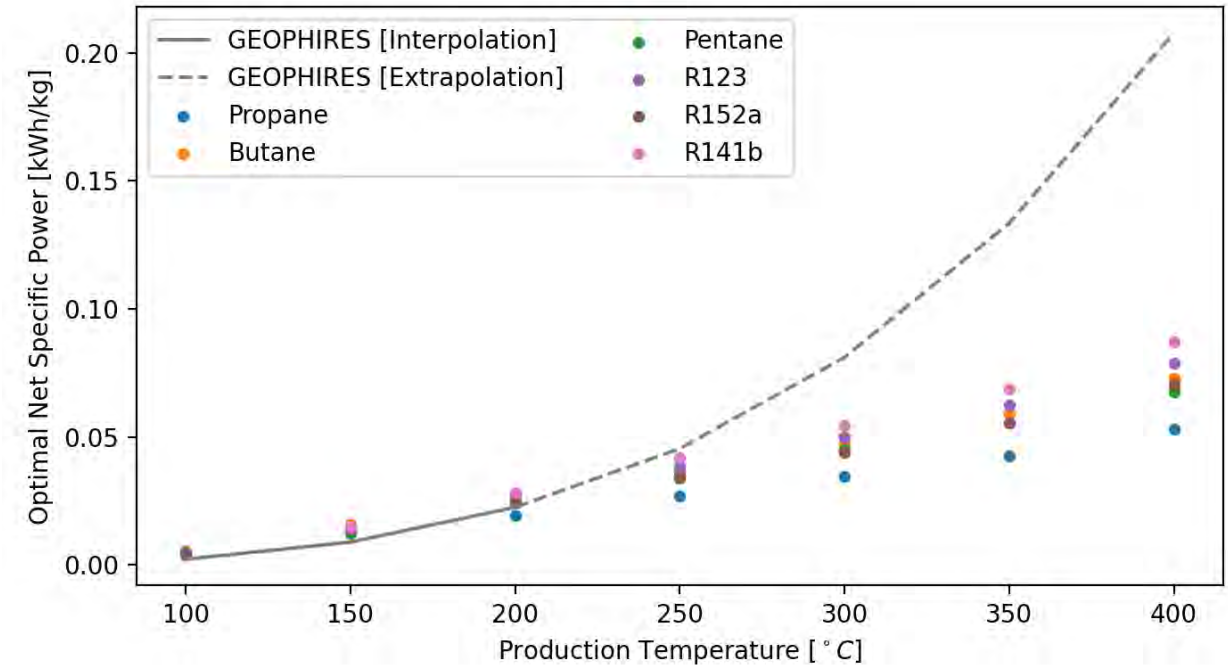

Figure 6: Comparison of the proposed ORC power plant versus the GEOPHIRES correlations in modeling the net optimal power output across a range of geofluid production temperatures and binary working fluids.

Although optimized for on-design operational conditions, the same power plant should also be reoptimized when operational conditions change. This task is called off-design optimization. In off-design settings, the optimization objective was to simultaneously maximize net power output and reinjection temperature by controlling the turbine inlet temperature, turbine inlet pressure, turbine outlet pressure, working fluid mass flow rate, and difference between working fluid temperature at the condenser outlet and ambient temperature. In addition to bound constraints, 16 inequality constraints and 7 equality constraints were used. Inequality constraints were identical to the on-design optimization setup. Equality constraints were set to ensure mass and energy balance across the system components and constrain the off-design solution to the on-design surface areas of the preheater, evaporator, and condenser. The degradation in the turbine isentropic efficiency because changing the working fluid mass flow rate off-design was also modeled as a second-degree parabola following (Beckers 2022). In this process, the nondominating sorting genetic algorithm (Deb et al. 2002) was used to optimize this dual-objective problem.

Integrating the optimization framework into this study directly would be computationally expensive. To avoid this difficulty, on- and off-design simulations were conducted across a range of conditions. Seen in Figure 6, butane was found to be among the most efficient binary fluids for the range of interest. A total of 387,475 off-design optimization runs were conducted for production temperature, ambient temperature, and geofluid mass flow rate ranges of 125–400°C, -40–40°C, and 20–200 kg/s, respectively. For each on-design setting, third-degree polynomial fits were generated to map the off-design production temperature, ambient temperature, and geofluid mass flow rates to net power output and reinjection temperature, achieving mean absolute errors of 1.5 MWe and 1.1°C, respectively. Figures 7 and 8 show the variation in net power output and reinjection temperature across off-design parameters for an on-design configuration with production temperature, ambient temperature, and geofluid mass flow rate of 150°C, 20°C, and 80

kg/s, respectively. Net power output increases with increasing off-design geofluid production temperature and mass flow rate. Meanwhile, the variation in net power output was not monotonic with ambient temperature where changing the latter off-design required significant adjustments to the mass flow rates of the working fluid; hence, the isentropic turbine efficiency would degrade accordingly. Meanwhile, Figure 8 shows operating with relatively low geofluid mass flow rates resulted in cases with excessive parasitic losses at the feed-in pump and air fan; hence, the ORC binary power plant could not be operated with positive net power output given the thermodynamic constraints of the system.

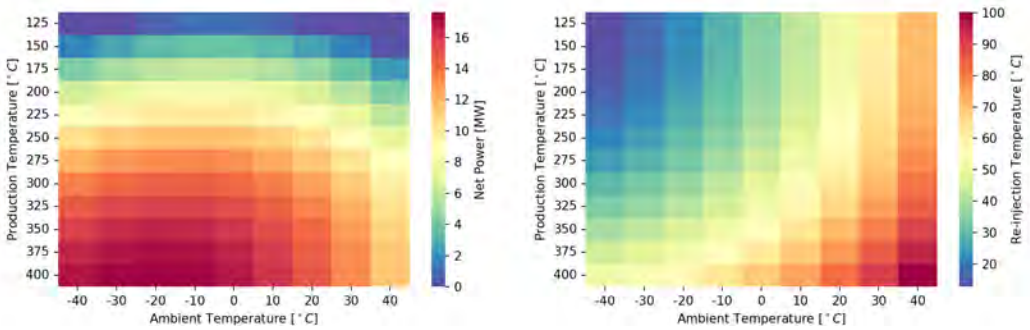

Figure 7: Off-design net power output and reinjection temperature at a constant off-design geofluid mass flow rate of 80 kg/s, optimized for an on-design configuration with production temperature, ambient temperature, and geofluid mass flow rate of 150°C, 20°C, and 80 kg/s, respectively.

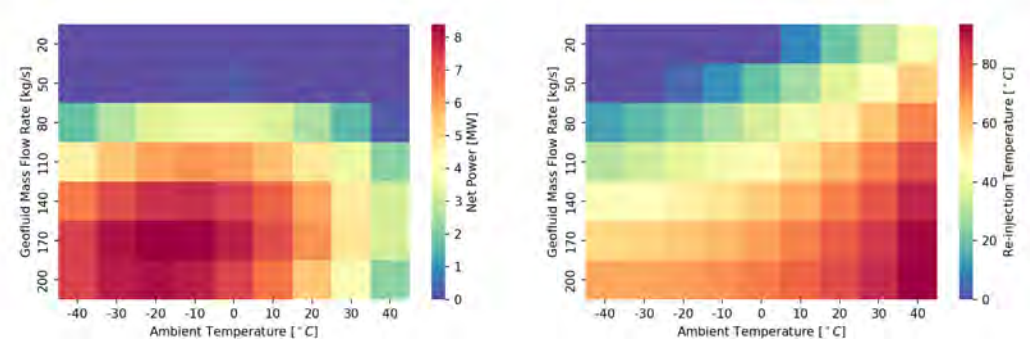

Figure 8: Off-design net power output and reinjection temperature at a constant off-design production temperature of 150°C, optimized for an on-design configuration with production temperature, ambient temperature, and geofluid mass flow rate of 150°C, 20°C, and 80 kg/s, respectively.

2.4 FGEM Model

We used the Flexible Geothermal Economics Model (FGEM) to evaluate the techno-economics of geothermal systems with various operational strategies, such as baseload and flexible operation (Aljubran and Horne 2024a). FGEM couples technical, economic, and market modules at either high- or low-frequency time frames and incorporates a diverse array of parameters, from geothermal resource and plant design to operational dispatch strategies and power market dynamics. This unique integration yields valuable insights into the viability of flexible geothermal power systems and their harmonization within the existing energy landscape.

The FGEM workflow requires several user inputs, including a configuration file, data files, and a dispatch strategy. Upon input validation, FGEM then performs sequential modeling through

distinct modules, each modeling the techno-economic aspects of specific components within the system. These modules include the subsurface reservoir, single-phase wellbore flow dynamics and heat transfer, weather patterns, power plant performance (single-flash or binary systems), energy storage units (e.g., thermal and/or electrochemical energy storage technologies), and power market dynamics (e.g., wholesale, capacity, green energy credits, PPA). For various flash and binary power plant types, FGEM captures the effect of hourly variations in ambient temperature, which govern power plant efficiency and injection fluid temperature.

We incorporated the SBT subsurface model of the multiloop well design with test location nearby the Lightning Dock geothermal power plant, New Mexico. We used hourly time stepping to emulate changes in ambient temperature, which was forecasted at hourly resolution using the Sup3rCC model (Buster et al. 2024). In addition, we integrated our newly developed off-design ORC power plant model into FGEM, which allows capturing variations in power generation and reinjection temperatures. We used FGEM's financial models to estimate project capital expenditures (CAPEX), operating expenses (OPEX), and LCOE with a discount rate of 7% and investment tax credit (ITC) of 30%. In FGEM, we adopted spatially variant transmission line costs based on $2/mile-kW (Aljubran and Horne 2024c). Various drilling rates were considered in this work to evaluate the viability of the system in consideration across scenarios.

To evaluate the value of flexibility in closed-loop systems in the absence of a PPA, it was required to attain power market forecasts. We adopted the 2022 NREL Cambium dataset for the state of New Mexico, which provides forecasts spanning 2024–2050 (Gagnon et al. 2021). Considering 30-year-lifetime geothermal power plants constructed in 2024, there was a need to extrapolate these forecasts beyond 2050. Thus, we extrapolated the Cambium market forecasts linearly based on yearly growth/decline to cover the desired period of 2024–2055. Note Cambium comes with four forecast scenarios: MidCase, MidCase95By2050, HighRECost, and LowRECost. MidCase is a BAU scenario where no nascent technologies are considered while production tax credits and ITCs from the Inflation Reduction Act do not phase out. MidCase95By2050 is like MidCase, except it considers a constraint that enforces 95% decarbonization by 2050 and includes nascent technologies. HighRECost and LowRECost are also like MidCase, except with high and low renewable energy costs, respectively. Meanwhile, because Cambium does not offer projections for the renewable energy credits (RECs) markets, we adopted publicly available forecasts provided by Energy and Environmental Economics, Inc. (E3 Inc. 2022). These are based on an open-source avoided-cost calculator developed for the California trading hub NP15. Particularly, we assumed these RECs forecasts provide reasonable projections across power markets in the United States.

3. Results and Discussion

To understand the potential benefits of flexible power generation to closed-loop systems, we considered four operational strategies: baseload, seasonal, generation maximization, and revenue maximization. In baseload operations, the production flow rates were held constant at 80 kg/s throughout the project lifetime. Seasonal dispatch involved production flow rates of 125 kg/s during July–October and 80 kg/s otherwise, with the premise of increasing generation during the summer when demand for electricity is greater. Generation maximization involved a dynamic controller that attempts to maximize power generation by changing the production mass flow rate within the range of 10–125 kg/s. Revenue maximization involved varying mass flow rates to follow the wholesale energy price of the MidCase Cambium scenario. Prices were rescaled to

resemble mass flow rates with the range of 10–125 kg/s. Meanwhile, all other time-series parameters (e.g., geothermal production temperature, ambient temperature, power plant performance, power market pricing) were allowed to change across scenarios. We considered a 7-MW ORC power plant at a cost of $2,442/kW. Based on proximity to the nearest transmission line, interconnection cost was at a rate of $130/kW. Because of the thermosiphon effect, no injection or production pumps were required. As a baseline, we assumed a drilling cost of $1,000/m; hence, the total system drilling cost was $87 million. In addition, 15% contingency cost was introduced to account for unplanned expenditure. Figure 9 shows the CAPEX breakdown, which was dominated by drilling costs because of the significant drilling lengths required to achieve the system in consideration. Optimistically, we assumed this system was associated with zero water losses to the rock in the subsurface, self-flowing with no pumping requirements, and run independently with negligeable labor needs at the wellsite and power plant. Hence, the system in consideration was assumed to have zero OPEX.

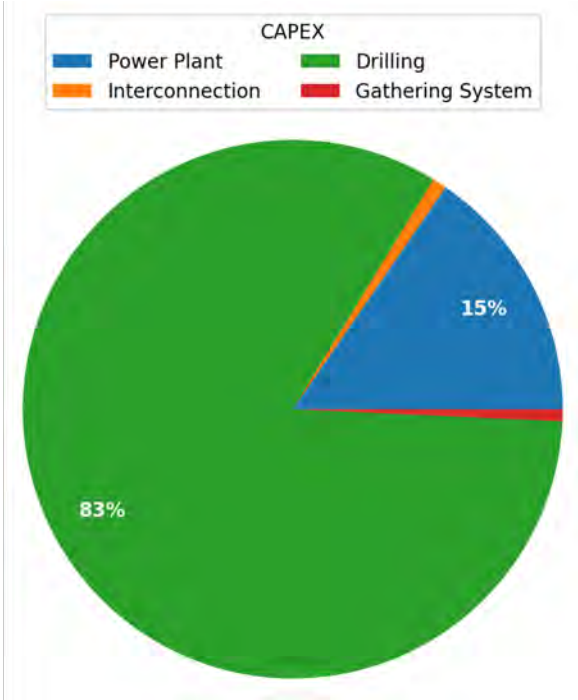

Figure 9: Breakdown of CAPEX costs for the project considered in this study.

Figure 10 shows several operational parameters throughout the 30-year project lifetime for the baseload scenario. Though the field (i.e., total) production mass flow rate was held constant, changes were driven by the diurnal and seasonal oscillations of the ambient temperature and the decline in production temperature. Following the decline in the production temperature, power generation started at the installed nameplate capacity of 7 MW and eventually converged to approximately 3 MW, on average. Reinjection temperatures started at about 100°C and eventually converged to about 50°C. Elevated ambient temperatures in the summer resulted in a drop in power generation, because of the decrease in power plant thermal efficiency, and an increase in reinjection temperatures.

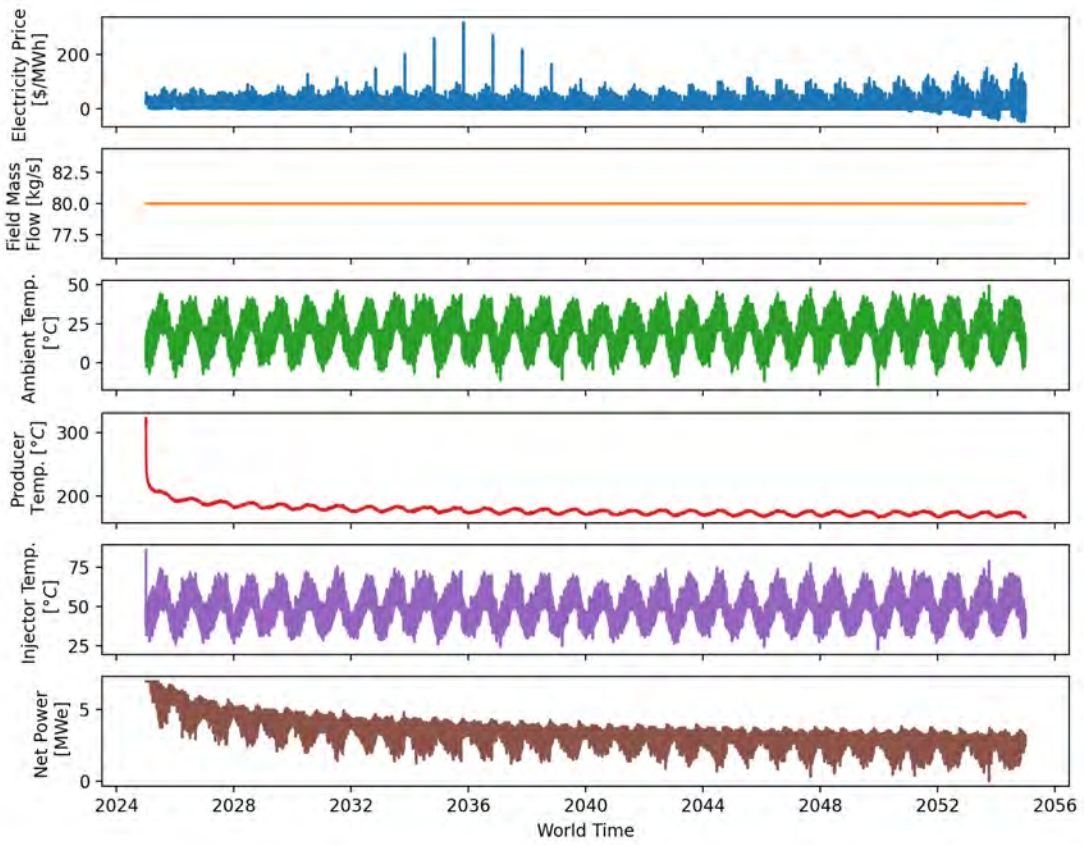

Figure 10: Operational parameters of the baseload strategy over the lifetime of the closed-loop project in consideration.

Figure 11 illustrates several operational parameters over the 30-year project lifetime operated with the seasonal dispatch strategy. The field production mass flow rate varied seasonally, which allowed the closed-loop system to recharge and achieve power output of nearly 5 MW even at later stages of the project lifetime. It is important to note the closed-loop system was rapidly responsive to changes in the production mass flow rates, allowing quick charge and discharge of conductively transferred heat. Despite these adjustments, the annual decline in production temperature is evident, starting around 300°C and steadily decreasing over the project duration. Reinjection temperatures oscillated seasonally, starting near 100°C and stabilizing around 60°C, on average—slightly higher than the baseload scenario. Net power output fluctuated more dynamically compared to the baseload scenario, reflecting the variable mass flow rates and ambient temperature impacts on the system's thermal efficiency. This strategy highlights the potential for optimizing geothermal power generation by aligning production with market demand and seasonal thermal efficiency variations.

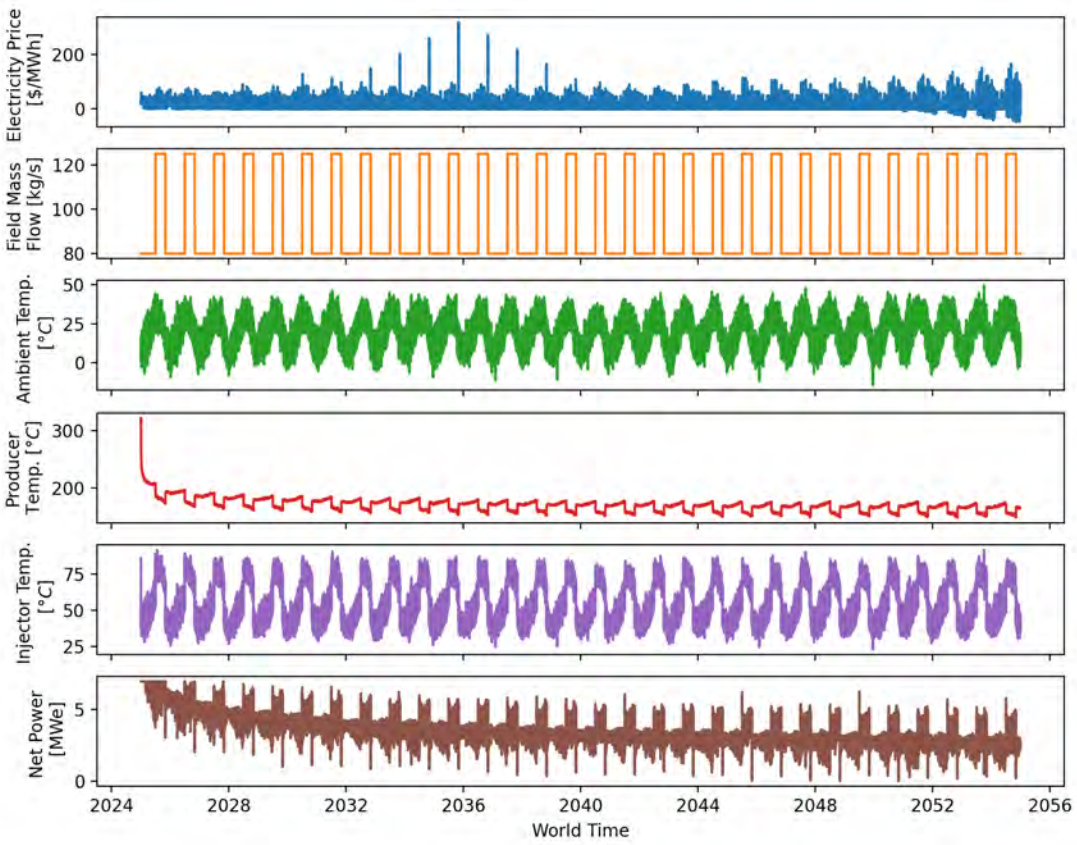

Figure 11: Operational parameters of the seasonal strategy over the lifetime of the closed-loop project in consideration.

Figure 12 shows several operational parameters over the 30-year project lifetime operated with the generation maximization dispatch strategy. During the first year of operations, when the reservoir temperature was still high, this strategy elected to reduce the mass flow rate while still operating at the nameplate power capacity of 7 MW. As the geothermal production temperature declined, the dynamic controller elected to increase the mass flow rates to the maximum allowable value of 125 kg/s with the objective of maintaining the power plant output at its nameplate capacity. However, this was found to have a counterproductive effect where higher mass flow rates would conductively cause the subsurface resource temperature to deplete even further with a quick response time. With 125 kg/s flow rates, the reservoir temperature stabilized at around 180°C at quasi-steady conditions. Reinjection temperatures oscillate seasonally, starting near 100°C and stabilizing around 70°C, on average, slightly higher than the baseload and seasonal scenarios. Net power output fluctuated around an average of 4 MW.

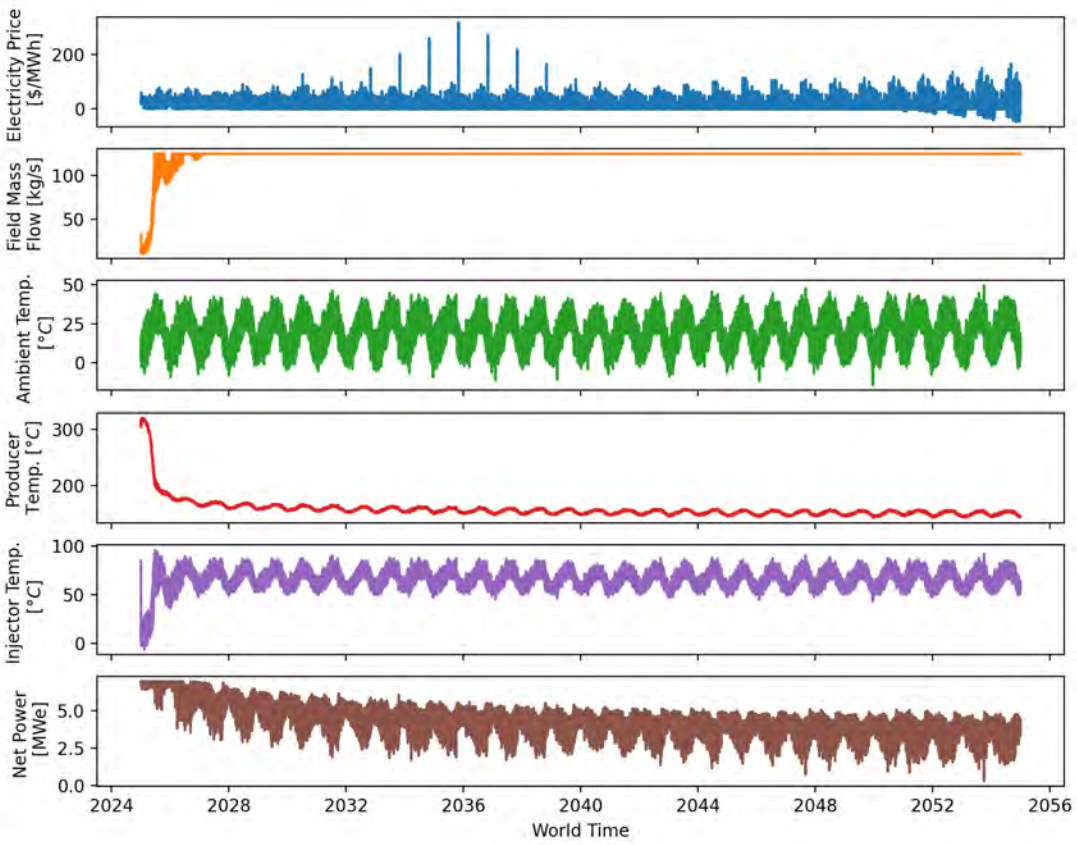

Figure 12: Operational parameters of the generation maximization strategy over the lifetime of the closed-loop project in consideration.

Figure 13 shows several operational parameters over the first year of operations under the revenue maximization dispatch strategy. Production mass flow rates had the same frequency as the wholesale energy market price while being limited to a range of 80–125 kg/s. This had the benefit of boosting generation during hours of the year when the wholesale market energy prices were higher. This approach resulted in a quasi-steady reservoir temperature of around 210°C and reinjection temperature of nearly 50°C, on average. This approach allowed the net power output to oscillate between near-zero and the power plant nameplate capacity of 7 MW even at latter stages of the project lifetime.

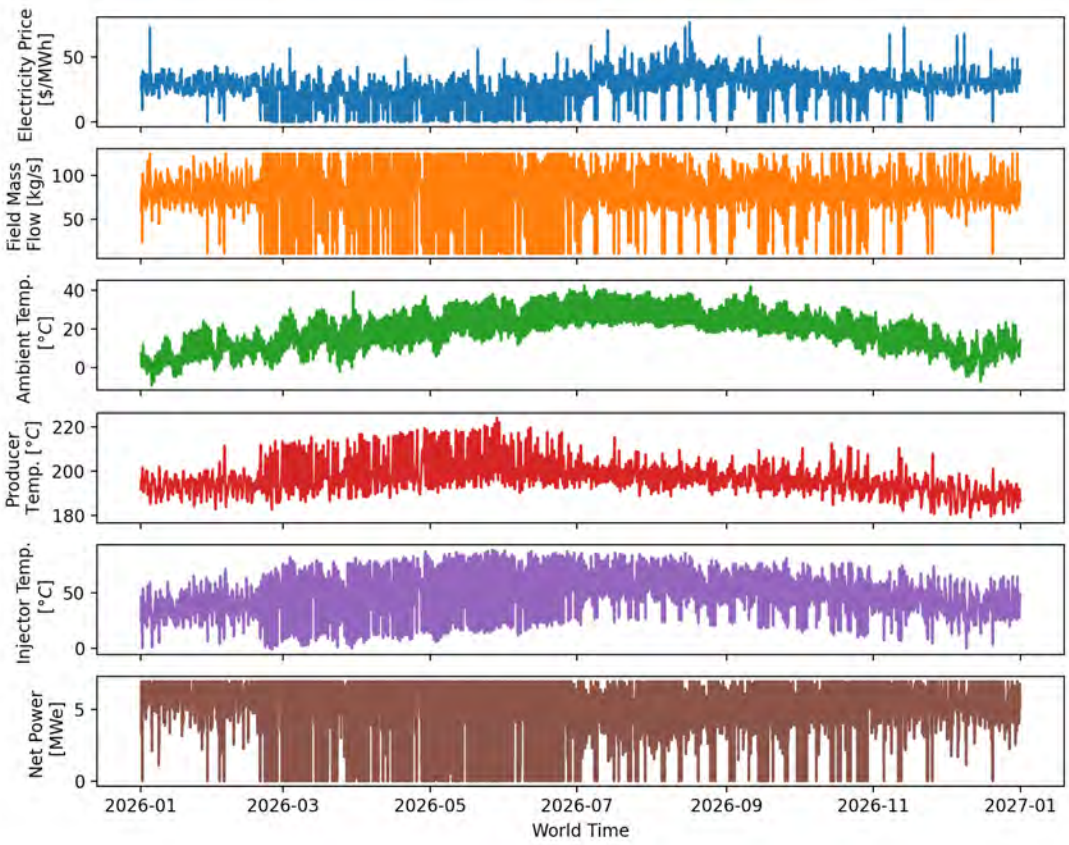

Figure 13: Operational parameters of the revenue maximization strategy over the first year of the closed-loop project in consideration. We chose to zoom in on the first year of operations for visual convenience.

Figure 14 compares the economic performance of the different strategies in terms of LCOE and return on investment (ROI). ROI here is defined as project lifetime net income divided by upfront capital costs. Baseload, seasonal, generation maximization, and revenue maximization had LCOE of $191, $180, $155, and $216/MWh, respectively. Both generation maximization and seasonal dispatch resulted in reduced LCOE compared to the BAU baseload strategy because they were associated with greater net power output, on average, as seen in Figure 15. However, despite the significant improvement in LCOE, at $1,000/m drilling costs, flexible generation still had LCOEs significantly higher than the 2035 target LCOE of $45/MWh set by DOE for geothermal projects. In addition, all these projects were unprofitable (ROI < 100%) when operated under the MidCase scenario of the 2022 Cambium forecasts. Nevertheless, we observed all flexible generation strategies yielded improved ROI, with revenue maximization ranking on top.

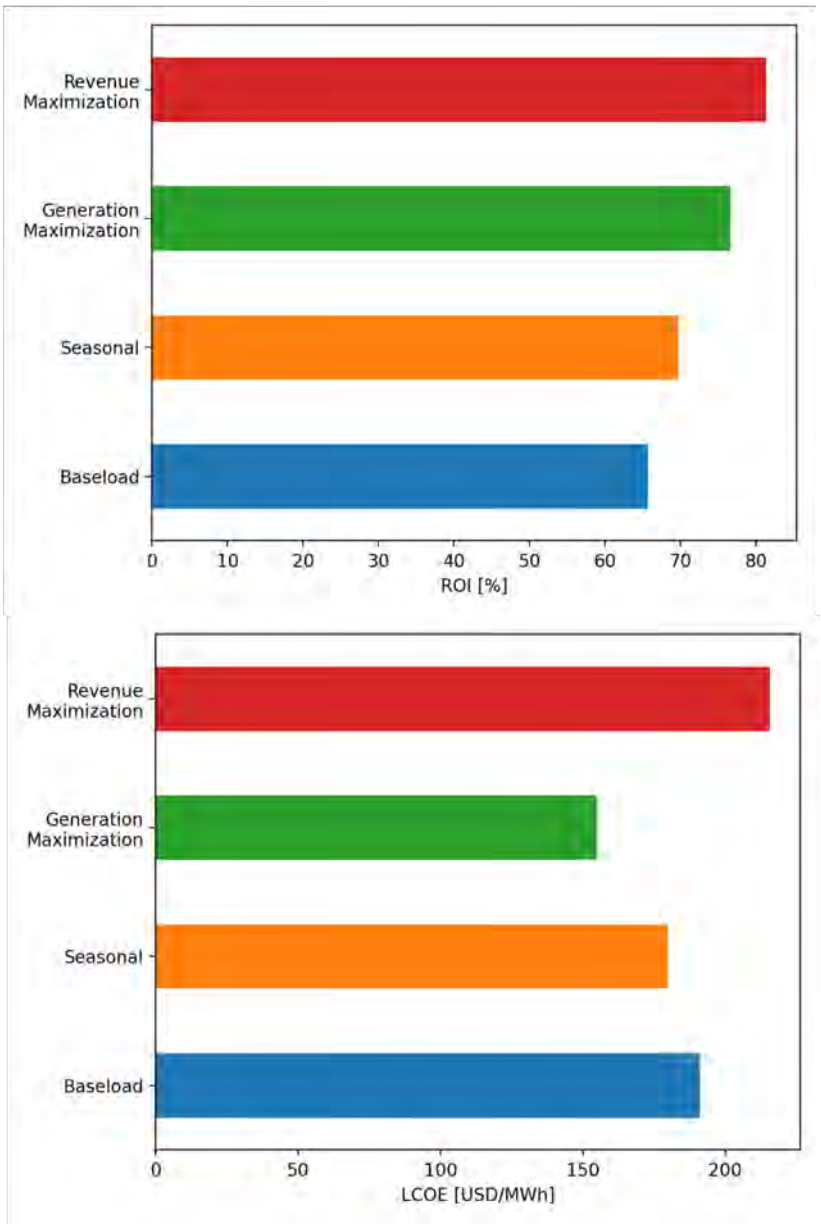

Figure 14: Bar charts showing ROI (top) and LCOE (bottom) across the different dispatch strategies of the closed-loop system in consideration.

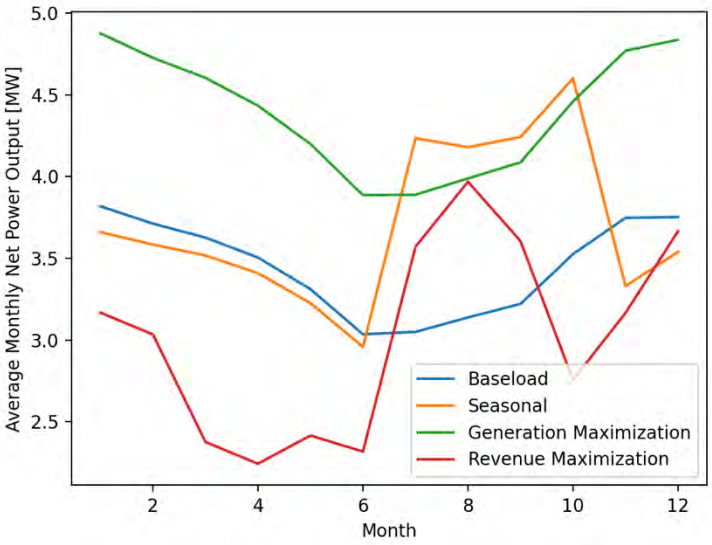

Figure 15: Average monthly net power output under different operational strategies of the closed-loop system in consideration.

With a drilling cost of $1,000/m and discount rate of 7%, closed-loop geothermal systems with flexible operation have high LCOE in the range of $150–220/MWh (Figure 14). We explored the impact of drilling and discount rates on LCOE in the case of baseload and generation maximization dispatch operations (Figure 16). Under the highly optimistic scenario of $200/m drilling cost and 5% discount rate, operating the closed-loop system in consideration under baseload and generation maximization dispatch strategies resulted in LCOE values of $60 and $49/MWh, respectively.

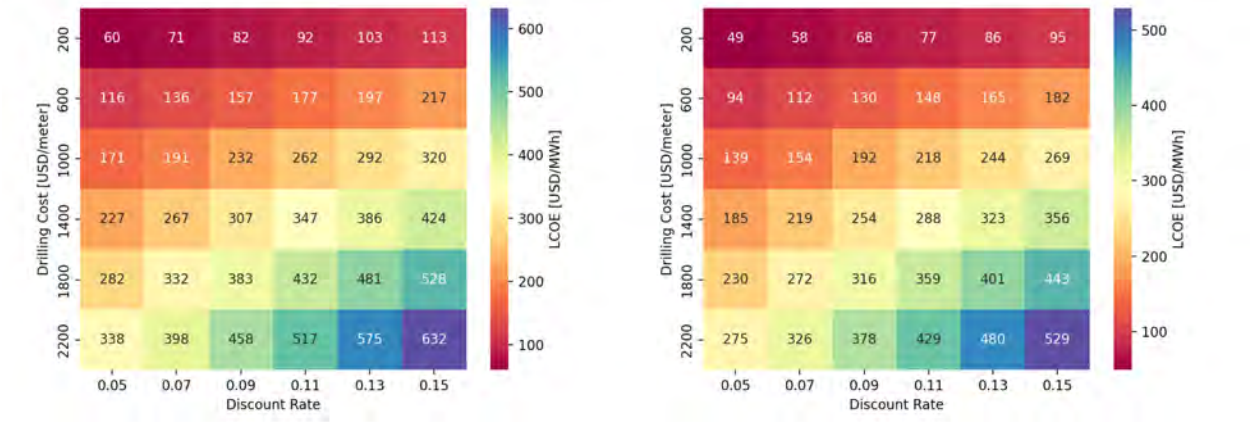

Figure 16: Sensitivity analysis of LCOE with respect to drilling and discount rates of the baseload (left) and generation maximization (right) dispatch strategies.

4. Conclusions

In this project, we coupled FGEM with the SBT model to investigate the techno-economic performance of the flexible operation of closed-loop geothermal systems. We modeled a multiloop system with 12 lateral passes, 7-km vertical depth and total drilling length of approximately 87

km. The geothermal gradient was set to 60°C/km, and hourly ambient temperature conditions were assumed for New Mexico based on the Sup3rCC future weather dataset. Future market electricity prices for New Mexico were based on the Cambium dataset.

We simulated four scenarios with hourly time stepping: 1) baseload scenario with nominal flow rate of 80 kg/s, 2) seasonal dispatch scenario with summer flow rate of 125 kg/s and 80 kg/s the rest of the year, 3) generation maximization scenario where a dynamic controller attempts to maximize net power output by adjusting the flow rate (within a range of 10–125 kg/s), and 4) revenue maximization scenario where a dynamic controller adjusts flow rate (within a range of 10–125 kg/s) to maximize net revenue considering Cambium MidCase wholesale electricity prices.

Considering $1,000/m drilling cost and 7% discount rate, the maximum generation scenario resulted in the lowest LCOE of approximately $150/MWh. The highest ROI was for the revenue maximization scenario, with an ROI of 80% (based on lifetime income and cost). Obtaining LCOE below $70/MWh requires a very low drilling cost and low discount rate. For, example, when drilling at $200/m (about 5 times lower than current drilling costs) and with a discount rate of 5%, the LCOE for the base case scenario is $60/MWh and for the generation maximization scenario is $49/MWh.

Keywords

Advanced Geothermal Systems, AGS, VIT, Closed loop, Insulated tubing, k value

ABSTRACT

Vacuum Insulated Tubulars (VITs) have emerged as a promising technology for enhancing the efficiency of Advanced Geothermal Systems (AGS). By significantly reducing heat transfer between the cold fluid injected through the annulus and the hot fluid produced through the VIT, these vacuum-insulated designs ensure minimal heat loss from the geothermal fluid as it travels from the reservoir to the surface, thereby maximizing energy extraction efficiency. The performance of VITs is evaluated using the K-value metric, where lower K-values indicate superior insulation properties and reduced heat transfer through the tubular walls.

Accurately determining the overall K-values of VITs involves addressing numerous uncertainties stemming from complex heat transfer mechanisms influenced by factors such as gas composition within the vacuum space, material properties, and construction quality. Experimental testing using an R&D VIT test bench allows for comprehensive assessment under various conditions by simulating expected downhole environments with varying temperatures, flow rates, and working fluids. This research outlines laboratory investigations conducted to analyze the K-values of two joints of VITs in a controlled geothermal setup, aiming to optimize VIT design for AGS applications and ultimately enhance energy efficiency and cost-effectiveness in geothermal systems.

1. Introduction

The concept of vacuum insulated tubulars (VIT) in the oil and gas industry dates to the 1980s, driven by the need to enhance thermal efficiency in the production and transportation of hydrocarbons, particularly in challenging environments such as the deepwater Gulf of Mexico, Arctic regions, and areas with permafrost. During this period, the industry began to recognize the potential benefits of VITs for thermal insulation. The initial applications were primarily in offshore drilling and production, where maintaining the temperature of the produced fluids was crucial to prevent hydrate formation and wax deposition. These early VITs were essentially just double-

walled pipes with a vacuum in the annular space, providing a barrier to conductive and convective heat transfer.

During the 1990s, significant advancements in VIT technology were driven by the increasing complexity of oil and gas extraction projects. Improved manufacturing techniques and materials enhanced the durability and efficiency of VITs. The VIT offering described in this paper introduced several innovations, including the use of multilayer insulation (MLI) within the vacuum space and advanced getters to maintain the vacuum over extended periods. These improvements enabled more extensive use in high-temperature and high-pressure (HTHP) environments.

In the 2000s, the application of VITs expanded beyond offshore drilling to onshore and Arctic operations [5]. The industry began to focus on optimizing the design and installation of VITs to maximize thermal performance while minimizing costs. Computational modeling and simulation tools became essential in designing VIT systems, predicting thermal behavior, and optimizing the insulation performance for specific field conditions. The use of VITs in steam-assisted gravity drainage (SAGD) operations for heavy oil recovery became particularly prominent. VITs helped maintain the steam temperature in injection wells, improving the efficiency of the SAGD process and reducing energy consumption.

By the 2010s, VIT technology had matured, with several oil and gas companies adopting standardized VIT designs for various applications. The focus shifted towards enhancing the reliability and ease of installation of VITs. Modular and pre-fabricated VIT systems became more prevalent, significantly reducing installation time and costs. Additionally, advancements in non-destructive testing (NDT) techniques enabled better quality control during both the manufacturing and installation processes.

The utilization of VITs in geothermal applications, particularly in AGS, leverages these decades of technological evolution to address specific challenges associated with heat transfer and energy efficiency. Experimental VIT testing plays a critical role in this context by enabling engineers to simulate expected downhole environments and assess performance under varying conditions. The R&D VIT test bench, for instance, allows for the measurement of K-values not only under ambient conditions but also across a range of temperatures and flow rates, providing a more accurate and comprehensive understanding of system performance. This capability is crucial for refining VIT designs to meet specific performance goals, whether maximizing production temperatures and heat extraction or optimizing the levelized cost of energy (LCOE) and installation costs.

Addressing the uncertainties in accurately determining K-values necessitates comprehensive modeling approaches, rigorous experimental validation, and ongoing refinement of testing methodologies. Factors such as gas composition within the vacuum space, material properties, construction quality, and dynamic operating conditions must be meticulously considered to ensure reliable K-value determinations. Through such dedicated research efforts, the efficiency and performance of closed-loop geothermal systems can be significantly optimized, contributing to the sustainable development and utilization of geothermal energy resources.

This paper aims to outline laboratory research conducted to analyze the k-values of two joints of a VIT in a geothermal setup within a lab environment. Both cold and hot fluids will flow through the VIT system in a coaxial design to mimic an AGS closed loop system, with temperatures

measured throughout the system to model and determine the K-values. This VIT test bench used for this testing has two main advantages:

1. K-values can be measured not only under ambient conditions but also at various temperatures and flow rates, allowing for greater accuracy of the entire system.

2. The test bench enables the assessment of new products (such as connections and insulators) in simulated working conditions during the design phase, providing a more accurate prediction of thermal performance and overall, well efficiency.

In conclusion, the investigation into vacuum insulated tubulars (VITs) for Advanced Geothermal Systems (AGS) represents a crucial step toward realizing the full potential of geothermal energy. The use of VITs in geothermal wells offers significant benefits, including reduced heat loss and enhanced energy extraction efficiency. Accurately determining K-values, not only through general experimental data but through project-specific testing, is essential for optimizing VIT design, as it directly impacts thermal performance, energy efficiency, and cost-effectiveness. The complexities and uncertainties in determining K-values highlight the need for rigorous research and experimentation. By addressing these challenges through comprehensive modeling, experimental validation, and refinement of testing methodologies, we can ensure reliable K-value determination and optimize the efficiency and performance of closed-loop geothermal systems. This paper underscores the importance of ongoing research efforts aimed at analyzing and improving the thermal properties of VITs, ultimately contributing to the sustainable development of geothermal energy resources.

2. VIT and Geothermal Applications

High quality Vacuum Insulated Tubulars (VITs) play a crucial role in coaxial closed-loop geothermal systems by maintaining the thermal integrity of the geothermal fluid as it circulates between the surface and the subsurface. In these systems, VITs are used to minimize heat loss during the transport of heated fluid from deep underground reservoirs to the surface. The vacuum insulation within the tubulars significantly reduces conductive and convective heat transfer, ensuring that the fluid retains its high temperature throughout the journey from the subsurface to the surface. This efficiency is vital for maximizing the energy extraction from the geothermal source and improving the overall system performance.

Moreover, VITs contribute to the structural integrity and reliability of coaxial closed-loop geothermal systems. These tubulars are designed to withstand the high-pressure and high-temperature conditions typical of geothermal environments. Their durable construction and advanced insulation properties allow for consistent and long-term operation, reducing the need for frequent maintenance or replacement. Additionally, the use of VITs in these systems helps to prevent thermal degradation of the surrounding geological formations, further enhancing the sustainability and environmental friendliness of geothermal energy extraction. Overall, VITs are integral to the success of coaxial closed-loop geothermal systems, offering both thermal efficiency and durability.

2.1 VIT Performance Parameters and Challenges for Geothermal Applications

VITs in geothermal applications must maintain their insulating properties over long periods, often a 30-year time frame, without significant degradation. This involves using materials and construction methods that ensure long-term vacuum stability and resistance to corrosion from geothermal fluids.

Over time, maintaining the vacuum within VITs can be difficult due to potential leaks and material outgassing. Even small breaches can lead to a loss of vacuum and reduced insulation efficiency, necessitating regular monitoring and maintenance. The quality of VIT manufacturing and the use of highly optimized materials and processes significantly extend the life expectancy of vacuums in severe environments.

In summary, while vacuum insulated tubulars offer significant performance benefits for geothermal applications, they also present several challenges that need to be addressed. Overcoming these challenges requires advances in materials science, manufacturing techniques, and installation practices to ensure the long-term viability and efficiency of VITs in geothermal energy production.

3. VIT k-value calculation

The overall calculation of thermal conductivity (k value) for VITs involves the combination of several factors. The thermal conductivity for most of the pipe, denoted as k_{pipe}, is primarily controlled by the vacuum. This value, which is measured during manufacturing, typically ranges between 0.004 and 0.006 W/m·K, reflecting the high insulation performance of the vacuum annulus within the pipe body. The most critical factor for overall VIT performance, however, is the thermal conductivity of the connections on the extremity of the pipe, referred to as $k_{connection}$ and illustrated in Figure 1 below. It is estimated that heat losses in the connection are responsible for over 75% of the overall heat loss of the entire VIT string [4]. One of the objectives of this testing program will be to confirm the overall impact of the connection on VIT thermal performance.

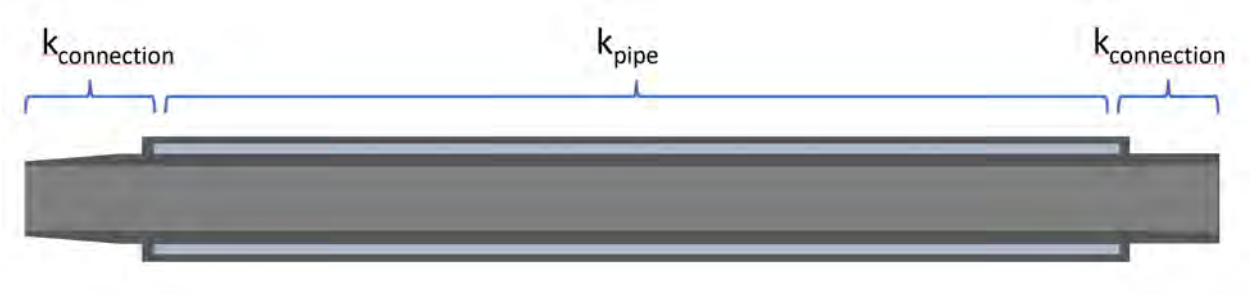

Figure 1: Thermal conductivities (k values) of VIT

During VIT production, the vacuum is tested and confirmed, but the overall thermal performance of the entire joint is not measured. There are heat losses at the extremities of the pipe where there is no vacuum, and these sections heavily contribute to the overall thermal performance of the VIT. There are multiple effects to be considered:

- Conduction between inner and outer pipe at weld joint
- Flow pattern convective effects at the change in OD profile [2]
- Non metallic insulating sleeves to lower heat transfer from connection

Figure 2: Thermal conductivities (k values) of VIT in made-up condition

3.1 VIT k-value modeling

When assessing geothermal applications for VIT, current state-of-the-art analysis is with Wellcat™ software, an oil and gas standard software developed by Halliburton. Wellcat™ is a very capable tool, and provides a basic option for VIT modeling. However, the software has limitations for inputs of k-value and the impact of k-value with flowrate and flow state.

Vallourec has developed an in-house, web-based program specifically aimed at coaxial closed loop analysis. This program provides accurate analysis of fluid temperatures for a multitude of input variables (well dimensions, temperature gradients, flow rates, fluid types, formation heat transfer, etc.). The figure below shows an example of the temperature outputs, and also highlights the importance of insulated tubing in closed loop systems.

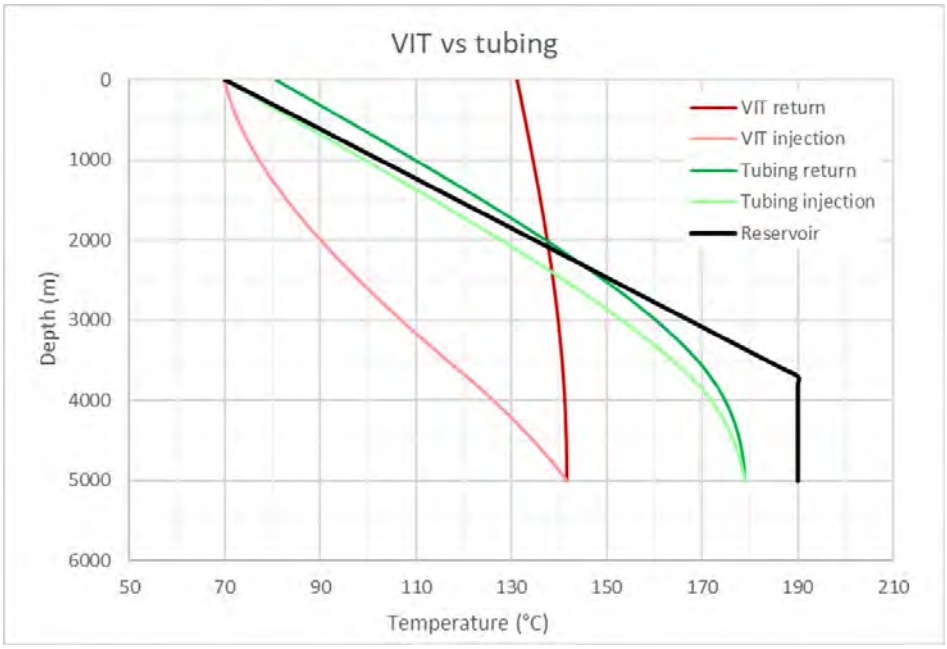

Figure 3: Example of closed loop results, VIT (red) vs non VIT (green) tubing in a closed loop system

In this example of a closed loop system, the use of standard non-insulated tubing (represented by the green lines in Figure 3) shows only a marginal heating of the production fluid from surface injection to return. By comparison, the use of vacuum insulated tubing (in red) shows how much heat is retained on the return from bottomhole to surface, allowing for more thermal energy potential [3]. For easier comparison, all variables between the two situations are fixed (flowrate, well geometry, etc).

All computational software benefits from having field and/or experimental data to corroborate the calculations. The aim of the VIT test bench will be to improve the predictive accuracy of modeling software and allow for subsurface and surface equipment optimization.

4. Test bench setup, parameters

The fundamental principle of this VIT test bench is straightforward: to accurately measure the thermal efficiency of an entire VIT joint. This is done by enclosing the VIT joint within a casing, circulating hot oil inside the VIT, and measuring the heat transferred to the water flowing over the VIT.

The VIT test bench comprises a full-length R3 (~40ft) 4.5” x 3.5” L80 VIT pipe. To test heat transfer within the VIT, hot oil is circulated inside the inner pipe annulus. An external oil reservoir is wrapped with an induction heater and then the oil is pumped into the VIT. To improve the even distribution of heat to the inner diameter (ID) of the VIT, oil flows along a rotating shaft with impellers, rather than simply flowing through the system. The goal is to achieve a steady-state temperature where the heated oil flows consistently, and the inlet and outlet temperatures of the oil are stable. Additionally, the oil temperatures are measured at multiple points within the system to ensure proper temperature distribution.

To measure the thermal conductivity of the VIT, water is circulated in the annular space between the VIT and the outer casing. Upon entering and exiting the system, the water temperature is precisely measured. The temperature delta represents the amount of heat loss from the VIT, and is calculated.

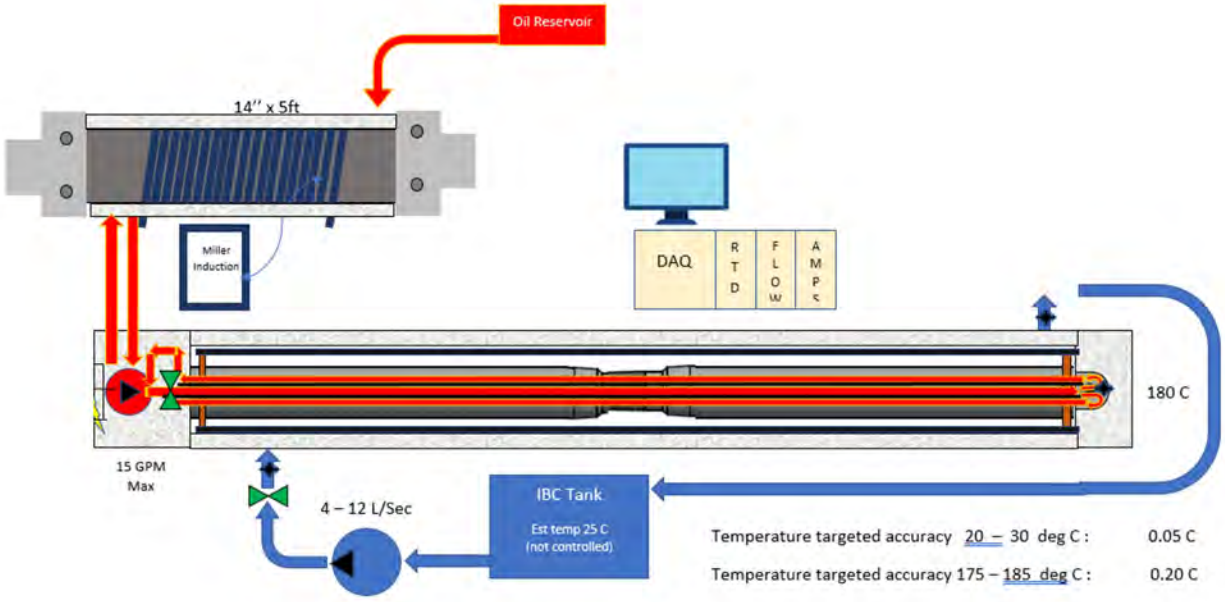

Figure 4: VIT test bench schematic

The VIT is placed inside an outer casing, composed of 7" x 0.540" pipe. Therefore, the annular space for water flow around the VIT is calculated as follows:

$$Area = \frac{\pi}{4}(D_o^2\text{-}D_i^2)$$

$$D_o = 7.0" - 2*0.54 = 5.92"$$

$$D_i = 4.50"$$

$$= \frac{\pi}{4}(D_o^2\text{-}D_i^2) = 11.62in^2$$

with a radial gap of:

$$D_o - D_i = 5.92" - 4.50" = {}^{1.42"}/_{2} = 0.71"$$

The oil is circulated inside the 4.5" x 3.5" VIT, with an ID of 2.992", equating to an internal area of:

$$Area = \frac{\pi}{4}D_{\square}^2 = 7.03 \text{ in}^2$$

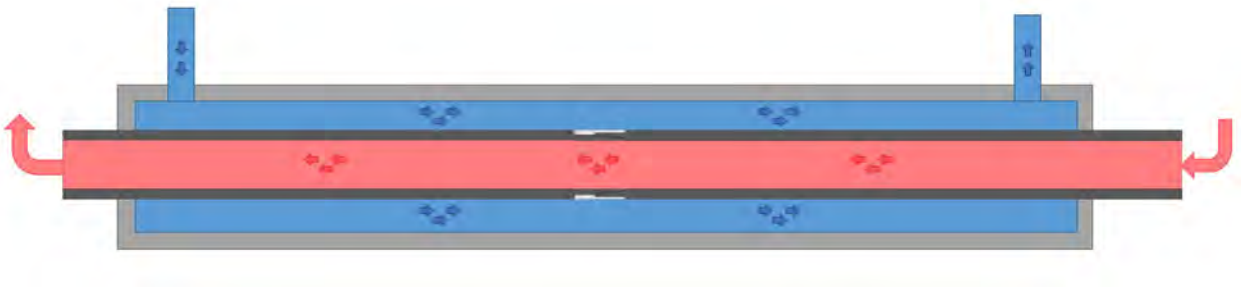

Figure 5: Flow direction for VIT test bench

To verify the performance of the VIT, the heat transfer from the inner medium to the outer medium is measured. The outer fluid flows in the opposite, coaxial direction to the inner fluid, and the flow rate can be precisely adjusted to accurately emulate downhole conditions.

5. Initial testing results

Tests were initially conducted to establish a baseline for a common VIT size with available field data. A 4.5” x 3.5” VIT with a premium thread was selected for this initial test.

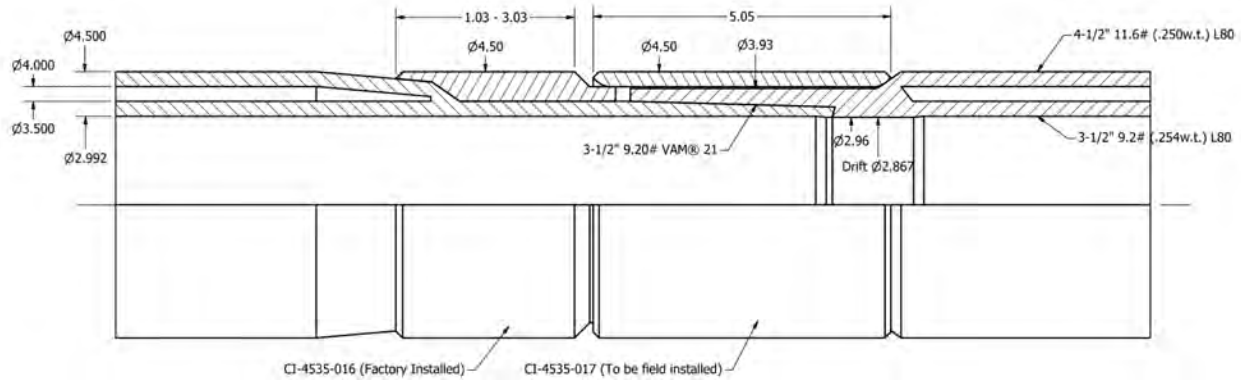

Figure 6: 4.5” x 3.5” VIT with premium threads

The testing program includes tests with the annular fluid flow at four different flow rates (20 gpm, 30 gpm, 40 gpm, and 50 gpm). The flow rate is adjusted after the working fluid stabilized at a set temperature of 180°C. The temperature of the annular fluid (water) was measured at the system's inlet and outlet over a period of 2 hours. After this testing period, the flow rate was adjusted, the oil temperature was re-stabilized, and the test was repeated at the next flow rate. This procedure was repeated multiple times to ensure data consistency.

As shown in the graph below, the temperature difference between the inlet and outlet decreases as the flow rate increases. This predictable trend occurs because higher flow rates allow less time for the fluid to interact with the hotter elements of the VIT. Additionally, the consistent temperature of the VIT working fluid oil (shown in Figure 8) demonstrates that the VIT is in a steady-state

condition. Thus, any change in the temperature of the annular water fluid is due to heat transfer, not external sources.

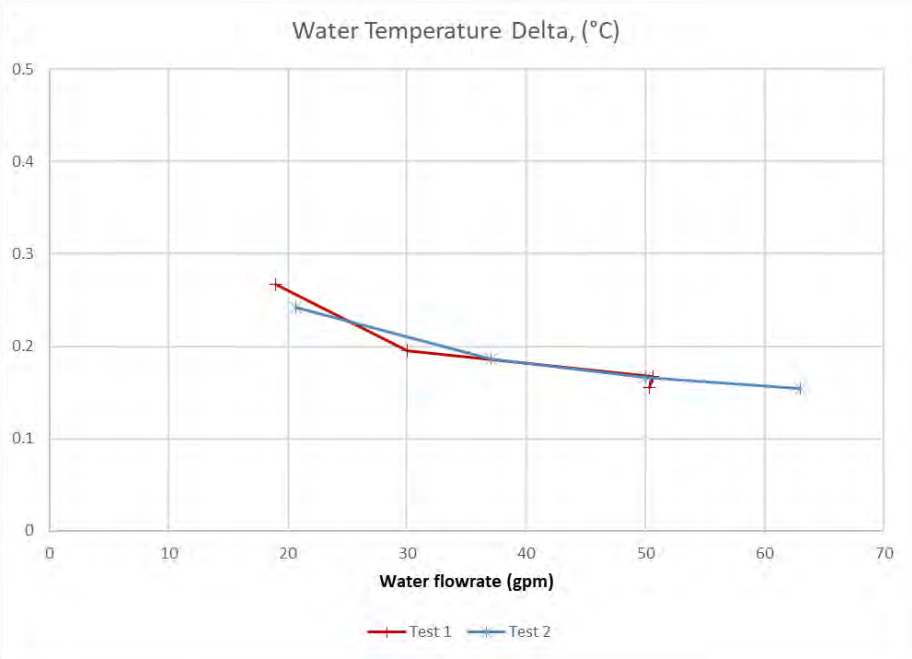

Figure 7: Test results with coupling insulator

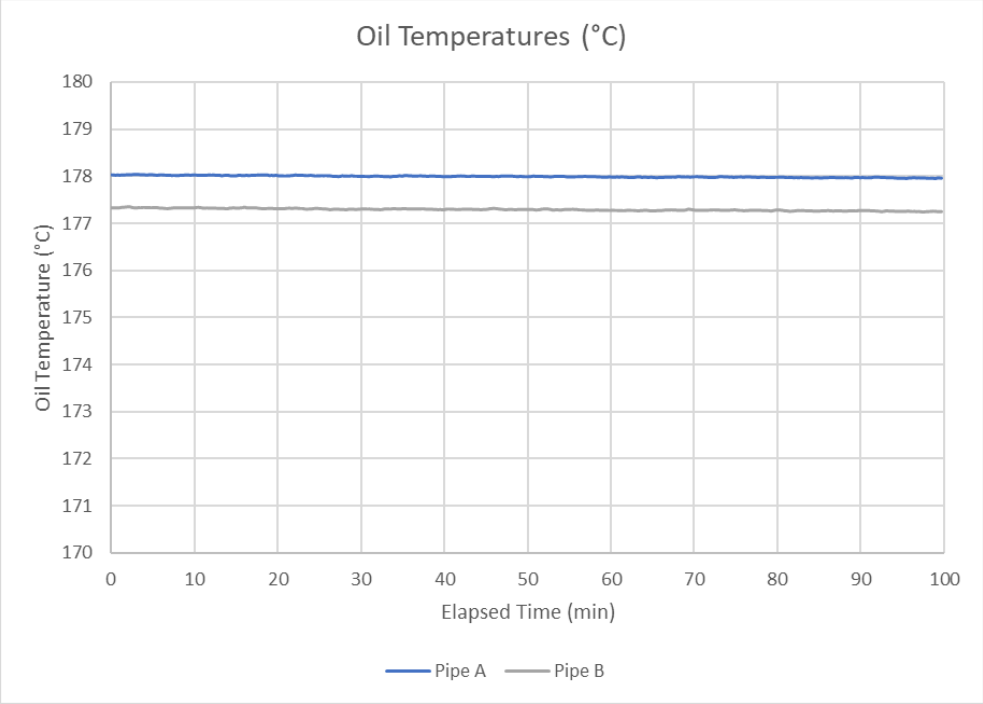

Figure 8: Example of oil temperature measured inside the VIT for the duration of a test (20gpm with insulator)

To calculate the k-value based on these results, the temperature differential between the inlet and outlet temperature of the water is compared to the stabilized oil temperature inside the inner pipe of the VIT.

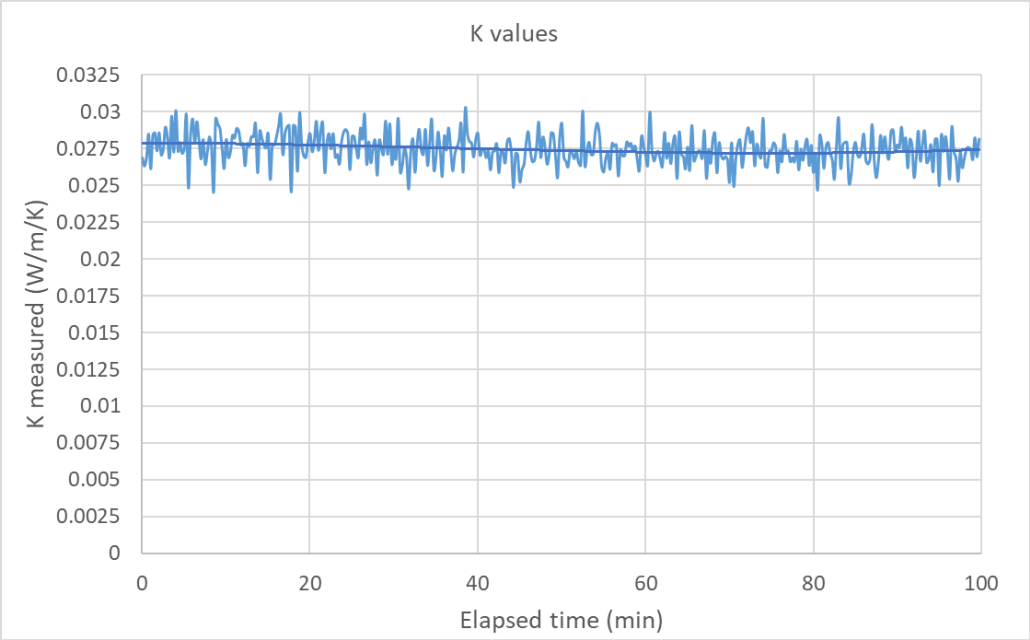

Figure 9: K-value result stability over duration of test (50gpm test with insulator)

As shown in the chart below, the k value is calculated and plotted for the multiple tests at each flowrate. The proximity of these k values indicate that the 1) VIT test bench is consistent and repeatable and 2) the k value slightly changes with an increase of flow rate.

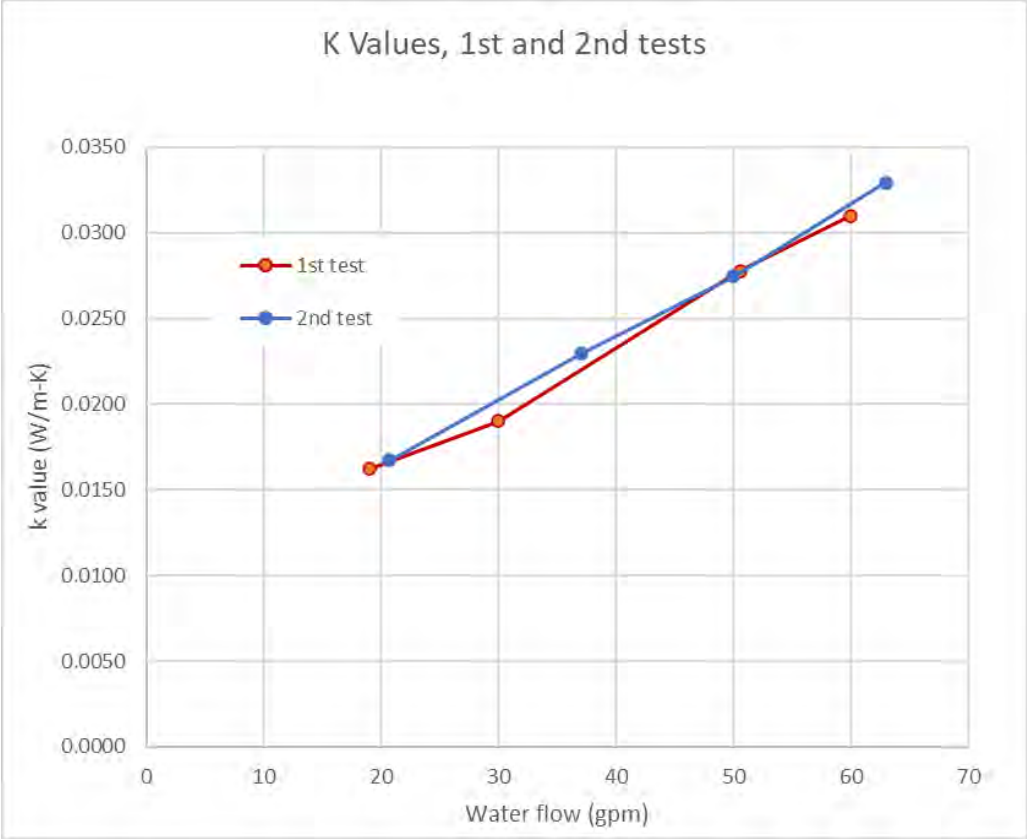

Figure 10: K-value results at different flow rates

6. Additional testing

Following this initial testing condition, additional tests are ongoing to further correlate the testing data to known, measured data.

The initial test configuration featured a 4.5” x 3.5” VIT with a connection insulator, tested to 4 different water flowrates. The next planned test will repeat the same temperatures and flowrates with the same VIT, but the coupling insulator surrounding the connection will be removed. This test (denoted in Figure 11 as “Test 2”) will determine the increase in thermal conductivity with the removal of the coupling insulator. The final test in the program (Test 3) will repeat the same flowrates with the same configuration of VIT, but will only include the vacuumed pipe without a connection. This test will provide a baseline and comparison to the thermal conductivity of the vacuumed pipe, which is directly measured during the manufacturing process.

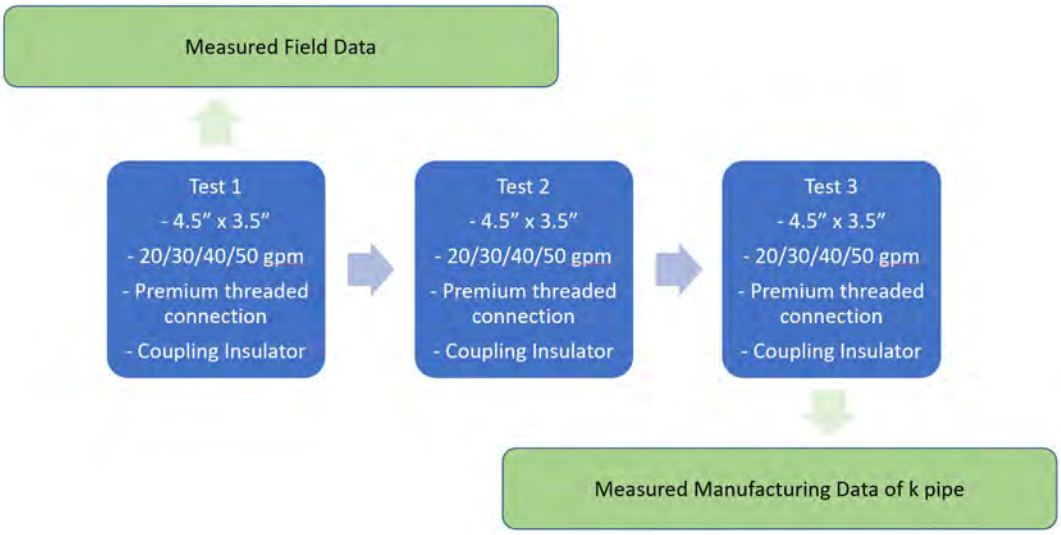

Figure 11: Test program details and objectives

7. Data application

The testing conducted with the VIT test bench provides significantly more accurate k-value measurements of VIT systems, better simulating downhole environments. Moreover, the results have been used to enhance the accuracy of VIT and geothermal predictive modeling. Upcoming field tests, scheduled for completion by the end of 2024, will allow for further comparison and fine-tuning, providing more precise simulations for potential geothermal applications.

This improvement in accuracy also allows for better VIT optimization in wells, which can be achieved in several ways. Firstly, the overall string length can be adjusted to ensure the optimum surface temperature for either heat generation or direct use. The increased confidence in VIT performance reduces the margin of error, thereby minimizing resource wastage. Additionally, improved k-value accuracy and VIT predictive modeling can identify new sectors of the geothermal market that could benefit from insulated pipes. The performance model is directly linked to techno-economic analysis, offering more precise and appealing LCOE and ROI figures for potential users. The VIT test bench enables dynamic k-value testing, verifying thermal conductivity at various temperatures and flow rates, a first for the industry. This further enhances the accuracy of predictive modeling and optimization under specific operating conditions.

8. Next steps

Following the benchmark testing performed on the 4.5" x 3.5" premium connection VIT for proper calibration and tuning, the VIT test bench has numerous applications. Firstly, the bench can be adapted to emulate specific user conditions, enabling physical validation and qualification testing of VITs before field deployment. This not only provides end users with confidence in the product's performance but also enhances the accuracy of predictive modeling.

Additional testing is planned for Vallourec's super-hot rock VIT connection, designed for use at temperatures up to 400°C. This connection offers premium insulative properties without the need for a thermoplastic (PTFE) coupling insulator, which currently lowers the overall temperature rating to 250°C.

Closed-loop geothermal, advanced geothermal systems, next-generation geothermal, reservoir simulations, reservoir convection

ABSTRACT

Over the past few years, advancements in closed-loop geothermal systems (CLGS), also called advanced geothermal systems (AGS), have sparked a renewed interest in these types of designs. CLGS have certain advantages over traditional and enhanced geothermal systems (EGS), including not requiring in-situ reservoir permeability, conservation of the circulating fluid, and allowing for different fluids, including working fluids directly driving a turbine at the surface. CLGS may be attractive in environments where water resources are limited, rock contaminants must be avoided, and stimulation treatments are not available (e.g., due to regulatory or technical reasons). Despite these advantages, CLGS have some challenges, including limited surface area for heat transfer and requiring long wellbores and laterals to obtain multi-MW output in conduction-only reservoirs.

CLGS have been investigated in conduction-only systems. In this paper, we explore the impact of both forced and natural convection on the levels of heat extraction with a CLGS deployed in a hot wet rock reservoir. We bound potential benefits of convection by investigating liquid reservoirs over a range of natural and forced convective coefficients. Additionally, we investigate the effects of permeability, porosity, and geothermal temperature gradient in the reservoir on CLGS outputs. Reservoir simulations indicate that reservoir permeabilities of at least ~100 mD are required for natural convection to increase the heat output with respect to a conduction-only scenario. The

†This work was authored in part by the National Renewable Energy Laboratory, operated by Alliance for Sustainable Energy, LLC, for the U.S. Department of Energy (DOE) under Contract No. DE-AC36-08GO28308.

impact increases with increasing reservoir temperature. When subject to a forced convection flow field, Darcy velocities of at least 10^{-7} m/s are required to obtain an increase in heat output.

1. Introduction

In this paper, we present numerical reservoir simulation results exploring the impact of natural and forced convection on closed-loop geothermal heat extraction. Closed-loop geothermal systems (CLGS), also known as advanced geothermal systems (AGS), rely on subsurface heat extraction through a pipe-in-pipe (coaxial) or U-loop type heat exchanger with the heat transfer fluid staying within the heat exchanger and not entering the surrounding reservoir rocks. These designs have recently gained increased interest and investment as a "geothermal anywhere" technology as they do not require in-situ reservoir permeability or fluid pathways—they can be designed for drilling into impermeable reservoirs or can target permeable, convection-dominated reservoirs. However, by constraining the fluid within the heat exchanger, the heat transfer area is limited, which impacts the thermal performance of the system.

When evaluating the performance of CLGS, the focus is often on systems located in conduction-only media (e.g., White et al. 2024; Beckers et al. 2022; Beckers and Johnston 2022; Beckers et al. 2023). Here, we simulate a porous medium instead of impermeable dry rock and investigate how much heat extraction increases with the presence of water flow through the porous medium. We conducted a range of simulations and explored the impact of porosity, permeability, and reservoir temperature on overall heat extraction through both natural and forced convection. Natural convection is driven by temperature gradients in the hot wet rock, while forced convection represents the situation when there is a natural background flow in the porous medium. While forced convection is not common, there are some geothermal reservoirs where these conditions may occur.

Two prior studies investigated CLGS in a porous medium subject to natural convection. Oldenburg et al. (2016) considered a U-loop design with one 1.1-km-long lateral at 2.5 km depth and bottom-hole temperature of 250°C. CO_2 as heat transfer fluid was injected at the surface at 60 kg/s and 75°C. The scenario with negligible permeability (heat conduction-only) resulted in a long-term heat production of about 1.5 MW_{th}. The scenario with a permeable zone (permeability of 10^{-10} m^2 or about 100 D) of 40 m thick around the lateral resulted in long-term heat production of about 3.5 MW_{th}. Similarly, White et al. (2024) simulated a U-loop configuration with a 4-km-long lateral at 2.5 km depth and bottom-hole temperature of 190°C. Water was injected at 30°C and 15 kg/s. Available power (i.e., net exergy production) after 25 years of operation in a heat conduction-only reservoir is about 290 kW_e. When simulated in a porous medium allowing for natural convection, the available power increases with increasing permeability. For a permeability of 50 mD, the available power after 25 years is about 295 kW_e, while for a permeability of 500 mD, it increases to about 530 kW_e.

We chose a subset of possible convection conditions to explore here: a U-tube configuration for a hot wet rock reservoir with liquid water between an impermeable overburden and underburden. Liquid reservoirs are common. We did not simulate a specific location. Instead, we assumed a simplified reservoir with uniform matrix porosity and permeability, most similar to a sedimentary basin. However, geothermal wells can be deployed in a variety of systems, including steam reservoirs and magmatic reservoirs.

The paper consists of five sections including this introduction section. Section 2 presents our research methods and discusses the models developed using two simulation codes, Sierra Thermal/Fluids: Aria, a generalized Galerkin finite element method code (Notz et al. 2016) and COMSOL (COMSOL 2019). Natural convection and forced convection results are presented in Sections 3 and 4, respectively. Overall conclusions are provided in Section 5.

2. Simulation Methods

Simulations exploring the impact of convection were conducted in both Aria and COMSOL. A U-tube configuration was chosen, as it was anticipated that natural convection will have the largest impact on a horizontal well, and we aimed to bound the potential impacts of convection. The Aria simulations explored reservoir heat extraction through a full U-tube configuration. The COMSOL simulations focused on a 100-m-long section of a lateral of a U-tube configuration. The different codes were used to explore different conditions in the parameter space, then compared for two analogous configurations. Using the two codes allows us to compare the independently developed models with one another to see how well they agree with one another. A good agreement in this benchmarking gives us confidence that we can trust the results to have broader applicability.

2.1 Aria Simulations

The impact of natural convection on a U-loop configuration was investigated. The computational domain is made up of two 2.5-km vertical wells that are modeled as hot dry rock (conduction-only). These connect to a 1-km horizontal section of hot wet rock (conduction and convection) that is made up of permeable layers. The impermeable domain is modeled as 2D axisymmetric with a radius of 150 m. The permeable domain is investigated through a 3D numerical simulation and measures 1 km × 250 m × 250 m. Relatively higher permeability hot wet rock is 125 m thick (white and yellow blocks in Figure 1) sandwiched between an overburden and underburden of lower permeability hot dry rock. The permeable and impermeable sections are decoupled from each other, except through the heat exchanger, which runs the entire length of the domain and has a diameter of 44.45 cm (17.5 in.), a standard large well size.

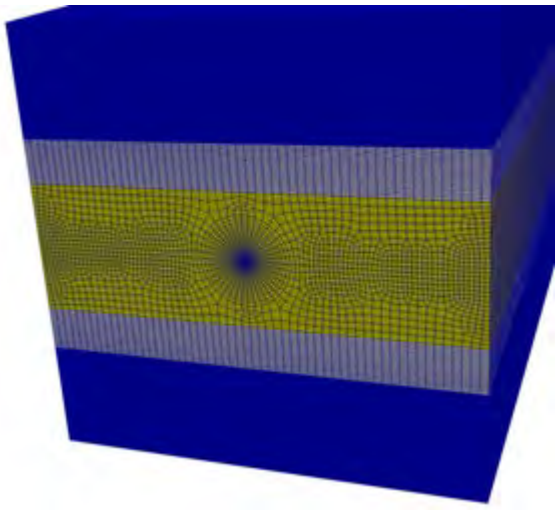

Figure 1: Computational domain in Aria for the permeable reservoir

The mass and heat flow in the hot wet rock are modeled as single-phase Darcy flow with the formation fluid modeled as pure liquid water. The variation of fluid density with temperature due to the heat exchanger gives rise to buoyantly-driven convection currents, drawing warmer water to the heat exchanger and allowing cooled water to pool below the heat exchanger. The domain is initially at hydrostatic pressure, and the initial formation temperature is set according to the depth and geothermal gradient. The vertical sides are impervious to heat and mass flow and can be considered symmetry planes. The top and bottom surfaces are maintained at the initial temperatures.

The working fluid for the heat exchanger was liquid water and was injected into the borehole at 30°C. Parameters that were studied include the mass flow rate of the working fluid (2 and 10 kg/s), porosity of the rock (1%-25%), permeability of the rock (1 mD-20 D), and the geothermal gradient within the rock (30°C/km, 60°C/km, and 90°C/km). The lower porosities are consistent with typical deep geothermal reservoirs and the higher (10%-25%) were chosen to match what was investigated by Oldenburg et al. (2016). The lower end of the permeability range was selected to match what is seen in various well locations. The upper values were chosen to evaluate what conditions are necessary to see a significant impact from convection. The geothermal gradient values are consistent with typical values found within the first few kilometers' depth of the crust. We simulated heat extraction over 20 years and compared output temperature over time and heat output at the 20-year mark for the different porosities, permeabilities, and geothermal gradients.

2.2 COMSOL Simulations

2.2.1 Natural Convection

We developed models in COMSOL to explore the impact of natural convection on heat extraction with water flowing through a pipe in a porous medium (Figure 2). The heat exchanger has a length of 100 m and diameter of 6 in. (15.2 cm) and is placed at the center of the porous medium, with dimensions of 250 m × 100 m × 250 m. The porous medium was placed at a depth of 3.5 km (center of the block). A 62.5-m-thick impermeable layer of overburden and underburden is placed on top and below the porous medium, respectively. We simulated three temperature gradients: 30°C/km, 60°C/km, and 90°C/km, which correspond to temperatures of, respectively, 130°C, 235°C and 340°C at 3.5 km depth (assuming 25°C at the surface). Water is injected in the pipe at 30°C and 2 kg/s. We imposed a temperature-dependent density function for the water in the porous medium to induce a pressure gradient (due to changes in temperature), resulting in natural convection currents. We also specified a temperature-dependent viscosity correlation for the water in the porous medium. The water in the pipe and porous medium is assumed to have a constant specific heat capacity of 4,200 J/kg/K. The rock has a dry thermal conductivity of 2.83 W/m/K. The flow boundary is set to a no-flow boundary condition for all exterior surfaces. The temperature at the top (x = 187.5 m), bottom (x = -187.5 m), left (y = -125 m) and right (y = 125 m) boundary is set to a constant boundary temperature condition (equal to the initial rock temperature). The other surfaces are set to a no-heat flux boundary condition (i.e., at the front (z = -50 m) and back (z = 50 m) domain boundaries). No fluid can enter or leave the porous medium. We simulated heat extraction over 20 years and compared heat output at the 20-year mark for different temperature gradients, permeabilities and porosities.

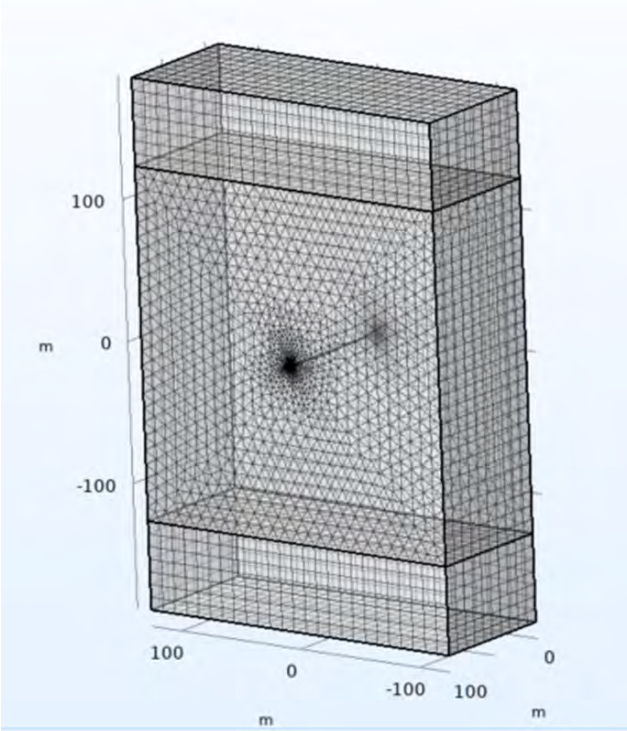

Figure 2: Computational domain in COMSOL for studying natural convection

2.2.2 Forced Convection

Forced convection represents the scenario where a natural background flow exists in the reservoir. In some reservoirs, pressure differentials can naturally occur, forcing in-situ water to flow through the reservoir. We developed a model in COMSOL to investigate the impact of a forced convection flow field on the heat extraction with water flow through a pipe placed in a porous medium (Figure 3). The heat exchanger has a length of 100 m and diameter of 6 in. (15.2 cm) and is placed at the center of a 100 m × 100 m × 50 m porous medium block. The porous medium is initially at a uniform temperature of 100°C. Water is injected in the pipe at 50°C and 2 kg/s. A uniform and constant Darcy flow is imposed through the porous medium entering on one end (at a constant 100°C) and leaving the domain at the other end. A uniform flow field is a highly simplified assumption but nonetheless can provide insights on the level of water flow needed to see an impact. The water in the pipe and porous medium is assumed to have constant properties with density of 1,000 kg/m^3 and specific heat capacity of 4,200 J/kg/K. The rock has a dry thermal conductivity of 2.83 W/m/K. We simulated heat extraction over 20 years and compared the heat output for different Darcy fluid flow velocities.

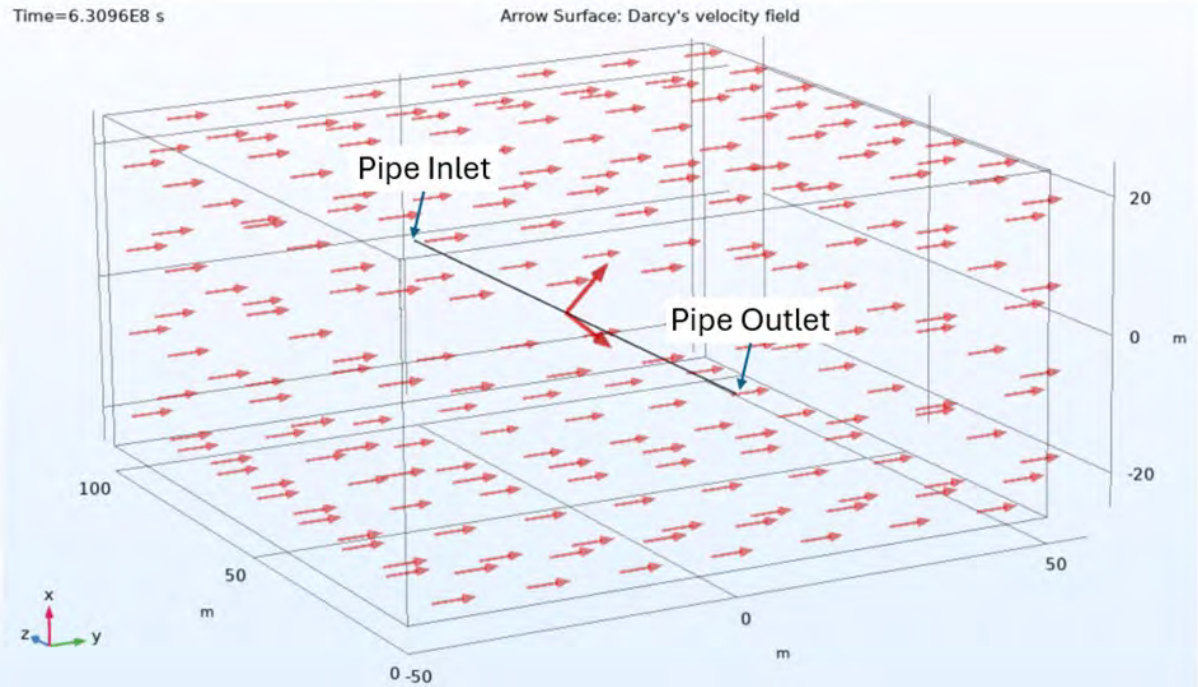

Figure 3: Computational domain in COMSOL for studying forced convection

3. Natural Convection Results

3.1 Aria Results

Qualitative indication of convection can be seen by visualizing the flow field within the permeable hot wet rock (shown in Figure 4). Variation in fluid density due to temperature causes cooler water to flow downward, as warmer water is drawn up to the heat exchanger. This density difference gives rise to a pair of counter-rotating, buoyantly-driven convection cells on either side of the tube. The strength of these vortices varies with the different convective conditions (primarily affected by permeability and temperature gradient) and drives the temperatures produced by the heat exchanger.

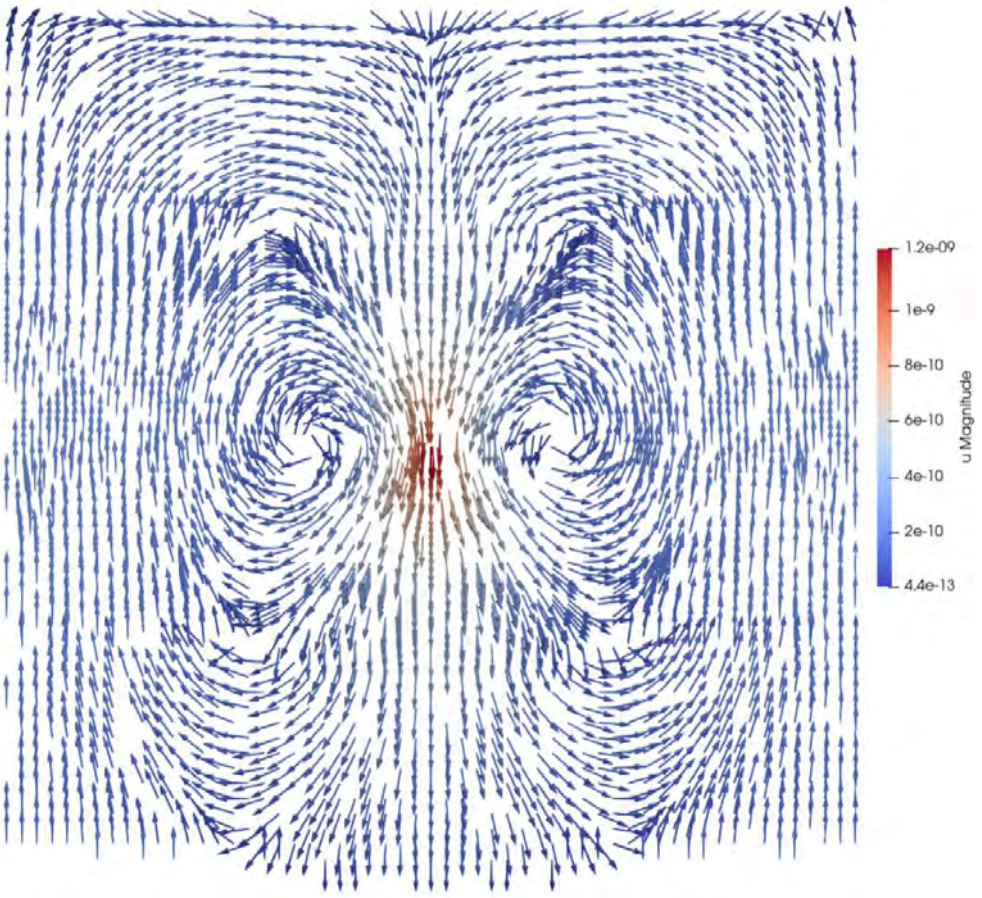

Figure 4: Cooled, denser formation water induces a downward flow near the closed-loop heat exchanger, giving rise to a pair of counter-rotating, buoyantly-driven convection cells on either side of the tube. Heat exchanger (not shown) is in the center of the velocity field, into/out of the page.

We explored the qualitative and quantitative impact of convection on (1) the steady 20-year heat output of the well and (2) the production temperature over the lifespan of the well. Both were compared to a conduction-only case to indicate the potential benefit of convection for different conditions. Figure 5 shows the increase in heat output from convection compared to conduction for varying permeability and two mass flow rates. At low permeability, there is no increase in heat output over conduction. At 500 mD, there is a low increase (<10% increase in heat output). At 1 D and above, heat output increases with increasing permeability. Notably, the higher mass flow rate of 10 kg/s increases the impact of convection over conduction on heat output. We explore these differences further by investigating the production temperature over the lifespan of the well.

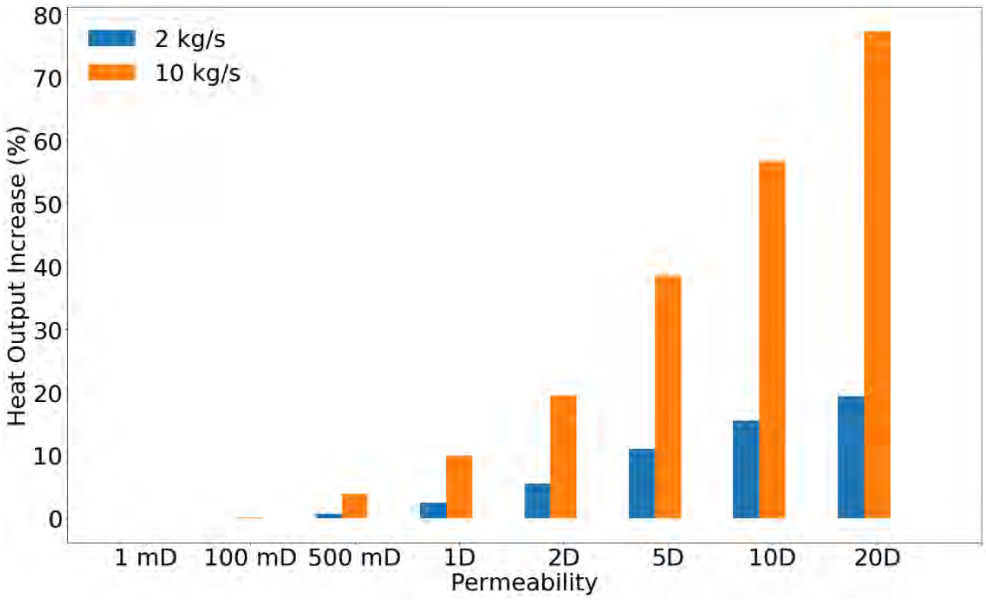

Figure 5: Increase in heat output due to natural convection versus the heat conduction-only scenario for 30 C/km geothermal gradient and 1% rock porosity at working fluid mass flow rates of 2 and 10 kg/s

Figure 6 shows the production temperature over time for the 10 kg/s case shown in Figure 5. As before, we see a minor increase in temperature at 500 mD and higher production temperatures as we increase the permeability. The 10 kg/s flow rate experiences a spike in production temperature that subsequently decreases over the lifespan of the well. The 2 kg/s flow rate (not shown) experiences a similar trend with permeability. The lower flow rate produces higher production temperatures; however, the higher flow rate sees a greater relative impact of convection on production temperature with permeability. These results are consistent with the differences we see with flow rate on the heat output increases.

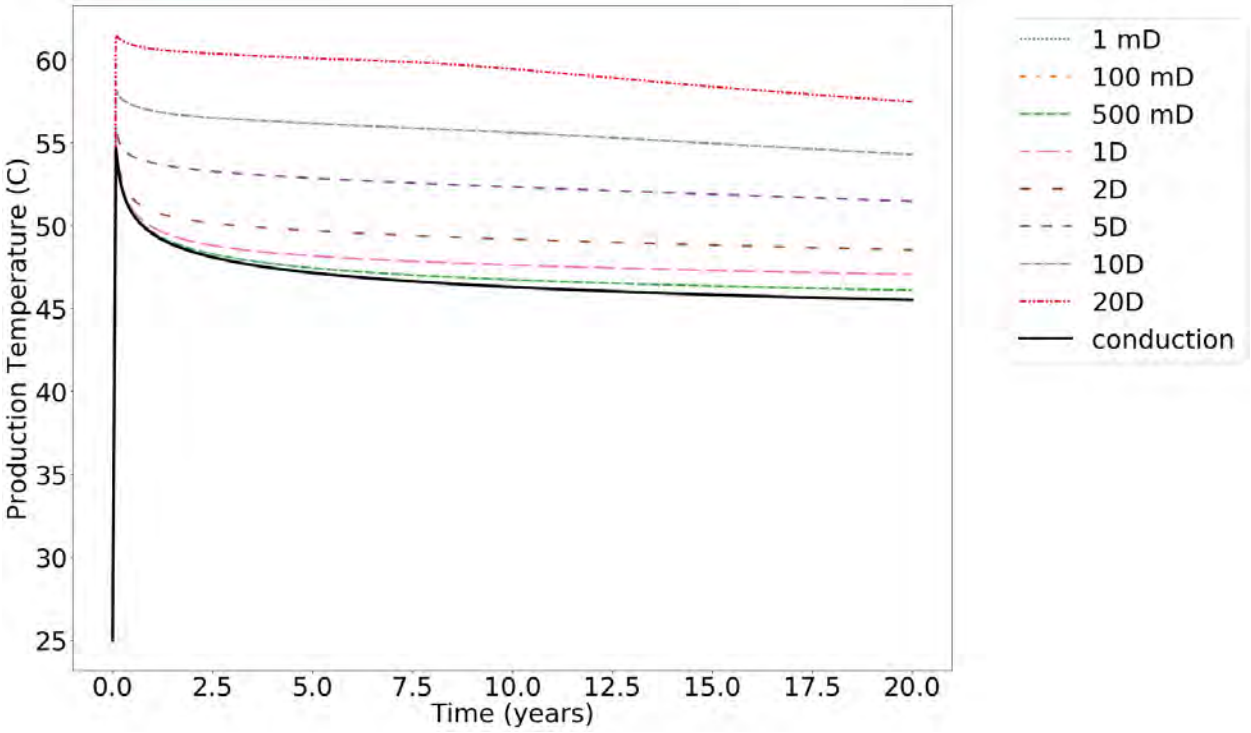

Figure 6: Comparison of production temperatures for varying permeability at 1% rock porosity and a 30 C/km geothermal gradient. Results are shown for a working fluid with a mass flow rate of 10 kg/s. Permeability begins to have a clear impact at approximately 1 D.

Results shown thus far were kept at a constant rock porosity and geothermal gradient. Porosity (increased at a constant permeability) had a negligible impact on production temperatures and heat output; increasing porosity above 1% did not show an increase in production temperature for either mass flow rate at a permeability of 1 D. We also varied the geothermal gradient, which impacted the temperature experienced by the lateral portion of the well in the hot wet rock as well as the vertical portions of the well in the hot dry rock. Figure 7 shows the impact of geothermal gradient on production temperature. Geothermal gradient has the largest impact on production temperature for both conduction and convection cases of any parameters we varied. This is anticipated, as a higher gradient results in a larger temperature difference to drive the convection in the porous rock.

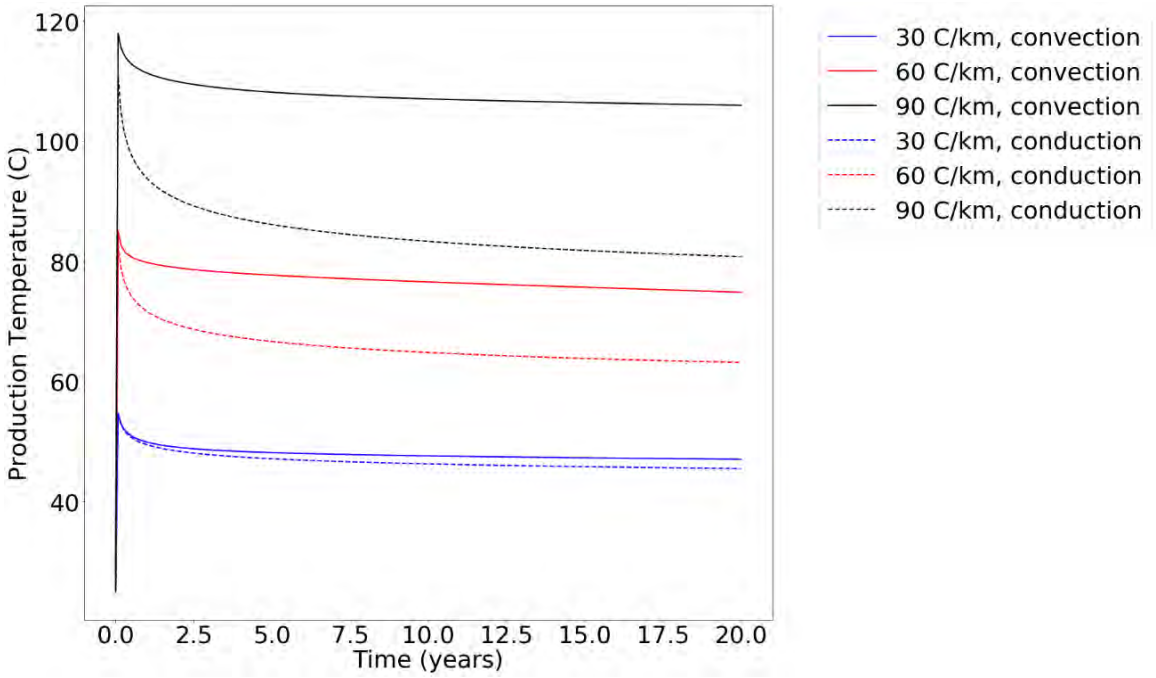

Figure 7: Effects of geothermal gradients for 1 D permeability and 10% porosity for 10 kg/s working fluid mass flow rate. Solid lines indicate the convection cases, while dashed lines indicate the conduction cases.

Both flow rates indicate that convection has a larger benefit when the geothermal gradient is higher. For the 10 kg/s cases, we see production temperatures increases of 1˚C, 12˚C, and 25˚C for 30 ˚C/km, 60 ˚C/km, and 90˚C/km, respectively. We see a similar trend at 2 kg/s, but the benefit of convection for each geothermal gradient is higher for the higher mass flow rate.

3.2 COMSOL Results

Figure 8 presents the long-term increase in heat production relative to the conduction-only scenario for porous medium permeabilities ranging from 1 µD to 1 D (approximately 10^{-18} m^2 to 10^{-12} m^2) and three temperature gradients. An increase of 100% means the heat production has doubled. The results suggest that for this scenario, a minimum permeability of 10 to 100 mD for the higher gradient cases and more than 100 mD for the lower gradient case is required to obtain an increase in heat output with respect to the conduction-only scenario. The boost in heat output increases with higher rock temperatures, a result of the larger density-driven driving force and lower viscosity at higher temperatures. Figure 9 presents the simulation results for different porosities but constant permeability (100 mD) and geothermal gradient (60°C/km). For all porosities considered, the heat output was about 37% higher than the scenario with heat conduction only. Increasing the porosity slightly decreased the boost in thermal output (i.e., increase of 37.6% for 1% porosity vs. increase of 37.2% for 20% porosity).

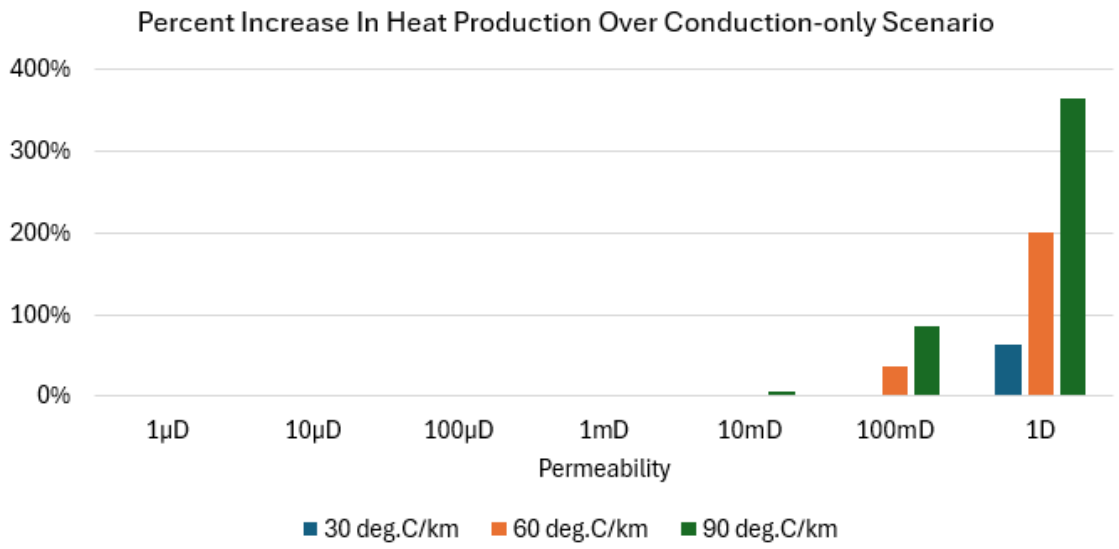

Figure 8: Increase in heat output due to natural convection versus the heat conduction-only scenario for three different geothermal gradients and a range in permeabilities

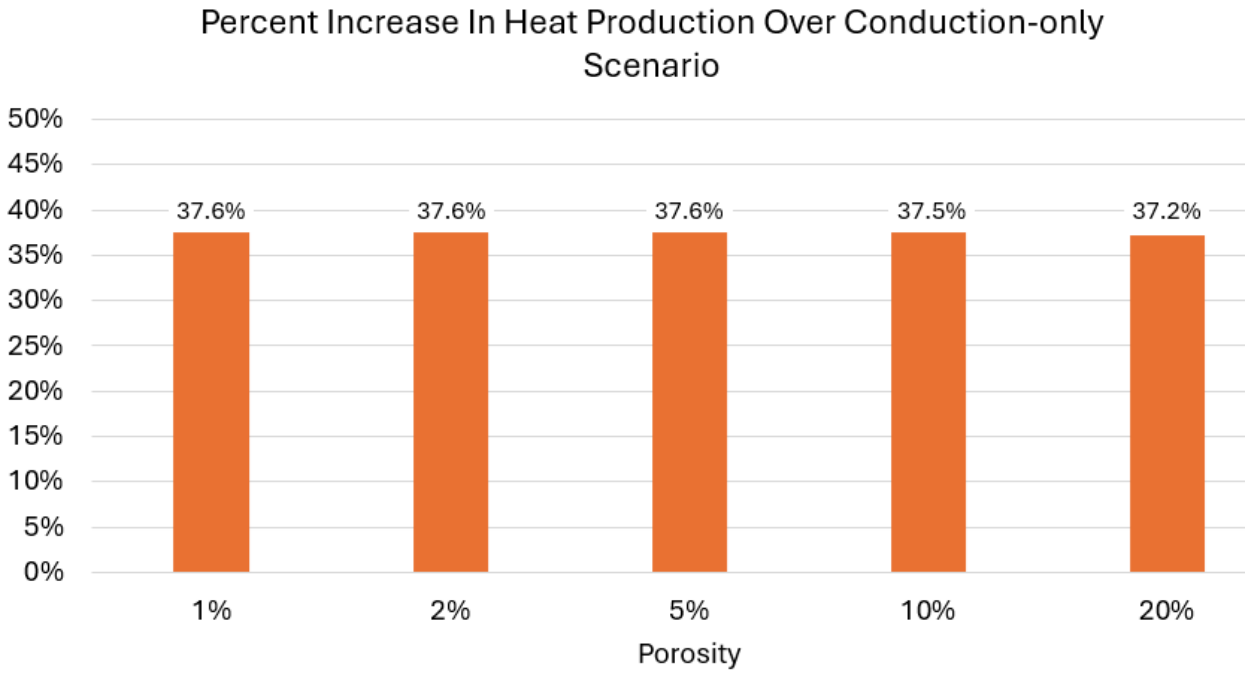

Figure 9: Increase in heat output due to natural convection versus the heat conduction-only scenario for a porosity in the range 1 to 20%. For all scenarios, the geothermal gradient is 60°C/km and the porous medium permeability is 100 mD.

3.3 Comparison Between Aria and COMSOL Simulations

We ran simulations with both Aria and COMSOL to verify the two codes against each other, to determine that results were not dependent on the code used. To confirm the applicability of the results between the two simulation codes, verification cases were run at permeabilities representing low convection (50 mD) and high convection (500 mD). Note that the comparatively high convection case is lower than previously presented results; here, the goal was to investigate code comparisons for realistic rock permeabilities. In Aria, we ran a full U-tube configuration with 2.5 km vertical wellbore lengths and a 1-km lateral length. In COMSOL, we ran the first 100 m of the lateral at a depth of 2.5 km (i.e. the temperatures are consistent with that depth for the geothermal gradient used in the Aria simulation). The difference in domain arose because Aria was run on HPC, while COMSOL was run locally. The production temperature presented from *both* simulations is the temperature 100 m into the lateral. Cases were run with 1 kg/s flow rate of working fluid (water). Because the Aria simulation is a full U-tube configuration, conduction was set to be negligible in the vertical wells; temperatures at the start of the lateral (where the COMSOL simulation begins) varied by less than 1˚C.

Figure 10 shows the results comparing Aria and COMSOL. Models agree well with each other at both permeabilities. At 500 mD, we see a difference of several degrees Celsius, corresponding to a difference of about 10% in heat output. At 50 mD, the predicted temperature difference is negligible. A few differences exist between the Aria and COMSOL model, likely explaining the discrepancy in production temperature for the 500 mD case. Two key differences include: (1) COMSOL only simulates the water density and viscosity as a function of temperature while Area simulates all water properties as a function of both temperature and pressure, and (2) the COMSOL model has about 20,000 mesh elements (and runs on a local computer) while Aria has over 800,000 elements (and runs on high-performance computing machines). The small difference in thermal output at higher permeabilities is deemed acceptable in this study as we investigate high-level trends such as permeability required for natural convection to cause an impact and order of magnitude increase in heat output due to natural convection.

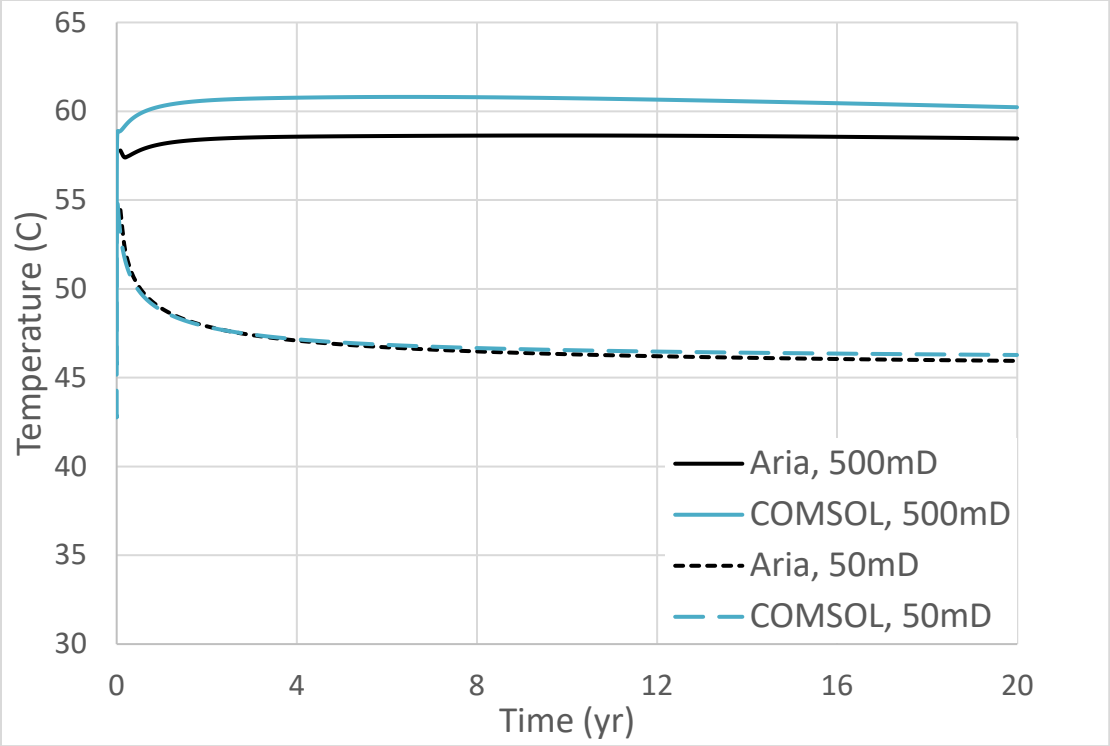

Figure 10: Comparison of Aria and COMSOL results for production temperature for an analogous case. Heat production estimated with both tools agrees within a few percent.

4. Forced Convection Results

Figure 11 presents the increase in thermal output after 20 years of operation (expressed as thermal output with convection versus thermal output without convection) for Darcy flow velocities ranging from 10^{-10} to 10^{-5} m/s. The results indicate that a minimum Darcy velocity of 10^{-7} m/s is required to impact thermal output with heat extraction increasing rapidly with increasing Darcy velocity. A Darcy velocity of 10^{-7} m/s corresponds to a water mass flux of about 10^{-4} kg/s/m^2. Equivalently, water flowing at a Darcy velocity of 10^{-7} m/s will have migrated about 3.15 m after 1 year.

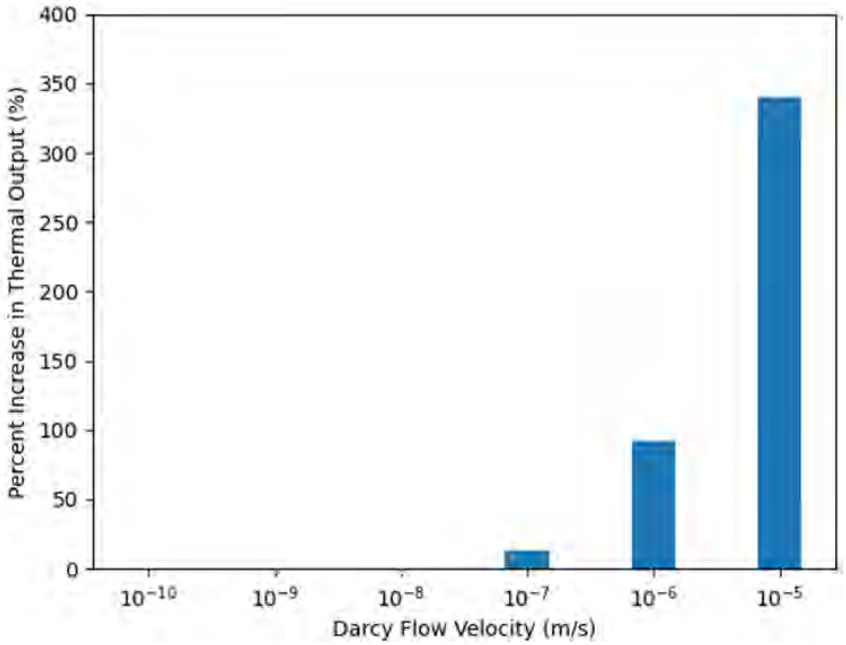

Figure 11: Percentage increase in thermal output with forced convection as a function of Darcy flow velocity. A Darcy velocity of at least 10^{-7} m/s is required to obtain an increase in heat production with convection.

5. Conclusions

In this work, we applied two simulation codes, Aria and COMSOL, to explore the impact of forced and natural convection on production temperature and heat output with closed-loop heat exchangers. At sufficiently high Darcy velocities (either due to an imposed field with forced convection or as a result of buoyancy-driven convection cells with natural convection), the water flow in the reservoir replenishes the removed heat around the heat exchanger, resulting in a boost in production temperature and heat output with respect to the conduction-only scenario.

For studying natural convection, we explored the impact for a range of permeabilities (1 μD to 20 D), porosities (1% to 25%) and geothermal gradients (30 to 90°C/km). We focused on U-loop designs with the horizontal lateral(s) located in a porous medium. Simulation results with both simulation codes indicate an increase in heat output is obtained due to natural convection with a permeability of at least ~100 mD. For higher permeabilities (1 D and larger), the production temperature and heat output rapidly increase with increasing permeability. An increase in reservoir temperature increased the impact of natural convection, while porosity only had a minor effect. Typical permeabilities at 2 km depth in the continental crust are on the order of 1 mD, several orders of magnitude smaller than the permeabilities required for natural convection to have a significant impact on thermal output. Overall, results were very sensitive to natural permeability; thus, the simulation results suggest that the most impact on heat extraction is through higher permeability reservoirs.

In this work, we made several choices to constrain possible range of convection. For example, all simulations considered a permeable hot wet rock section sandwiched between an impermeable overburden and underburden. A single case investigating the removal of the overburden and underburden found negligible differences between the two cases. Thus, one was investigated to constrain the impacts of convection. However, other design and geologic systems are feasible and

warrant further investigation. Additionally, the focus of this work was on water reservoirs. Additional cases in steam reservoirs could be investigated.

Abstract

The super-hot enhanced geothermal systems were simulated to generate remarkably high megawatts of electricity per well, while in practice, the extreme underground conditions proved to be challenging for long-term production operations. This paper presents a comprehensive investigation into Multilateral Closed Loop Geothermal Systems (CLGS) using water and supercritical CO2, targeting enhanced power generation in high-temperature geothermal environments up to 350°C, while eliminating production issues such as heavy corrosion and scale formation.

Focused on optimizing system performance and ensuring well integrity, the study employs advanced flow and thermal models alongside mechanical simulation models to investigate the heat production performance of CLGS under different well design and production settings and examine the behavior of casing and cement under the subsurface temperatures. By exploring multilateral well completion techniques and varying operational parameters such as the number of laterals, injection pressure, and mass flow rate, the research identifies strategies to maximize energy recovery and minimize the levelized cost of electricity.

Significant enhancements in power generation are demonstrated, particularly with the use of supercritical CO2, which despite its lower specific heat capacity, achieves higher temperature outputs at increased resource temperatures, effectively lowering electricity costs. Sensitivity analyses highlight the critical impact of well design on system efficiency, revealing optimal flow rates and the importance of insulated tubing to prevent heat loss. Structural modeling results further indicate potential failure risks due to stress concentrations at crucial lateral junctions in the well architecture. Key findings include a production temperature decline of 15-20°C after 20 years and significant economic benefits from increasing resource temperatures and the number of lateral sections. The paper underscores the potential of CLGS to significantly improve the economic and operational sustainability of geothermal power generation, offering robust insights into the strategic deployment of these systems in challenging geothermal environments.

1. Introduction

The demand for sustainable energy is increasing with the rising population and growing global economy. Fossil fuel-generated energy has the highest consumption records over the last century, significantly impacting the manmade release of carbon dioxide into the atmosphere (Ritchie et al., 2024). Despite its potential as a cost-effective source of energy production, geothermal energy utilization remains notably low, comprising a mere 0.24% of the global energy consumption in 2022 (IEA, 2023). The theory and calculations on paper indicate that the planet Earth has an enormous amount of sustainable and recoverable geothermal energy that is capable of supplying heat and electricity to humanity for a long time (Tester et al., 2006). Special emphasis should be placed on the term “recoverable” which heavily relies on the existence of sophisticated technology. The enthalpy recovery efficiency of the existing geothermal production wells decreases over time due to limited well depth and technology (Soltani et al., 2019).

Multilateral closed-loop geothermal systems, also known as Advanced Geothermal Systems (AGS), offer a promising approach for heat extraction from low-permeability formations, which are more common than highly permeable hydrothermal systems. These systems operate by circulating fluids through a closed-loop wellbore system, exchanging heat with the surrounding rock without permeating the reservoir. While CLGS has been proposed for nearly a century, recent attention and commercial investment have revitalized interest in their potential. Proponents highlight advantages such as minimal need for reservoir stimulation, reduced risk of induced seismicity, and the ability to repurpose abandoned wells or extract heat without producing reservoir fluids. However, challenges remain, including ensuring sufficient contact area with the rock for effective heat extraction and managing the costs associated with drilling and connecting multiple loops of horizontal wells. Given the significant debate surrounding the feasibility, performance, and cost-competitiveness of CLGS, a comprehensive and independent evaluation of their techno-economic performance is essential in guiding future investments and developments in closed-loop geothermal technology.

There are several sophisticated multilateral CLGS designs proposed by various companies around the world but most of them rely on the further development of the already advanced technologies to enable the realization of concepts such as U-shaped well drilling and application of exotic materials. This study investigates the feasibility of closed-loop geothermal systems completed with tried and tested multilateral well technologies using structural, fluid flow/thermal, and techno-economic models. In the subsequent sections, detailed descriptions of the models employed in this study are provided, including the finite-element structural model, dynamic multiphase flow/thermal model, and techno-economic model. Next, the results are presented, and their implications are discussed accordingly. Specifically, the well integrity aspects are analyzed, flow and thermal performance are studied, and economic evaluation is conducted. Sensitivity analyses are provided to study the impact of well design, number of lateral sections, and subsurface temperature. Finally, conclusions are drawn based on the findings in the last section.

2. Literature Review

2.1 Geothermal energy resources

Geothermal energy, stemming from the Earth's internal heat content, presents diverse resources for power generation (Cheng, 1979). This internal heat originates from both residual heat from planetary accretion and the ongoing radioactive decay of isotopes within the Earth's crust (Turcotte

& Schubert, 2002). The Earth's mantle, exhibiting plastic behavior due to high temperatures and pressures, facilitates convective movements, leading to varying temperature gradients. Typically, the geothermal gradient through the crust ranges between 25 to 30 °C per km of depth in most of the world. The conductive heat flux averages 0.1 MW/km². These values are much higher near tectonic plate boundaries where the crust is thinner (Pollack et al., 1993). They may be further augmented by combinations of fluid circulation, either through magma conduits, hot springs, or hydrothermal circulation. Earth's interior temperature and pressure are high enough to cause some rock to melt and the solid mantle to behave plastically. Parts of the mantle flow upward since it is lighter than the surrounding rock. Temperatures at the core-mantle boundary can reach over 4000 °C (7200 °F) (Lay et al., 2008).

The Geovision report by the U.S. DOE (2019) provides a detailed classification of geothermal resources and applications accordingly. Hydrothermal systems are natural reservoirs of hot water or steam located beneath the Earth's surface. These systems occur when water percolates deep into the Earth's crust, heats up, and then rises to the surface through fractures and faults, forming hot springs, geysers, and fumaroles (Browne, 1978). Enhanced Geothermal Systems (EGS), on the other hand, involve engineering techniques to create or enhance geothermal reservoirs where natural conditions are not optimal. This typically involves drilling deep into the Earth's crust and fracturing the rock to create pathways for fluid circulation. Water is injected into the fractured rock, where it heats up by the surrounding heat sources, and then extracted to the surface to generate electricity (Olasolo et al., 2016). Distinct from the systems mentioned above, the Closed Loop Geothermal Systems (CLGS) utilize heat exchange technology to transfer heat between the Earth and a closed-loop fluid circulation system. These systems typically involve drilling boreholes into the ground, circulating a heat transfer fluid through underground pipes, and then transferring the heat to a heat exchanger at the surface to generate electricity or provide heating and cooling for buildings (Tester & Smith, 1977). The CLGS provides full isolation of the working fluid from contacting the surrounding formations or reservoir fluids, only allowing the heat transfer to occur from the formation through the well cement and casing to the working fluid (Hecht-Méndez et al., 2013).

2.2 Types of geothermal power plants

Geothermal power plants are used to convert thermal energy into electrical energy using steam turbines (DiPippo, 2012). There are three main types of geothermal power plants (See Figure 1), and they employ different technologies based on subsurface fluid characteristics and temperatures (U.S. DOE, 2019). Dry steam, flash steam, and binary cycle power plants are the primary types utilized. Dry steam power plants directly utilize high-temperature hydrothermal fluids, primarily composed of steam, to drive turbines and generate electricity (Zarrouk & Moon, 2014). Flash steam plants, the most prevalent, exploit high-pressure fluids from underground reservoirs, inducing rapid vaporization in the flash tank and sending the vapor to drive turbines (Mosaffa & Zareei, 2018). Binary-cycle power plants, capable of utilizing lower temperature resources, employ a secondary fluid with a lower boiling point than water. This fluid, heated by geothermal fluids through a heat exchanger, undergoes vaporization to drive turbines and produce electricity (Ghasemi et al., 2013).

While conventional and closed-loop geothermal technologies offer avenues for thermal and electric energy production, they face significant limitations in accessing the vast potential of geothermal resources. Research indicates that only a small fraction, approximately 2%, of the

Earth's geothermal resources are accessible through conventional means, primarily due to the limited availability of permeable regions conducive to traditional geothermal technologies (Geiser et al., 2016; Khankishiyev et al., 2023a). Consequently, a substantial portion of geothermal energy remains untapped, particularly within the hot dry rock formations lying beneath impermeable layers. For instance, a comprehensive study in 2006 highlighted that the identified geothermal capacity in the United States stood at 2.8 GW, whereas an additional 25 GW of resources were identified, with an estimated 90 GW more suspected to be available (Tester et al., 2006). Despite these vast opportunities, technological advancements are imperative to harness this potential effectively (Khankishiyev, 2024). As of the end of 2023, global installed geothermal power generation capacity across 24 countries stood at 16.1 GW, with the United States alone accounting for 3.8 GW (Ediger & Akar, 2023). However, with projects planned or under development, geothermal energy could potentially become accessible in up to 82 countries, indicating a growing global interest and potential for expansion in the geothermal energy sector (Lund et al., 2022).

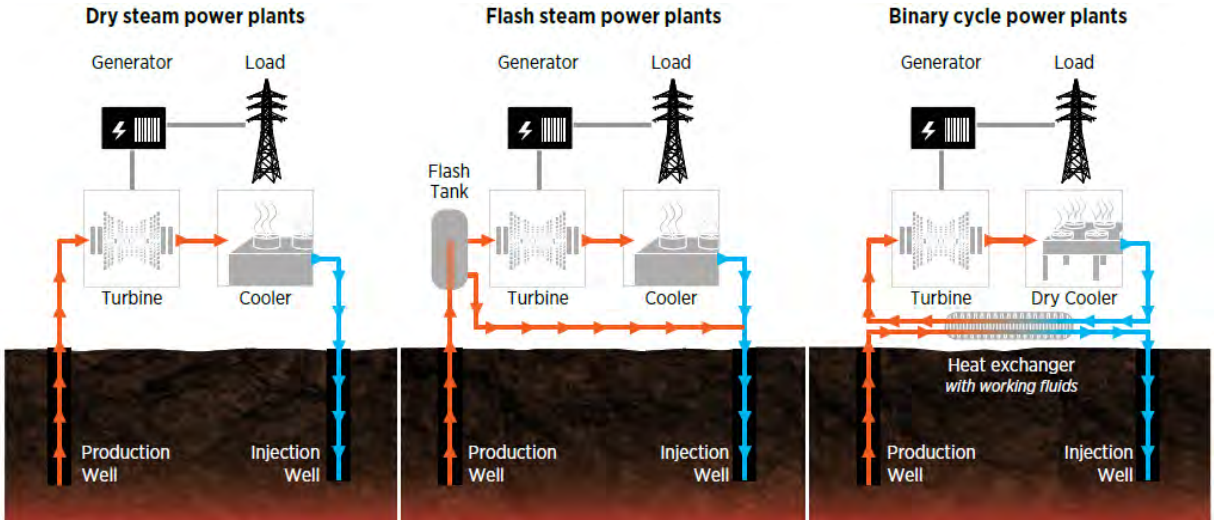

Figure 1: Geothermal power-plant configurations employed based on subsurface fluid characteristics and temperatures: dry steam, flash steam, and binary cycle. Although the illustration uses the production and injection well that is typical for the EGS, these power plant configurations are being used for hydrothermal and CLGS applications as well. (U.S. DOE, 2019)

2.3 Problems associated with the Hydrothermal and Enhanced Geothermal Systems

Geothermal energy has long been recognized as a sustainable power source, yet its development is not without significant challenges and costs (Khankishiyev & Salehi, 2023; Vivas et al., 2020). Operational difficulties extend beyond technical complexities to encompass political, cultural, and environmental concerns. The chemical composition of geothermal fluids poses a considerable risk to well integrity due to potential scaling and corrosion issues, which are prevalent in geothermal utilization (Khankishiyev et al., 2024 (a)). Kruszewski and Wittig (2018) conducted a comprehensive analysis of failure modes in 20 high-enthalpy geothermal wells worldwide, including locations in Iceland, Italy, and Japan. Geothermal wells encounter various production problems that impact efficiency and output. Scaling and mineral deposition reduce fluid flow and heat transfer efficiency, while corrosion of steel components compromises well integrity (Karlsdóttir & Thorbjornsson, 2012; Klapper et al., 2019). Erosion of casing and tubing due to high-velocity fluid flow leads to maintenance needs and reduced well integrity, with erosion-corrosion accounting for significant damages in geothermal systems (Kurata et al., 1992; Nogara & Zarrouk, 2018). Wellbore leaks resulting from casing corrosion or faulty connections can have

severe impacts, including dangerous steam eruptions, highlighting the importance of prompt detection and mitigation (Kalvenes, 2017; Phi et al., 2019). Moreover, reservoir decline over time presents a significant challenge to sustained energy production, necessitating effective reservoir management techniques (Beckers et al., 2017; Zais & Bodvarsson, 1980). The lack of permeability and reservoir fluid is another main limiting factor for the development of EGS in high-potential super-hot dry rock geothermal resources, which can be eliminated by the application of multilateral CLGS (Chen & Jiang, 2015; Hu et al., 2024; Khankishiyev et al., 2023b).

2.4 Multilateral CLGS concepts

Multilateral Closed Loop Geothermal Systems (CLGS) adapt concepts from the oil and gas industry, allowing for the drilling and completion of multiple lateral boreholes within a single main bore (Nalla & Shook, 2004). These systems offer alternative well-construction strategies for vertical, inclined, horizontal, and extended-reach wells, aiding in reducing both capital and operational expenditures while enhancing production. In super-hot deep geothermal wells where costs are high, multilateral designs offer significant economic efficiencies, aligning with the goals of reducing overall project expenses and increasing productivity (Stimac et al., 2010). The Technology Advancement of Multilaterals (TAML) provides a classification system for multilateral junctions, facilitating comparisons between different designs based on support and hydraulic integrity. There are six recognized multilateral completion levels in the industry with higher TAML levels indicating increased complexity and cost (Hogg, 1997). These completion levels can be applied in various well geometries. Figure 2 shows some of the geometries for the multilateral well completions, while there are even more complex designs such as U-shaped wells proposed by several companies (Toews et al., 2020; Vany et al., 2020).

Multilateral CLGS functions by utilizing a circulating fluid inside the laterals to absorb heat stored underground, which is then transported to the surface via the production string and discharged through a heat exchanger (Wang et al., 2020). A greater number of laterals and extended lateral sections provide a higher surface area for better heat exchange. This heat can be utilized for various purposes, including the production of electrical energy or direct applications like district heating or greenhouse heating. To generate power, the extracted heat is typically transferred to a binary process, such as an Organic Rankine Cycle (ORC) or Kalina cycle, especially suited for the expected low to medium fluid temperatures recovered from the geothermal reservoir (Hecht-Méndez et al., 2013). Since the system is isolated from the formation, different types of working fluids such as chemically treated water and supercritical CO2 can be applied to increase the enthalpy recovery efficiency from the rocks (Hu et al., 2020).

2.6 Feasibility of multilateral CLGS

Multilateral CLGS wells offer several advantages over other geothermal technologies. Firstly, they are geographically and geologically independent, as they do not rely on specific hot fluid flow rates or frackable hot rock zones underground. This independence simplifies planning processes and reduces the risk of encountering limiting factors associated with location (Yuan et al., 2021). Secondly, CLGS operates without physical interaction between the circulating fluid and surrounding formations, minimizing environmental impact and eliminating technical issues such as severe corrosion and scale formation (Hu et al., 2020). Lastly, the placement of maintenance-intensive components at the surface ensures reliable long-term operation predictions, with some estimates suggesting operational lifetimes of up to 30 years or more (Beckers et al., 2022).

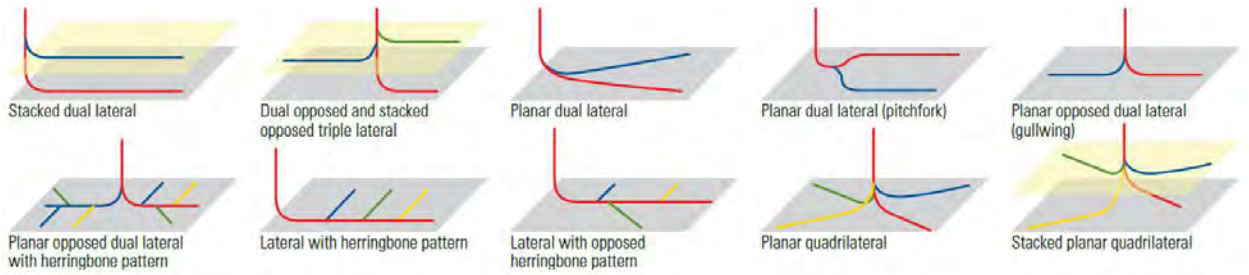

Figure 2: The geometry of a multilateral well is intricately shaped by the production targets, considering their depths and lateral extents. These wells can feature laterals on the same horizontal plane or follow the same vertical direction but at different depths, offering a versatile configuration for targeting multiple zones within a single reservoir. (SLB, 2021)

In a particular modeling study, Song et al. (2018) used numerical methods to carry out CLGS heat production performance for a U-shaped well where two wells are connected underground and one of them is used to inject cold water, while the other is used to produce the hot water. The study revealed that CLGS exhibits a stable production region with the potential for electricity generation, with outlet temperature and thermal power remaining nearly constant in this region. Additionally, inlet temperature significantly influences heat extraction performance, suggesting an optimal range of 30°C to 40°C, while the wellbore diameter has minimal impact on heat production, indicating that larger diameters are unnecessary for CLGS applications, helping to reduce drilling costs. Figure 3 illustrates the model results after 20 years of production. With 3500 m true vertical depth, 6000 m long horizontal section, and 130°C subsurface temperature at depth, 63°C outlet temperature was simulated when the inlet temperature was 40°C.

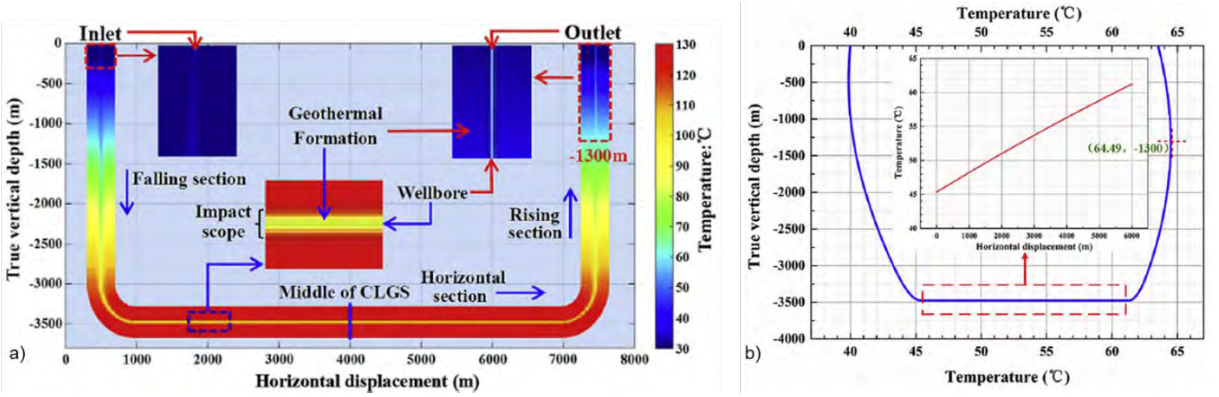

Figure 3: Numerical CLGS model results after 20 years of production: a) Temperature contours of the U-shaped CLGS wellbore and near-wellbore formation; b) Temperature profile of the working fluid inside the descending, horizontal section, and ascending sections. The subsurface temperature at the horizontal section is 130°C (Song et al., 2018)

Sun et al. (2018) used the same numerical model but changed the circulation fluid to CO2 to measure the impact. The outlet temperature was estimated to be as high as 96°C when 6°C CO2 was injected into the loop with a 4 kg/s flow rate. It was also observed that increasing the flow rate to 14 kg/s decreased the outlet temperature by about 50%. One of the important observations from the application of CO2 as a working fluid was that the relationship between outlet CO2 temperature and inlet pressure exhibited a discontinuous or contrary behavior, with outlet temperature initially increasing with inlet pressure up to 28 MPa before decreasing, attributed to the Equal-Enthalpy

theory, indicating the presence of an optimal inlet pressure for achieving the highest outlet fluid temperature.

Wang et al. (2021) conducted a numerical modeling of multilateral CLGS using a co-axial well design as shown in Figure 4 over 30 years. Energy ratio results indicated that with a reservoir temperature of 250°C, the total energy output increased by 77.43% compared to a reservoir temperature of 150°C. Increasing the number of lateral wellbores significantly enhanced the total energy output, with the maximum increase range reaching 119.11% when comparing 6 lateral wellbores to 2 lateral wellbores. The maximum outlet temperature change due to varying wellbore size was only 1.49°C, indicating minor effects on the system's performance.

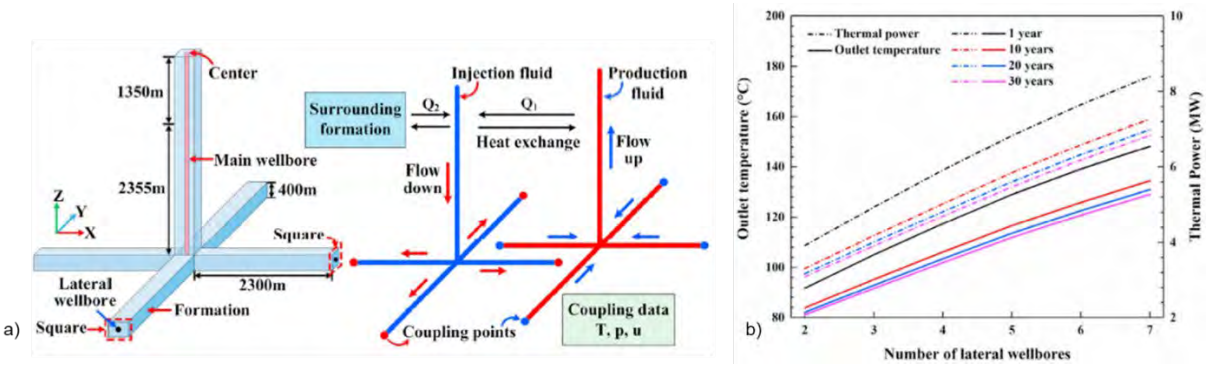

Figure 4: Numerical CLGS modeling using co-axial well design: a) Schematic of the computational model with 4 lateral sections; b) Outlet temperature and thermal power profiles vs. the number of lateral sections over 30 years of production.

In another comprehensive study, Beckers et al. (2022)showed that average heat production rates ranged from about 2 to 15 GWh per year for co-axial designs and from 9 to 67 GWh per year for U-loop designs. Levelized cost of heat estimates varied from approximately $20 to $110 per MWh for greenfield co-axial systems and $10 to $70 per MWh for U-loop systems, while electricity production ranged from 0.12 to 7.5 GWh per year with levelized costs ranging from $83 to $2,200 per MWh. Overall, the findings highlight the importance of minimizing drilling costs to make closed-loop geothermal systems economically viable, especially for electricity production.

3. Model Description

This section describes the models developed to explore the potential of the CLGS systems and carry out sensitivity analysis for multiple design factors. In general, three models are developed: the dynamic flow model, the techno-economic model, and the finite-element structural model. The use option of the extracted hot fluid in this model is the electricity generation using the Organic Rankine Cycle (ORC). Overall, the CLGS model is composed of surface facilities such as high-pressure high-flow rate pumps and heat exchangers and a subsurface component which is a multilateral well with three horizontal sections.

3.1 Dynamic Flow and Thermal Model

The dynamic flow model is developed in a commercially available steady-state multiphase flow simulator (SLB, 2024). The schematic diagram of the multilateral well is illustrated in Figure 5 below. For most of the analysis, a multilateral well with three horizontal sections is used while single and dual lateral sections are also simulated. The well deviation survey, rock temperature, and thermal conductivity are given in Table 1 below. The true vertical depth of all three horizontal

sections is 2500 m. The well has three parts: a vertical section (0-2134 m MD), a build-up section (2134-2987 m MD), and three 1220 m long horizontal sections (2987-4207 m MD). The horizontal sections are placed 120 degrees apart from each other to ensure minimum interference of the heat transfer medium in near-well formation. The ground temperature at the surface is 15°C and the ambient temperature at 2500 m TVD is 150°C. The average thermal gradient is 0.054 °C/meter for the whole interval. The rock-specific heat capacity is set to 840 J/(kg.K) for the whole interval. The thermal conductivity of the rock is set to 3 W/(m.K) from the surface to 1600 m TVD and 3.6 W/(m.K) to 2500 m TVD, which is close to the thermal conductivity of granite.

Table 2 shows the dimensions of the casings, liner, and tubing, including setting depth and diameters. The thermal conductivity of the carbon steel casings and liner are set to 48 W/(m.K). The fluid is pumped through the annulus and produced through the insulated tubing that has a thermal conductivity of 0.01 W/(m.K). There are several commercially available vacuum-insulated tubing (VIT) products provided by different manufacturers with this level of thermal conductivity. The cement around the surface and intermediate casing is two inches thick while it is set to one inch for the liner. The thermal conductivity value for the cement is set to 1.557 W/(m.K) according to the commonly used H and G class cements in well construction. Since cement has higher thermal conductivity than water and drilling mud, the annulus between casings is filled with cement up to the surface.

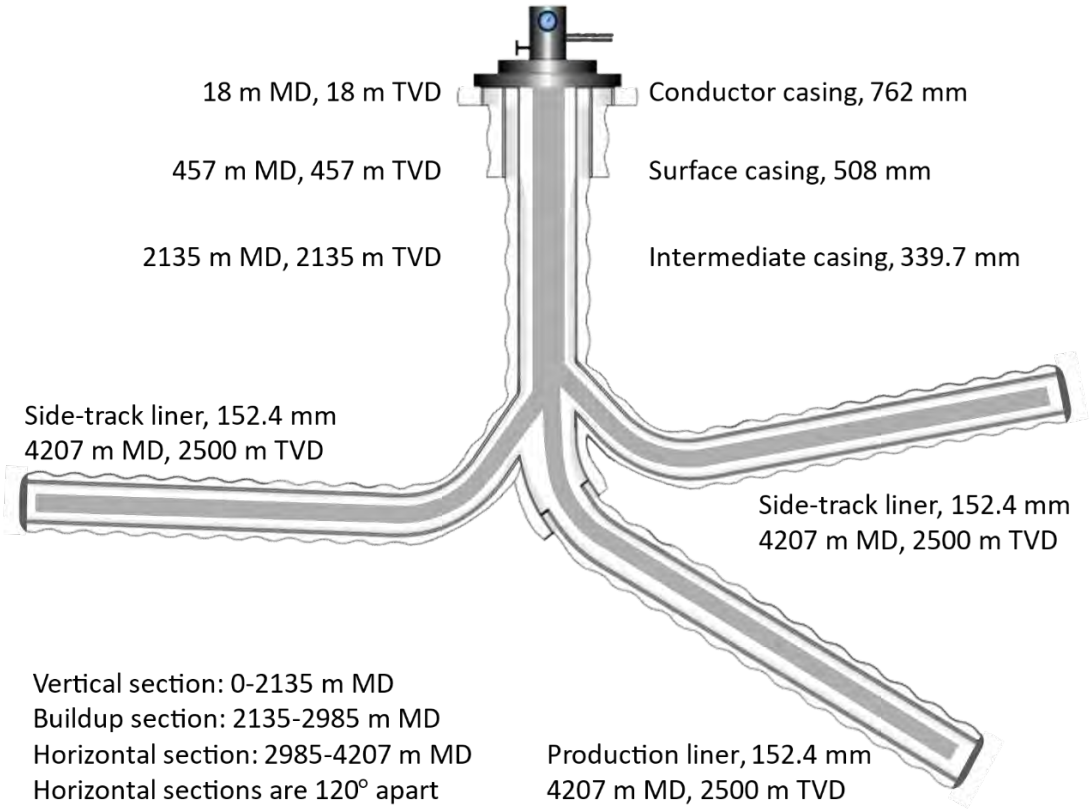

Figure 5: Schematic diagram of the multilateral well developed in steady-state flow simulator

Table 1: Well deviation survey, subsurface temperature, and rock thermal conductivity. The data on the last row of the table is the same for all three lateral sections.

MD, m	TVD, m	Horizontal section, m	Angle, deg	Rock temperature, °C	Rock thermal conductivity W/(m.K)
0	0	0	0	15	3
1000	1000	0	0	69	3
1600	1600	0	0	101	3
2134	2134	0	0	130	3.6
2198	2195	20	17	134	3.6

Water and supercritical CO2 are the two fluid types used in the simulations at different injection flow rates and pressures. The thermal conductivity and specific heat capacity of the water are 0.6055 W/(m.K) and 4185 J/(kg.K) respectively. The thermal properties of sCO2 change with increasing pressure and temperature which is continuously calculated by the compositional fluid during simulations. For example, at 100°C temperature and 15 MPa pressure, sCO2 has around 0.045 W/(kg.K) thermal conductivity and 1600 J/(kg.K) specific heat capacity at 20 MPa pressure and 35°C temperature. To keep the CO2 under supercritical conditions, pressure and temperature at the surface facilities are kept above 7.5 MPa and 35°C.

The steady-state multiphase flow simulator incorporates a wide variety of industry-standard multiphase flow correlations that have been developed through decades of research, as well as industrial data collection and analysis. The model enables the calculation of pressure losses, flow

velocities, and flow regimes at any node given in the system. The heat transfer modeling part of the simulator provides an accurate estimation of the heat transfer from the rock to the circulating fluid through cement and casing. The model recalculates the temperature and pressure-dependent fluid properties during the simulation at any given depth in the well to achieve accurate flow and thermal modeling. The simulator carries out comprehensive energy-balance calculations accounting for convection, conduction, Joule-Thomson cooling and heating, and frictional heating.

3.2 Finite-element Structural Model

One of the best advantages of the closed-loop geothermal system is the isolation of the wellbore from the surrounding formation. The circulating fluid does not encounter the surrounding rock and formation fluid, thus preventing challenges such as corrosion and scale precipitation. However, the integrity of the wellbore and stress distribution around it is still as important as it is for other geothermal systems and has been investigated through several numerical studies (Wu et al., 2021). In this research, stress regimes around the multilateral junction are modeled to study the stress distribution in the casing-cement-formation medium using a finite-element mechanical modeler (ANSYS, 2024). Three types of cylinder stresses (radial, hoop, and axial) are critical for assessing different failure mechanisms around the wellbore (Kang et al., 2022). Radial stress is a normal stress that acts either towards or away from the well central axis. Hoop stress is defined as normal stress that occurs in the tangential direction around the wellbore. Axial stress refers to a normal stress that runs parallel to the well central axis, influencing its longitudinal stability.

The temperature around the formation is 130°C. The stress and pressure data are sourced from the Utah FORGE geothermal project database (Ye et al., 2022). The schematic of the 2D finite element model is given in Figure 6 below. It shows the side view of the junction section and the top view of the cross-sections 1 and 2. The angle between the main and lateral wellbore is 15 degrees and the distance between the cross-sections is 0.5 m.

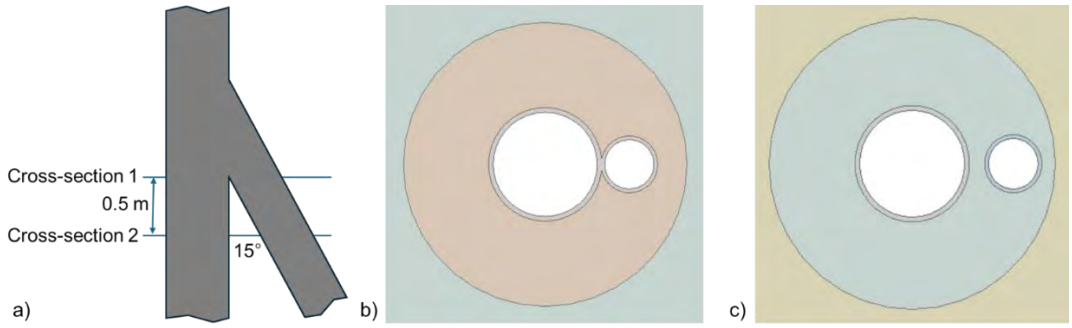

Figure 6: Schematic diagram of the structural model developed in finite-element simulator. a) The side view of the multilateral window interval, b) Cross-section 1, c) Cross-section 2

The details of the structural model are as follows:

- Main bore casing: OD 339.7 mm and ID 320.4 mm
- Lateral bore liner: OD 152.4 mm and ID 131.8 mm
- Cement thickness: 50 mm
- Formation with and length: 7 meters (it must be at least 10 times bigger than the cement outer diameter to avoid boundary effect during simulation)
- Formation temperature: 130°C
- Depth: 2134 m
- Minimum horizontal stress gradient: 14 kPa/m

- Maximum horizontal stress gradient: 17.4 kPa/m
- Pore pressure gradient: 0.43 psi/ft

Table 3: Material properties of steel casing, cement sheath, and formation for the structural model. The thermal properties are taken from Bu et al. (2017) and Olmeda et al. (2013). The formation rock properties are taken from the Branch and Balmer (1953).

Model Component	Parameter	Value
Steel casing	Young's modulus, E_s (GPa)	200
	Poisson's ratio, v_s	0.3
	Thermal expansion coefficient, α_s (10^{-6}/K)	11.43
	Thermal conductivity, K_s (W/m.K)	45
Cement sheath	Young's modulus, E (GPa)	12.5
	Poisson's ratio, v_c	0.34
	Thermal expansion coefficient, α_c (10^{-6}/K)	9.4
	Thermal conductivity, K_c (W/m.K)	0.3
Formation	Young's modulus, E_f (GPa)	68.9
	Poisson's ratio, v_f	0.26
	Thermal expansion coefficient, α_f (10^{-6}/K)	8
	Thermal conductivity, K_f (W/m.K)	2.9

3.3 Techno-economic Model

The levelized cost of electricity is estimated using a techno-economic model developed in an open-source geothermal simulator (Beckers & Ross, 2023; NREL, 2024). The model combines the reservoir, surface plant, and economic models together using empirical relationships. In this study, however, the results of the flow and thermal model are used as an input for the techno-economic model. The end use of the temperature is set to the generation of electricity through ORC that uses low-boiling point working fluid. The heat extracted from the CLGS using water or sCO2 is transferred to this working in the heat exchanger. The techno-economic tool uses equations developed by Augustine (2009) to convert heat into electricity using thermal efficiency correlations.

Capital costs and operation and maintenance (O&M) costs are estimated using basic cost correlations. For calculating the overall capital costs of the system, drilling costs and surface plant expenses are evaluated. Drilling expenses are derived by multiplying the total drilling depth by a standard cost per meter, which is typically set at $1,000/m, due to the unique aspects of closed-loop well designs, such as lengthy open-hole laterals, and the potential for greater than typical drilling depths (Beckers et al., 2023). The costs of the surface plant are determined by the capacity of the plant, with specific cost metrics derived from the research of Beckers and Johnston (2022) and Beckers and McCabe (2019). A default value of $3,000/kWe is used for calculating the cost of electricity generation infrastructure. O&M costs are computed as a percentage of the investment in surface plant infrastructure, set at 1.5% by default, as identified in studies by Beckers and

Johnston (2022). Due to the closed-loop nature of the system, which prevents fluid exposure to the environment, issues related to scaling and corrosion are not expected, thus eliminating wellfield maintenance expenses. Pumping costs for direct use are included, calculated based on specified electricity rates. For power generation, the required pumping power is deducted from the total electrical output of the plant. Costs related to exploration, potential well redrilling, well field maintenance, or land leasing are excluded from capital and O&M cost considerations (Beckers and McCabe, 2019).

Table 4: Values of some parameters for the techno-economic model

Parameter	Value
Well Configuration	CLGS with three multilateral sections
Number of wells	Two production wells, $1000/m
Heat transfer fluid	Water and sCO2
End-use	Electricity
Temperature, flow rate, and pressure	Imputed from flow and thermal models
System Lifetime	20 years
Power plant cost	$3,000/kWe
Total O&M cost	$44k/year
Total capital cost	$32.4M

4. Results and Discussion

4.1 Production forecast over 20 years

The flow and thermal and thermal model simulations were run for sCO2 and water at 10-40 kg/s mass flow rates. The model provides the temperature of the fluid along multiple nodes in the closed-loop system. Figure 7 shows the flowing water temperature profile along the annulus in the descending and horizontal sections of the CLGS and inside the tubing along the horizontal and ascending sections at the start of the production. The simulation results for the sCO2 at the beginning of production are given in Figure 8. The injection temperature for both fluids is 35°C while the injection pressure is calculated by the model based on the system pressure loss dominated by the friction to achieve system outlet pressure of 0.5 MPa for water and 20 MPa for sCO2. Both plots show that the heat transfer to the circulating fluid starts at around 600 m down in the annulus. At lower flow rates, the fluid heats up in the descending section of the well more than at higher flow rates. However, the main heating occurs in the horizontal sections of the well. Once the fluid enters the insulated tubing at higher flow rates (30-40 kg/s), the fluid temperature remains relatively constant as it travels through the tubing in horizontal and ascending sections. Whereas at lower flow rates (10-20 kg/s), the fluid temperature decreases by 5-15°C because of heat loss from the hotter fluid in the tubing to the colder fluid in the annulus since low flow rates give more time for the heat transfer to occur. Despite the reservoir temperature of 150°C, the water reaches a maximum of 141°C at 10 kg/s rate and 99°C at 40 kg/s. On the other hand, sCO2 reaches a maximum of 147°C at 10 kg/s and 125 at 40 kg/s. The reason is that sCO2 has a smaller specific heat capacity compared to water. The same reason also causes the sCO2 to lose heat by 25-35°C as it travels through the tubing in horizontal and ascending sections. Overall, the water temperature at the wellhead was estimated to be higher when the water was used (98-130°C) compared to sCO2 (90-118°C).

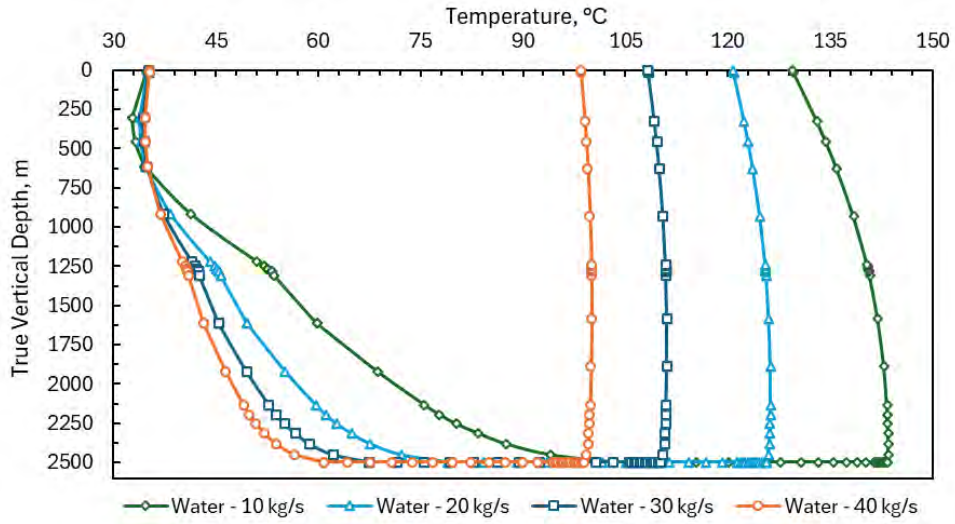

Figure 7: Flowing water temperature profile along the flow path at the start of production

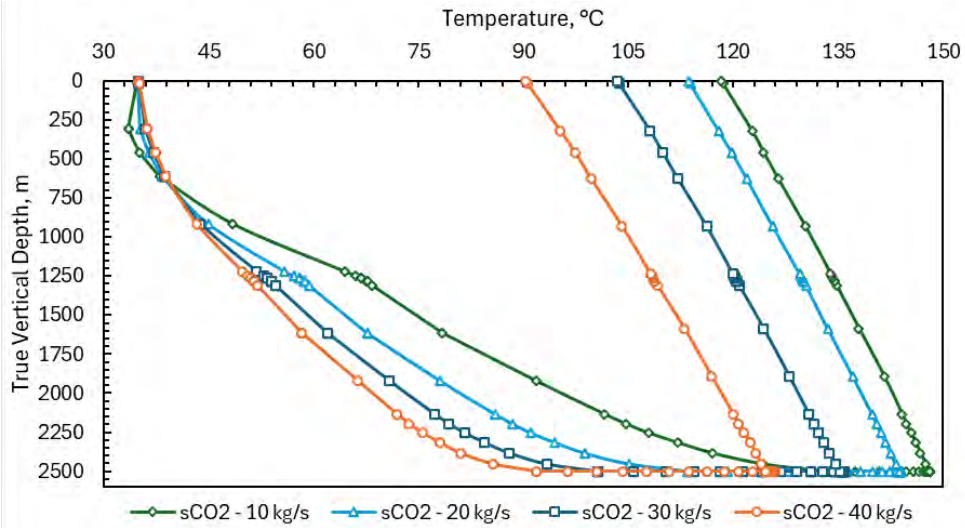

Figure 8: Flowing sCO2 temperature profile along the flow path at the start of production

The simulation was carried out for 20 years of production using both fluid types. The outlet temperature versus time for 10-40 kg/s water and sCO2 flow rate over is shown in Figure 9. After 20 years of production, production temperature at the wellhead decreased by 15-20°C for both fluid types and all flow rates. A rapid decline occurred within the 6 months of production, while it was slower for the rest of the years. It can be explained by the low thermal conductivity of the formation. The heat transfer from the formation to the circulating fluid is limited to conduction only in closed-loop systems. Although geothermal energy is renewable, heat extraction is faster than heat recovery in the near-wellbore formation. Also, heat transfer happens faster when the differential temperature between near-wellbore formation and circulating fluid is higher. Compared to continuous production, the intermitted production during the most demanding hours of the day would enable the temperature of the formation around the wellbore to increase back to the initial temperature. After 20 years, the produced water temperature was still higher than the sCO2 temperature (84-109°C for water and 73-96°C for sCO2).

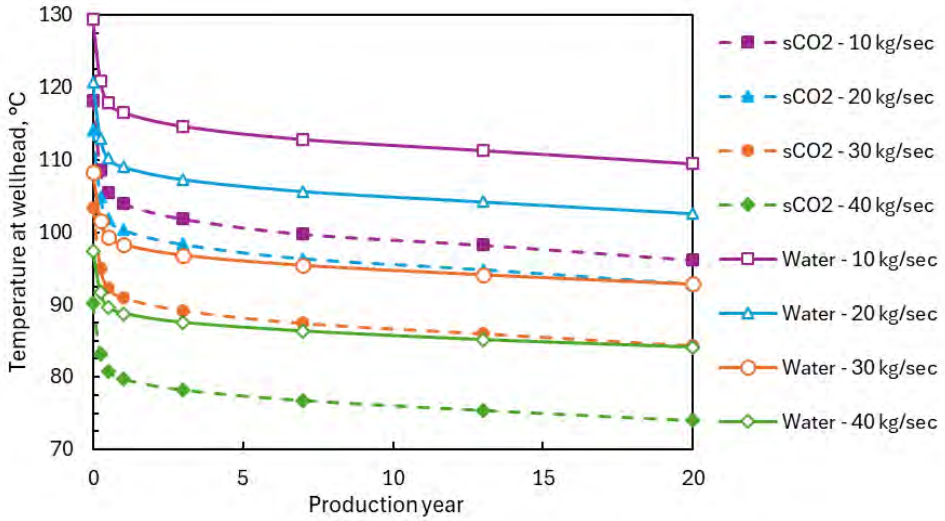

Figure 9: Temperature of the water and sCO2 at the wellhead over 20 years of production forecast

4.2 Impact of resource temperature

One of the most important factors to consider in order to achieve more affordable geothermal energy is drilling into hotter formations at lower cost. In this section, the depth and design of the multilateral well were kept the same while the resource temperature was increased from 150°C to 350°C at 2500 m TVD. The geothermal gradient from the surface to 2500 m TVD is kept constant. The mass flow rate was set to 40 kg/s for water and sCO2. The results in Figure 10 show that outlet water temperature increased from 99°C to 213°C. This increase was even higher for sCO2 (from 91°C to 261°C). Above 175°C resource temperature, the sCO2 outlet temperature was above water temperature, whereas the produced heat of water was still above that of sCO2 since water has higher specific heat capacity. The techno-economic model results showed that the levelized cost of electricity would decrease from 29.7 cents/kWh to 14.2 cents/kWh using water when the rock temperature was 350°C. Similarly, the cost was estimated to drop from 49.7 cents/kWh at 150°C to 17.5 cents/kWh at 350°C.

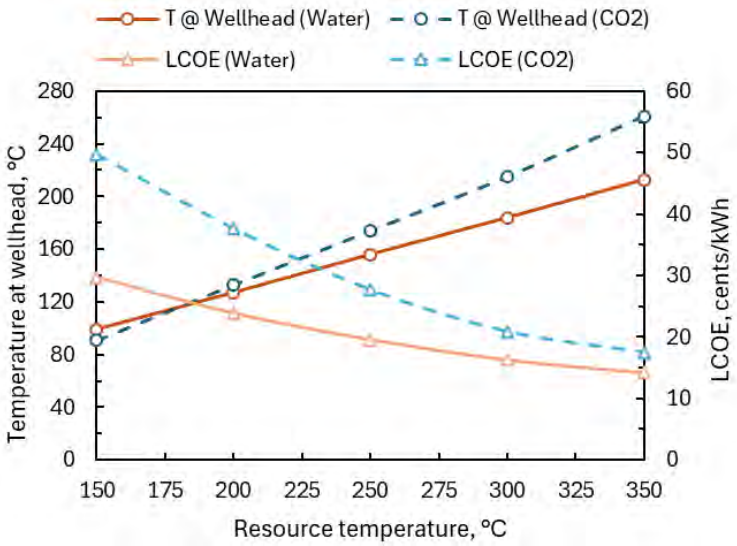

Figure 10: Impact of resource temperature on fluid temperature at the well outlet and LCOE

4.3 Impact of injection rate

The mass injection rate of the circulating fluid has a direct impact on how much heat will be produced from the closed-loop system. Therefore, the mass flow rate of water and sCO2 from 1 kg/s to 80 kg/s were used in the flow and thermal model to estimate the outlet temperature and system pressure loss. The system pressure loss shows how much pumping pressure will be required to create circulation in the closed-loop system. Higher pressure loss means more pumping power is needed, which increases the cost of the operations. The formation temperature at 2500 m TVD was 150°C and injection pressure was set to 20 MPa. The impact of injection mass flow rate on outlet temperature and system pressure loss for water and sCO2 is plotted in Figure 11 below. The outlet temperature reached the highest value of 129°C and 114°C for water and sCO2 accordingly at a 10 kg/s rate and gradually fell to around 75°C as the flow rate increased up to 80 kg/s. Meanwhile, the system pressure loss was negative or close to zero at flow rates up to 20 kg/s. Up to this rate, the pressure increase due to the volumetric expansion of the circulating fluid was bigger than the frictional pressure loss. Increasing the flow rate up to 80 kg/s frictional pressure loss resulted in system pressure loss rising up to 28 MPa for water and 24 MPa for sCO2. Overall, the outlet temperature and system pressure loss for sCO2 application was smaller than that of water.

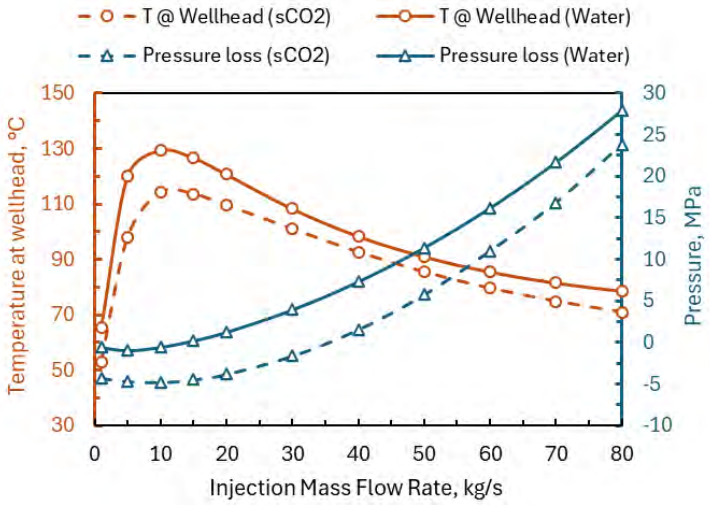

Figure 11: Impact of injection mass flow rate on outlet temperature and system pressure loss

Although the 10 kg/s injection rate yielded the highest temperature for water and sCO2, it is not the optimal flow rate when the overall heat production and LCOE are considered. According to Figure 12, the highest heat production of 5.6 MW is achieved at around 40 kg/s water flow rate when the LCOE was estimated to be the lowest at around 27 cents/kWh. Above 40 kg/s of water rate, the produced heat gradually decreased and LCOE slightly increased (4.6 MW and 32.8 cents/kWh at 80 kg/s). The heat production using sCO2, on the other hand, kept rising to 2.7 MW at an 80 kg/s mass flow rate, which also caused LCOE to increase to 61 cents/kWh. The optimal mass flow rate of sCO2 can be identified by looking at the LCOE trend, which is 40 kg/s providing 45 cents/kWh electricity. In general, water recovered three times more energy from the closed-loop system and resulted in 40% cheaper electricity generation compared to the application of sCO2. It was shown in the previous section that this difference was much smaller when the CLGS was developed at high subsurface temperatures.

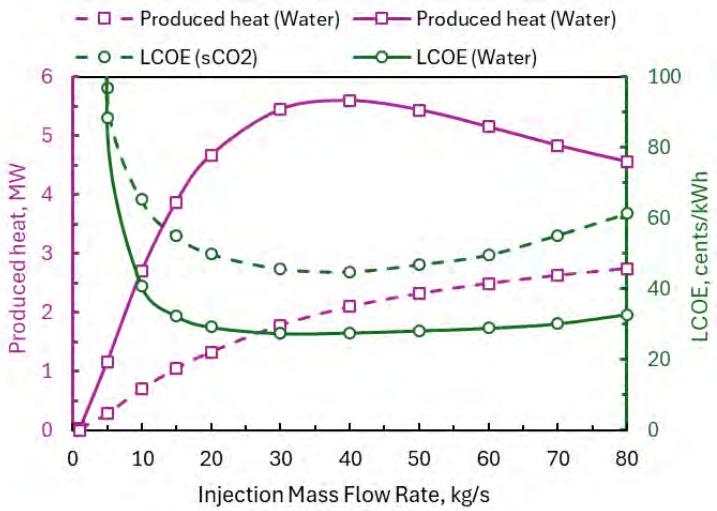

Figure 12: Impact of injection mass flow rate on produced heat and levelized cost of electricity

4.4 Impact of injection pressure

Simulations showed that injection pressure has no impact on the heat extraction from the well when the water is used. The thermal properties of the water stayed constant under the given injection pressures. However, the thermal properties of the supercritical CO2 changed as the injection pressure increased from 12 MPa to 24 MPa. In all four cases, the resource temperature was 150°C and the mass flow rate was set to 40 kg/s. It was observed that at higher injection pressures, the temperature of the sCO2 in the horizontal section annulus reached bigger values and less heat loss occurred as the fluid traveled upward through the tubing. For example, at 12 MPa injection pressure, the fluid reached to maximum of 111°C at the end of the horizontal section and decreased to 62°C (49°C heat loss) at the wellhead, whereas at 24 MPa, a maximum of 127°C at the end of the horizontal section and fall to 95°C (32°C heat loss) at the wellhead.

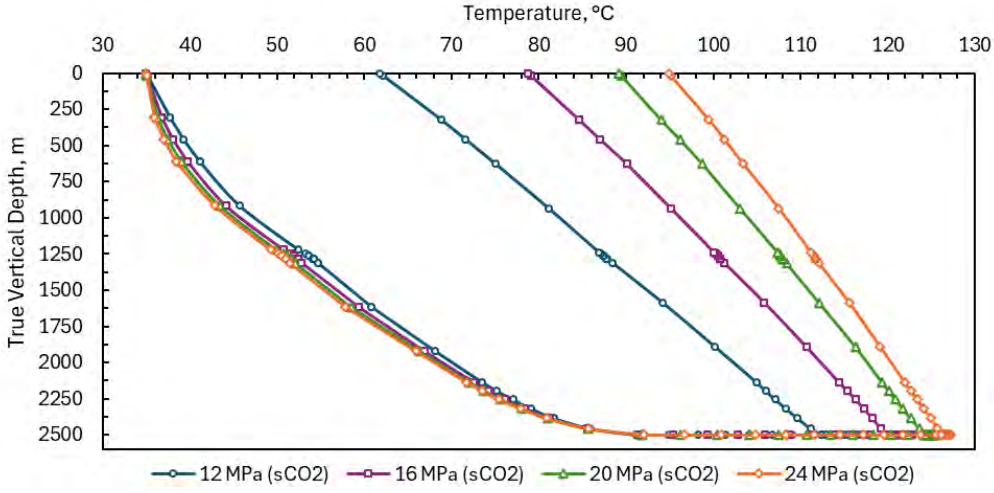

Figure 13: Impact of sCO2 injection pressure on outlet temperature

4.5 Impact of the number of lateral sections

Since the heat transfer in closed-loop systems occurs through conduction only, the total surface area around the lateral wellbore section is very important to recover more heat from the surrounding rock. Therefore, the number of horizontal sections from one to three was modeled keeping the injection temperature and mass flow rate at 35°C and 40 kg/s accordingly. The system

outlet pressure was set to 0.5 MPa for water and 20 MPa for supercritical CO2. The simulation result for the temperature profile along the wellbore is plotted in Figure 14. It shows that for the case of one 1220-meter horizontal section, the temperature of the water rises to 75°C before entering the insulated tubing and stays relatively constant as it is produced. And for sCO2 this value is 104°C before entering the tubing and 74°C at the wellhead. For the case of three 1220-meter lateral sections, circulating water reached a maximum temperature of 100°C before entering the insulated tubing and dropped to 98°C as it is produced at the wellhead. Similarly, the sCO2 temperature increased up to 126°C before entering the insulated tubing and produced at 90°C at the wellhead. The simulation showed that a longer total length of the horizontal section results in more heat transfer to the fluid and higher producing temperature. Although increasing the number of laterals increased the well construction cost from $8 million to $15 million, the LCOE dropped from 51 cents/kWh to 27 cents/kWh. As mentioned earlier, the positive contribution of higher production temperatures to the LCOE outweighs the increasing capital expenditure due to high well development costs.

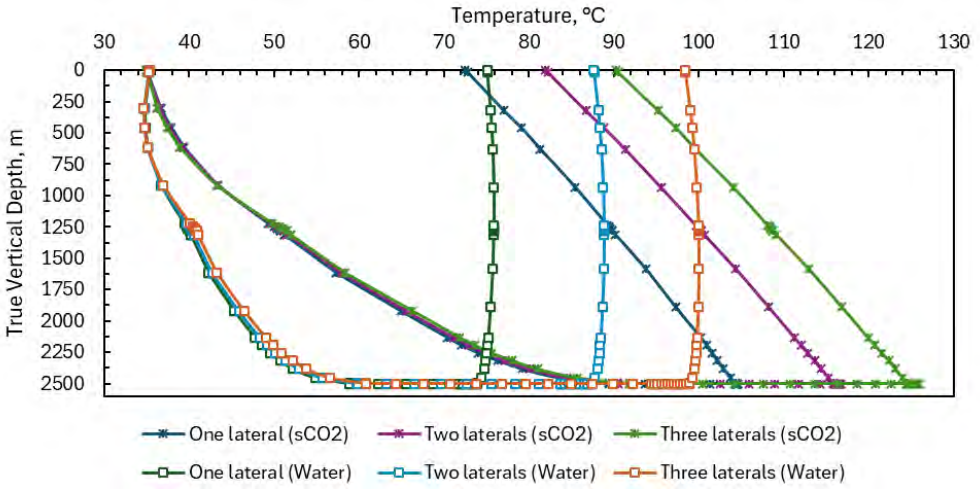

Figure 14: Impact of the number of laterals on temperature profiles along the well

4.6 Impact of casing and tubing size

To evaluate the impact of casing and tubing size on outlet temperature, three well designs were developed, only changing the size of the liner and tubing installed in the lateral sections as given in Table 5 below. From Case 1 to Case 3, the lateral sections become bigger in terms of diameter, creating more surface area for heat transfer and less obstruction for the fluid flow.

Table 5: Three cases with different liner and tubing sizes to evaluate the impact on the outlet temperature and system pressure loss

Design #	Liner OD, mm	Liner ID, mm	Tubing OD, mm	Tubing ID, mm
Case 1	136.8	114.7	89.5	71.7
Case 2	154.0	131.9	101.7	83.9
Case 3	180.5	158.4	120.5	102.7

Since the sCO2 thermal properties are impacted by the system pressure, water is used as a circulation fluid for the simulation of these three cases. The resource temperature was 150°C. Water injection temperature and pressure were fixed at 35°C and 7.5 MPa respectively. The

resulting outlet temperature profiles against injection mass flow rate are provided in Figure 14. It was confirmed through simulations that a bigger wellbore size results in slightly better heat recovery from the formation. For example, by changing the wellbore size from Case 1 to Case 3, the temperature at the wellhead increased from 85°C to 95°C at a 40 kg/s injection rate. Another advantage of a bigger wellbore was proved to be the smaller injection pressure. As shown in Figure 15, changing the design from Case 1 to Case 3 dropped the system pressure loss from 11 MPa to negative 3MPa, which means thermal expansion of the fluid provides more pressure support than frictional pressure loss. The difference becomes much bigger as higher injection mass flow rates are applied. At 80 kg/s, Case 1 resulted in around 10 times bigger pressure loss compared to Case 3 well design.

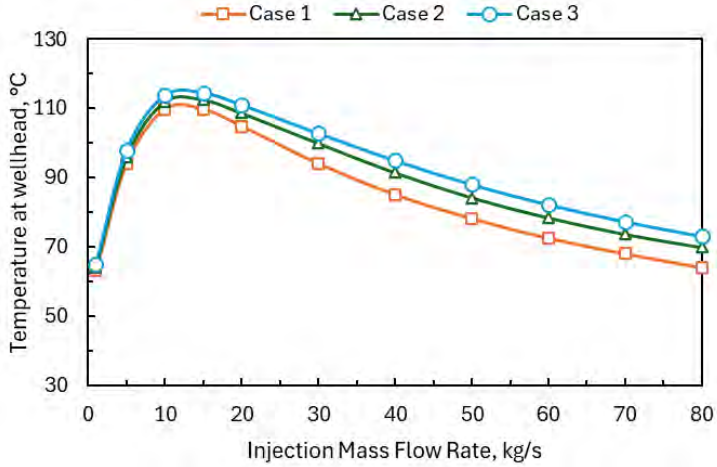

Figure 15: Impact of casing and tubing size on water outlet temperature

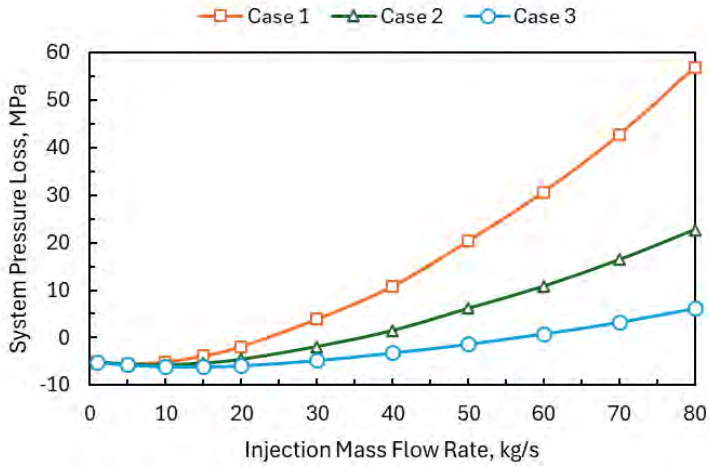

Figure 16: Impact of casing and tubing size on system pressure loss

4.7 Impact of tubing insulation

To prevent the heat of the fluid inside the production tubing from transferring to the colder fluid circulating in the annulus, production tubing must be insulated. The most common carbon steel material used for tubing manufacturing has a thermal conductivity value of around 48 W/(m.K). For comparison, granite rock has a thermal conductivity of around 2.99 W/(m.K) with a high porosity and 3.62 W/(m.K) for ones with a low porosity. That means, if the tubing is not insulated, the heat would be lost to colder fluid in the annulus faster than it was gained from the hot formation.

Therefore, insulated tubing with overall thermal conductivity ranging from 0.01 W/(m.K) to 10 W/(m.K) was tested in the simulation models using water as a circulating fluid. The injection temperature was set to 35°C and production pressure was set to 0.5 MPa while the rock temperature was 150°C at 2500 m TVD. As expected, production temperature decreased significantly as the thermal conductivity increased. Compared to the most conductive tubing, the production temperature was at least two times bigger with the least thermally conductive tubing. For example, at a 40 kg/s water injection rate, the produced water temperature was 98°C when the tubing with 0.01 W/(m.K) thermal conductivity was used, while it was 49°C when the thermal conductivity was increased to 10 W/(m.K).

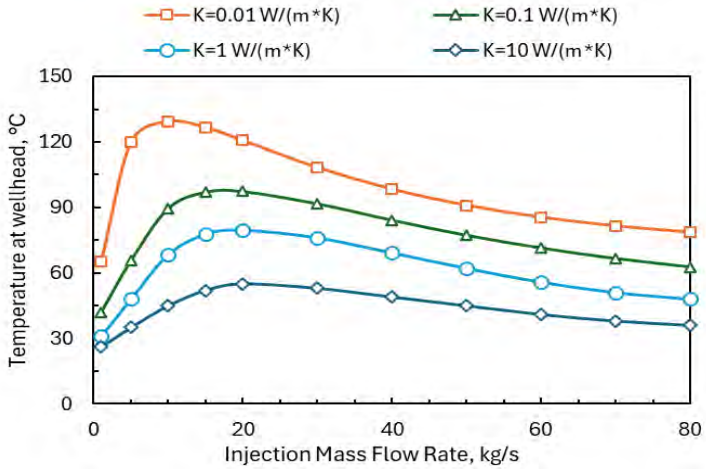

Figure 17: Impact of tubing insulation on water outlet temperature

4.8 Structural modeling results

In the structural modeling results section, an analysis of the equivalent stress distribution within the cement sheath is presented, focusing specifically on cross-sections 1 and 2, as depicted in Figure 18. A considerable disparity in stress levels is observed, with the equivalent stress at the top cross-section found to be 23% higher than at the bottom cross-section. Despite the minimal vertical distance of 0.5 meters between these two sections, the strength of the rock at both locations is assumed to be consistent. This assumption leads to the conclusion that a heightened risk of failure is exhibited by the top section, which experiences higher stress. Importantly, the intersection between the main and lateral bores is identified as the critical zone for potential failure. This analysis highlights the importance of careful stress distribution assessment and proactive failure risk management in junction zones of the multilateral well designs.

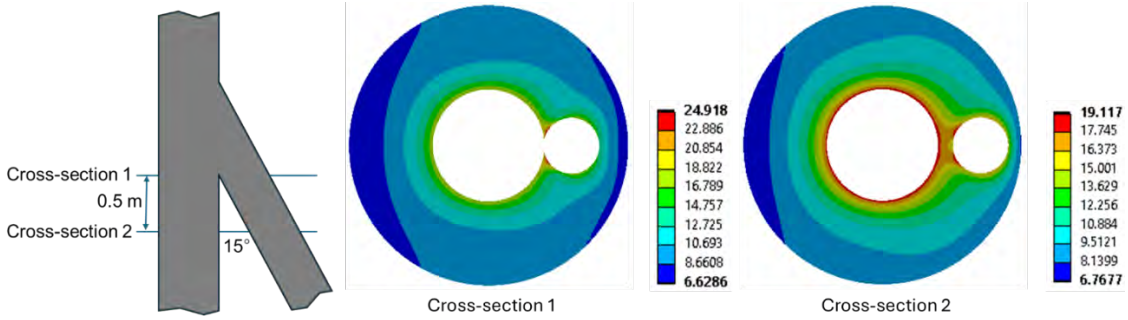

Figure 18: Equivalent stress distribution within the cement sheath for cross-sections 1 and 2. The unit of the color bar is MPa.

Conclusion

In summary, this study provides a comprehensive analysis of Multilateral Closed Loop Geothermal Systems (CLGS) using both water and supercritical CO2 as a circulation fluid, demonstrating substantial potential for enhancing power generation while eliminating issues related to corrosion and scale formation. Notably, the use of supercritical CO2, despite its lower specific heat capacity compared to water, contributes to higher temperature outputs in scenarios involving higher resource temperatures, reducing the levelized cost of electricity effectively. Moreover, the findings underscore the critical importance of optimal design parameters, including the number of lateral sections and the size of casing and tubing, which significantly influence heat transfer and system efficiency. The study also explores the necessity of insulation in production tubing to prevent heat loss, ensuring more sustainable energy production. Additionally, structural modeling results indicate significant stress challenges, especially at critical junctions within the well architecture, which could impact long-term operational integrity. Key findings from the study include:

- The simulation results demonstrate that lower flow rates allow for greater heating in the descending section of the well, but the most significant heating occurs in the horizontal sections, where higher flow rates (30-40 kg/s) maintain relatively stable fluid temperatures as they travel through insulated tubing.
- Optimal flow rates for both water and sCO2 were identified to be 40 kg/s considering the heat production and levelized cost of electricity.
- After 20 years of operation, a production temperature decline of 15-20°C was observed for both fluid types across all flow rates, reflecting the slow thermal recovery rates of the surrounding formations.
- Increasing the resource temperature from 150°C to 350°C resulted in outlet temperatures for water rising from 99°C to 213°C and for sCO2 from 91°C to 261°C. This enhancement also led to a significant drop in the levelized cost of electricity from 29.7 cents/kWh to 14.2 cents/kWh using water.
- Increasing the number of laterals and their length increases the well construction cost.
- The addition of lateral sections, from one to three, not only increased the heat recovery from 75°C to 100°C for water but also decreased the levelized cost of electricity (LCOE) from 51 cents/kWh to 27 cents/kWh, despite increasing well construction costs from $8 million to $15 million.
- Utilizing insulated tubing with a thermal conductivity of 0.01 W/(m.K) significantly maintained higher fluid temperatures (98°C for water at a 40 kg/s injection rate), compared to 49°C when the conductivity was increased to 10 W/(m.K).
- The equivalent stress at the top cross-section of the cement sheath is found to be 23% higher than at the bottom, highlighting a higher risk of failure at the top section due to the stress concentration near the junctions between the main and lateral bores.

These findings demonstrate the technical viability and economic potential of CLGS, especially when designed with consideration for optimal flow rates, insulation, resource temperatures, and structural integrity at critical junctions.

Ground Source Heat Pumps, Horizontal Directional Drilling, FEFLOW, Numerical Simulation, Thermal Response Test

ABSTRACT

Ground Heat Exchangers (GHEs) drilled using Horizontal Directional Drilling (HDD) technology have been proven to be a cost-efficient way of installing ground source heat pump systems (GSHP). They can also be installed in places where conventional horizontal ground heat exchangers (HGHE) would not be possible e.g., due to lack of land.

For the purpose of this research a two-day thermal response test has been conducted on a GHE installed in a double layered horizontal borehole in Saga City, Japan in March 2022. The two boreholes have a length of 59 m and 56 m, respectively. The maximum depth reached was 5 m for the upper borehole and 9.5 m for the lower borehole. Based on the installed GHEs dimensions and the geology of the test side a numerical model was developed in the numerical simulation software Finite Element subsurface FLOW system (FEFLOW) and validated with the temperatures of the heat medium at the return point and the outlet of the GHE measured during the Thermal Response Test (TRT).

After validation, the model was used to carry out a sensitivity analysis for different field layouts for HDD GHEs. The study investigated the optimum design for several layouts. The layouts chosen to utilize 2 to 4 GHEs either connected parallel or in series and simulate their performance. To compare the different layouts and find the optimum design at the location, a gym next to the installed GHE in Saga was used. Based on the gym's heating loads and an assumed coefficient of performance (COP) of 5.5 for cooling and 3.5 for heating the performance was compared. Lastly long-term simulations were carried out to compare the performance of several layouts over a long time period and investigate the influence on the ground.

1. Introduction

For the year 2019, the residential sector in Japan accounts for 159 million tons of CO2 emission, 74.3 million tons of this can be accounted for heating, cooling and hot water supply. To reduce this amount, Japan plans to continue to develop technology that reduces carbon emissions, and increase the use of renewable energies as power sources. This is necessary to achieve the goals of the Japanese government, formulated as the long-term strategy under the Paris Agreement, which aims to reduce greenhouse gas emissions by 46% in 2030 and to net zero until the year 2050 (The Government of Japan (2021).

A reliable system used worldwide, that can provide a solution to reduce greenhouse emissions caused by heating and cooling in residential buildings, are GSHP systems. In 2019, a total of 2662 facilities have been equipped with GSHP systems in Japan. Combined these GSHP have an installed capacity of 163 megawatts (MW), out of which 44% are used in residential buildings (Yasukawa et al. 2020). Even though installation in residential housing makes up for the majority of projects, bigger scale projects are also a common worldwide, and in Japan can be found, for example, in Tokyo Sky Tree (Bina et al. 2020).

GSHP systems are commonly installed either in boreholes or in shallow trenches. Both methods have their advantages and disadvantages and depending on the situation can be the preferred method. In Japan, GSHP systems installed in boreholes come with the problem of high drilling costs in comparison to America, other Asian countries, or Europe. HGHE, which are installed in trenches dug by excavators to remove the soil, are cheaper to install than boreholes (Bina et al. 2020). However, the large land requirement is, in a country like Japan, is another problem. To solve this problem alternative installations of HGHE have been investigated. Fujii et al. (2012) and Fujii et al. (2013) investigated the use of Slinky-Coil HGHE. They developed a model using FEFLOW, which takes into account the energy balance at the land surface. Based on this modeling and field tests they conducted a long-term cooling and heating test and showed that double-layer slinky coils could increase the heat exchange capacity remarkably. They also optimized the design by investigating the installation depth, the direction of circulation and the influence of the reflectance of the surface. Pu et al. (2018) investigated the effect of pipe arrangement, pipe spacing, buried depth and bending number of the pipes. They revealed that the difference between an in-line arrangement and a staggered arrangement is depending on the offset displacement and that for small offsets in-line arrangements showed better results. They also showed that the main factor affecting the thermal efficiency of HGHE is the thermal interference between adjacent pipes. Shi et al. (2022) looked into the performance of HGHE in four different configurations based on a 3D numerical model that considers atmosphere-soil interactions. They studied the effects on the thermal performance as well as the economic efficiency. Their results showed that from the investigated arrangement, serial connected tubes outperformed tiled-tube, spiral-tube and slinky coil HGHE under the tested conditions. They also showed that increased tube spacing can greatly increase performance due to lower thermal interference. Another way to improve performance was examined by Saeidi et al. (2023) by attaching fins to a HGHE for cooling operations. They investigated the effect of different materials used for the fins, position of fins, and the length and diameter of fins. They found that copper was best suited for heat transfer and larger diameter fins increase heat transfer, whereas longer fins beyond 1 m length do not further increase performance. They also found that fins are more favorable when installed on HGHE instead of vertical GHE. While a lot of research focused on improving HGHE, other researchers tried to combine HGHE with existing technologies to further increase usage. Léveillée-Dallaire et al. (2023) installed

Slinky-Coil HGHE under a greenhouse in Canada and showed the use of HGHE with limited space. The results of their study showed how much percent of the greenhouses heating and cooling could be covered. They also found that when installed under a greenhouse, the heating performance increases, while cooling becomes less effective. Further approaches to combine HGHE with other technologies have been conducted by Dacquay et al. (2020) who combined GHE with sewage pipes. Their study showed that the system has a profitable lifespan of 25 years and highlighted key parameters affecting the system. Further results included that the installation depth and that the thermal properties of the high-density polyethylene pipe used do not influence the performance. It was also shown that for a sustainable behavior the sewage pipe capacity was at 50% and 75%. Another way to improve HGHE suggested by Bottarelli et al. (2022) was the use of phase change materials in the backfilling. The results showed that these could help deal with peak loads in harsh weather and therefore recommend the use in climates with hot summers and cold winters. However, they found that the main effect can be observed in summer, while in lower temperatures in winter water was as suitable as the phase change material. A good summary of the majority of the recent GSHP studies is provided by Rashid et al. (2023). However, it is evident from this overview that conventional vertical GSHP and HGHE are the subject of the majority of studies.

A third way to install GHE is the use of HDD technology. In Japan this technology has first been introduced by Hamada et al. (2007). HDD is a drilling method used to install pipes or cables which does not require to disturb the surface by digging a trench. The drilling is launched from equipment at the surface and follows a pre-defined path. It is a highly flexible method which can reduce drilling cost by reducing work time needed for construction and reducing land surface requirements. Furthermore, it is also capable of drilling very varying boreholes that can be adapted to many locations' requirements. HDD drilling is commonly known for its use in the installation of pipes and cables under obstacles such as roads, railroads, or rivers.

In North America HDD is already frequently used to install GHEs either by inserting a U-Tube or by drilling large U-shaped boreholes. Grupp and Fortunato (2014) describe a system installed on the American West Coast, where several U-Tubes were inserted into HDD boreholes and field test conducted. They described the biggest challenge faced during trials was the missing regulations for this kind of technology and under sizing of the installed GHE. Dacquay, Lohrenz, and Fujii (2022) utilized an HDD drilled HGHEs in two layers to develop and evaluate a software and hardware package that calculates future ground hear exchanger temperatures to avoid thermal imbalance. The installation method used allowed for the use of a bigger diameter by inserting a single pipe into the borehole. Similar, Bina et al. (2020) investigated and simulated a HDD HGHE installed in Saga, Japan. By utilizing their model, they investigated the influence of nominal diameter, horizontal length, installation depth, and groundwater flow on the system. They also compared the results of an economic analysis with a regular vertical GSHP system to show the cost efficiency of HDD drilled HGHE. However, by just installing a single layered system, they found that a lot of energy got wasted returning the heat medium to the inlet above ground, due to the length of the borehole. On the same project location Tsuya et al. (2021) conducted test to determine the influence of the flowrate and flow-direction in the HGHE. They conducted a TRT on the HGHE and showed its applicability to this kind of system. During the testing the flow direction was reversed and showed a declining heat exchange rate. After testing they conducted sensitivity studies to show the influence of the flow rate on the heat exchange capacity and determined the optimum flowrate for the field test area. Their research also showed that for pipes with larger diameters higher flowrates are required to maintain a good performance. The same test

site has been used in a modified state by Lein et al. (2024). In their research the test site was expanded to a double layered HDD drilled HGHE. This was done based on previous research that showed layering HGHE can improve the performance (Fujii et al. 2012). The authors investigated the applicability of water injection into the boreholes to improve performance. This has been proven effective in vertical GHE (Inoue et al. 2014) and as HDD drilled HGHE combine the properties of HGHE and vertical GHE, they can benefit from layering and water injection both. The study considered several parameters for water injection, like injection rate, injection temperature, injection place, and permeability of the underground. The results showed improvement of heat exchange rates for higher injections rates up to 2 L/min. They also showed the influence of the geology and injection place that can alter result significantly when the ground is impermeable and water injection occurs in all boreholes.

A lot of research conducted is done by utilizing simulations. When simulating HGHE it is important to consider the interaction between ground surface and the atmosphere, especially the heat flow. The heat flow is influenced by many parameters, like atmospheric temperature, solar radiation, and others. Tang and Nowamooz (2020) showed the importance of this interaction in their simulations by conducting them when considering the interaction between atmosphere and soil and without it. For this they developed a model that considers the energy water balance on the land surface. Nam and Chae (2014) coupled models for ground heat transfer, ground surface heat and ground heat exchanger to predict the heat exchange rate in case studies. The investigated ground heat exchanger was installed in the foundation of a building, with the goal of creating a design tool for HGHE. With this they achieved good results for heating, however cooling operations need more input data due to factors like heat emissions of mechanical equipment not being considered. To consider the interaction between surface and atmosphere this paper will use the approach by Fujii et al. (2019) using the Sol-Air temperature (SAT). The SAT uses several parameters and combines them into a new variable that was used as a new input for their simulations. Using the SAT led to good results in the analysis they conducted in the same area as this study.

The literature study does point out several gaps in the overall research on HDD drilled HGHE. Design analysis have been frequently carried out in many studies as shown in literature research, but mainly focusing on HGHEs. Especially the interaction and performance of several HDD drilled HGHE has not been well investigated yet. This is where this paper aims to fill the knowledge gap and help improve design decisions for HDD HGHE systems. On the base of a field test conducted in Saga, Japan on a double layered HDD HGHE and an adjacent gym, several designs for HDD HGHE have been tested and compared as the main objective of this paper. Following a TRT, the measurement results were utilized to build and validate a numerical model in FEFLOW. This model was then adapted to investigate five different designs. These include the original system installed, ring shaped HGHE, two parallel HGHEs, angled HGHEs, serial connected HGHE and two double layered HGHE in a staggered arrangement. To investigate their performance a gym next to the original installed HDD HGHE was used as reference. After calculating the required heating and cooling loads for one year and the necessary heat exchange rate, each design was compared with each other. For the parallel system and the angled system sensitivity studies have been carried out to determine suitable distance and angles respectively, to achieve optimal performance for the location. Lastly long-term simulations have been carried out over a span of 10 years for the same systems to determine long-term performance, influences on the ground and sustainability of the system.

2. Field Test and Numerical Modelling

On the southern island of Kyushu in Japan, in the city of Saga, a double layered HDD drilled HGHE was constructed. The drilling and connection of the HGHE, seen in Figure 1, were done under the parking lot of Biotex Co. Ltd. in two U-shaped boreholes. The upper and lower boreholes have a length of 59 meter (m) horizontally and a depth of 5 m and 56 m and a depth of 9.5 m respectively. Inside the borehole high density polyethylene pipes with an outer diameter of 60 mm and an inner diameter of 52 millimeter (mm), and a thermal conductivity of 0.42 watt per meter-kelvin (W/m/K) was installed. The annular space of the borehole with a diameter of 114.3 mm was naturally filled and eliminates the need for grouting or casing.

Figure 1 Drilling and connection of the boreholes

On its path, seen in Figure 2 the borehole crosses through the different geological layers at the location which consist of clay and sand, shown in Figure 3. At a depth of 3.8 m clay is interrupted by a thin sand layer before reaching a depth of 7 m, and being replaced with sand. Laboratory measurements carried out on samples from the location have given a thermal conductivity of 0.951 W/m/K for clay and 1.261 W/m/K for sand in water-saturated conditions. The groundwater level at the test site was measured at a depth of -0.98 m.

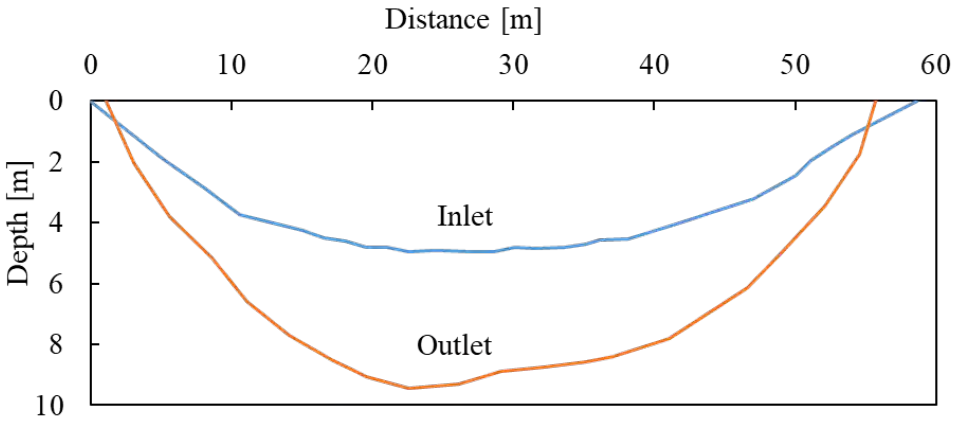

Figure 2 Drill path of the boreholes

The test field's location is situated in the temperate climate zone with no dry season and hot summer (Cfa) according to the Köppen climate classification (Kottek et al. 2006). The weather in Kyushu is characterized by hot summers with high precipitation and moderately cold winters with low precipitation.

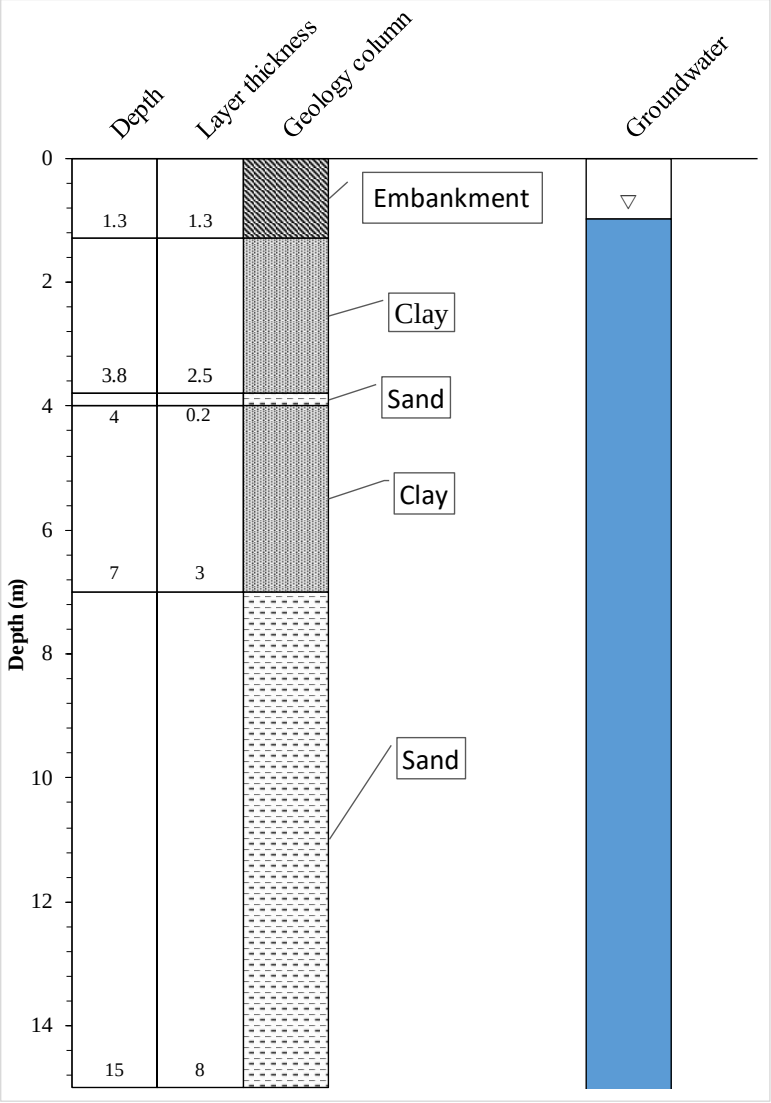

Figure 3 Geological column of the test area

2.1 Results of the Field Test

In spring of 2022, a field test took place. From March 24 to March 26 a TRT was conducted using the testing equipment of Akita University shown in Figure 4. The apparatus has a total capacity of 10-kilowatt (kW) heating, which is split to two heaters with a capacity of 6 kW and 4 kW respectively.

Figure 4 Testing equipment of Akita University

For the TRT, a constant heat load of 5 kW with a flow rate of 20 liter per minute (L/min) was applied on the system. As a heat medium water was utilized. One benefit of installing the double-layer HGHE is that inlet and outlet are now located close to each other, which eliminates heat losses occurring when installing a single-layer HGHE where the heat medium is transported back above ground. During the TRT several parameters have been measured and can be seen in Figure 5. The temperature was measured at three points, the inlet, the turn-point and the outlet. Furthermore, the flowrate and ambient temperature were recorded and the average heat exchange rate was calculated to be at around 5.21 kW (43.79 watt per meter (W/m)). During the last quarter of testing rain started, which decreased the temperature in all three points measured. The total amount of rainfall of 59 mm was observed at the local weather station in Saga City. Due to the HGHE not being fully completed and thus allowing the inflow of water, this behavior can be explained. Another factor that explains this behavior is the installation method itself. Due to the drilling being shallow in the beginning and having a low angle a sizeable amount of the GHE is closer to the surface than normal HGHEs and can be influenced by rain faster.

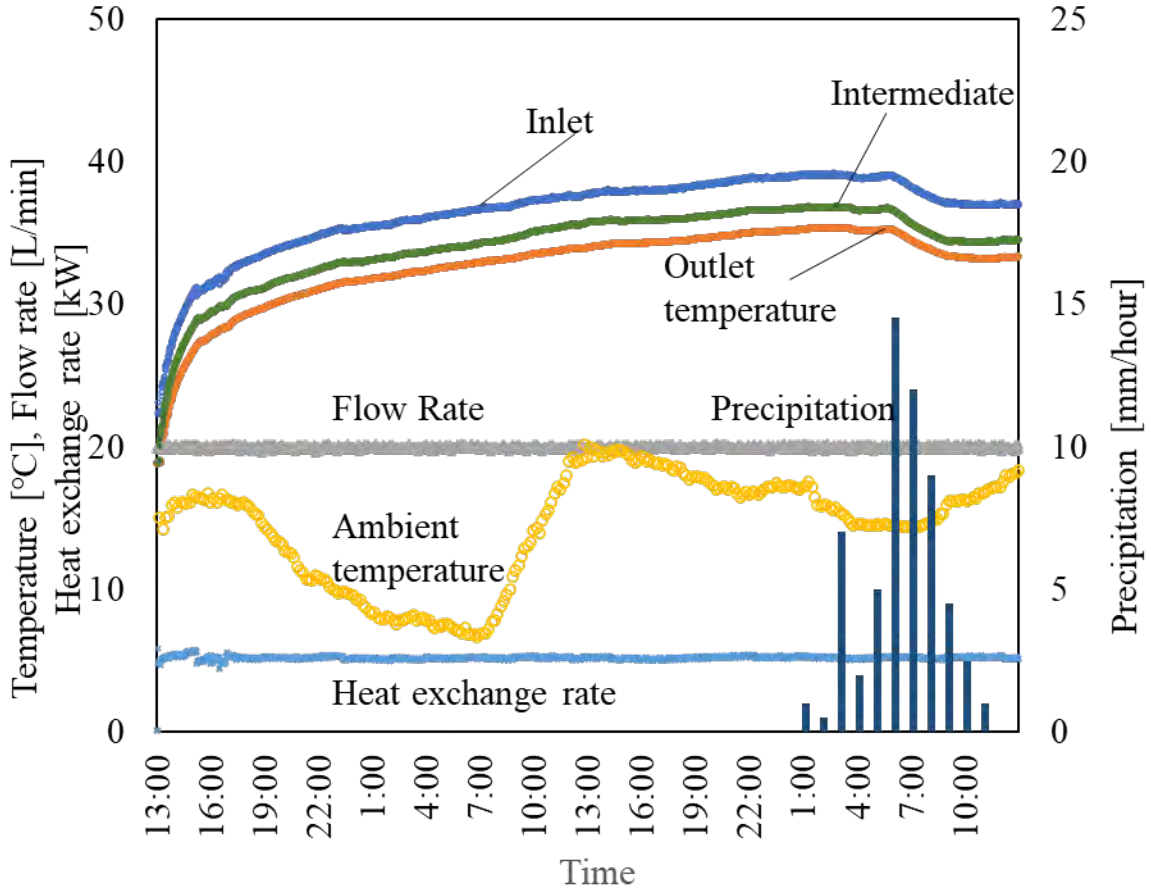

Figure 5 Result of the Thermal Response Test

2.2 Numerical Modeling

Using FEFLOW 8.1 (Diersch 2013) as software, a numerical was created to simulate the problem. FEFLOW uses the following three equations to simulate mass and heat transport:

$$\frac{\partial}{\partial t}(\varepsilon_\alpha \rho^\alpha) + \frac{\partial}{\partial x_i}(\varepsilon_\alpha \rho^\alpha v_i^\alpha) = \varepsilon_\alpha \rho^\alpha Q_\rho^\alpha \quad (1)$$

$$v_i^\alpha + \frac{k_{ij}^\alpha}{\varepsilon_\alpha \mu_\alpha}\left(\frac{\partial p^\alpha}{\partial x_j} - \rho^\alpha g_j\right) = 0 \quad (2)$$

$$\frac{\partial}{\partial t}(\varepsilon_\alpha \rho^\alpha E^\alpha) + \frac{\partial}{\partial x_i}(\varepsilon_\alpha \rho^\alpha v_i^\alpha E^\alpha) + \frac{\partial}{\partial x_i}(j_{iT}^\alpha) = \varepsilon_\alpha \rho^\alpha Q_T^\alpha \quad (3)$$

Mass conservation, Momentum conservation, and Energy conservation are expressed by the Equations 1 to 3 respectively. With ε being the porosity, α the ground thermal diffusivity in square meter per second ($m^2 s^{-1}$), ρ the gas density in kilogram per cubic meter (kg m^{-3}), v_i the vector of pore velocity in meter per second (m s^{-1}), Q_ρ the fluid mass sink/source in per second (s^{-1}), $k_{ij}$the permeability tensor in square meter (m^2), μ the dynamic viscosity of gas in kilogram per meter per second (kg $m^{-1} s^{-1}$), p the gas pressure in pascal (Pa), g_j the gravitational vector in meter per

second squared (m s^{-2}), E the internal thermal energy density in square meter per second squared (m^2 s^{-2}), x_i the cartesian coordinates (m), j_{iT}^{α} the Fourier's heat flux vector in kilogram per cubic second (kg s^{-3}), and Q_T the source of heat (kg $m^{-1}s^{-1}$).

Figure 6 shows the dimensions of the model. To create the model, the well path was imported using an Auto CAD file and the map function of FEFLOW.

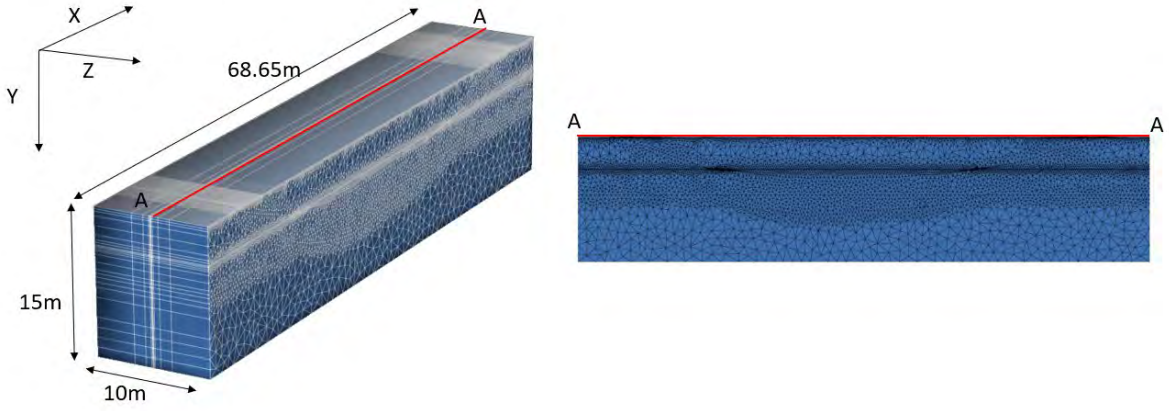

Figure 6: Dimensions of the model

The mesh of the model consists of a total of 162,252 elements which were refined and defined in a way around the HGHE to have at least 5 m of blank mesh existing to prevent any influence from any boundary conditions. The boundary conditions of the model are displayed in Table 1.

Table 1: Boundary Conditions	
Fluid Flux:	No inflow from the bottom or the sides of the model, inflow from the top according to rainfall observed
Hydraulic Head:	No groundwater flow
Boundary Condition:	Adiabatic at peripheral boundaries 19.7°C at the bottom boundary of 15 m (average of SAT) SAT from the surface
Soil:	
Thermal Conductivity:	Clay: 0.951 W/m/K, Sand: 1.261 W/m/K
Heat Capacity:	2.52 Megajoule per cubic meter kelvin ($MJ/m^3/K$)
Pipe:	
Thermal Conductivity:	0.42 W/m/K

To obtain the initial conditions of the ground temperature at the start of the TRT, a 2.5-year long simulation was used utilizing the SAT, as no temperature measurements of the underground were taken. With the data of this simulation Equation 4 was created and imported into the model:

$$T=-0.00388092*y^3-0.15539878*y^2-2.04325121*y+10.91131541 \quad (4)$$

With T being the temperature (°C) and y the depth.

The SAT was used for the as the temperature input on the surface of the simulations to consider the influence of the atmosphere. This method was been proven as accurate based on previous studies in the same location utilizing this method. The SAT is used in the simulations instead of the air temperature as an input and considers more parameters as shown in Equation 5:

$$SAT=\theta_0+1/\alpha_0((1-\alpha_s)*J-\varepsilon*J_{eh} \quad (5)$$

With θ_0 being the ambient temperature (°C) and J the solar radiation in watt per square meter (W/m²). Both were derived from the local weather station in Saga City. α_0 and α_s are the coefficients for heat transfer between air and soil in watt per square meter kelvin (W/m²/K) and the Albedo (0.3 for soil), respectively. Lastly, ε is the dimensionless factor for long wave emission and J_{eh} the effective emission (W/m²).

To validate the model the inlet temperature measured during the TRT was used as input data to simulate the turning point and outlet temperature. Figure 7 shows the result of the history matching using the two temperatures simulated, which both show a good match throughout the whole time of the TRT. The average errors for the turning point temperature are 0.17°C and 0.09°C for the outlet temperature.

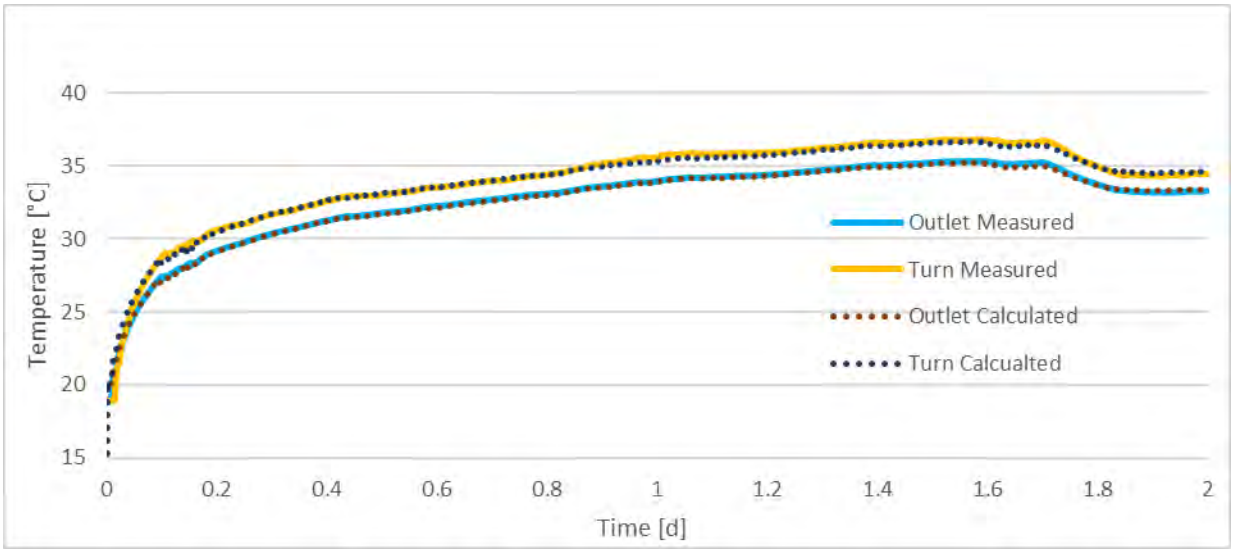

Figure 7: Results of history matching

3. Design Boundary Conditions and Input Data

3.1 Input Parameters

To simulate the performance of the different designs, the heat loads required for a gym next to the originally installed HGHE will be used. The outline of the gym can be seen in Figure 8. The gym covers a total surface area of 1027.35 m² and a roof area of 328.76 m².

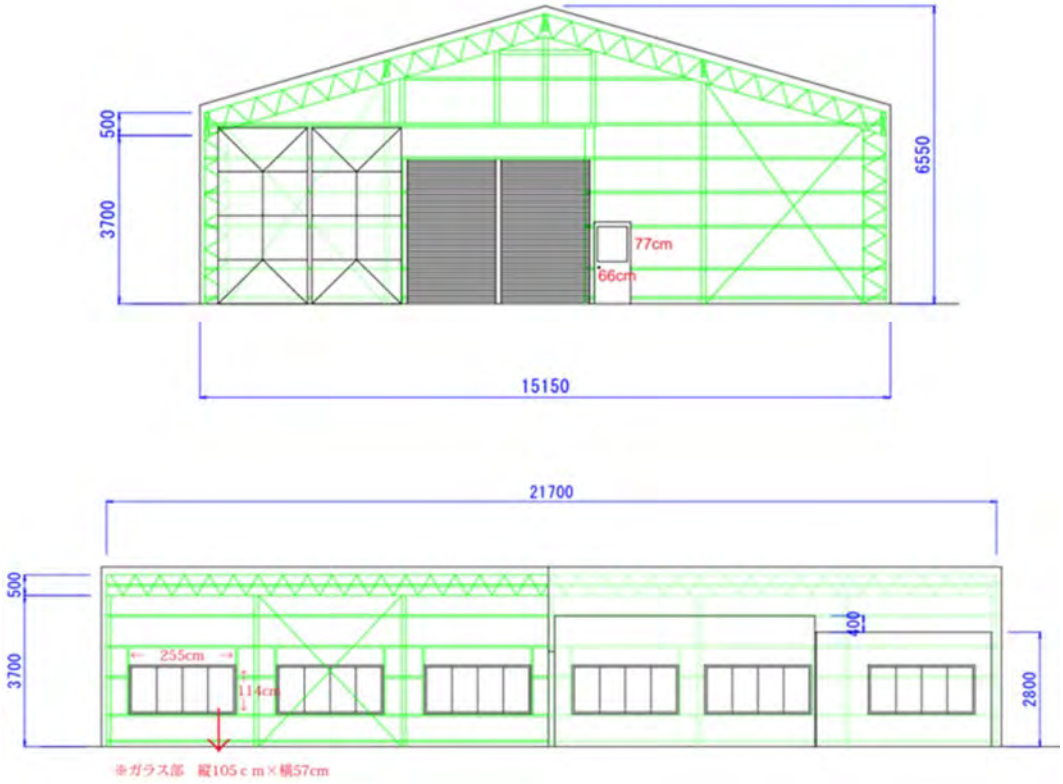

Figure 8: Geometry of the gym

To calculate the heat loads for the gym the Equations 6 and 7 have been used.

$$Q_h = \frac{U*A_e(T_i - T_o)}{A_f} - \frac{I*\eta}{A_f} \quad (6)$$

$$Q_c = \frac{U*A_e(T_o - T_i)}{A_f} + \frac{I*\eta}{A_f} \quad (7)$$

Where Q_h and Q_c are the heating and cooling heat loads (W/m²), U the average heat transfer coefficient (0.87 in the case of Saga City), A_e the surface area of the building (m²), A_f the roof area of the building (m²), T_i the target room temperature (°C), T_o the outside Temperature, I the solar radiation (W/m²) and η the average solar heat gain rate. The weather data for the calculations have been taken from the local weather station in Saga City. The required heat exchange rate for the gym can be seen in Figure 9. For the calculations a constant coefficient of performance (COP) of 5.5 for cooling and 3.5 for heating was assumed.

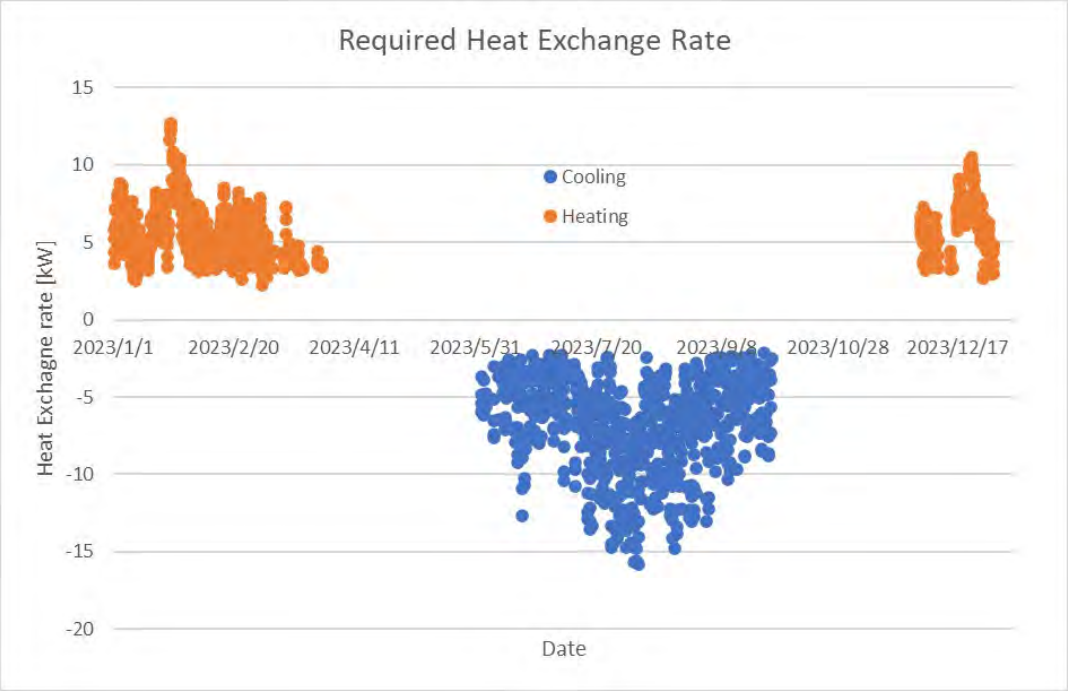

Figure 9: Required Heat Exchange Rate for the gym

Afterwards Equation 8 was used to calculate the required heat exchange in the GHE for a set flowrate:

$$q=\dot{Q}*Cp*\rho*\Delta T \quad (8)$$

Where q is the amount of heat transfer (W), $\dot{Q}$ is the volumetric flowrate in cubic meter per second (m^3/s), Cp the specific heat of the heat exchange fluid in kilojoule per kilogram kelvin (kJ/kg*K), ρ the density of the fluid (kg/m^3) and ΔT the temperature difference between inlet and outlet.

As input on the surface the SAT based on weather data from the year 2023 was used. This data was measured at the local weather station and the SAT was calculated by using Equation 5.

3.2 Boundary Conditions

To guarantee comparability of design the following boundary conditions have been set as seen in Table 2.

Table 2: Boundary Conditions	
Heat Load:	According to gym calculations
COP:	Heating: 3.5 Cooling: 5.5
Target Room temperature:	Heating: 20°C Cooling: 24°C
Daily Operation Time:	15:00-19:00
Flowrate:	30 L/min
Pipe length:	120 m and 240 m
Surface:	SAT
Heat Medium:	Water

For the case studies the simulation time will be set to 1 year to cover the heating and cooling period. Heating was done from December to March and cooling operations occurred from June to September. The operation time was set from 15:00 to 19:00 according to the usual usage for the gym. Furthermore, the total land area covered by the GHE was limited to a size of 1 hectare. The geology of the model will be based on the original geology in Saga as well as the size and properties of the GHE.

4. Sensitivity Studies

To evaluate different designs the following section will cover a sensitivity analysis to show the influence of the designs chosen. In total six different designs with two pipe lengths have been investigated, which are displayed in Table 3 and Table 4:

Table 3: Total Pipe length 120m

Straight:		Original HGHE installed in Saga
Ring:		Total pipe length of about 120 m with a radius of 20 m

Table 4: Total Pipe length 240 m

Parallel arrangement:		2 layers 120 m pipe length in each system 60 m per layer
Staggered arrangement:		1 layer 120 m pipe length in each system 60 m length per pipe
Series arrangement:		2 layers 120 m each 60 m per layer
Angled arrangement:		2 Layers 120 m pipe length in each system 60 m per layer

For some of the designs, sensitivity analysis have been carried out to determine ideal design parameters.

4.1 120 m Pipe Length

To achieve comparability the performance of the originally in Saga installed system was simulated using the boundary conditions for the gym described in the previous chapter. The result of this simulation can be seen in Figure 10.

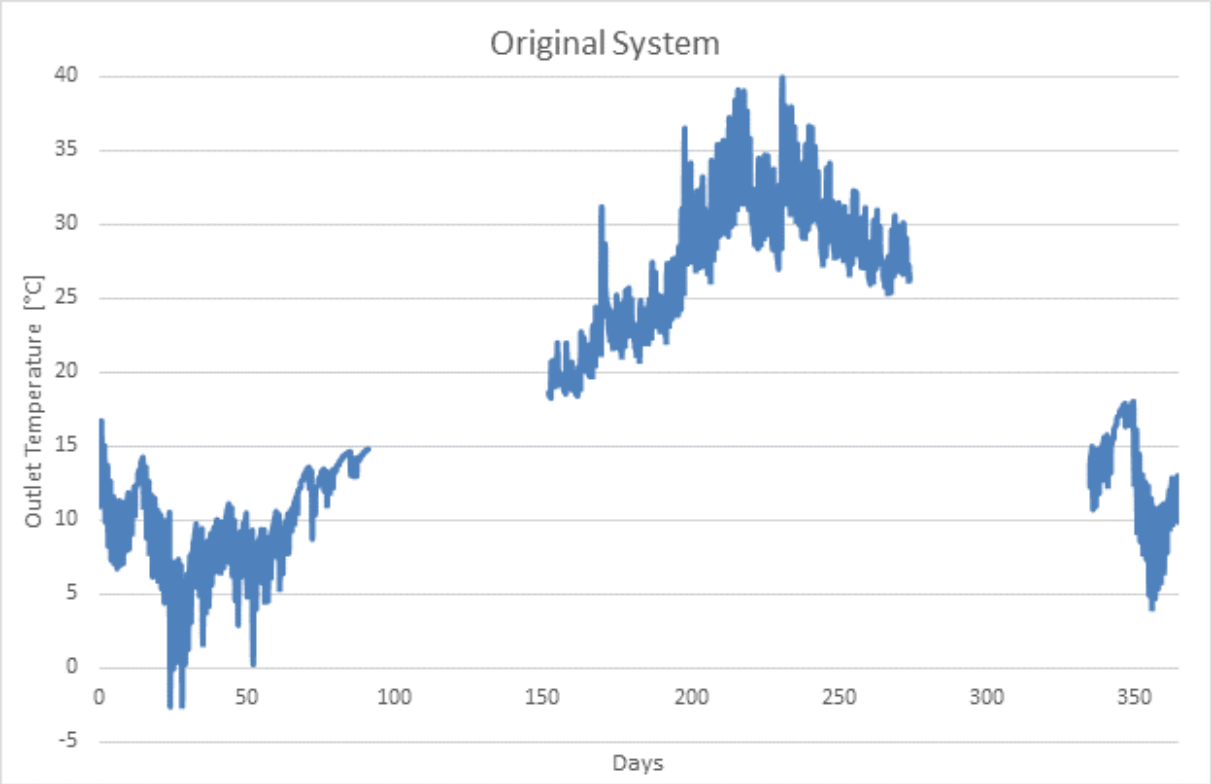

Figure 10: Performance of the original system

The data from this simulation will mainly be used as a comparison to other designs, however it is already visible that this system reaches negative degrees for the outlet temperature in winter and up to 40°C in the summer which is usually undesirable, therefore it was concluded that a larger system is more desirable.

The second sensitivity study conducted with a pipe length of 120 m was an HDD HGHE in the shape of a ring. It was chosen to conduct it with this pipe length as this was, according to the installing company, the smallest drilling radius possible. Figure 11 shows the performance of the ring shaped GHE, installed at a depth of 5 m, compared to the original system. Comparison of the two arrangements shows only small differences in the performance. This difference can be explained by the installation depth of the system. While the straight arrangement is a double-layer installation, the ring was only installed in one layer. If installed at the same depth as the upper layer (5 m), the performance will be slightly worse for the ring, caused by the better performance of deeper installed HGHE. Similar behavior is observed when the HGHE is installed at a depth of 10 m, equivalent to the deeper borehole, which leads to slightly better performance than a system with a straight arrangement. However, no further testing on this shape has been conducted, as a field test utilizing this design is currently being planned.

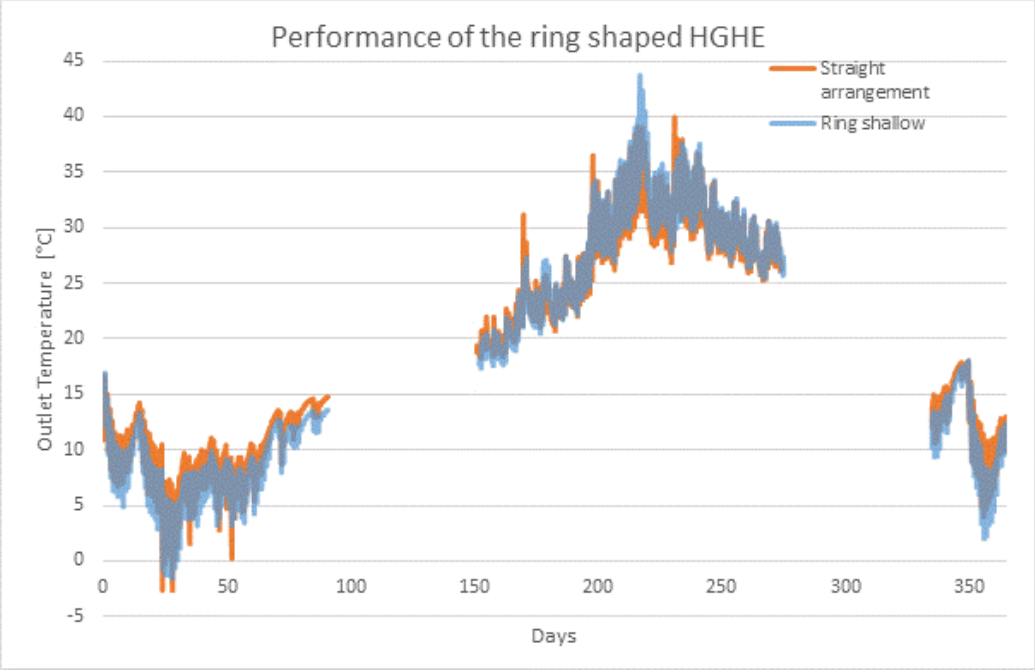

Figure 11: Performance of the ring-shaped HDD HGHE

4.2 240 m Pipe Length

For a pipe length of 240 m the performance of four different systems has been investigated. Beforehand for the 2 parallel Systems and the Angled System the influence of the distance between the systems and the angle has been investigated. For this a constant heat load of 10 kW and a flow rate of 30 L/min was applied to the system over the course of 30 days. The result for the 2 parallel systems can be seen in Figure 12.

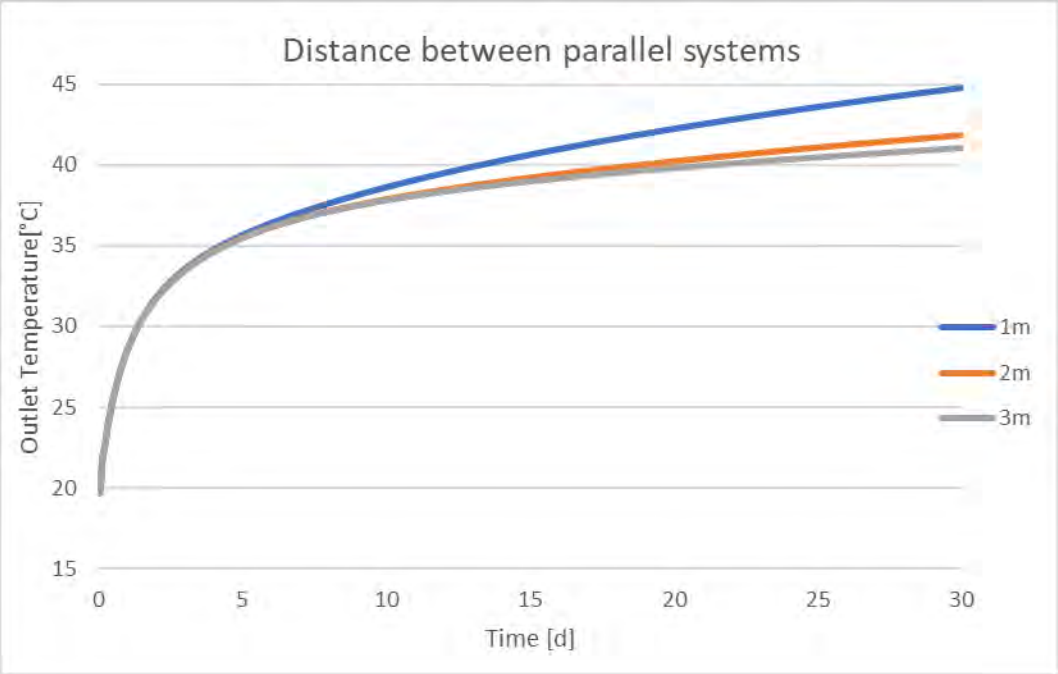

Figure 12: Distance between parallel systems

The simulation shows that for this kind of arrangement a wider spacing between the systems is preferable. As the interference on each other becomes noticeable smaller with increasing spacing a distance of 3 m has been chosen for the analysis to use the available space as efficiently as possible. For the angled arrangement angles of 15°, 30° and 45° between the pipes have been investigated, which can be seen in Figure 13.

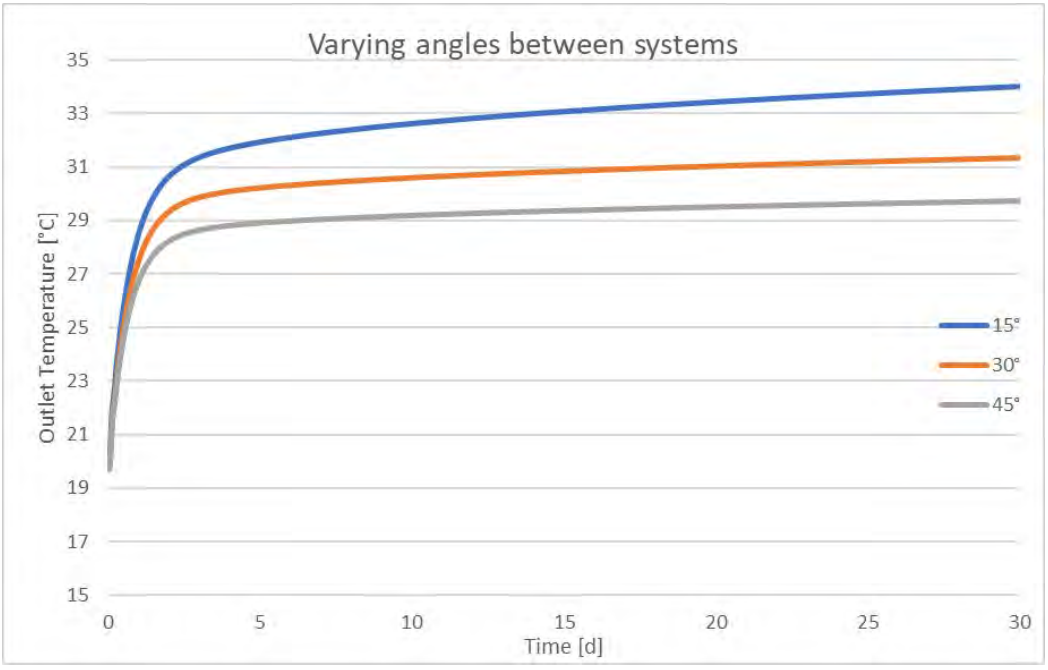

Figure 13: Comparison of varying angles

Larger angles in this design mean a large increase in land usage. This behavior can be seen in Figure 14, where that distance between the turning point of the systems increases by about 34.6 m when comparing an angle of 15° and 45° between the pipes. This design was tested with the idea of drilling several boreholes from one starting point in a circular pattern. Based on this idea, and the results from the simulation an angle of 30° was chosen for the sensitivity study. While an angle of 45° would result in a better performance when just utilizing two or three systems, choosing an angle of 30° between the systems would allow the installation of 4 more systems when installing them in a full 360° circle.

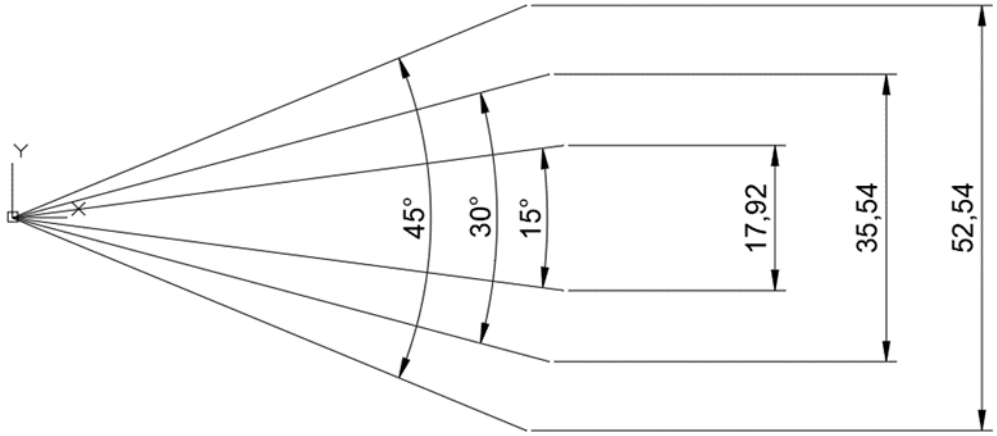

Figure 14: Distance between the turning point for different angles

The results of the comparison of the systems utilized for the gym in Saga can be seen in Figure 15. The first thing to notice is that a system with a pipe length of 240 m is much more suitable for the gym compared to a system with 120 m pipe length. During peak loads the outlet temperature does not surpass 33°C for cooling or fell below a temperature of 5°C in heating. When comparing the performance of the systems, it can be seen that the angled system has the best performance. This can be explained with the wide spacing between the pipes and therefore lower thermal interference between the systems. However, the much larger land requirement of this kind of system mean consideration has to be taken when using more than two systems like in the study. Surprisingly there is only a very small difference between two parallel systems and a serial connection of two systems, with the later one having a slightly better performance. This shows that for the chosen parameters the thermal interference was only minimal and a design can be selected based on land availability. The results also agree with previous research done on conventional HGHE, where series connections had a better performance, compared to other designs. This means that serial connected designs, that would e.g. surround a house, can be a promising way of installing HDD HGHE, which would not require a lot of additional land. The performance of the staggered system was very comparable to the parallel system, however, when peak loads occurred it performed much worse. This can be explained by former observations in research that showed that certain staggered arrangements of pipes might perform worse than in line arrangements like in the parallel system. As only one type of staggered arrangement has been tested in this research, more work needs to be conducted to get more reliable results.

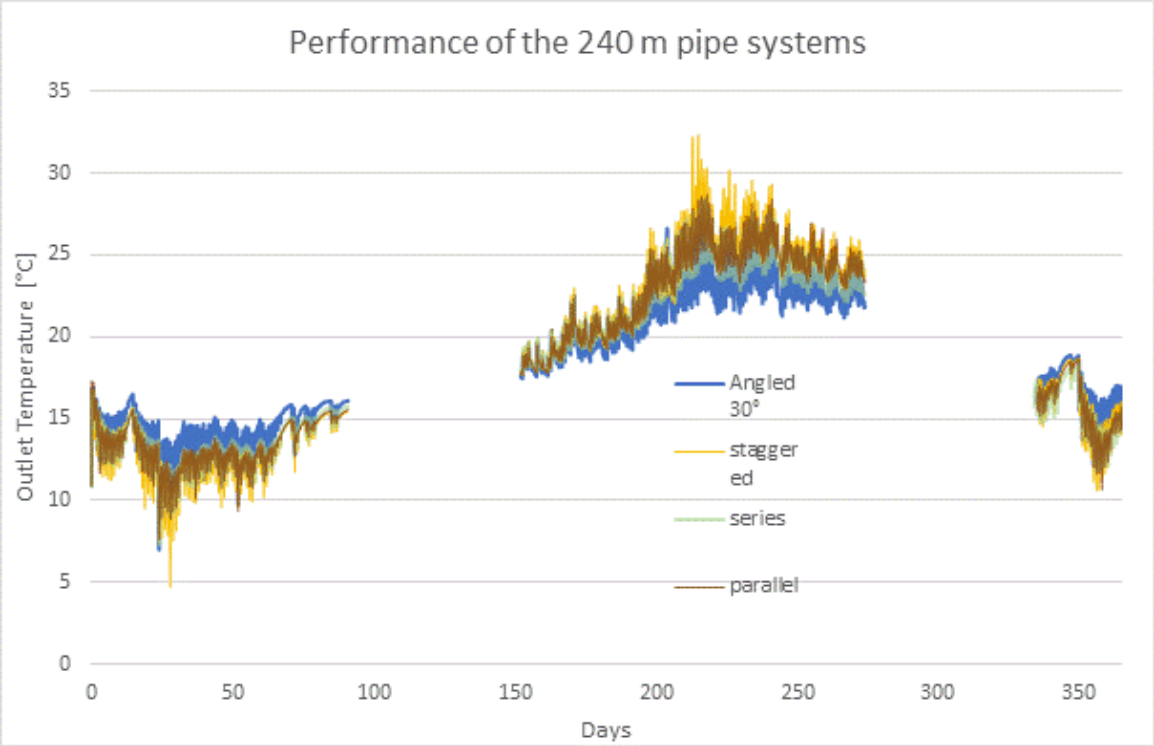

Figure 15: Comparison of results with 240 m pipe length

5. Long Term Simulations

The last chapter of this paper will focus on long-term simulations to analyze the impact on the ground and long-term sustainability. Results of the first three years of the 10-year simulations can be seen in Figure 16. Exemplary the performance of the angled system was shown, as the best performing system. The first thing to notice is that all simulations show the same behavior in year two, where outlet temperatures are much higher than in the first year. The reason for this is the difference in temperatures in different years. For the simulations weather data based on 2023 has been used. However, the initial conditions are set at the start of the year 2023, which makes them influenced by weather data from the year 2022, which was a lot colder than the following year. However, after one year this effect disappears. The two peaks appearing in summer and winter can be explained by the use of the data from the gym for repeated years, which had two peaks each, during cooling and heating operations.

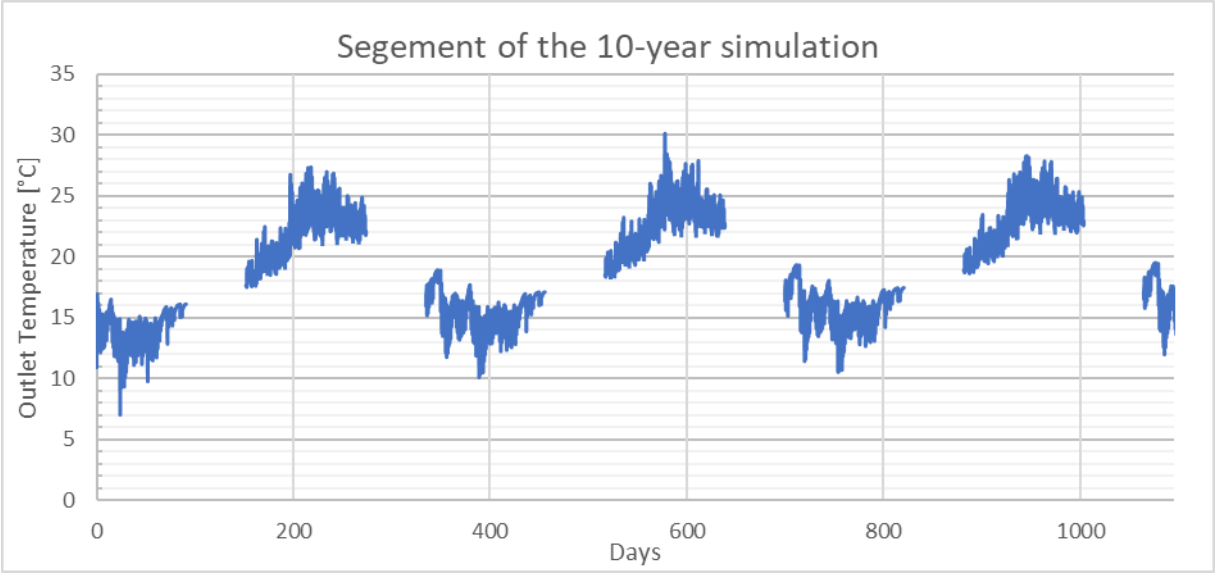

Figure 16: Segment of the 10-year simulation

Something that can be noted overall is that over the course of ten years there is a slight increase in average outlet temperature. This can be observed in all systems tested to a certain degree, ranging from 1.5°C to 3°C. In the smaller systems this development is stronger and in general shows an energy imbalance and the fact that the ground cannot recover enough during the rest periods. This energy imbalance can also be seen in the required heat and cooling loads, with 4.73 MW for cooling and 3.48 MW for heating. For long-term performance this will mean a drop in efficiency of the system. A slight increase in temperature of the ground can also been seen in Figure 17. While the changes have a very small magnitude, especially around the lower pipe they are clearly visible.

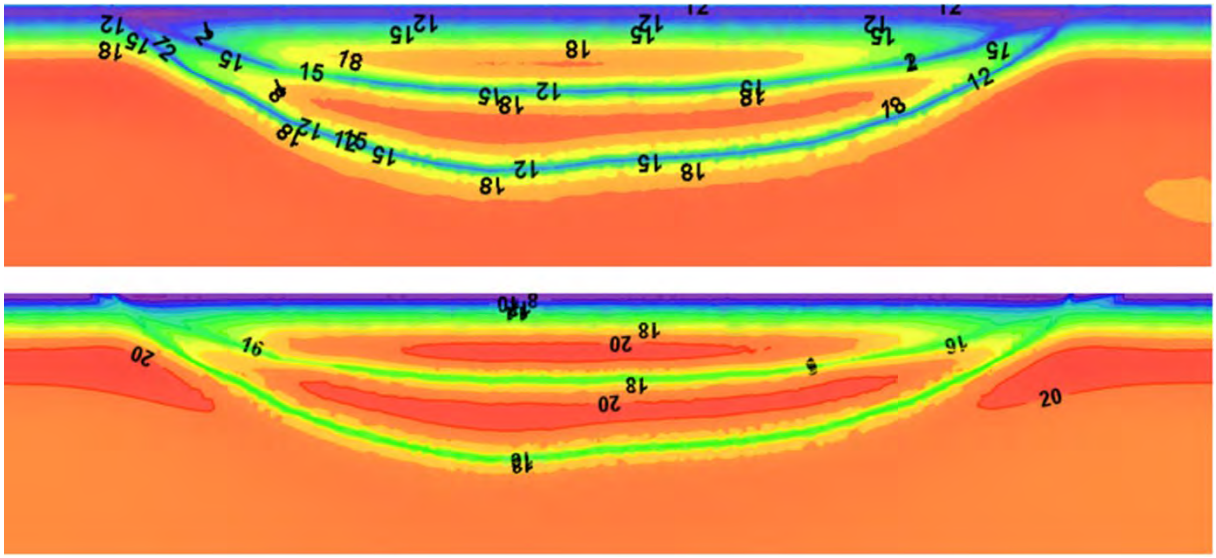

Figure 17: Temperature development in February of year 5 and 10

6. Conclusions

In this study, a field test and numerical simulations were done to optimize field design for HDD drilled HGHE. A TRT was performed on an HGHE installed in Saga City, Japan, in March 2022. The HGHE consisted of two boreholes with a diameter of 114.3 mm at a depth of 5 m and 9.5 m and a length of 59 m and 56 m, respectively.

Based on this the field test, geology and the wells a numerical model was related in FEFLOW and validated using history matching of the turn point temperature and the outlet temperature measured during the TRT. The model was then used to evaluate several installation designs based on heat load calculations for a building and their long-term performance. The evaluated shapes were, the original system, a ring-shaped system, a parallel system, a serial connected system, a staggered system and an angled system. The building used for the calculations was a gym adjacent to the original project in Saga City. Based on the usage hours and the design of the gym the required heat load for the year was calculated and afterwards used in the simulations as input. The results can be summarized in the following points:

- The ring shape has a similar performance like the straight system and will be further investigated in following studies. The performance depends strongly on the installation depth of the ring, and is better when installed at a deeper depth.
- The other arrangements performed in the following order: angled > series > parallel > staggered. With the difference between the performance of series and parallel arrangement being minimal.
- Different arrangements still can be preferable over better performing arrangements due to the large space requirements for e.g. the angled arrangement
- Long-term performance has shown an energy imbalance in the system that would lead to a temperature increase of 1.5°C to 3 °C, depending on the system.

Overall, it was shown that the high flexibility of HDD drilling allows for the installation of different designs that can be adapted to the situation needed. Future research should focus on the field testing of designs, the large-scale application of designs, and the additional testing for certain arrangements, like the staggered arrangement tested.

Genetic algorithm, Optimization, Borehole thermal energy storage, Recovery efficiency

ABSTRACT

Borehole Thermal Energy Storage (BTES) represents an advanced technology tapping into the Earth's sub- surface to store and extract thermal energy for both heating and cooling purposes. The performance of BTES systems hinges greatly on selecting the right operational parameters. Among these parameters, the flow rates during charging and discharging phases play a pivotal role in determining the system's efficiency in recovering heat. In this research, we introduce the application of a Genetic Algorithm as a tool for optimizing these operational parameters within a baseline BTES model. The model itself was developed using FEFLOW and was subjected to simulation over a 3-year period. Following each 3-year simulation, the Genetic Algorithm iteratively adjusted the operational parameters to achieve the optimal configuration, maximizing heat recovery from the BTES system. Additionally, sensitivity analysis was carried out to examine the influence of BTES system size and borehole spacing on heat recovery efficiency. The results demonstrate that the Genetic Algorithm successfully optimized parameters, resulting in improved heat recovery efficiency. Furthermore, the sensitivity analysis revealed that a closer borehole spacing is associated with higher recovery efficiency.

1. Introduction

Historically, non-renewable energy sources like fossil fuels have dominated the global energy landscape. However, increasing reliance on renewable energy is crucial for reducing carbon emissions. Thermal energy storage (TES) emerges as a promising solution, allowing excess energy to be stored and utilized during peak demand periods (Lanahan and Tabares-Velasco, 2017). Underground thermal energy storage (UTES) utilizes subsurface reservoirs to store thermal energy. Two primary methods include aquifer thermal energy storage (ATES) and borehole thermal energy storage (BTES). While ATES systems face challenges due to hydrogeologic conditions,

BTES systems offer a viable alternative (Akta¸s and Kir¸ci¸cek, 2021; Shi et al., 2023). BTES systems store heat in soil or rock environments during peak heat periods and extract it when the heat is needed, contributing to grid stability and reducing energy demand fluctuations (Pourahmadiyan et al., 2023).

Despite the potential of BTES systems, optimizing their efficiency, particularly in terms of recovery efficiency, remains a significant challenge (Wo-loszyn, 2018; Casasso and Sethi, 2014). Manual calibration of parameters is common but time-consuming and uncertain (Zhang, 2016). To address this, modern optimization techniques like particle swarm optimization (PSO), simulated annealing (SA), and genetic algorithms (GA) are proposed (Kennedy and Eberhart, 1995; Press and Teukolsky, 1991). PSO mimics the collective behavior of birds and fish but struggles with complex datasets (Eltamaly et al., 2020). SA, inspired by metallurgical annealing, excels at identifying global optima but may get trapped in local extrema (Delahaye et al., 2019; Eren et al., 2017). GA, inspired by natural selection, offers versatility and parallelism, making it suitable for multidimensional optimization problems (Slowik and Kwasnicka, 2020; Yang, 2021).

In this study, GA was employed to optimize two critical operational parameters—charging and discharging flow rates for BTES systems (Pourahmadiyan et al., 2023). This optimization aims to maximize energy storage and recovery while minimizing losses, operational costs, and greenhouse gas emissions (Zhang, 2016; Possemiers et al., 2014). By utilizing GA, the study seeks to contribute to the advancement of sustainable energy solutions and address the challenges associated with manual calibration methods (Wo-loszyn, 2018; Casasso and Sethi, 2014).

2. Methodology

2.1 Finite element model

The FEFLOW software, which is a finite element modeling tool, was employed to simulate and compute temperature variations in the subsurface while transferring heat during charging and discharging. The temperature changes in the ground around the borehole can be expressed through the following equation:

$$\rho \cdot c \cdot \frac{\partial T}{\partial t} = \nabla \cdot (k \cdot \nabla T) + Q$$

where ρ (kg/m^3) is the density of the ground, c ($J/(kg * K)$ is the specific heat capacity of the ground, and T (^0C) is the temperature, t is time, k ($W/(m * K)$) is the thermal conductivity of the ground, Q (J/s) is the heat source and sink in the system.

The study considered a BTES system with a circular configuration, primarily because the favorable packing density it provides for boreholes within a designated area. This allows for the efficient installation of more boreholes in a given space, thereby optimizing the overall thermal energy storage capacity of the system. To streamline our model, we focused on one quadrant of the circular BTES system, as shown in Figure 1b.

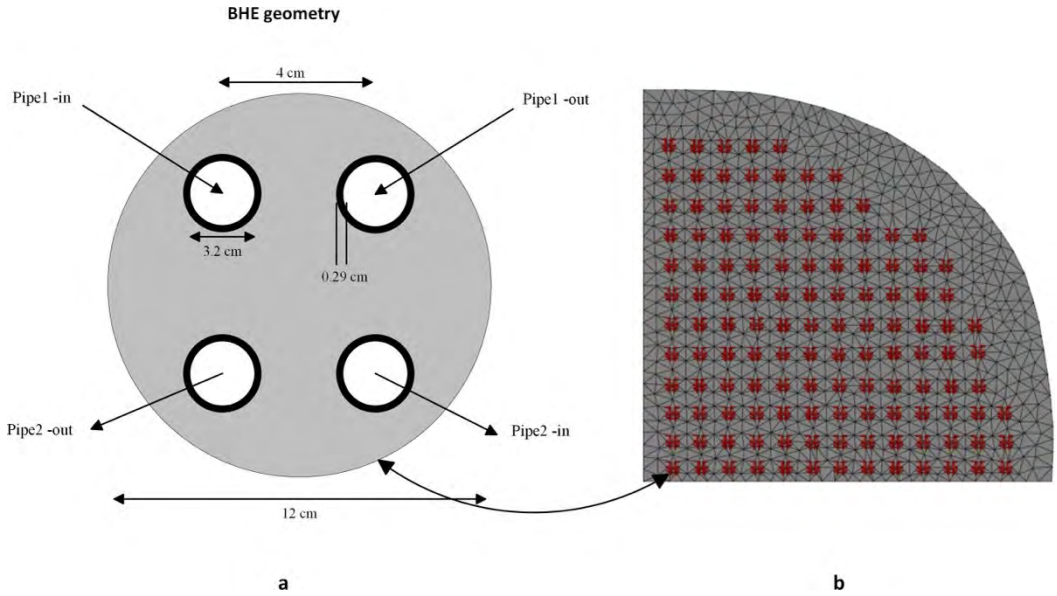

Figure 1: Finite element model grid for this study

The FEM model employed is a homogeneous system with a depth of 30 m, comprising 6 layers and a vertical discretization of 5 m. The modeling of BHEs utilizes a quasi-stationary analytical model based on work by Eskilson and Claesson (1988). The model considers the configuration of double U-shaped BHEs connected in parallel. The borehole diameter is 12 cm, with a pipe separation of 4 cm between each U-shaped BHE. The pipes have a diameter of 3.2 cm, and the thickness of the pipe walls is 0.29 cm. Figure 1a shows the cross-section of the borehole heat exchanger.

2.2 Finite element model

The optimization procedure is detailed in Algorithm 1. Specifically, this study employs a genetic algorithm as the optimization method.

Algorithm 1: Optimization of Parameters Using Genetic Algorithm and FEFLOW

Model Set: N_w = Number of parameters
Set: N_{pop} = Number of population
Set: N_{gen} = Number of generations
begin
  Generate new population, **New$_{pop}$** = (N_{pop}, N_w)
  for *generation* = 1, 2, ⋯ , N_{gen} **do**
    Implement the fitness function
    for i = 1, 2, ⋯ , N_{pop} **do**
      Insert parameters into the Feflow model
      Run Feflow model and calculate recovery efficiency (RE)
    Select the best chromosomes in the current population to join the mating pool:
    for i = 1, 2, ⋯ , N_{pop} **do**
      Eliminate the chromosome with the least *RE*
    Replace it with the chromosome with the highest *RE*
    parent = (N_{pop}, N_w)
    Generate next generation using the crossover function:
    offspring = (N_{pop}, N_w)
    Add variation to the offspring using the mutation function:
    New$_{pop}$ = (N_{pop}, N_w)
  end

In this study, a genetic algorithm is employed to regulate two operational parameters (charging and discharging flow rate), while the grout thermal conductivity and the thermal conductivity of the ground remains fixed. The objective of this optimization process is to obtain an optimum recovery efficiency (RE). The RE is computed on a yearly bases, such that for each year cycle, the first half of the year computes the quantity of heat stored and the second half of the year computes the amount of heat retrieved from the BTES system, Figure 2.

$$RE = \frac{\nabla \mathrm{H}_{recovered}}{\nabla \mathrm{H}_{stored}} \times 100\%$$

This study considered two BHE spacings, a 2.5 m spacing and a 10 m spacing. The genetic algorithm ran for 30 generations because, following a pilot experiment, there was a considerable reduction in recovery efficiency differences from the 25th generation to the 30th generation. The objective was to explore the efficacy of mathematical algorithms in obtaining optimal parameters for a BTES system design. Algorithm 1 shows the process of implementing the optimization. During the optimization process, three scenarios were considered, as shown in Table 1. These scenarios are presented to analyze the impact of the number of boreholes and their spacing on the overall heat recovery efficiency. The implementation of the genetic algorithm for the optimization process is illustrated in algorithm 1.

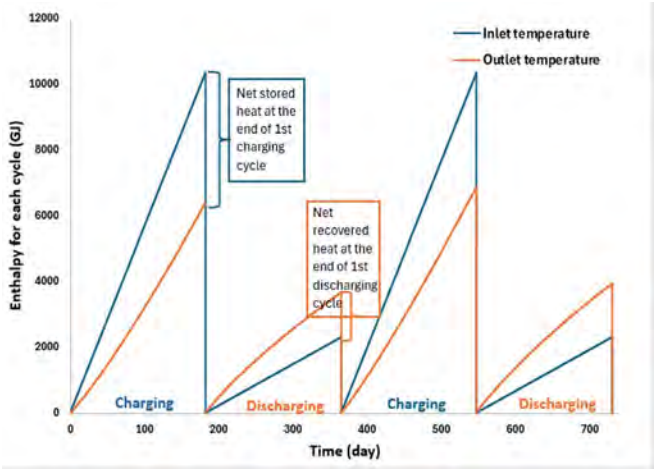

Figure 2: Recovery efficiency calculation

Table 1: Scenarios studies.

Scenarios	BHE spacing (m)	Number of BHEs
1	2.5	127
2	2.5	37
3	10	13

2.3. Results

2.3.1. Optimization for 2.5 m BHE spacing

The optimization procedure for BTES with a 2.5 m BHE spacing considered two distinct scenarios. In the first scenario, a substantial number of BHEs, approximately 127, were deployed, as indicated in scenario 1 of the table. The second scenario involved fewer BHEs, approximately 37, as depicted in scenario 2. The outcomes of the optimization process for these two scenarios are depicted in Figures 3 and 4.

For scenario 1, after 30 generations, the optimal recovery efficiency reached approximately 65% by the 28th generation. At this juncture, the charging and discharging flow rates were approximately 18 m^3/day and 39 m^3/day, respectively. Scenario 2, with fewer BHEs, achieved an approximate recovery efficiency of 52.9% by the 29th generation. The charging and discharging flow rates were approximately 20.5 m^3/day and 36.9 m^3/day, respectively. The results of the analysis provide compelling evidence indicating a direct relationship between the increase in discharging flow rates and the corresponding rise in recovery efficiency. Upon closer examination of Figure 3, a discernible trend emerges wherein successive generations witness a notable uptick in both discharging flow rates and recovery efficiency. This suggests a positive correlation between these variables over time.

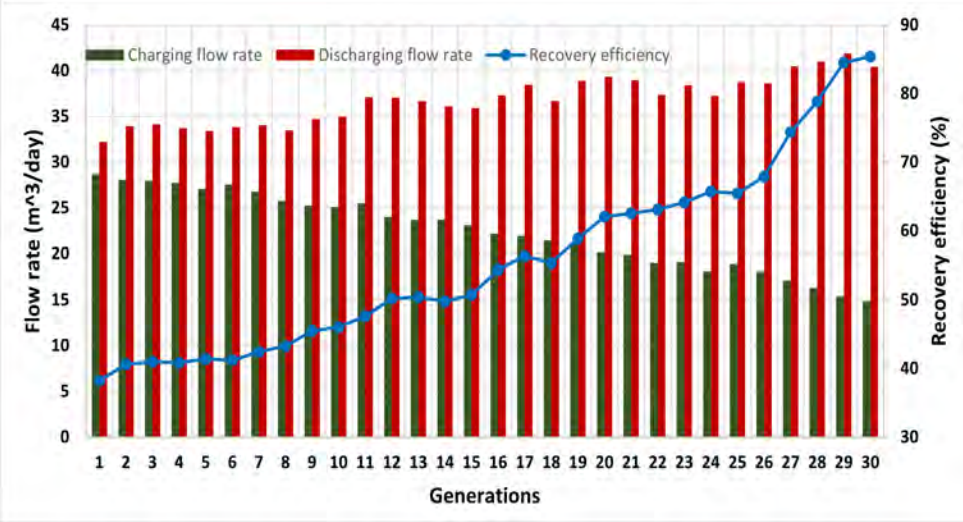

Figure 3: Optimal parameters and recovery efficiency for scenario 1

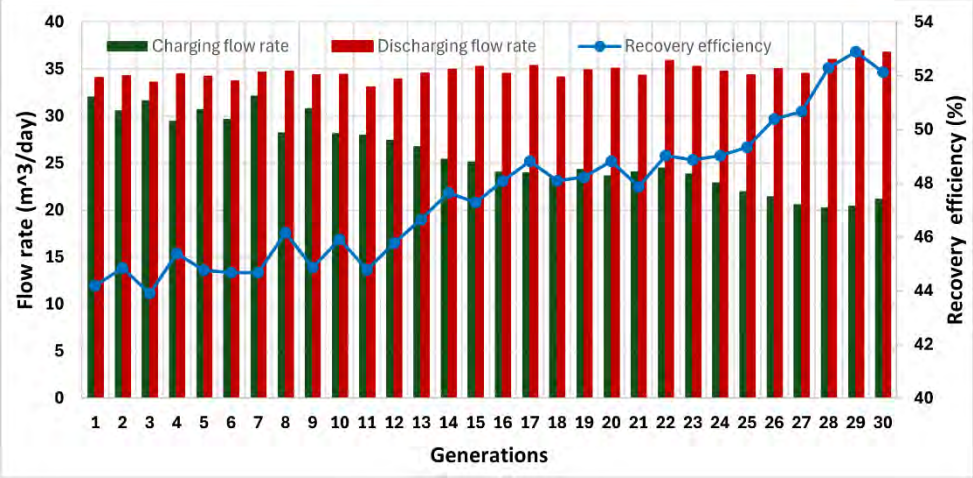

Figure 4: Optimal parameters and recovery efficiency for scenario 2

Furthermore, Figure 4 further bolsters this observation by highlighting instances where the algorithm generates higher discharging flow rates, coinciding with significant spikes in recovery efficiency. These findings underscore the importance of monitoring and optimizing discharging flow rates as a crucial factor in enhancing overall recovery efficiency within our operational processes. By comprehending and harnessing this relationship, we can effectively enhance our process performance and achieve greater efficiency.

2.3.2. Optimization for 10 m BHE spacing

This optimization procedure was conducted with a 10 m BHE spacing, as illustrated in scenario 3. After 30 generations, the optimal recovery efficiency reached approximately 14.9% in the 30th generation (Figure 5). The charging and discharging flow rates were 24.8 m^3/day and 36.2 m^3/day, respectively. Throughout the optimization process, there was minimal improvement in the overall recovery efficiency. This becomes particularly apparent when analyzing the trends in both charging and discharging flow rates. Across successive generations, there were negligible changes (either increase or decrease) between the previous parameters of charging and discharging

flow rates and the subsequent ones generated. However, an interesting pattern emerges when there's a notable disparity between the discharging and charging flow rates, particularly when the former exceeds the latter. In such instances, a significant increase in recovery efficiency was observed. Moreover, a stark contrast in the flow rate dynamics between this scenario and scenarios 1 and 2 is noteworthy. Here, both the charging and discharging flow rates appear to be relatively high. This deviation from the previous scenarios, where the charging flow rates were notably lower compared to discharging flow rates, can be attributed to the larger distances between the BHEs. The greater distance between the BHEs necessitates a higher flow rate to effectively circulate heat through the system and extract it efficiently. Consequently, the requirement for higher flow rates in this scenario underscores the intricate interplay between system design parameters, such as BHE spacing, and operational variables like flow rates, all of which impact the overall efficiency and effectiveness of the system.

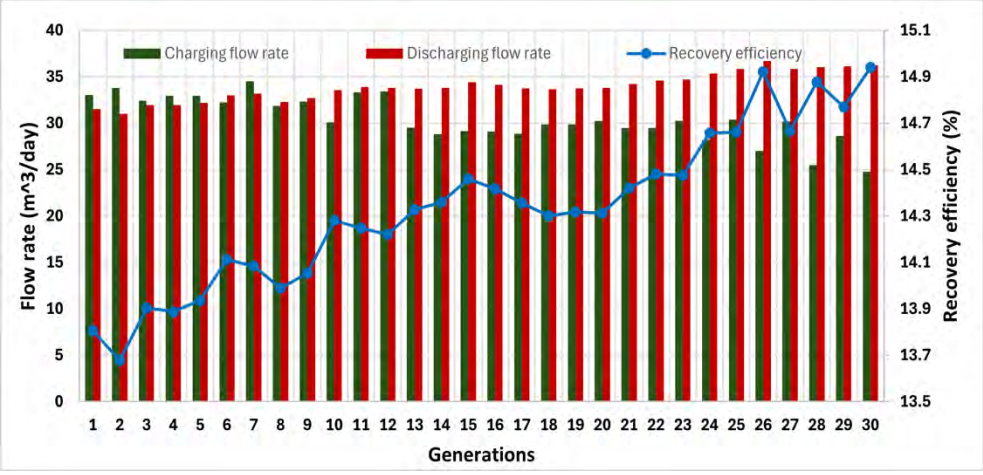

Figure 5: Optimum parameters and recovery efficiency for scenario 3

The recovery efficiency for a 3-year cycle is depicted in Figure 6 for both 2.5 m (scenario 1) and 10 m spacings. The difference in recovery efficiency between the two BHE spacings widens with each successive year, indicating that the 2.5 m spacing will continue to recover more heat than the 10m spacing in additional cycles.

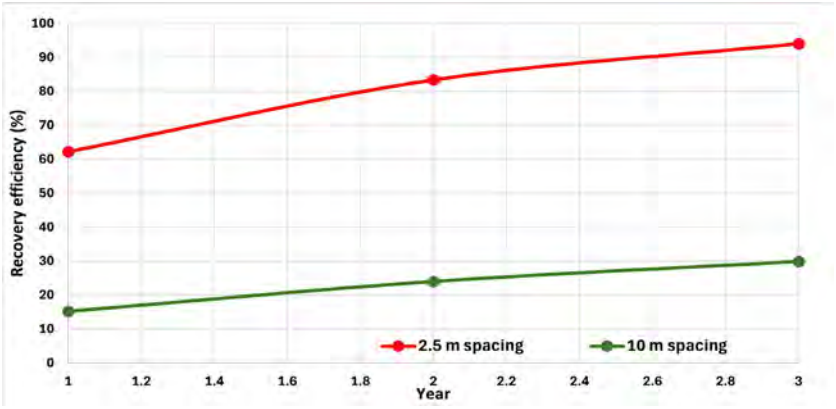

Figure 6: Recovery efficiency for a 3-year cycle

2.3.3. Base case vs optimum case

In scenario 1, the BTES system underwent a six-year simulation cycle to conduct a comparative analysis between a base case scenario, characterized by a charging and discharging flow rate of 20 m^3/day, and the optimized configuration of scenario 1. Throughout this simulation, the dynamic interaction between charging and discharging cycles and their subsequent impact on outlet temperature variations emphasized the crucial significance of optimizing operational parameters to achieve optimal system performance.

Figure 7 offers a comparative overview of the recovery efficiency between the base and optimized scenarios. In the initial year, the base case achieved a recovery efficiency of 34.1%, while the optimized scenario demonstrated a significantly higher efficiency of 62.2%. This disparity in recovery efficiency indicates that a larger portion of the injected energy is recovered during the discharging phase in the optimized scenario, thus enhancing the energy efficiency and cost-effectiveness of the BTES system. Moreover, it suggests a reduced environmental impact, as the system operates more efficiently, minimizing energy wastage.

To comprehensively assess the long-term effectiveness of the BTES system, it is essential to examine the recovery rates across multiple cycles. Over the course of the six-year cycle, the base case peaked at a recovery efficiency of 60.6%, whereas the optimized scenario consistently surpassed this, achieving a significantly higher recovery efficiency of 96.5%. The widening disparity in recovery efficiency between the optimized and base scenarios with each successive cycle underscores the optimized scenario's ability to extract more heat per cycle compared to the base scenario, indicating sustained superior performance over time.

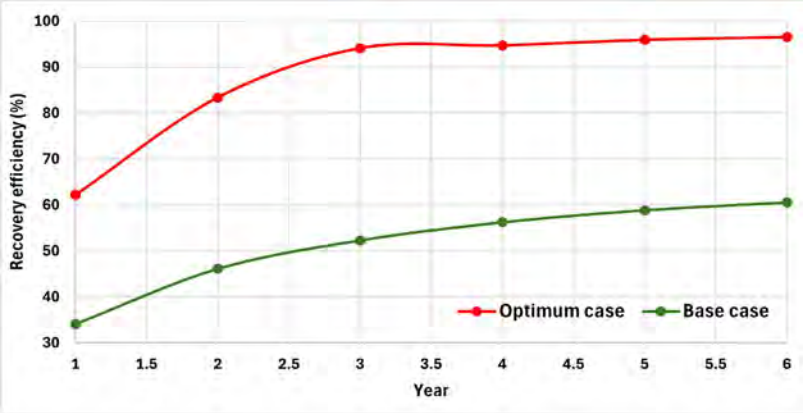

Figure 7: Recovery efficiency of base case and optimum case

3. Conclusion

This research study aimed to regulate the operation of BTES systems by utilizing a genetic algorithm to search for appropriate parameters for maximizing energy recovery. The study focused on design, operational, and geological parameters. Design parameters included thermal conductivity of the grout and BHE spacing, with two spacing configurations considered. The geological parameter was the subsurface's thermal conductivity, of which both the subsurface's thermal conductivity and the grout thermal conductivity were held constant. The optimization algorithm focused on

operational parameters, such as charging and discharging flow rates. The recovery efficiency was computed at the end of of each year of simulation.

The results highlighted the intricate relationship between recovery efficiency, BHE spacing, and the volumetric charging and discharging flow rates within the BTES system. It was evident that smaller BHE spacing correlated with higher recovery rates, while, within a specific BHE spacing, higher discharging flow rates contributed to enhanced recovery efficiency. However, an interesting observation emerged regarding the interplay between BHE spacing and flow rates during charging. It was noted that when the BHE spacing was smaller, the flow rate during charging tended to be lower compared to configurations with larger BHE spacing. This suggests a trade-off between BHE spacing and flow rates during charging, indicating the need for careful consideration when optimizing these parameters. Moreover, an optimal BTES model was developed and compared against the base case. The findings revealed that the optimal model achieved an impressive recovery efficiency of 96.5% over a simulated six-year period. This highlights the effectiveness of optimizing system parameters in maximizing energy recovery and overall system performance.

By delving into the impact of various parameters on system performance, this study contributes to the use of mathematical algorithms for obtaining optimal parameters, ultimately enhancing the efficient design and operation of BTES systems.

ABSTRACT

Much of Japan's geothermal resources cannot yet be economically exploited, although geothermal energy is potentially a very valuable domestic energy source for Japan. Therefore, many industries and research institutes in Japan have been researching and developing technologies to utilize geothermal energy.

Since 2020, we have been studying the development of a geothermal power generation system using supercritical carbon dioxide (sCO_2) circulation, sCO_2 geothermal power system. It is expected that the thermal efficiency of a geothermal power system can be improved and that the environmental impact of installing the system can be reduced by using sCO_2 as the working fluid.

We have conducted laboratory experiments to simulate the closed loop system by sCO_2 circulation and demonstrated thermosiphon phenomena in which sCO_2 could spontaneously circulate in the U-shaped closed loop system due to its density difference with temperature. In addition, we constructed a numerical simulation model to calculate the sCO_2 flow in the U-shaped closed loop system and estimated the amount of electricity generated by the system. In addition, the numerical simulation model was used to find the appropriate power generation cycle and conditions for the sCO_2 geothermal power system to achieve maximum power output.

In the past fiscal year, we have conducted numerical simulation studies on the heat extraction efficiency of the sCO_2 geothermal power system in a geothermal reservoir with hot water using

TOUGH3 (ECO2N V2.0). And we have estimated the sustainable amount of electricity generated by an semi-open loop sCO_2 geothermal power system based on the results of reservoir simulations. We found that power output increases with higher reservoir temperature, deeper injection wells, and lower injection temperatures, and that a development targeting a 1 km^2 geothermal reservoir at a depth of 4,000 m and a temperature of 300℃ is expected to generate approximately 10 MWe of power.

1. Introduction

In October 2020, Japan declared its intention to achieve carbon neutrality by 2050[1]. In the Sixth Strategic Energy Plan, which was revised in 2021[2], the share of renewable energy in the electricity mix in 2030 was significantly revised upward significantly from 22-24% to 36-38%, and the introduction of renewable energy is expected to be accelerated in the future. The target for geothermal power generation has been set at the same level as in the Fifth Strategic Energy Plan, and it is considered necessary to step up efforts to further increase the amount of installed geothermal power generation. And the Strategic Energy Plan mentions the development of technology to increase and stabilize the amount of steam available for geothermal power generation by artificially injecting water from the ground as an example. Therefore, the development and implementation of enhanced geothermal system (EGS) technology is an urgent issue in Japan (Kaieda, 2015).

Since 2020, the authors have started research on the development of technology for EGS using sCO_2 as a heat extraction medium by utilizing high-temperature underground rocks. In EGS using sCO_2 as a working fluid, the thermosiphon phenomenon has been proposed (e.g., Atrens et al., 2009), in which sCO_2 circulates naturally without requiring a driving force for the fluid. This is a phenomenon in which sCO_2 in a closed loop is heated in the hot reservoir rock after injection, becomes low density due to the large change in density relative to the change in temperature of the sCO_2, rises to the surface due to buoyancy, cools as power is generated above ground, and then becomes high density and flows down to the underground due to gravity (Higgins and Oldenburg, 2016). In addition, the following effects can also be expected.

- Because sCO_2 has a low viscosity, it can be injected at high pressure to create finer fracture surfaces with high heat exchange efficiency.
- The high density and compressibility of sCO_2 is also expected to improve the efficiency of heat extraction in production wells.
- CO_2 that does not contribute to circulation is sequestered underground as minerals, which is expected to prevent CO_2 leakage from CCS reservoir.
- Utilizing high-temperature sCO_2 reduces the required flow rates for achieving the same power output, enabling turbines and other equipment to be smaller in size.

[2] https://www.meti.go.jp/english/press/2021/1022_002.html

Thus, a sCO_2 geothermal power system has many advantages, including the expansion of geothermal power generation sites, including deep underground areas that have not yet been utilized, dramatic increase in the amount of geothermal power generated, effective utilization of abandoned geothermal wells where hot water cannot be obtained, cost reduction and scenic enhancement due to compact surface facilities, etc. However, there are no examples of sCO_2 geothermal power systems being developed in Japan, and demonstrations of such systems have only just begun in the United States and other countries (Alvarado, 2023, Chandrasekar, 2023, Kerr, 2023, and Klenner, 2023). In addition, because of the complex geological structure of the bedrock in Japan, it is necessary to develop a unique sCO_2 geothermal power system that is compatible with this geological structure, and consistent research and development from system design to on-site demonstration is required.

A sCO_2 circulation experimental apparatus was constructed at Central Research Institute of Electric Power Industry (CRIEPI) as part of the New Energy and Industrial Technology Development Organization (NEDO) project "Development of a carbon dioxide circulation geothermal power generation system" in order to demonstrate the thermosiphon phenomenon, which has been shown theoretically but not yet verified, through laboratory experiments and to clarify the conditions under which the phenomenon can occur (NEDO, 2022).

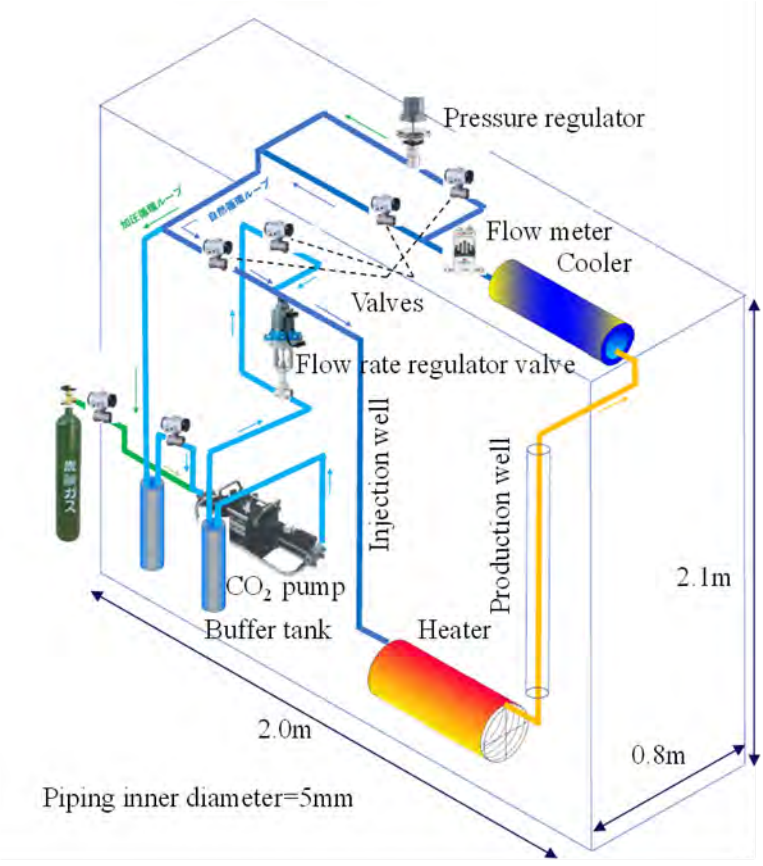

Figure 1: Closed loop sCO2 circulation experimental apparatus conceptual diagram (NEDO, 2022)

The purpose of this study is to conduct a feasibility study of the sCO_2 geothermal power system in the preliminary stage of technology demonstration, and to identify the elementary technologies required for the demonstration. We have conducted laboratory experiments to simulate the closed loop system by sCO_2 circulation and demonstrated thermosiphon phenomena in which sCO_2 could spontaneously circulate in the U-shaped closed loop system caused by its density difference with temperature. In addition, we have constructed a numerical simulation model to calculate the sCO_2 flow in the U-shaped closed loop and estimate the amount of electricity generated by the system (Nakao et al., 2023). And now we have started numerical simulations for semi-open loop systems through sCO_2 circulation.

2. Plant simulation for semi-open loop sCO_2 geothermal power system

In this project, JOGMEC has developed an innovative geothermal power generation technology that does not rely on hydrothermal resources by injecting sCO_2 into geothermal reservoirs and extracting heat from geothermal resources. We have conducted wellbore simulation and thermal efficiency analysis for a closed loop sCO_2 geothermal power system consisting of a sCO_2 injection well, a production well, and multiple lateral wells connecting the wellbores, and reported the results at GRC2023 (Nakao et al., 2023).

In this report, geothermal reservoir simulation and plant simulation (wellbore simulation and thermal efficiency analysis) were conducted for an semi-open loop sCO_2 geothermal power system, as shown in Figure 1, which consists of a sCO_2 injection well, a production well, and a reservoir constructed by hydraulic fracturing (EGS reservoir). The calculation flow of the plant simulation is shown below.

i. Reservoir simulation: The coupled transport of groundwater and injected sCO_2 between the injection and production wells was simulated using a planar two-dimensional five-spot model which was based on a model by Pruess (Pruess, 2006). TOUGH3[3] developed by LBNL, was used as the numerical code to calculate the temperature, pressure, and flow rate of circulating sCO_2 at the bottom of the injection and production wells.

ii. Plant simulation: Using a wellbore simulator developed by CRIEPI, the temperature, pressure, and flow rate of circulating sCO_2 (assumed to be pure CO_2 in this report) at the injection and production wellheads were calculated based on the circulating sCO_2 conditions at the bottom of the injection and production wells. Then, the power output of the sCO_2 geothermal power system was calculated using EnergyWin (Koda 1999, Takahashi 2007, Nakao 2011), a general-purpose analysis software developed by CRIEPI, by converging the temperature and pressure conditions at the power generation plant so that the sCO_2 conditions to be returned to the injection well were equal to the sCO_2 conditions set in the wellbore simulation. The relationship between the thermodynamic state and fluid properties of sCO_2 is based on the database of REFPROP 10 (NIST, 2022).

2. Geothermal reservoir simulation

2.1 Numerical simulation model

To investigate the heat extraction of the sCO_2 geothermal power system in a geothermal reservoir with hot water, numerical simulations were conducted using a planar two-dimensional five-spot model. When injection and production wells are arranged as staggered, it is possible to model only part of the target area due to symmetry. This five-spot modeling has been used in many previous studies. In reality, it may be difficult to construct as many wells as in the 5-spot model due to economic reason and so on. Injected fluid loss could be caused by many reasons, if the number of wells is not enough as 5-spot model. As a result, CO_2 suppletory could be required at the surface continuously. So, in reality, there are many problems to consider, but in this study, we focus to evaluate plant simulation simply. Thus, we created 5-spot model based on a five-spot model by Pruess (2006) using a distance of 707.1 m between injection and production wells (Figure 2). Matrix-fracture heat exchange was modeled using the “multiple interacting continua” (MINC) method (Pruess et al., 1982,1985) with subgridding of matrix blocks into five continua. This means highly idealized and homogenous reservoir conditions as illustrated in Table 1. Injection and production wells were given as fixed temperature and pressure grids. The other conditions of the model are shown in Table 1. In this study, chemical reaction was not considered in order to avoid the complexity of calculations as this first step study, but we plan to consider interaction with CO_2 and rock in the future work.

Table 2 shows the simulation cases of this heat extraction study. It can be classified into 3 cases of initial reservoir temperatures (300, 250 and 200 °C). In each case, calculations were performed

in 16 different initial conditions: 4 patterns of initial reservoir pressures (10, 20, 30 and 40 MPaA) multiplied by 4 patterns of injected sCO_2 temperatures at the bottom of the injection well (80, 100, 120 and 140 °C[4]). A numerical code, TOUGH3, which is a numerical simulator of non-isothermal flows of multi-component, multi-phase fluids in three-dimensional porous and fractured media, was used. The ECO2N V2.0 EOS module was used, which allows the thermal-hydraulic calculation of sCO_2 in a temperature range from 10 to 300 °C and a pressure up to 60 MPaA.

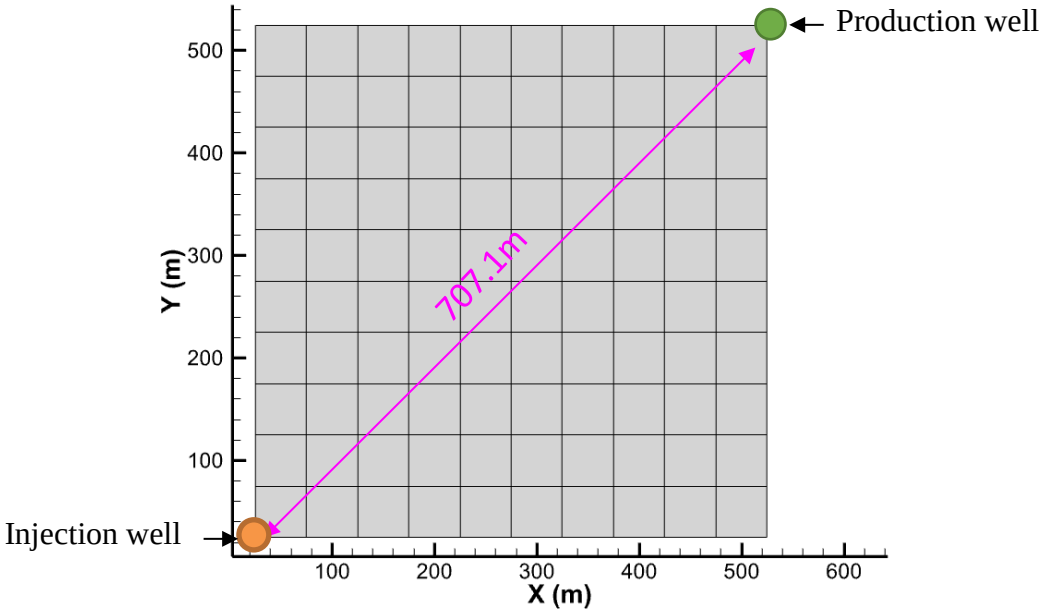

Figure 2: Schematic diagram of a planar two-dimensional five-spot model in this study. Side boundary condition is Neuman type, zero flux boundary here.

Table 1: Model parameters used in this heat extraction study.

Reservoir	Value	Unit
Thickness	305	m
Fracture spacing	50	m
Fracture volume fraction	2	%
Permeability in fracture domain	5.0×10^{-14}	m^2
Porosity in fracture domain	50	%
Permeability in matrix domain	5.0×10^{-18}	m^2
Porosity in matrix domain	15	%

[4] In this paper, the temperature of injected sCO_2 is used as a parameter to compare and verify the effect of natural circulation due to density difference of sCO_2 and the effect of increasing sCO_2 temperature at the production wellhead by injecting sCO_2 at high temperature. Note that these temperatures are those at the bottom of the injection well, which are below 40°C at the injection wellhead depending on the conditions.

Rock grain density	2650	kg/m^3
Rock specific heat	1000	J/kg/°C
Rock thermal conductivity	2.1	W/m/°C
Production/Injection	Value	Unit
Pattern area (1 unit area in a symmetrical well arrangement)	1	km^2
Injector-producer distance	707.1	m
Pressure at injection well grid	Initial reservoir pressure plus 1MPa	
Pressure at production well grid	Initial reservoir pressure minus 1MPa	

Table 2: List of numerical simulation cases for this heat extraction efficiency study.

	Case 1	Case 2	Case 3
Initial reservoir temperature of the model (°C)	300	250	200
Initial reservoir pressure of the model (MPaA)	10, 20, 30 and 40		
Injected sCO_2 temperature (°C)	80, 100, 120 and 140		

2.2 Results of geothermal reservoir simulation

The production gas (almost exclusively CO_2) mass flow rate, pressure, and temperature at the bottom of the production well in each case are shown in Figure 3 through 5, respectively. The pressure at the bottom of the production well was estimated by a radial model, which was run separately using the pressure and mass flow rate results from these five-spot model studies. The internal diameter of the production well was assumed to 8.5 inches. The sCO_2 injection temperature on the horizontal axis is the temperature calculated from the conditions at the bottom of the production well based on wellbore simulation described in Section 3.1 below.

The mass flow rate of the production gas is the average value for the period when CO_2 reaches (breakthrough) the production well and the flow rate and the temperature are stable (10 to 20 years after the start of sCO_2 injection, referring Figure 6). In the five-spot model, all side, upper and lower face boundaries are Neumann boundary, therefore no fluid and heat flux towards into or outward the model which means the leak-off is zero in the model. That is, the only flow into and out of the model is through the arbitrary specified well grid. It is clear that within the scope of this study, the higher the pressure or the lower the initial reservoir temperature, the higher the produced gas mass flow rate tends to be. The pressure at the bottom of the production well showed almost no difference due to the initial reservoir temperature. The temperature at the bottom of the production well showed almost no difference due to the sCO_2 injection temperature. There was no temperature drop in the production well 10 to 20 years after the start of injection, and the initial reservoir temperature was maintained.

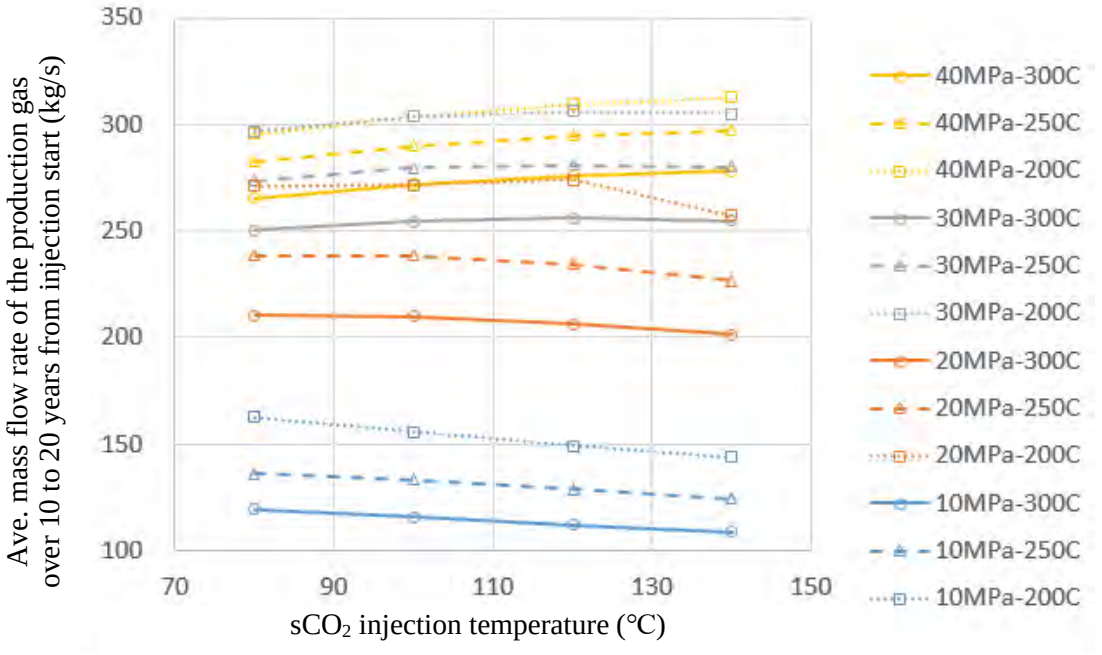

Figure 3: Mass flow rate of the production gas at the bottom of the production well. Each value is averaged over 10 to 20 years from the start of sCO_2 injection. In the left side indicates the initial reservoir pressure, and right side indicates the initial reservoir temperature.

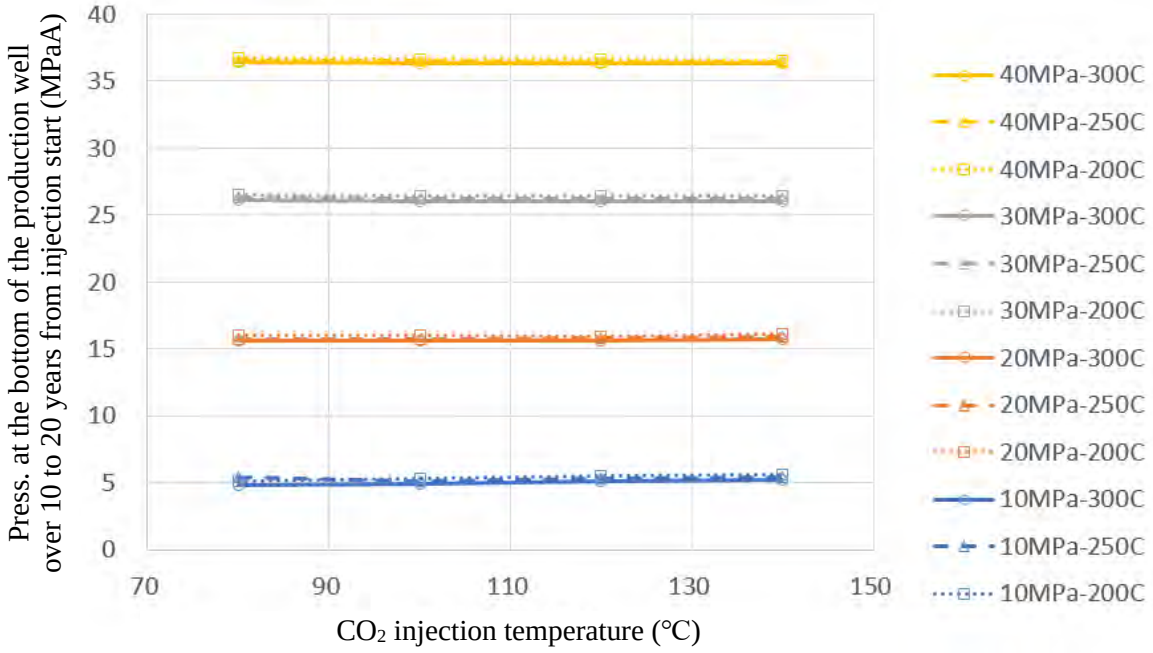

Figure 4: Pressure at the bottom of the production well. Each value is averaged over 10 to 20 years from the start of sCO_2 injection start time. In the left side indicates the initial reservoir pressure, and right side indicates the initial reservoir temperature.

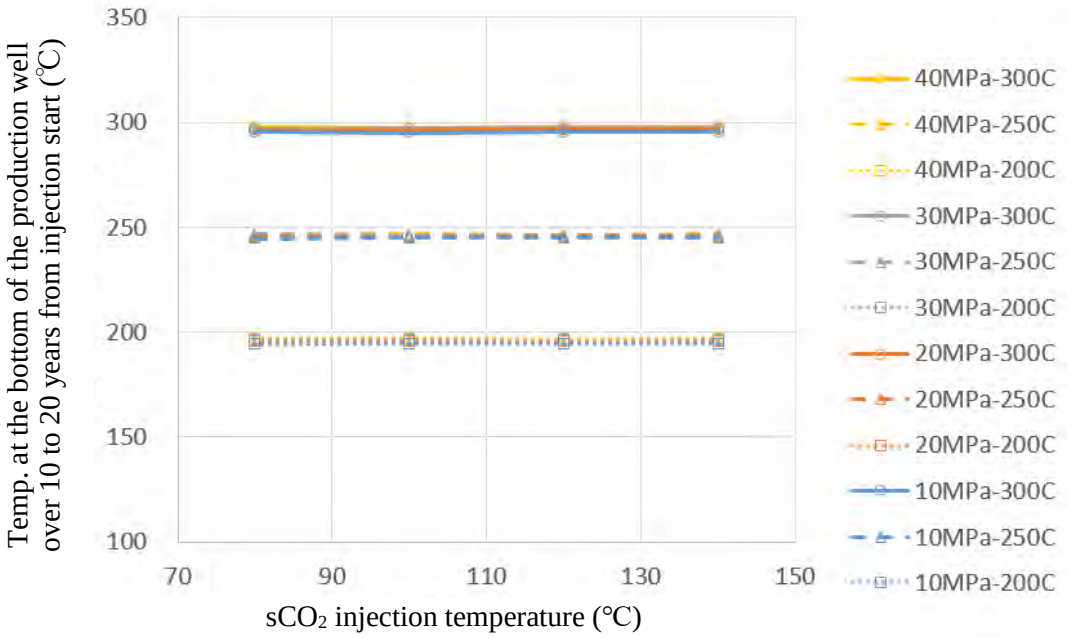

Figure 5: Temperature at the bottom of the production well. Each value is averaged over 10 to 20 years from the start of sCO_2 injection. In the left side indicates the initial reservoir pressure, and right side indicates the initial reservoir temperature.

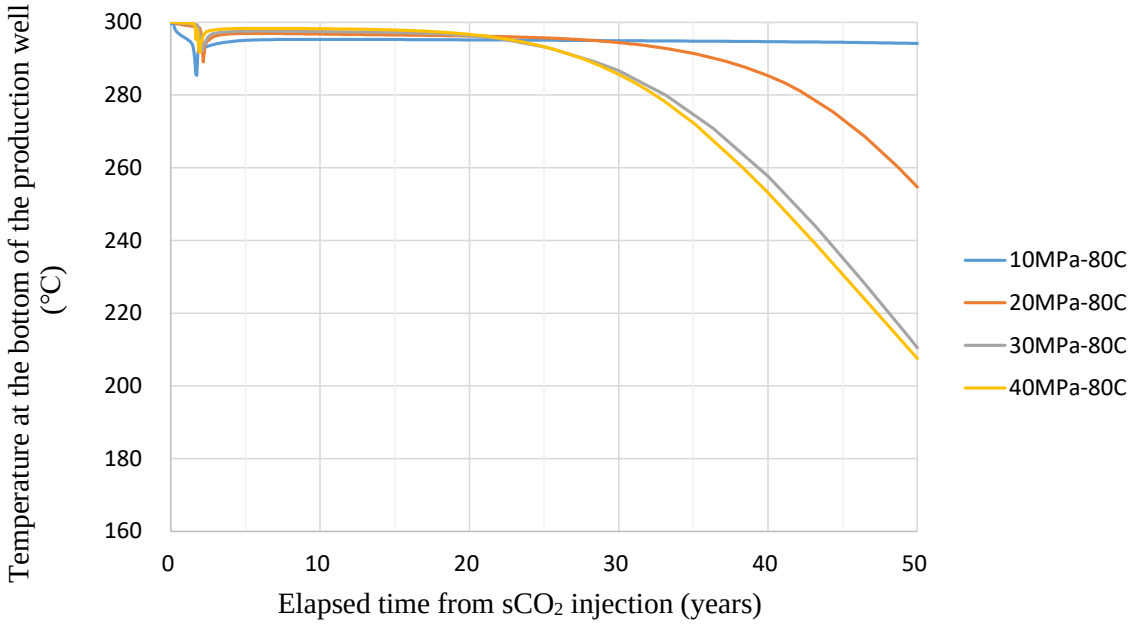

Figure 6 Temperature variations at the bottom of the production well in some cases in which the initial reservoir temperature is 300 ℃ and injection sCO_2 temperature is 80 ℃. The value in the legend indicates the initial reservoir pressure.

3. Plant simulation

3.1 Wellbore simulation method and conditions

The wellbore simulations were conducted using the same methods as in the previous report (Nakao et al., 2023). The flow path of the wellbore simulation is shown in Figure 7. Both the injection and production wells were drilled vertically. The heat exchange between the rock and the working fluid (sCO_2) is governed solely by heat conduction, and there is no CO_2 leakage from either well.

The temperature, pressure, and flow rate of the circulating sCO_2 at the bottom of the injection and production wells are based on the results of the reservoir simulation described above. However, the results of the five-spot model analysis for a 1 km square area showed that the flow rate of circulating sCO_2 was over 100 kg/s, which is fairly large flow rate for a well with a normal well diameter and would cause a large pressure loss. Therefore, in this wellbore simulation, the circulating flow rate per well is used as 1/4 of the reservoir simulation results.

Based on these numerical conditions, the temperature and pressure changes from the bottom of the injection well to the injection wellhead and from the bottom of the production well to the production wellhead are calculated using a wellbore simulator when sCO_2 is flowing in the well as the circulating medium. However, the internal diameter of the well is assumed to be constant, and the flow is assumed to be steady and one-dimensional.

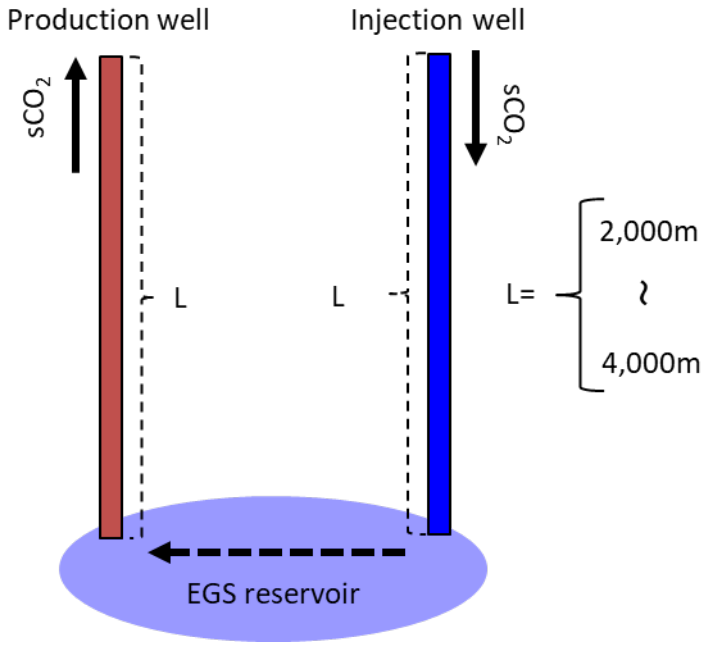

Figure 7: Flow path of the wellbore simulation

Table 3 shows the numerical conditions for wellbore simulation. In this study, as mentioned above, the results corresponding to approximately 15 years after the start of sCO_2 injection are used for the estimation the power generation potential at the time when a relatively stable circulation state is reached after the start of sCO_2 injection.

Table 3: Numerical conditions for wellbore simulation

Parameter	Value	Unit
Depth of injection and production wells	2,000 3,000 4,000	m
Inner diameter of flow path	0.216	m
Roughness of the flow path	4.57×10^{-5}	m
Temperature at ground	15	℃
Temperature of reservoir	200 300	℃
Thermal conductivity of rock	2.1	W/m/K
Specific heat of rock	1,000	J/kg/K
Density of rock	2,500	kg/m^3
Time from initial state of the EGS reservoir	15	years

3.2 Thermal efficiency analysis method and conditions

Through the wellbore simulation mentioned above, differences in sCO_2 conditions at the injection and production wellheads, in other words, turbine differential pressures and enthalpy differences between the injection and production wellheads, can be determined. Therefore, in the thermal efficiency analysis, plants that can sufficiently recover these turbine differential pressures and enthalpy differences were assumed for each analysis condition, and the power generation output was estimated.

Figures 8 and 9 show the configuration of the thermal efficiency analysis model and T-s diagram for sCO_2 geothermal power system constructed by EnergyWin. Based on the results of thermal efficiency analyses of six different power generation cycle models conducted in previous studies, the recuperation power generation cycle was selected as the simplest and most efficient power generation cycle (Nakao et al., 2023). This cycle is basically the thermodynamic Brayton cycle in which sCO_2 extracted from the production well is directly fed to a CO_2 turbine and expanded to near injection wellhead pressure to generate electricity, everything happens in the supercritical region. However, since the sCO_2 is still at a high temperature at the turbine outlet, the sCO_2 is returned to the subsurface through the injection well after heat recovery in the regenerative heat exchanger before being returned to the subsurface. A cooler and a CO_2 compressor are installed after the regenerative heat exchanger to adjust the sCO_2 pressure at the outlet of the CO_2 turbine and the sCO_2 conditions at the injection wellhead. Then, Table 2 shows the numerical conditions for the thermal efficiency analysis.

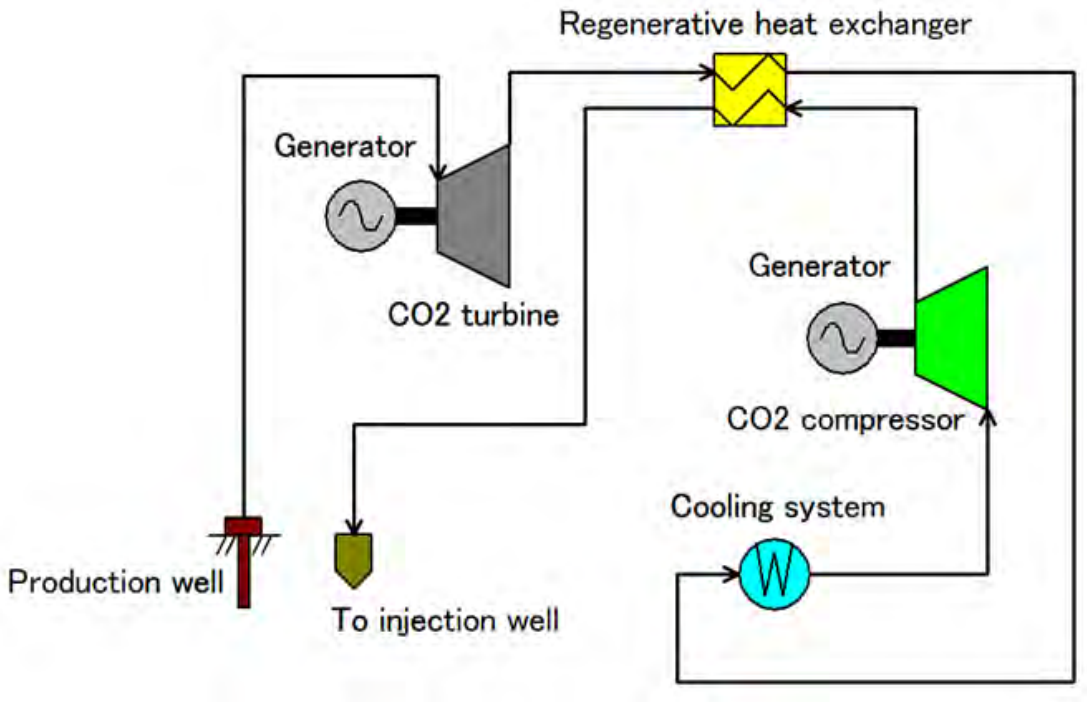

Figure 8: Configuration of thermal efficiency analysis model, Recuperation power generation cycle

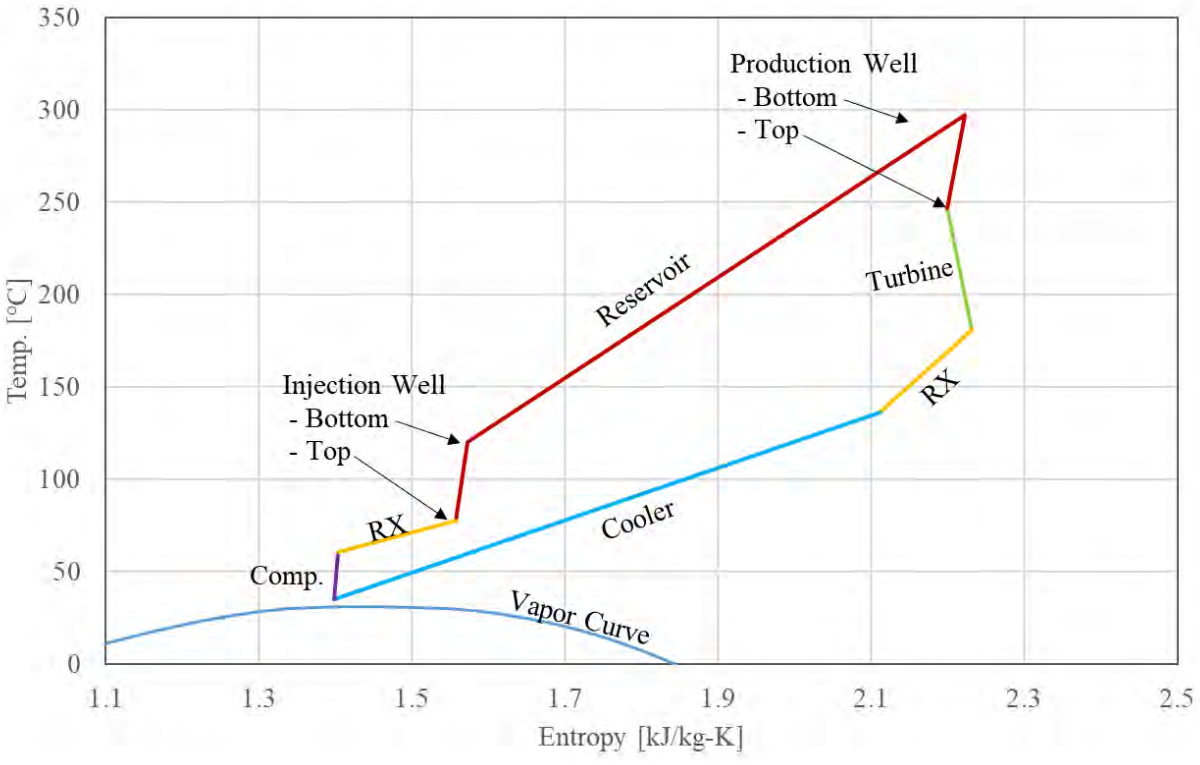

Figure 9: Example of T-s diagram of semi-open loop sCO_2 geothermal power system

Table 4: Numerical conditions for thermal efficiency analysis

Component		Property	Value	Unit
CO_2 turbine		Adiabatic efficiency	77.2	%
Generator		Mechanical efficiency	95	%
Regenerative heat exchanger		Temperature efficiency	90 or less	%
		Minimum ΔT	5 or more	℃
		Pressure loss	0.1	MPa
CO_2 compressor		Adiabatic efficiency	88	%
Cooling system	Cooler	Minimum ΔT	5 or more	℃
		Pressure loss	0.1	MPa
	Cooling tower	ΔT of coolant	5	℃
		Fan power supply	Based on actual data	kW
	Pump	Pump efficiency	80	%

3.3 Analysis results of plant simulation

In the plant simulation of the semi-open loop sCO_2 geothermal power system, the conditions for maximum net power generation output were obtained by taking the conditions of the bottom of the injection and production wells. The conditions that maximize the net power generation output of the power generation cycle were obtained by varying the regenerative heat exchanger outlet temperature and pressure of the cycle as parameters.

Figure 10 shows the net power generation output and gross power generation output of the system for each wellbore condition. However, since the sCO_2 flow rate used in the plant simulation is 1/4 of the flow rate from the reservoir simulation performed considering a two-dimensional five-spot production-injection problem for a 1 km square area, as described above, this figure shows the analytical results for the power generation output multiplied by four.

Higher reservoir temperatures result in higher sCO_2 temperatures and pressures at the production wellhead, resulting in higher power output from the power generation cycle. The deeper the well, the lower the sCO_2 temperature at the production wellhead, but the higher the pressure and the higher the expansion ratio of the turbine, the higher the power output of the power generation cycle. The higher the wellhead temperature of the injection well, the higher the gross power output of the cycle, while the net power output was lower. This is because the higher temperature at the injection wellhead results in a lower density of sCO_2, which requires a higher pressure at the injection wellhead. Since there is little difference in temperature and pressure at the production wellhead regardless of the temperature and pressure at the injection wellhead, and since more heat can be recovered from the waste heat at the turbine outlet by injected sCO_2, the gross power generation output is almost the same when expanded to the same pressure level. However, if a higher pressure is required at the injection wellhead, the net power generation is lower because of the greater

compression power required to raise the pressure to the injection pressure. For example, with a reservoir temperature of 300°C and a well depth of 4,000 m, increasing the injection temperature from 40°C to 90°C increases the CO_2 turbine power by approximately 2,100 kW, while the boosting power of the injected sCO_2 increases from approximately 1,200 kW to 4,800 kW, resulting in a decrease of approximately 1,700 kW in the net power generation output.

In this study, the maximum net power generation output was estimated to be approximately 10.5 MW for the case where the reservoir temperature is 300°C, the well depth is 4,000 m, the injection wellhead temperature is 54.4°C, and the injection wellhead pressure is 15.1 MPaA.

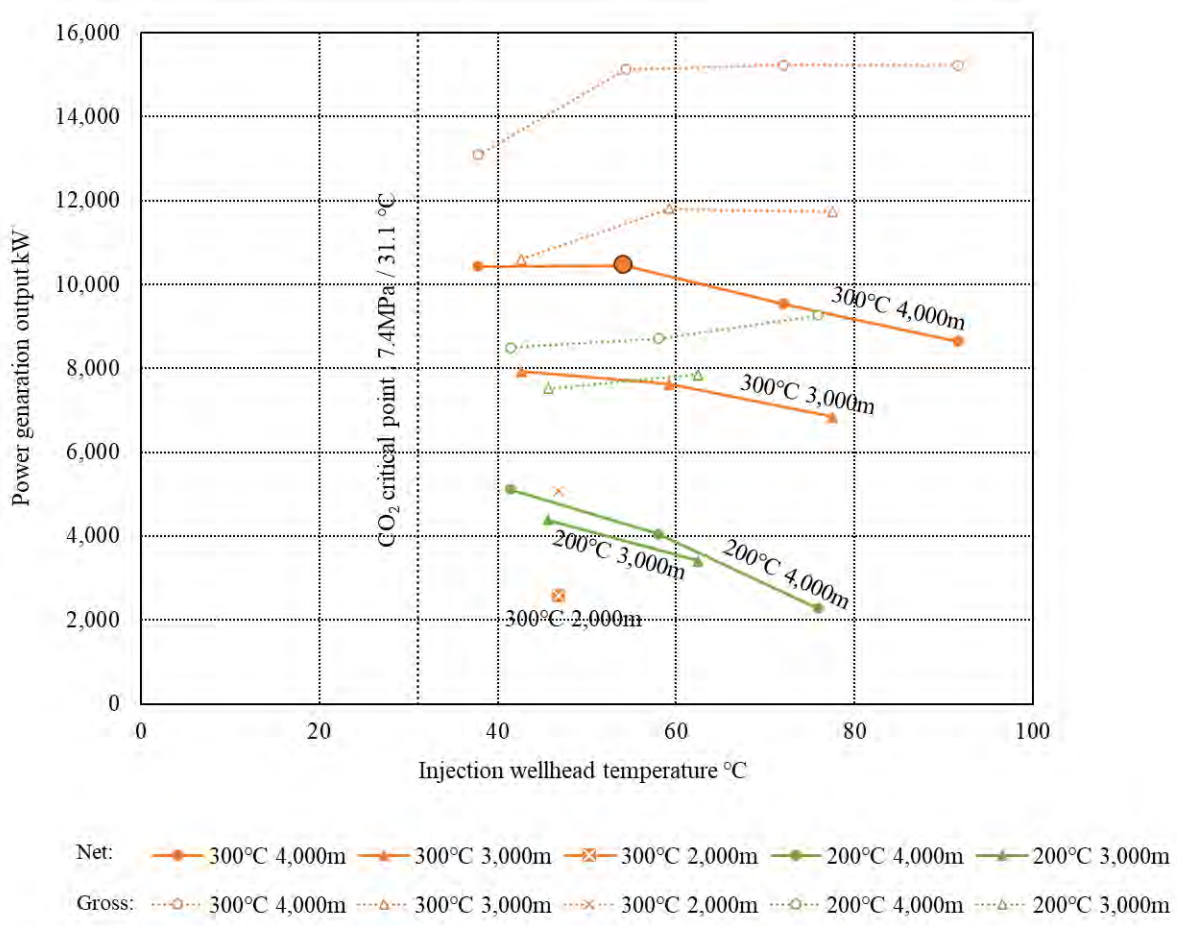

Figure 10: Relationship between the injection wellhead temperature and gross/net power generation output of the semi-open loop sCO_2 geothermal power system

4. Conclusion

We have estimated the sustainable amount of electricity generated by an idealized semi-open loop sCO_2 geothermal power system based on the results of reservoir and plant simulations. And we found that net power generation output increases with higher reservoir temperature, deeper injection wells, and lower injection temperatures, and that a development targeting a 1 km square geothermal reservoir at a depth of 4,000 m and a temperature of 300°C is expected to generate approximately 10 MW. However, under these conditions in this paper, the waste heat above 150°C

at the outlet of the CO_2 turbine cannot be fully regenerated, and much heat is discharged outside the system. In the future, further improvement is needed, such as considering a combined-cycle power generation system using a binary power generation system as a bottoming cycle.

In this study, the production gas was assumed to be pure CO_2 during the period when CO_2 reaches (breakthrough) the production well and the flow rate is stable (10 to 20 years after the start of sCO_2 injection). However, if we are considering that the transition from a water-bearing reservoir to a CO_2-dominated reservoir, it may pose some geochemical challenges, such as generation of acidic fluids and precipitation of mineral phases within the reservoir that might reduce flow rates of circulating sCO_2. Furthermore, catastrophic damage to the power generation facilities may occur. Therefore, it is necessary to evaluate the geochemical effects of sCO_2 injection on water-bearing reservoirs in the next phase of this project.

Our future goal is to estimate the geothermal development potential of the sCO_2 geothermal power system when applied in Japan, after conducting a cost and economic analysis.

Geomechanics, In-Situ Stress Estimate, Closed-Loop Geothermal, Germany

ABSTRACT

Eavor Technologies Inc. (Eavor™) is currently drilling a complex, multi-lateral closed-loop geothermal system (an "Eavor-Loop™") in the Geretsried area, Bavarian Molasse Basin, southern Germany. A total of four Eavor-Loops are planned for the location, and spud for Loop 1 was in July 2023. The target for the Eavor-Loop development is the Jurassic Malm carbonate formation.

Geomechanics, including in-situ stress estimation, is important in Eavor-Loop designs to evaluate wellbore stability, mud weights, operating pressures, and to optimize well orientations. GEN-1 and GEN-1ST-A1 are nearby offset wells and were used to constrain the geomechanical model pre-drill. However, within the academic community, there is considerable uncertainty over the stress regime in the Bavarian Molasse Basin. Normal faulting, strike slip and reverse faulting regimes have all been predicted in relatively close proximity.

As part of the completion of the first loop, a series of Formation Integrity Tests (FITs) were completed by Eavor. These data points provide new insights into the possible stress regime. This paper will present the pre-drill and current estimates for the stress regime for the Geretsried area, and the planned future data collection. The understanding of the stress regime will impact the chosen mud weights while drilling, and the optimal drilling direction for future loops, to reduce the likelihood of wellbore instability.

Introduction

Eavor Technologies Inc. (Eavor™) is a closed-loop geothermal energy company founded in Calgary, Alberta, Canada in 2017. An Eavor-Loop™ is an innovative geothermal solution for power generation and district heating. The key technical differentiator is the use of a subsurface multilateral closed-loop system that relies only on conductive heat transfer, as opposed to convection or fluid flow like in a conventional geothermal system. A full-scale prototype of the first-generation closed-loop system was successfully built and tested at the Eavor-Lite™ facility in 2019, in sedimentary rock in Alberta.

In 2023, Eavor spudded its first commercial scale project in Geretsried, Germany. This project is an Eavor-Loop 1.0 design, in the Jurassic Malm carbonate formation. To complete the Eavor-Loop, two wells (here named GEL-A1 and GEL-B1) are drilled to a depth of ~4.5 km and landed at a ~90° inclination in the Malm. The wellbores are cased and cemented into the Malm formation. GEL-A1 was landed slightly higher than GEL-B1, and these wells will become the sidetrack points for the multilateral sections of the loop. This analysis was performed at the time of completion of the landing of the main wellbores (Q1 2024).

A series of multilateral sidetracks are planned to be drilled ~3 km from the mainbores, with each associated well from GEL-B1 and GEL-A1 connected at the toes to complete the closed-loop system. Further geoscience data and image logging are planned to be collected in both the vertical and lateral wells. An example schematic demonstrating an operating Eavor-Loop 1.0 design, as compared to the proto-type Eavor-Lite, is shown in Figure 1.

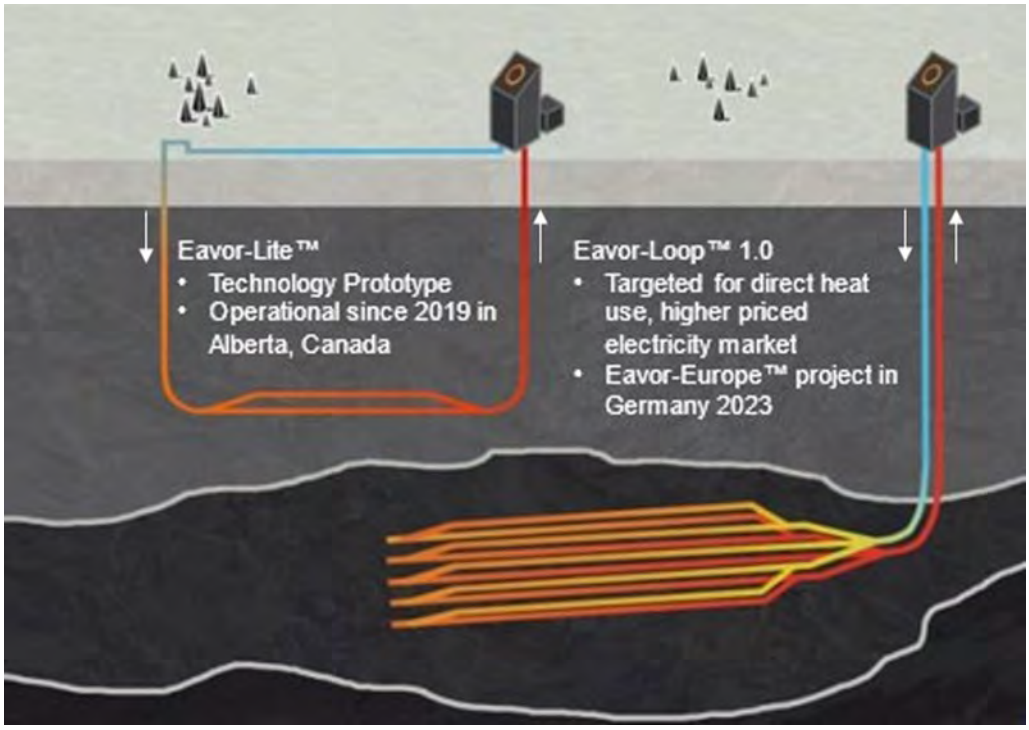

Figure 1: Schematic comparison of Eavor-Lite and Eavor-Loop 1.0 design. Note that this is for visualization purposes and does not display the final well plans or relative sizes of the loops at Geretsried.

GEN-1 and GEN-1ST-A1 are offset wells, drilled from the same pad as GEL-A1 and adjacent to GEL-B1, which were used to constrain the geomechanical model. GEN-1 and GEN-1ST-A1 were intended to be conventional geothermal wells but failed to find sufficient permeability (Backers et al., 2022). They were drilled in 2013 and 2017, respectively, and useful data were collected to refine the in-situ stress estimates. There are a few other further offset wells that have had relevant data collection, including the Unterhaching Gt 1, Hofolding 1, and Grambach 1 (Figure 2).

Figure 2: Surface locations of the Eavor-Loop and offset wells GEN-1 (and 1ST-A1), Unterhaching Gt 1, Hofolding 1, Grambach 1 (Google Earth). Geretsried is located directly north of the Alps, and the Eavor-Loop is targeting the Jurassic Malm carbonate formation in the Bavarian Molasse Basin.

Understanding the in-situ stress tensor, which includes the three principal stresses and their orientations, plays an important role in wellbore stability prediction, trajectory optimization, drilling pressure limits, and cement program design. Since there is no salt or active faulting here, it is reasonable to assume that one of the principal stresses is near-vertical and is referred to as the overburden stress (S_v; Moos and Zoback, 1990). The other two principal stresses are perpendicular horizontal stresses, a minimum (S_{hmin}) and a maximum (S_{Hmax}).

Both the magnitude and azimuth of the in-situ stresses can vary laterally and with depth, making the task of estimating the stress tensor notoriously difficult. In addition to this, there is uncertainty over the stress regime in the Bavarian Molasse Basin, as normal faulting, strike slip and reverse faulting regimes have all been predicted in the areas adjacent to Geretsried. The Bavarian Molasse Basin is located directly north of the Alps and is a classic foreland basin (Reinecker et al., 2010), which has implications on the present-day stress regime at Geretsried.

This paper will focus on a discussion of the stress estimate for the Eavor-Loop 1.0 project in Geretsried, Germany, based on the learnings from the recent Formation Integrity Tests (FITs).

Literature Review

Within the academic community there is considerable uncertainty over the stress regime in the Bavarian Molasse Basin, which has been reviewed in Reinecker et al. (2010), Drews et al. (2019), Ziegler & Heidbach (2020), Backers et al. (2022), and Ahlers et al. (2022). There are numerous other publications which cover this topic, but a detailed review of these is out of scope for this paper. Instead, the cited papers are used to demonstrate the wide variability in stress approximations. Normal faulting ($S_{hmin} < S_{Hmax} < S_v$), strike slip ($S_{hmin} < S_v < S_{Hmax}$) and reverse faulting ($S_v < S_{hmin} < S_{Hmax}$) regimes have all been predicted within a relatively small geographic area. Here, the focus of this review was on the Bavarian Molasse Basin and more locally on the Geretsried area.

As presented by Reinecker et al. (2010), four-arm caliper and image logs were analyzed in 137 wells with a depth of investigation that ranged from surface to 6000 mTVD. A total of 1348 borehole breakouts and 59 drilling-induced fractures were observed in 98 wells in the Bavarian Molasse Basin. The breakouts were often observed to have large angular widths (> 60°) and high eccentricities (> 50% more than bit size). They occurred at shallow depths; less than 600 mTVD in 27 wells, and with some breakouts observed at less than 100 mTVD. The observation of breakouts at shallow depths suggests that the horizontal stress magnitudes (or, at least S_{Hmax} magnitude) are high in the Bavarian Molasse Basin. Based on these observations, Reinecker et al. (2010) speculated that a strike slip or thrust faulting stress regime presently exists in the shallow Bavarian Molasse Basin.

In Drews et al. (2019), leak-off tests (LOT), FIT and cementation pressure data were analyzed and the implications on the present-day stress regime in the Bavarian Molasse Basin were discussed. The primary case study used in this paper was a LOT completed at 825 mTVD at the Unterhaching Gt 1 well (Figure 2) in a shale unit. The authors showed that all values obtained from the LOT are significantly lower than the estimated S_v (i.e., fracture propagation pressure of ~1.58 SG), implying that either a normal faulting or strike slip stress regime is present at this well location. Additionally, they stated that using a coefficient of sliding friction (μ_s) of 0.6 in the critically stressed crust equation results in a strike slip stress regime assumption. However, by using $\mu_s = 0.4$, the critically stressed crust equation indicates a normal faulting stress regime. The authors argued that the correct lithological context has not been considered before this study, and that a $\mu_s = 0.4$ is more representative for the shale. Based on this, they suggested that a normal faulting regime may be present in the shallow Bavarian Molasse Basin.

Ziegler & Heidbach (2020) generated a high-resolution 3D stress model of the Bavarian Molasse Basin. The resulting uncertainty in the modelled stress state was due to variability in the stress magnitude data records used for calibration. As a result, there were larger uncertainties in the modelled S_{Hmax} magnitude and significantly smaller uncertainties in the S_{hmin} magnitude, since S_{hmin} is typically easier to quantify. From the Ziegler & Heidbach 3D stress model, the principal stresses were extracted in the project area. At the closest modelled depth to the Eavor-Loop target interval (4,443 mTVD), which is presumed to be associated with the Malm, Ziegler & Heidbach predict a strike slip regime with $S_v = 2.50$, $S_{Hmax} = 4.65 \pm 1.13$ SG, and $S_{hmin} = 1.79 \pm 0.18$ SG. Ziegler & Heidbach also contemplated the existence of a transtensional regime ($S_{hmin} < S_{Hmax} \sim S_v$) but based on evidence from FIT data they suggested that a strike slip regime was more likely.

Backers et al. (2022) estimated the Geretsried Malm stress field as part of the ZoKrateS project. The ZoKrateS project was a multistage hydraulic fracture stimulation of the Malm in GEN-1ST-A1 in 2021 (LIAG, 2021). The GEN-1ST-A1 well was initially drilled in 2017 and re-entered 4 years after the initial drill, and it was found to be stable and in good hole condition. Backers et al. (2022) referenced an internal report which suggested a strike slip faulting regime, with S_v = 2.48 SG, S_{Hmax} = 2.72 SG, and S_{hmin} = 1.63 – 2.15 SG. Similar to Drews et al. (2019), they suggested that μ_s may be lower than 0.6 since a clay rich filling of the discontinuities should be assumed.

Ahlers et al. (2022) provided a continuous finite element prediction of the crustal stress with focus on the sedimentary basins in Germany. The study by Ahlers et al. (2022) included a larger area as compared to Ziegler & Heidbach (2020), which may lead to higher uncertainty in the Bavarian Molasse Basin. The 3D model was calibrated with minimum expected values for both S_{hmin} and S_{Hmax} magnitudes. Internally at Eavor, the X, Y, Z stress data was extracted over the project area, and a python code was then written to calculate S_v, S_{Hmax}, S_{hmin} at this location, using eigenvectors for stress direction and eigenvalues for principal stress magnitude. At the closest depth to the target interval (4,366 mTVD), which is presumed to be associated with the Malm, they predict a normal faulting regime with S_{hmin} = 1.40 SG, S_{Hmax} = 1.78 SG, S_v = 2.40 SG. However, Ahlers et al. (2022) stated that the Bavarian Molasse Basin results are very inconsistent compared to the rest of Germany. Below 1000 mTVD, S_{Hmax} predictions appear to split into two groups with both normal faulting and strike slip results.

Table 1 summarizes the in-situ stress states identified by Ziegler & Heidbach (2020), Backers et al. (2022) and Ahlers et al. (2022), for the Malm target interval in the Bavarian Molasse Basin.

Table 1: In-situ Stress Estimates in the Malm, Geretsried (Bavarian Molasse Basin) from recent studies.

Study	S_{hmin} (SG)	S_v (SG)	S_{Hmax} (SG)	Regime
Ziegler & Heidbach (2020)	1.79 ± 0.18	2.50	4.65 ± 1.13	Strike Slip
Backers et al. (2022)	1.63 – 2.15	2.48	2.72	Strike Slip
Ahlers et al. (2022)	1.40	2.40	1.78	Normal

Based on the most recent publications, it appeared that normal and strike slip faulting were more likely for the Geretsried area, with the possibility of stress changes with depth. These were the two most likely stress regimes carried in the pre-drill analysis. However, a reverse faulting regime also can't be ruled out at this point due to the high uncertainty identified by Reinecker et al. (2010).

While there is significant uncertainty in the stress magnitudes at Geretsried, the S_{Hmax} azimuth prediction is consistent. This can be seen in the World Stress Map (Heidbach et al., 2018) data points from borehole breakout and drilling induced tensile failure (Figure 3). Most indicators point to a N/S azimuth. The S_{Hmax} azimuth is expected to be highly uniform here (Reinecker et al., 2010).

Figure 3: World Stress Map over the Geretsried area (Heidbach et al., 2018). All indicators in the area are from drilling induced fractures or borehole breakouts and suggest a S_{Hmax} azimuth close to N/S. Project site is indicated by the star.

Offset Well Data

The overburden stress can be calculated from the density of the rock formations in the subsurface. There were no density logs collected in the GEN-1 and GEN-1ST-A1 wells due to regulatory restrictions, washouts, and a lean acquisition program. Instead, Gardner's equation was used to calculate density from sonic data in the offset wells GEN-1, GEN-1ST-A1, Grambach-1, and Hofolding-1 (Figure 2). A moving average of 30 m was applied before integrating the different density profiles to obtain a range of S_v profiles of which the minimum and maximum were deemed representative for the uncertainty range. The maximum calculated S_v may still be on the low side because of washouts on the offset log readings. At the top of the Malm, the S_v was calculated to be 2.44 – 2.52 SG. There is more consistency in the S_v prediction in literature (Table 1) as compared to the horizontal stress values, so the overburden stress evaluation will not be the focus of this paper. For the pre-drill modelling, S_v = 2.45 ± 0.1 SG was carried.

Several successful FITs were completed in the GEN-1 well and were provided by the prior drilling operator Enex Power Germany GmbH (Enex). A FIT can represent a minimum value for the minimum stress estimates. The data points, which are summarized in Table 2, can be used to constrain the horizontal stress evaluation. These FITs were completed in preparation for the suspected high pore pressure zone deeper in the well.

Table 2: FIT data from the GEN-1 well; EMW = test result in equivalent mud weight units. Provided by Enex.

#	Well	Depth (mTVD)	FIT EMW (SG)	Formation	Lithology
FIT 1	GEN-1	2,925	1.45	Chattian Sands	Sandstone/Marl
FIT 2	GEN-1	2,941	1.85	Chattian Sands	Sandstone/Marl

Geretsried Eavor-Loop Data

A series of FITs were completed in both GEL-A1 and GEL-B1 wells. The equivalent mud weight value (EMW) of the planned FITs were chosen based on the required mud weights to complete the subsequent wellbore section. There is a known very high pore pressure located at Geretsried at ~3250 mTVD (Drews et al., 2020), so relatively high FITs were needed to ensure the well could achieve a safe mud weight for drilling.

FITs were conducted at drill out of the casing shoe, exposing ~5 m of open hole. The well was then pressured up to a desired EMW by pumping at a low and constant rate. No leak-off was observed for any of these FITs and pressure held for ~10 minutes. The results are in Table 3. When no leak-off is observed, it can be assumed that the pressure has not reached the fracture gradient, and therefore is likely lower than the minimum stress.

Table 3: FIT data from GEL-A1/B1; EMW = test result in equivalent mud weight units.

#	Well	Depth (mTVD)	FIT EMW (SG)	Formation	Lithology
FIT A	GEL-A1	767	1.70	Neuhofener Beds	Marl
FIT B	GEL-B1	769	1.74	Neuhofener Beds	Marl
FIT C	GEL-A1	2,905	2.15	Chattian Sands	Sandstone/Marl
FIT D	GEL-B1	2,899	2.15	Chattian Sands	Marl
FIT E	GEL-B1	4,163	1.85	Rupel-Tonmergel	Limestone
FIT F	GEL-A1	4,480	1.45	Malm	Limestone/Dolomite

2.15 SG is a notably high FIT value, but confidence is added since both wells were able to reach this without leak-off. S_V at this depth (~2,900 mTVD) is estimated to be ~2.35 SG, which implies that the minimum stress is approaching the overburden stress.

A lower FIT value was chosen for the Malm since the operations team did not want to risk fracturing the target interval for the Eavor-Loop. However, there were additional indications that the minimum stress may be quite high in the deeper sections of Geretsried, below the high pore pressure zone. For the cement job for the 11-7/8” shoe at 4,137 mTVD, accounting for both the mud and the cement, a very high equivalent circulating density was reached which resulted in a downhole pressure of approximately 1.97 SG EMW. Additionally, a cement squeeze was completed and a downhole pressure of 2.14 SG EMW was achieved. However, it is not certain whether this squeeze was connected to any fresh formation. No losses were observed in the cement job or squeeze, which suggests that these pressures are below the fracture gradient, and therefore below the minimum stress. This cement data can be used as a low confidence minimum stress indicator but not as conclusive data points.

Discussion

The objective of this paper is to reflect on how the newly acquired FIT data in the Geretsried area may affect the understanding of the in-situ effective stresses, and the stress regime. This is valid as of Q1 2024, as further data is planned to be collected, and the geomechanical model is continuously being refined while drilling.

No new material information was collected for S_v, so this estimate remained the same. The pore pressure (P_p) estimate was refined in two ways. There is currently uncertainty in the pore pressure trends, and both of the following cases are currently considered to be likely. S_v and both P_p estimates are displayed in Figure 4.

P_p Case 1 was determined from a review of the mud weights used in GEL-A1 and GEL-B1 and any influxes/losses that were observed while drilling the vertical section. However, there are no direct measurements of pore pressure in the field so an alternative pore pressure case from literature was also considered. P_p Case 2 was estimated based on the findings of Drews et al. (2020). The authors generated a 3D basin model which suggested that pressure likely already starts to build in the Chattian Sands. This early pressure build was not observed in either in GEL-A1 or GEL-B1, and the Chattian Sands section was successfully drilled with near hydrostatic (~1.1 SG) mud weights. However, the Chattian Sands are very low permeability so any high pore pressure likely would not be detected during drilling (Drews et al., 2020).

To generate preliminary lower bounds on the minimum stress curves, S_{hmin} was anchored to the highest FIT data point (2.15 SG at ~2,900 mTVD in both GEL-A1 and GEL-B1). The Effective Stress Ratio (ESR, Zoback, 2010) was used to calculate a continuous profile of S_{hmin}, using S_v and both pore pressure estimates (Equation 1). The ESR from P_p Case 1 was calculated to be ~0.83, and ~0.67 for P_p Case 2. Minimum S_{hmin} cases resulting from Equation 1 are shown in Figure 4.

Equation 1: Effective Stress Ratio (ESR)

$$ESR = \frac{S_{hmin} - P_p}{S_v - P_p}$$

Uncertainty remains for the S_{Hmax} approximation, and consequently also for the stress regime. The GEL-A1 and GEL-B1 FIT values at ~2,900 mTVD were very high relative to S_v, and it is known that an increased pore pressure can lead to a higher fracture gradient and minimum stress. Based on the uncertainty in the pore pressure at this interval, it is currently possible that the ~2,900 mTVD FITs were high from pore pressure related effects, or from regional stress effects. However, since the fracture gradient is approaching S_v, it appears unlikely that strong normal faulting is present at this depth. This would suggest at least an isotropic ($S_{hmin} \sim S_{Hmax} \sim S_v$), combined strike slip/reverse ($S_{hmin} \sim S_v < S_{Hmax}$), or reverse faulting regime ($S_v < S_{hmin} < S_{Hmax}$) at the depth of ~2,900 mTVD. Further data would need to be collected to refine the S_{Hmax} approximation.

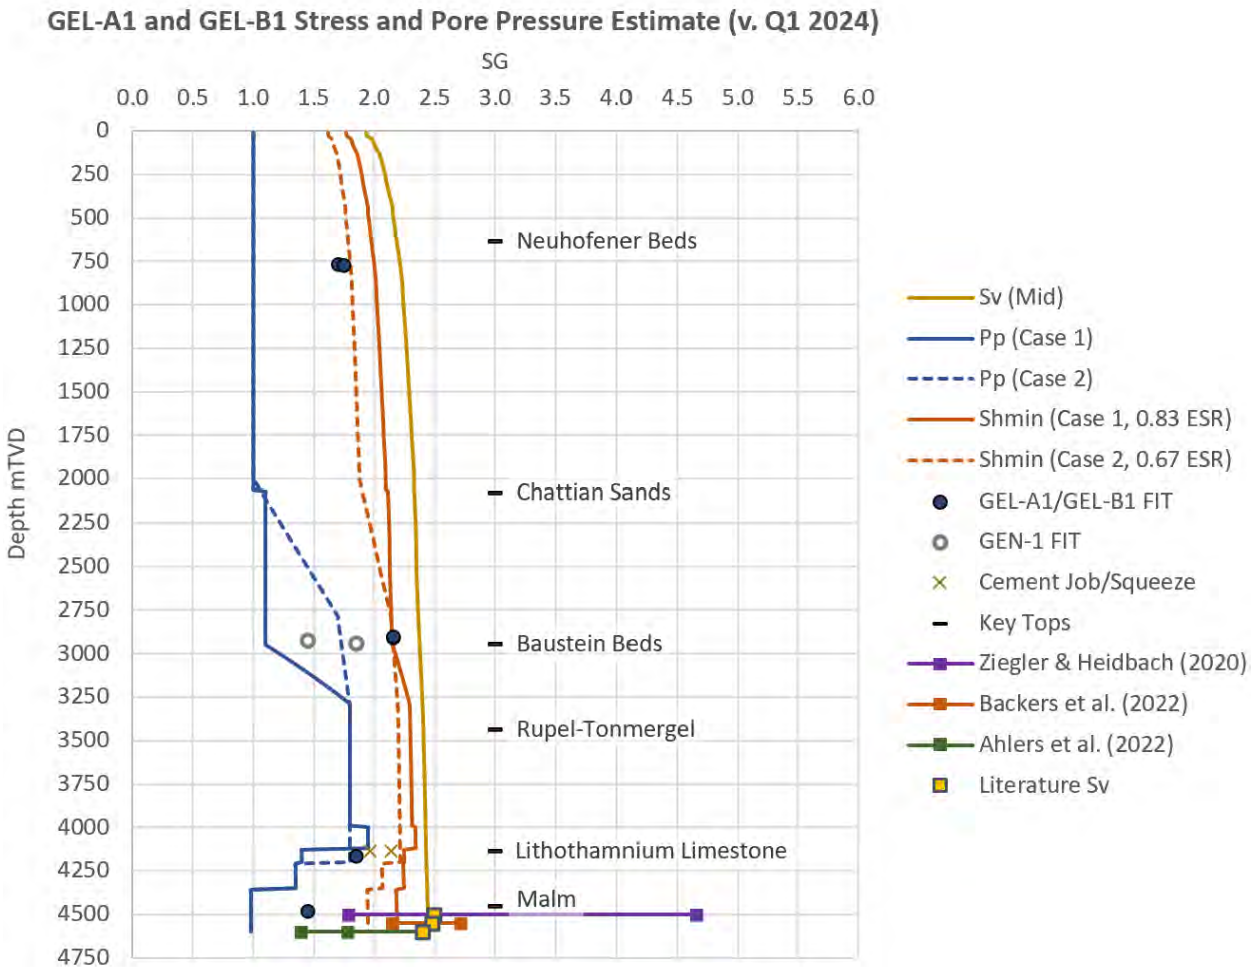

Figure 4: GEL-A1 and GEL-B1 Stress and Pore Pressure Estimates as of Q1 2024. FIT (high confidence) and cement data (low confidence) are shown, compared to literature Malm stress approximations by Ziegler & Heidbach (2020), Backers et al. (2022) and Ahlers et al. (2022) (Table 1). The S_{hmin} (ESR) curves are estimated from the ~2,900 mTVD GEL-A1 and GEL-B1 FITs, paired with the pore pressure cases.

To optimize the drilling of the Eavor-Loop, it is a priority to understand the in-situ stress in the Malm (~4,500 mTVD). The Malm is known to be underpressure (Drews et al., 2020), which affects the S_{hmin} estimate. As discussed, a lower bound S_{hmin} estimate was extrapolated to the Malm from an ESR (Equation 1, Figure 4). S_{hmin} Case 1 results in a generally higher minimum stress estimate than S_{hmin} Case 2. This method is one way of estimating the minimum S_{hmin} in the Malm, however there is uncertainty whether there could be a stress change with depth, where the ESR method would no longer apply.

Other than a difference in pore pressure between the Chattian Sands and the Malm, there are two explanations for why the minimum stress in the Malm at ~4,500 mTVD may be less than the FIT at 2,900 mTVD. The ESR approximation may be invalid if there is either active faulting between the Baustein Beds and the Malm, or a significant change in mechanical properties and stiffness which is affecting the stress distribution. There is limited tectonic activity that has been recorded near Geretsried, but blind thrusts in the area have been mapped on seismic by Shipilin et al. (2020).

As Loop 1 is drilled, more data will be collected to better understand the stress state and rock properties. Continued mudlogging and image logging are planned to be collected in both the vertical and lateral wells. If breakouts or tensile failure are observed in either the vertical or horizontal wells, this could help to refine the stress estimate. However, if the stress regime is reverse faulting, it would be challenging to refine all three stress magnitudes in the stress tensor, since the minimum stress would be S_v.

Additionally, it is possible that the FITs do not represent the lower bound of the minimum stress. If the formations have a high breakdown pressure, and have a high tensile strength, the FIT could overestimate the minimum stress (Zoback, 2010). If the stress uncertainty persists, an extended leak-off test (XLOT) should be considered while balancing the risk of operationally high pressures that would be required at these depths.

From the FIT data, an isotropic, combined strike slip/reverse or reverse faulting seems plausible in the Geretsried area at ~2,900 mTVD. At this depth, strong normal faulting would appear to be unlikely. However, a predominantly normal faulting regime in the Malm cannot be ruled out at this point, leaving open the possibility of a stress change at the depth of the Malm target interval (~4,500 mTVD). Geomechanical models must be continuously revised as a well is drilled. As Loop 1 progresses and the team learns more about the wellbore stability and stress state in the laterals, the drilling fluid can be updated to the optimized mud weight.

Summary

There is uncertainty in the stress regime in the area adjacent to the Geretsried Eavor-Loop project. Normal faulting ($S_{hmin} < S_{Hmax} < S_v$), strike slip ($S_{hmin} < S_v < S_{Hmax}$) and reverse faulting ($S_v < S_{hmin} < S_{Hmax}$) regimes have all been predicted within a relatively small geographic area (Reinecker et al., 2010; Drews et al., 2019; Ziegler & Heidbach, 2020; Backers et al., 2022; Ahlers et al., 2022). Prior to drilling the Geretsried Eavor-Loop, it was thought that normal faulting or strike slip faulting regimes would be more likely.

High FIT data points were collected in the GEL-A1 and GEL-B1 mainbores. At ~2,900 mTVD, FIT values of 2.15 SG were reached, approaching the expected S_v value (~2.35 SG). The FIT was repeatable in GEL-A1 and GEL-B1 with no leak-off observed. Due to this, it seems unlikely that the Geretsried area has a strong normal faulting stress regime at this depth, and it appears more plausible this interval is in either an isotropic ($S_{hmin} \sim S_{Hmax} \sim S_v$), combined strike slip/reverse ($S_{hmin} \sim S_v < S_{Hmax}$), or reverse faulting regime ($S_v < S_{hmin} < S_{Hmax}$). These FITs have provided new insights into the stress regime, as they are much higher than what is normally achieved in the Bavarian Molasse Basin.

However, in the deeper Malm there is still uncertainty in the stress. It is possible that the stresses change at the depth of the Malm, which could be due to either pore pressure affects, active faulting between the Baustein Beds and the Malm, or a significant change in mechanical properties and stiffness which is affecting the stress distribution. This remaining uncertainty highlights the importance of collecting stress information at multiple depths, and the requirement to characterize the target interval specifically. Further data collection is planned in the Eavor-Loop, including image logging in both the vertical and horizontal wells, which could potentially refine the stress state in the Malm. As drilling progresses in Geretsried, the stress environment will be continuously evaluated and refined to optimize the drilling program and future Loop 2-4 placement.

closed-loop; long well geothermal; semi-analytical solution; periodic source; modeling

ABSTRACT

Though long (e.g., tens of kilometers) closed-loop geothermal wells are under consideration for the extraction of subsurface heat, these wells might also serve as an efficient energy storage mechanism for electricity generation. Using a semi-analytic model solution, the potential for electric-grade heat storage as a function of ambient temperature (e.g., corresponds to depth of loop), well length, well diameter, and flow rate is evaluated. The following simplified cases for comparison of standard closed loop operation with energy storage operation were considered: [1] constant flow rate and constant temperature (90 °C) injection to represent the standard closed-loop base-case; and [2] constant flow rate and annual cycle sinusoidal temperature (90-150 °C) to represent seasonal (summer) charging while solar resources are peak. Initial temperatures for all scenarios considered herein are a uniform 175 °C. Electric-grade heat is assumed to be delivered whenever temperatures at the extraction point exceed 90 °C. For calculation purposes only, if temperature falls below 100 °C, it is assumed that heat delivered is sub-economic, so no electricity would be produced. For all scenarios, temperatures at the extraction well asymptotically approach the flow-weighted average injection temperature, but energy storage scenarios exhibited a damped time-varying signal that diminishes in magnitude with length of the loop. The asymptotic approach depends on initial temperatures in the rock and the heat extraction rate (a function of well diameter and flowrate). This analysis demonstrates that shorter closed loops can produce more electricity over time than longer closed-loops previously proposed for electricity production over typical engineering design lifetimes (e.g., 30 years). Although only a high-temperature scenario is considered herein, rock that is initially below boiling temperature would not host a standard closed-loop resource, but injection of hot water seasonally would asymptotically heat this low-temperature system to temperatures capable of electricity production. In other words, regardless of initial temperatures, closed loops could be used to store electricity with no critical minerals in the geothermal battery.

1. Introduction

In recent years, increased attention has been paid to renewable energy to reduce global warming and dependence on fossil energy. Geothermal energy has been proposed as one of the most important components of renewable energy due to its reliability, availability, and potential to supply baseload power (Zarrouk & Moon, 2014). A complementary technology to traditional geothermal resources is to store surplus energy from episodic renewables (e.g., wind and solar) for later use. Storage is often done with electrochemical batteries, but a potential alternative is underground thermal energy storage (UTES) which is technically feasible (c.f., Burns et al., 2020), and proven applications generally target low temperatures (< 90 °C, but often near local ambient air temperature). Methods like aquifer thermal energy storage (ATES) can store energy by injecting heated water into the aquifer (Burns et al., 2020; Qi et al., 2023); however, temperatures significantly above ambient background can cause rapid adverse geochemical changes, affecting structural stability and/or potentially leading to plugging and loss of permeability due to dissolution or precipitation of minerals.

Herein, we evaluate the potential to store and recover moderate-to-high-temperature fluid (>90 °C and >150 °C, respectively) in closed-loop systems. Closed loop systems that have been proposed for extraction of heat must be deep and long to access high temperatures and provide sufficient surface area to allow for long-duration delivery of electricity because radial conduction of heat to a well is an inefficient process (e.g., White et al., 2023). If heat is periodically injected, electricity production can be improved and could allow for the use of shorter length loops than is required for heat extraction only. As part of this research, the effect of time-varying injection temperature on heat delivered at the outflow for conversion to electricity is examined by comparing it to a base-case representing standard closed-loop operations. In particular, temperature and electric-grade energy at the outflow corresponding to different length loops is documented.

2. Method

A semi-analytic solution representing standard closed-loop heat extraction and periodic heat storage are used to solve the time varying heat flow problem in the Laplace domain (e.g., Arfken & Weber, 1995), and the solution is numerically integrated for the inverse Laplace transform (c.f., Zhou et al., 2022). We compare a simple sinusoidal input temperature to a constant input temperature, both at constant flow, then predict the delivered temperature and heat at distance along the loop to understand how heat would be delivered as a function of length of loop.

2.1 Conceptual Model

The conceptual model (Fig. 1) is used to illustrate the mathematical representation of the fluid and heat transport process within and near a horizontal long closed well (i.e., the loop) in a heat extraction or storage horizon. Vertical sections of the loop are assumed to be insulated to prevent heat exchange between colder shallower rocks and the loop. The surrounding rock is a conduction-only region that is assumed to be thick enough to avoid other impacts (e.g., heat exchange with other layers or hydrothermal systems), so mathematically, this region is assumed to be a semi-infinite system. The thermal property of the rock is assumed to be homogeneous with a uniform initial temperature (175 °C for all simulations herein). Water at a prescribed temperature is injected on one end of the well (left side in Fig. 1) and heat is advected towards the other with a constant flow rate (right side in Fig. 1). The analytic solution allows for variable temperature injection, and

two cases are compared herein: constant 90 °C for the standard closed-loop base-case, and sinusoidally varying 90-150 °C representing seasonal storage (i.e., period is yearly). The hypothesis is that seasonal charging with heat will maintain higher temperatures at the end of loops, allowing the production of more electric-grade heat with shorter loops. Water within the pipe is assumed to be well-mixed, and heat is exchanged with the surrounding rock through conduction in the radial direction perpendicular to the axis of the pipe. Because steel has higher thermal conductivity than rock, and pipes are comparatively thin, heat conduction through the pipe wall is not limiting, so the pipe is not explicitly represented. Thermal properties of materials filling the annular space between the loop and the rock are assumed to be the same as for the rock. The coordinate system is set as follows: the origin is at the center of the left end of the well. The *x-axis* is horizontal, pointing to the right; *r* is the radial coordinate in a vertical cross-section, pointing away from the center of the well; *R* is the radius of the well [L], *T* is temperature [Θ], *c*, *ρ,* and *k* are specific heat capacity [$L^2T^{-2}\Theta^{-1}$], density [ML^{-3}], and thermal conductivity [$MLT^{-3}\Theta^{-1}$] of the material. Notation *f* means flow property inside the well, and notation *b* means material property of the rock outside the well.

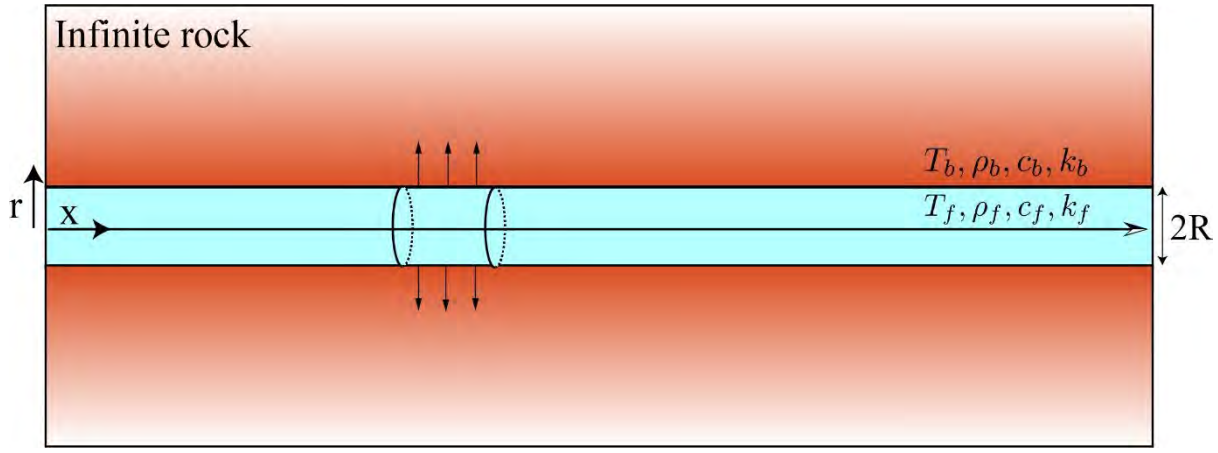

Figure 1: The 3D conceptual model of the closed loop long well system. The well is a cylinder that allows heat exchange radially with an arbitrarily large domain (assumed to be infinite for the solution). Water is injected on the left at a constant rate and variable temperature. As water flows in the direction x, the variations in temperature are damped, and over time as the borehole and surrounding rock are heated, temperature will asymptotically approach the average injection temperature for large distances.

Compared to traditional proposed use of closed-loops, which only extract heat, we postulate that periodic heat injection into closed loops is a way to store periodic excess energy in a system where geochemical plugging concerns are negligible (i.e., pipes). For instance, during summer, batteries are charged by electricity generated using solar panels or other intermittent sources of renewable energy for delivery hours or days later, but electric batteries cannot store energy for as long as geological thermal energy storage systems (e.g., weeks to years). While solar may seem an obvious choice, electricity from wind is also seasonal, and if some excess from the wind or solar glut periods could be stored long-term in high-temperature loops, this provides an option that does not depend on critical minerals used for chemical batteries.

Standard or literature supported values are selected for material properties and engineered system rates and sizes. Burns et al. (2024) indicated that effective bulk thermal conductivities for the Great Basin of the southwestern United States, where many geothermal systems have been identified, range from 2.4 to 3 W m^{-1} K^{-1}. Therefore, 2.6 W m^{-1} K^{-1} is used to represent the rock thermal

conductivity for all analyses herein. The density of granite is assumed to be 2,750 kg/m^3 and specific heat capacity is 790 J kg^{-1} K^{-1}. Using these three terms, one can calculate the thermal diffusivity as 37.75 m^2 per year. For estimates, we assume that after electric-grade heat is extracted, the colder water is injected at 90 °C (which gives our constant temperature for injection of the base case). For heat storage, it is assumed that heat can be extracted down to 90 °C, so heat added (stored) via the sine wave periodic heat source, is the heat corresponding to the difference between injected temperature and 90 °C. Thirty years is selected as the modeling time to correspond to a 30-year engineering lifetime of the facility.

Loop lengths of 15-20 km have been postulated for closed-loop systems, so herein the analyses consider 2, 5, 10, and 20 km. The injection rate is selected to be 0.1 m^3/s for a well radius of 0.2 m (White et al., 2023). For comparison, rates of ½ and twice this value (i.e., 0.05 and 0.2 m^3/s, respectively) are simulated.

2.2 Mathematical Model

Although the fluid flow rate is assumed to be constant, an annual sine wave heat source is used to represent periods of heat addition and extraction. If neglecting horizontal heat conduction inside the well, i.e., only considering a horizontally advective transport system, one has the following governing equation (described by notation *f*):

$$\frac{\partial T_f}{\partial t} = -\frac{Q}{\pi R^2}\frac{\partial T_f}{\partial x} - q \tag{1}$$

where Q is the volumetric flux of fluid inside the well [L^3T^{-1}], q is a heat sink term describing the heat loss to the rock through conduction [ΘT^{-1}], and it can be described by the following Eq. (2). The boundary condition on the left is described in Eq. (3), and the initial condition is in Eq. (4):

$$q = -\frac{2k_b}{\rho_b c_b R}\frac{\partial T_b}{\partial r}\Big|_{r=R} \tag{2}$$

$$T_f(x=0,t) = M\sin(\alpha t) + T_m \tag{3}$$

$$T_f(x,t=0) = T_0 \tag{4}$$

where T_m is the average injection temperature [Θ], M is the magnitude of the variation from mean injection temperature [-], α is the frequency [T^{-1}], and T_0 is the initial temperature inside the well [Θ].

For the rock outside the well (described by notation *b*), we only consider the heat conduction, and the related governing equation is:

$$\frac{\partial T_b}{\partial t} = \frac{k_b}{\rho_b c_b}\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T_b}{\partial r}\right) \tag{5}$$

where at the shell of the well ($r = R$), the temperature in bulk (T_b) equals to the temperature in the well (T_f), which is described in Eq. (6). Assuming that the rock has the same temperature as the well at the beginning, the temperature of the infinite long distance from the well will not change. The infinite radial boundary condition is described in Eq. (8), and the initial condition is in Eq. (7).

$$T_b(x,t,r=R) = T_f(x,t) \tag{6}$$

$$T_b(x,t=0,r) = T_0 \tag{7}$$

$$T_b(x,t,r=\infty) = T_0 \tag{8}$$

Using Laplace transform and Green's function of the modified Helmholtz equation (Arfken & Weber, 1995, Table 8.5) on Eqs. (1)-(8), one can solve the governing equations in Laplace space:

$$\overline{T_{f1}} = \left(M\frac{\alpha}{p^2+\alpha^2} + \frac{T_m - T_0}{p}\right)\exp\left[-\frac{\pi R^2}{Q}\left(p + \frac{2D_b}{R}\frac{\mathrm{K_1}\left(\sqrt{\frac{\mathrm{p}}{\mathrm{D_b}}}\mathrm{R}\right)}{\mathrm{K_0}\left(\sqrt{\frac{\mathrm{p}}{\mathrm{D_b}}}\mathrm{R}\right)}\sqrt{\frac{\mathrm{p}}{\mathrm{D_b}}}\right)x\right] \tag{9}$$

where T_{f1} is the temperature change inside the well [Θ] and defined as $T_f = T_{f1}+T_0$, the overbar symbol means the variable is in Laplace space, p is the Laplace transform operator, thermal diffusivity D is defined as $k/\rho c$ to represent heat conduct in fluid and rock, respectively [L^2T^{-1}], K_n is the second kind modified Bessel function with order n (n=0,1 in this research). By using the numerical inverse Laplace transform, one can get the final solution in the time domain as:

$$T_f = L^{-1}\left\{\left(M\frac{\alpha}{p^2+\alpha^2} + \frac{T_m - T_0}{p}\right)\exp\left[-\frac{\pi R^2}{Q}\left(p + \frac{2D_b}{R}\frac{\mathrm{K_1}\left(\sqrt{\frac{\mathrm{p}}{\mathrm{D_b}}}\mathrm{R}\right)}{\mathrm{K_0}\left(\sqrt{\frac{\mathrm{p}}{\mathrm{D_b}}}\mathrm{R}\right)}\sqrt{\frac{\mathrm{p}}{\mathrm{D_b}}}\right)x\right]\right\} + T_0 \tag{10}$$

By using the same method, one can obtain the semi-analytical solution with constant temperature boundary as:

$$T_f = L^{-1}\left\{\left(\frac{T_m - T_0}{p}\right)\exp\left[-\frac{\pi R^2}{Q}\left(p + \frac{2D_b}{R}\frac{\mathrm{K_1}\left(\sqrt{\frac{\mathrm{p}}{\mathrm{D_b}}}\mathrm{R}\right)}{\mathrm{K_0}\left(\sqrt{\frac{\mathrm{p}}{\mathrm{D_b}}}\mathrm{R}\right)}\sqrt{\frac{\mathrm{p}}{\mathrm{D_b}}}\right)x\right]\right\} + T_0 \tag{11}$$

Furthermore, the analytical solution in this study is in Laplace space and needs a numerical method to implement the numerical inverse Laplace transform (Zhou et al., 2022). The numerical inverse method used in this research is called the Gaver-Stehfest method. It is a discrete approximation of the Widder-Post inversion algorithm (Stehfest, 1970) and is implemented in Python with the mpmath package (The mpmath development team, 2023). (Verification of this model is provided in the supplementary material)

2.3 Energy Delivered Calculation

To estimate heat delivered, for each distance (x; corresponding to loop length), the difference between the extracted temperature and 90 °C is calculated. To convert this to thermal energy, multiply the temperature difference with injection rate (Q), density of water (ρ_f = 993.18 kg/m^3) and thermal capacity of water (c_f = 4181 J kg^{-1} K^{-1}), yielding electric-grade thermal energy extracted from the system. This thermal energy could be converted to electricity, but herein, a conversion efficiency was not assumed, so all comparisons are in terms of heat. It is recognized that a minimum temperature differential (above 90 °C) would be required to be economic, so for comparison purposes here, 10 °C (i.e., we assume electricity production stops if temperature drops below 100 °C) is used.

To evaluate total usable electric-grade heat over the life of the project (30-years), the heat flux is integrated over time (only when extraction is >100 °C), calculating the accumulated energy (AE) produced by the geothermal system as:

$$AE = \int_0^{t_{end}} Q c_f \rho_f T_{m,dif} dt \quad (12)$$

where t_{end} is the time interval to calculate the AE value [T]; $T_{m,dif}$ is the modified temperature difference calculated by the extracted temperature minus 90°C [Θ] and modified means the $T_{m,dif}$ will be set to zero if the difference is lower than 10 °C (because no energy will be extracted from the system).

3. Results and Discussion

Fig. 2 shows the extracted temperature change for the standard closed-loop heat-extraction only scenario at all four loop lengths for all three test injection rates. The dashed green line corresponds to the 100 ºC limit, the assumed limit where electricity production would cease because it is not economic. As postulated by other researchers (e.g., White et al., 2023), long loop lengths are required to allow continued electricity production for the full 30 years. From the 0.1m^3/s injection rate base-case, the model indicates that well length exceeding 10 km will have economically beneficial thermal production for the full 30 years. If using a higher injection rate, only an extremely long well (at least 20 km) will be economically beneficial for the duration. If the flow rate is slower, a well length greater than 5 km will produce heat beneficially.

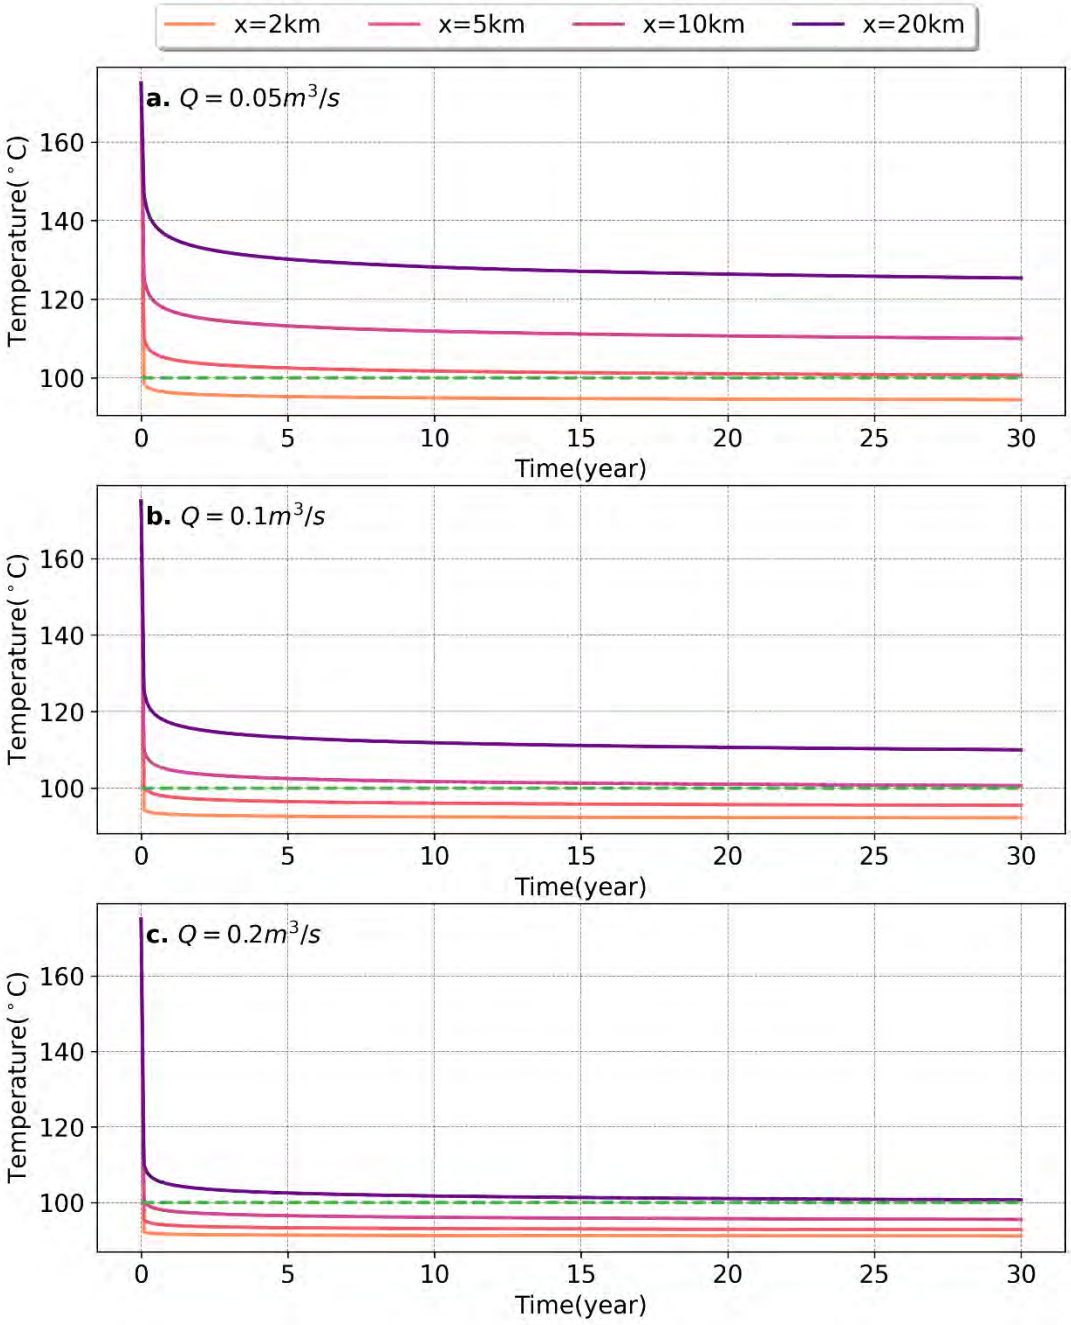

Figure 2. Extracted temperature change with different injection rate and well length under constant source condition. The green dashed line indicates the temperature at 100 °C.

Fig. 3 is analogous to Fig. 2, with the only change being the seasonal storage of heat. Unlike the extraction only case, all loop lengths could produce electricity in all of the 30 years of operation, but shorter loops and higher flow rates have some part of the year where electricity could not be produced.

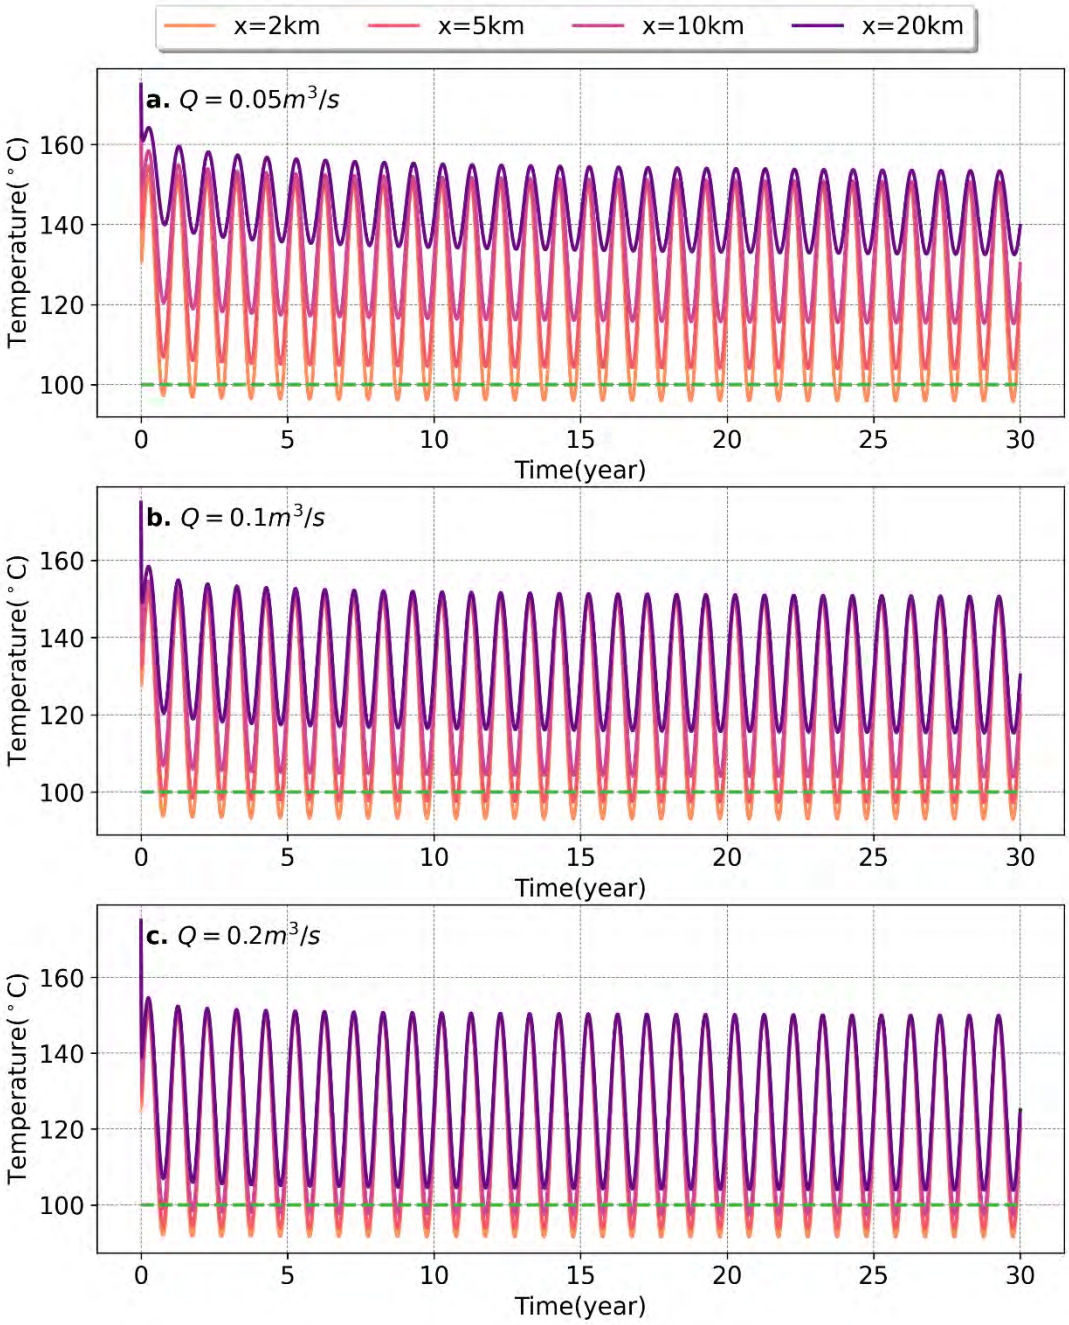

Figure 3. Extracted temperature change with different injection rate and well length under sine wave source condition. The green dashed line indicates the temperature at 100 °C.

A close examination of Fig. 3 reveals that the peaks and troughs shift a small amount in time for longer lengths, demonstrating that there is injection lag seen at the outflow with more lag for longer pipes, but the lag is still comparatively small (e.g., days to a few weeks) due to the high rate of flow through the pipe. A more pronounced effect is the damping of the range of oscillations with distance. Also, asymptotically, the sine wave for every profile will go to 120 °C on average (i.e., the average of the sine wave input), so examination of Fig. 3 also gives sense of longevity of the system.

Fig. 4 shows cumulative electric-grade energy delivered for all scenarios in Figs. 2 and 3, demonstrating that even with shorter pipes, periodic heat injection greatly increases long term heat delivery. With a careful comparison of Fig. 4 with Fig. 2-3; the following observations can be made: (1) Although a slower injection rate can lead to a higher extracted temperature, a higher injection rate results in a higher AE (i.e., there is an optimal flow rate that can be estimated); (2) For a standard injection rate, even a 5-km well with a periodic injection source can produce substantially more energy than a 20-km well with a constant source (i.e., with much lower drilling cost for a shorter loop, more energy can be supplied at a pseudo-steady rate); (3) As the injection rate increases, compared with the heat storage scenarios, the extracted AE with the constant source strategy shows minimal change (i.e., heat extraction from storage scenarios may be sensitive to storage and extraction choices, which cannot be evaluated using analytic solutions for long-loop extraction only scenarios).

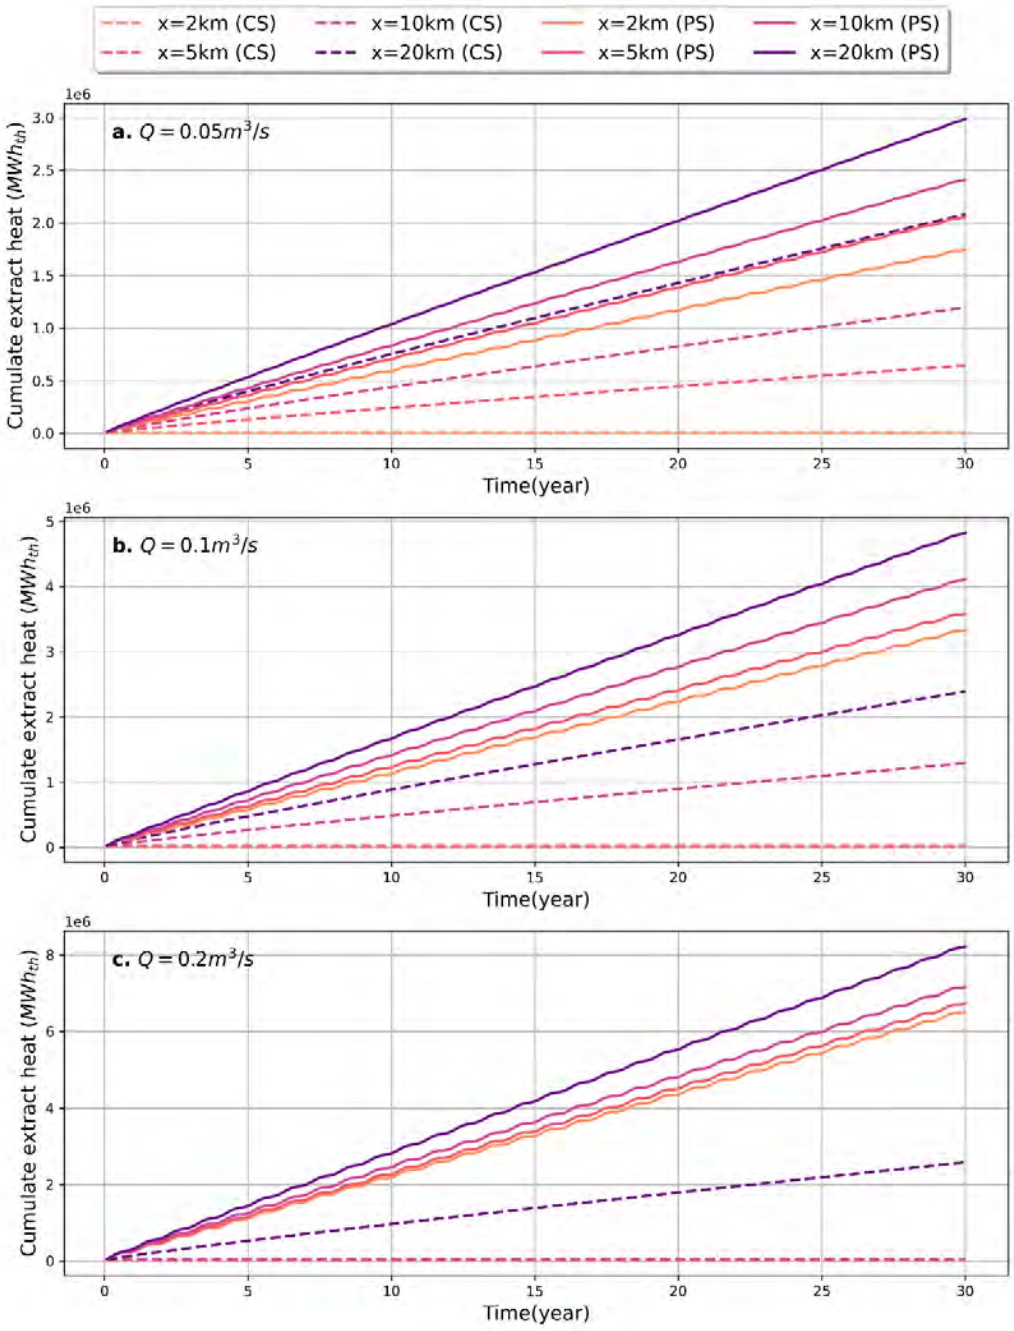

Figure 4. Accumulated extract heat energy change with different injection rates and well lengths under constant source conditions (solid line) and periodic (sine-wave) source conditions (dash line). In the legend, CS means constant source, and PS means periodic source. Cases that cannot produce economic beneficial energy are removed from the figure.

Although the horizontal well assumption simplified the boundary conditions and allowed comparison with loops for heat extraction only, for heat storage scenarios, temperature near the loop will be dominated by long-term average injected temperature. Because initial temperature becomes less important over time, loop depth and orientation can be flexible, so expensive horizontal wells might be replaced with less expensive configurations, including possibly coaxial designs.

4. Summary

This study uses a semi-analytical model to evaluate the potential of closed-loop geothermal long wells for heat extraction. An analytical solution to the radial advective-conductive unsteady heat transfer equation with heat injection and extraction was obtained in Laplace space derived using Green's function and Laplace transform. Numerical methods are applied to transform the solution in Laplace space to the time domain. By comparing the closed-loop long well systems under different conditions meant to compare standard long closed-loop operations with energy storage in closed-loops, the primary conclusions of this research are:

(1) Shorter loops can produce electric-grade energy at higher rates if surplus heat is periodically injected (stored).
(2) Injection rates can be optimized to produce more energy over the lifetime of the facility.
(3) With cost savings of drilling, periodic injection of heat could be more economically beneficial than a constant source well.

Acknowledgements

Notation

Parameter	Definition
C	Specific heat capacity [$L^2T^{-2}\Theta^{-1}$].
D	Thermal diffusivity, defined as $D = k/c\rho$ [L^2T^{-1}].
K	Thermal conductivity [$MLT^{-3}\Theta^{-1}$].
K_n	Second kind modified Bessel function with order n (n=0,1 in this research).
M	Magnitude of the variation from mean injection temperature [-].
P	Laplace transform operator.
Q	Volumetric flux of fluid inside the well [L^3T^{-1}].
Q	heat sink term describing the heat loss to the rock through conduction [ΘT^{-1}].
t_{end}	Time interval to calculate the AE value [T].
T	Temperature [Θ].
T_m	Average injection temperature [Θ].
T_0	Initial temperature inside the well [Θ].
T_{f1}	Temperature change inside the well [Θ] and defined as $T_f = T_{f1}+T_0$.

$T_{m,dif}$	Modified temperature difference calculated by the extracted temperature minus 90°C [Θ] and modified means the $T_{m,dif}$ will be set to zero if the difference is lower than 10 °C.
A	Frequency [T^{-1}].
P	Density [ML^{-3}].
AE	Accumulated energy [L^2MT^{-2}], defined by $AE = \int_0^{t_{end}} Q c_f \rho_f T_{m,dif} dt$.
Subscript f	Flow property inside the well.
Subscript b	Material property of the rock outside the well.

ABSTRACT

As the demand for sustainable energy sources intensifies, geothermal energy stands out as a promising solution. Efficient utilization of geothermal reservoirs relies on optimal borehole placement and density, a complex optimization problem. This paper introduces a novel algorithm leveraging simulated annealing to address the challenges associated with optimizing both the total number of boreholes and their spatial distribution in geothermal applications.

The proposed algorithm employs simulated annealing, inspired by the annealing process in metallurgy, to iteratively explore and refine the solution space. By systematically adjusting the temperature parameter, the algorithm balances exploration and exploitation, allowing it to escape local minima and converge towards a globally optimal solution. The objective is to minimize the total number of boreholes while maximizing their effectiveness in harnessing geothermal energy.

The algorithm's performance is evaluated through simulations on various geothermal reservoir scenarios. Results demonstrate its ability to adapt to diverse geological conditions and provide solutions that optimize the utilization of geothermal resources. This paper concludes with a discussion of the algorithm's potential applications, scalability, and contributions to advancing sustainable geothermal energy solutions.

1. Introduction

The gradual shift from fossil fuels to clean, affordable, and dependable energy sources necessitates the adoption of low-carbon technologies capable of meeting extensive commercial demands across all energy sectors (Piiponen et al., 2022). Geothermal energy originates from the Earth's core, approximately 2900 km beneath the surface, (Williams, 2024). This form of thermal energy is renewable, as it stems from temperatures surpassing those of the sun's surface, sustained by the ongoing radiogenic decay of natural isotopes. Borehole heat exchanger (BHE) and Ground Source Heat Pump (GSHP) systems harness geothermal energy, offering an eco-friendly alternative to traditional heating and cooling methods (Capozza et al., 2012; Yuan et al., 2016).

Geothermal heat offers a promising energy source with significantly reduced CO_2 emissions compared to conventional fossil fuels. Shallow geothermal systems are increasingly harnessed for heating and cooling applications in buildings and greenhouses (Lund and Toth, 2021). The capital investment and risk of the resource being less productive than hoped motivate development of data and tools to de-risk geothermal installations (CORDIS, 2023; Ireland Department for the Environment, Climate and Communications, 2023). To strengthen the competitive stance of geothermal energy in the renewable market, engineers need access to precise, adaptable, and efficient computational tools for effective system design and analysis.

Over the last four decades, geothermal systems have been analyzed through analytical, semi-analytical, and numerical modeling, dating back to works by Horne (1980) and Eskilson and Claesson (1988). Li and Lai (2015) and Zhao et al. (2020) have reviewed numerous models in this regard. Analytical models offer the advantage of computational speed, whereas numerical models can more easily accommodate complex geometries and boundary conditions, (Piipponen et al., 2022). In recent times, there has been a growing emphasis on optimizing the design and sizing of ground-source systems to elevate their environmental and operational efficiency (Alavy et al., 2013; Javed, 2012l Javed and Spitler, 2017; Kavanaugh and Rafferty, 2014; Ozbek et al., 2015; Rees, 2016). Engineers can consult established engineering guidelines (Kavanaugh and Rafferty, 1997; Stauffer et al., 2013), or standard planning software to determine the appropriate borehole length for a given energy demand. Still, research continues for optimization to further enhance the expected capacity of an installation. Current research efforts predominantly focus on enhancing the accuracy of design inputs (Claesson and Javed, 2018; Fujii et al., 2009), developing computationally efficient design methodologies (e.g., He et al., 2011; Javed and Claesson, 2011; Fossa et al., 2024), and determining optimal ground loop lengths (Cui et al., 2015; Hackel and Pertzborn, 2011).

Geothermal energy sources exhibit varying depths, ranging from shallow levels of tens to hundreds of meters, to intermediate depths extending several kilometers, and deeper levels where molten rocks generate exceptionally high temperatures (Al-Khoury, 2012). In a study by Piipponen et al. (2022), the influence of geological and engineering factors on the heat output of medium-deep geothermal boreholes was explored using the finite element method in COMSOL Multiphysics. By simulating various engineering parameters, the study employed a performance simulation approach to develop models of borehole heat exchangers (BHEs).

In Jain et al. (2015), the long-term response of operated engineered geothermal system (EGS) reservoirs was examined based on numerical stimulation of an optimized heat extraction process, (Clauser, 2003). They systematically varied parameters such as flow rate and well separation in

the subsurface, investigating various EGS configurations and their sustainability. The finite-difference method was employed to solve the transient coupled equations of fluid flow and heat transfer in a fluid-saturated porous medium, as implemented in the forward modeling code, SHEMAT (Clauser, 2003).

Schulte et al. (2016) presented an approach for the simulation and optimization of medium-deep borehole thermal energy storage (MD-BTES) systems. To optimize the design of an MD-BTES system, they evaluated numerous configurations representative of the range of variability in the design parameters. The seasonal operation was numerically simulated for each configuration to predict the thermal behavior of the MD-BTES system. The simulation of the operation of an MD-BTES system was based on the application of the standard Galerkin method, implemented in an adapted MATLAB® environment for finite elements. In their work, the algorithm is designed to assess hundreds of parameter combinations to reach an optimal solution. It halts only when the score of the best individual cannot be enhanced beyond a set fitness function tolerance after a specified number of stall iterations. Evaluating each configuration against the constraint demands substantial computational effort. Depending on the model size, a single numerical simulation can span from several days to weeks. To address this challenge, they employ a proxy model derived from a considerably smaller set of numerical training simulations using arbitrary polynomial chaos expansion.

Javed et al. (2019) presented a systematic and comprehensive investigation into sizing the ground-source heating and cooling system for a newly constructed kindergarten building in Oslo, Norway. One of the study's objectives was to examine the potential for optimizing the borehole system design by adjusting the building's envelope characteristics to balance the ground heating and cooling loads. The final phase involved conducting a sensitivity analysis on the proposed design to evaluate the influence of uncertainties in the design parameters. All design simulations were conducted using the Superposition Borehole Model, SBM (Eskilson, 1986).

Bayer et al. (2014) introduced a mathematical procedure for the optimization of BHE fields. The optimization approach aims to enhance efficiency by examining the overall underground temperature variations within the BHE field. For a specified energy demand, optimal efficiency is attained when minimizing the maximum temperature change. They presented a simulation technique that utilizes temporally and spatially superimposed line source equations. Additionally, a sensitivity analysis is conducted to ascertain the maximum temperature changes in the ground and to assess potential improvements through individual BHE workload optimization.

In Li et al. (2017) the effects of load optimization and geometric arrangement on BHE fields were investigated. The outlet fluid temperature served as the optimization target to examine how load distribution and geometric arrangement influence the performance of BHE fields. The authors presented four different borehole arrangements in one application. However, they did not provide specific justification for these arrangements over numerous others for the same application. Instead, they analyzed the outcomes of these arrangements in relation to the objective function.

Liu and Han (2023) utilized simulated annealing to optimize the length of a section of tunnel wall fitted with fluid loops for extracting heat from the surrounding rock. Their algorithm perturbs a COMSOL® 3D model of the tunnel domain and heat exchanger to select an optimal section length within predefined location constraints. The chosen section length must not exceed the length of the tunnel, and heat extraction must occur only where heat is available in the tunnel. Flow rate and

inlet temperature for the heat transfer fluid are kept constant, and the minimum length meeting the heating requirement is considered the optimum length.

The RowWise algorithm by Spitler et al. (2022) adjusts borehole spacing to determine the minimum number of boreholes needed to satisfy a user-specified load. Boreholes are arranged in rows, with the flexibility to rotate the orientation of the rows to evenly distribute them across a given land-space if necessary. Users can also define the perimeter of the space to comprise evenly spaced boreholes, potentially reducing the number of bores required in the field interior. The g-function is applied to the resulting array to compute the required borehole depth. As of 2022, the authors of Spitler et al. were working on methods to reduce calculation time for this approach. They also noted that finding a true global optimum for large fields is currently impractical. Global optimization methods capable of optimizing the placement of hundreds of boreholes are an active area of research, with potential applications in GHE design expected in the near future.

The work presented in this paper is part of The GeoCoHorT project, for which the National Energy Technology Laboratory (NETL) is building an in-ground heat exchanger design and simulation tool, which will be applied to the preliminary design and business case development for a transaction-controlled heating district in Limerick, Ireland. This application poses some special challenges. When considering urban applications of GSHP, available space for borehole arrays will be variable. Considering a transaction-controlled heating district (Hosseinnezhad et al., 2021; Maurer et al., 2023; O'Regan, et al., 2021), the design of the borehole array needs to enable useful energy storage and extraction for district thermal balance and efficiency.

The following study presents a novel algorithm that employs simulated annealing to address the challenges of optimizing both the total number of boreholes and their spatial distribution in geothermal applications. Inspired by the metallurgical annealing process, the algorithm iteratively explores and refines the solution space. To the best of our knowledge, such an algorithm has not been documented in the existing literature. Through systematic adjustment of the temperature parameter, the algorithm strikes a balance between exploration and exploitation, enabling it to avoid local minima and converge towards a globally optimal solution. The objective is to minimize the total number of boreholes while maximizing their efficiency in harnessing geothermal energy.

2. Methodology

2.1 Governing Equations

Global optimization presents significant computational challenges, and exact methods often face limitations when dealing with large instances. Simulated annealing is a probabilistic meta-heuristic known for its ability to escape local minima. Originating from the Metropolis algorithm, it was initially introduced in the realm of combinatorial optimization, (Kirkpatrick et al., 1983), where the objective function is defined within a discrete domain. Initially introduced for solving discrete optimization problems, SA has since been extended to continuous domains – for example, optimization of multimodal functions in a continuous domain (Corana et al., 1987; Zidane, 2022). Its notable advantage over other solution techniques has established SA as a practical approach for addressing complex optimization problems. The selection of cooling schedule and the subsequent candidate distribution are crucial factors in defining a simulated annealing algorithm, (Miki et al., 2002). In this study, SA is tailored to optimize both the total number and locations of boreholes within a specific field.

The heat transfer equation governing the ground under conditions of low Peclet number groundwater flow is provided as follows:

$$\left(\rho c_p\right)_{eff}\frac{\partial T}{\partial t} - k_{eff}\nabla.(\nabla T) + Q_b = 0 \quad (1)$$

The terms $\left(\rho c_p\right)_{eff}$ and k_{eff} represent the effective volumetric heat capacity (J/m^3·K) and effective thermal conductivity (W/m·K) of the ground, respectively, calculated using:

$$\left(\rho c_p\right)_{eff} = \varphi\rho_w c_{p,w} + (1-\varphi)\rho_s c_{p,s} \quad (2)$$

and

$$k_{eff} = \varphi k_w + (1-\varphi)k_s \quad (3)$$

where φ is the porosity, $\rho_w c_{p,w}$, k_w, $\rho_s c_{p,s}$, and k_s are the volumetric heat capacity and thermal conductivity for both water and soil respectively. Q_b is the energy introduced into the ground from the boreholes installed in the field.

2.2 Optimization Scheme

Given a field's dimensions, the proposed approach seeks to optimize the total number and configuration of boreholes to maximize the total energy extraction. The optimization adheres to the following constraints provided as input:

- The maximum allowable depth for borehole installation.
- The minimum distance allowed between two boreholes along the x-axis.
- The minimum distance allowed between two boreholes along the y-axis.
- The input and output fluid temperatures.
- The properties of the borehole material.

Therefore, the objective function for building-heat rejection to the ground could be written as:

$$\arg\max\left(Q_{b,x,y,t}\right) \quad \forall(x,y), t \in \Omega, \tau \quad (4)$$

where Ω and τ represent the computational domain and simulation time respectively.

The proposed algorithm simulates the random placement of a variable number of boreholes, leading to an energy change. If this change results in a positive energy difference, the new configuration with the higher energy state is accepted. Conversely, if the energy change is negative and lowers the energy state, the new configuration might still be accepted based on the Boltzmann probability factor (P) as shown below (eq. 5)

$$P = \exp\left(\frac{-\Delta E}{\Delta E_{ave} T_a}\right) \quad (5)$$

where ΔE is the cost difference between the current design and the previous one; ΔE_{ave} is the running average value of ΔE, it normalizes the change in the objective, and T_a is the "annealing

temperature" in SA; it correlates with the mobility of the optimization process to accept a higher-cost design.

3. Examples

This section provides three numerical simulation examples to showcase the capabilities of our model. The first example examines a homogeneous domain with 50 potential borehole installation locations. The second example addresses the same issue but with heterogeneous ground thermal properties. The third example presents a more complex scenario involving the potential installation of 264 boreholes.

3.1 Example 1

In a 100 m x 50 m domain (Figure 1), a minimum distance of 10 m is maintained between two boreholes along both the x and y axes, allowing for the potential installation of 50 boreholes, as illustrated in Figure 1. Each borehole is assumed to have a diameter of 15 cm and a thermal resistance of 0.05 mK/W. The maximum allowable depth for installation is 70 m. The soil is characterized by a uniform porosity of 0.2 and a water saturation level of 30%. The inlet and outlet liquid temperatures are set at 23.89 °C (75 °F) and 21.12 °C (70 °F), respectively. The soil temperature is assumed to increase linearly with depth, starting at 283 K at the surface and reaching a maximum of 293 K. This temperature is averaged over the length of the borehole depth.

In this example, the objective is to determine the optimal number and locations of boreholes from the available 50 sites to maximize the total injected energy over a one-year period. Given the vast number of potential combinations, exhaustively modeling all possibilities is impractical. For instance, selecting just 10 boreholes out of the 50 sites results in over 10 billion potential configurations. Figure 2 depicts two configurations of borehole selection – 15 and 24, respectively.

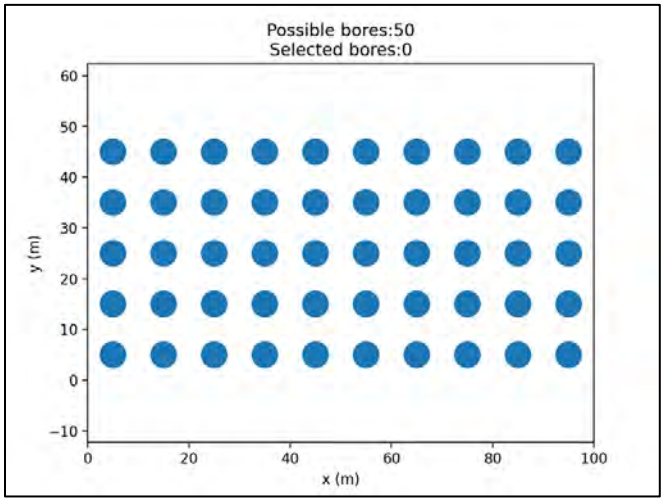

Figure 1: Domain showing the possible locations of 50 boreholes: Example 1.

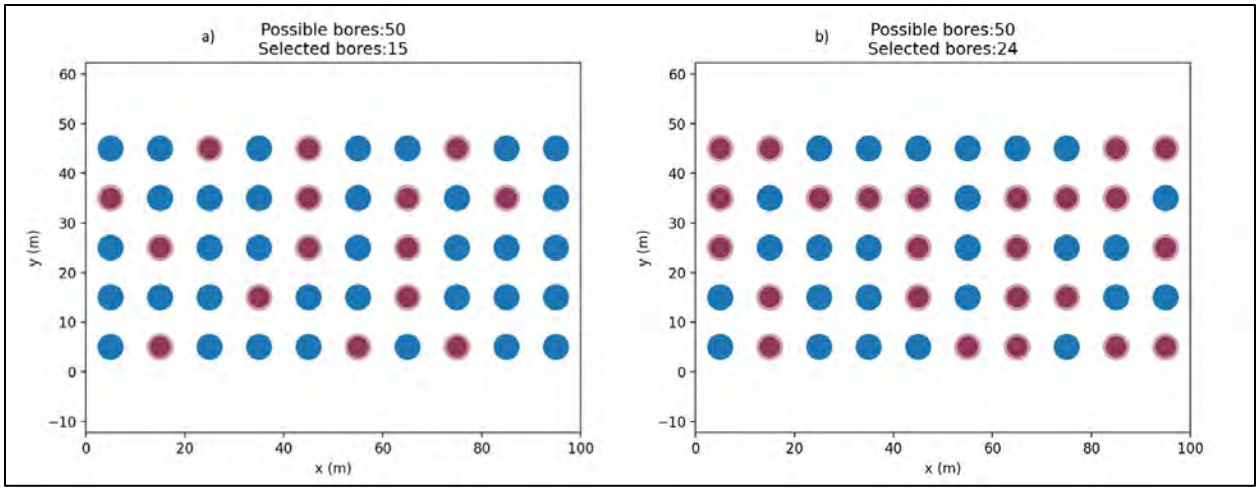

Figure 2: One case, selecting 15 (a) and 24 (b) boreholes to be installed from 50 possible locations: Example 1.

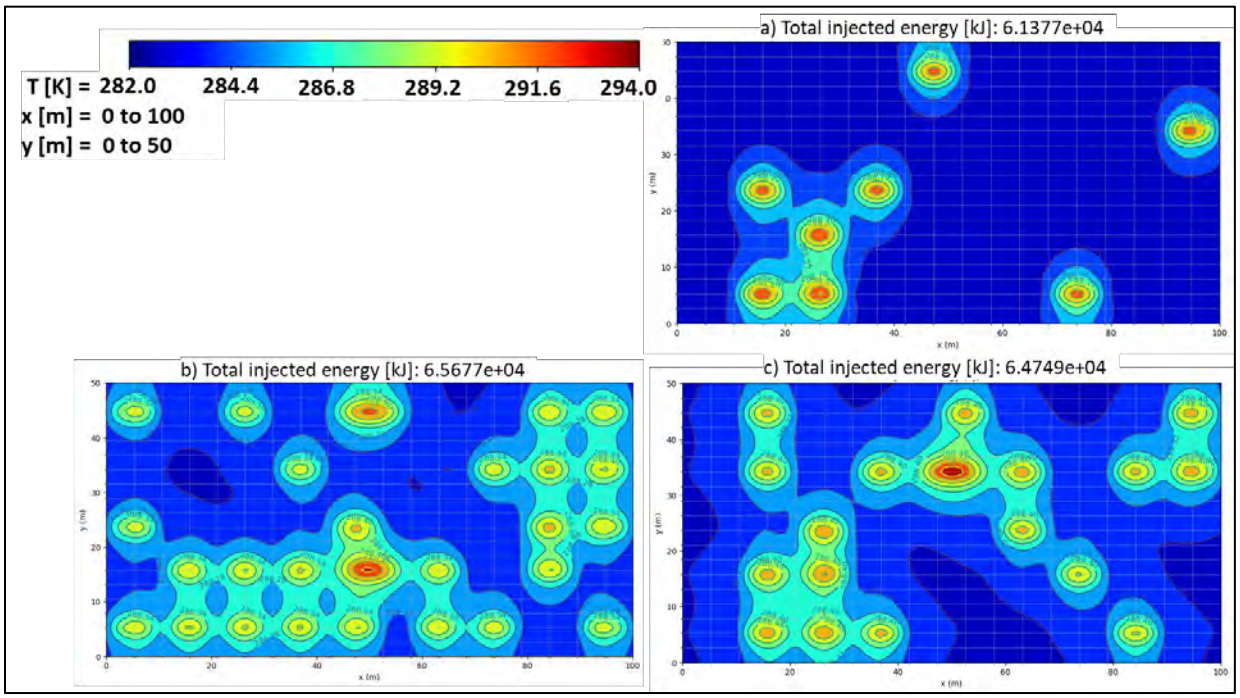

Figure 3: Temperature distribution [K] with three different configurations with 8 (a), 29 (b), and 19 (c) boreholes: Example 1.

The algorithm operates as follows: The minimum distance on the *x* and *y* axes between two boreholes determines the maximum number of boreholes that can be installed. The optimization goal is to maximize the total injected energy and to determine the number and distribution of boreholes that achieve this maximum. It's important to note that the optimal number and distribution may not be unique for a given problem.

The algorithm begins by randomly selecting a number of boreholes from the total possible combinations. Then, it generates a random distribution of these boreholes. At this point, the

algorithm has both the number of boreholes to be installed (N) and their distribution (D), both chosen randomly. The next step is to calculate the total injected energy (E) based on the selected N and D, and this energy value is stored.

The algorithm then repeats the process, generating a new set of borehole numbers and distribution $(N, D)_{new}$, which are used to calculate a new total injected energy $(E)_{new}$. If E_{new} is greater than the previously calculated energy (E), the new solution is considered better. If it's not, it still has a chance of being in the direction of a better solution. This acceptance probability is calculated using Boltzmann's probability distribution. A given optimization run conducted 30 annealing cycles, each comprising 20 trials.

An accepted distribution is determined by the Boltzmann probability, as explained in the previous section. Figure 3 displays the temperature distribution for three borehole configurations accepted by the algorithm during its progress to identifying the optimum. These occur at iteration 8, 19, and 29 as shown in Figure 4.

Figure 4 illustrates the relationship between the total injected energy in the field and the number of boreholes across all 30 annealing cycles. The results demonstrate an increasing trend in the injected load with each iteration, suggesting that the model converges towards maximizing the total injected energy. This ensures the selection of an optimal borehole number and geometric distribution for maximization.

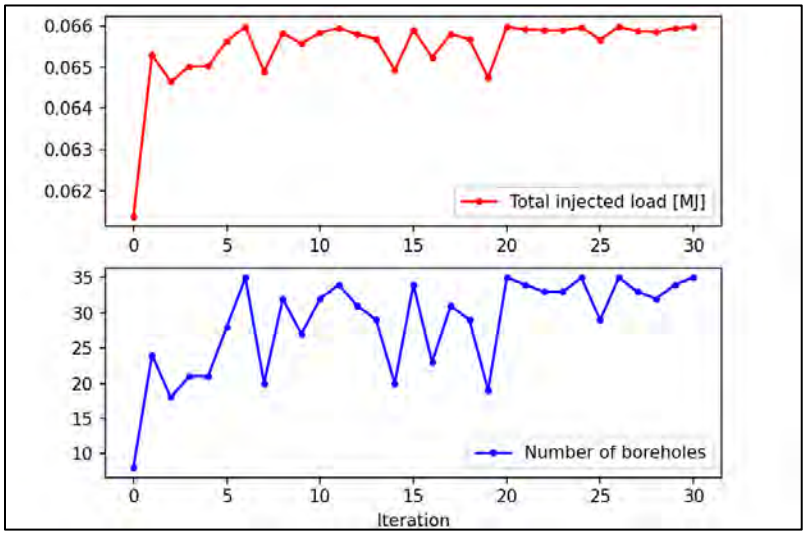

Figure 4: Variation in the injected load and the number of boreholes over the 30 annealing cycles: Example 1.

Figure 5 displays the optimal number and locations of selected boreholes that maximize the injected load in the field.

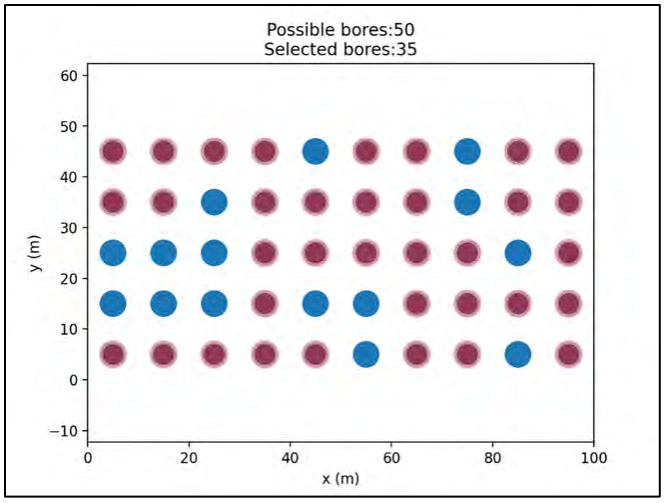

Figure 5: Locations and quantity of chosen boreholes optimizing the injected load: Example 1.

3.2 Example 2

This example retains the setup from the previous case but introduces a modification by incorporating a heterogeneous domain. The distributions of porosity and water saturation can be seen in Figure 6. Changes in these parameters influence the temperature distribution by impacting heat capacity, thermal conductivity, and the heat diffusion coefficient.

The domain's heterogeneity influenced the total injected energy compared to the homogeneous scenario. In the homogeneous case, the energy was 0.066 MJ, whereas it is now 0.063 MJ. Although the optimal number of boreholes remains 35, consistent with the homogeneous case, their arrangement differs, as illustrated in Figure 7. The fluctuation of injected energy and the total borehole count across annealing cycles is depicted in Figure 8. For reference, the temperature distribution of the configuration that maximizes the injected load is presented in Figure 9.

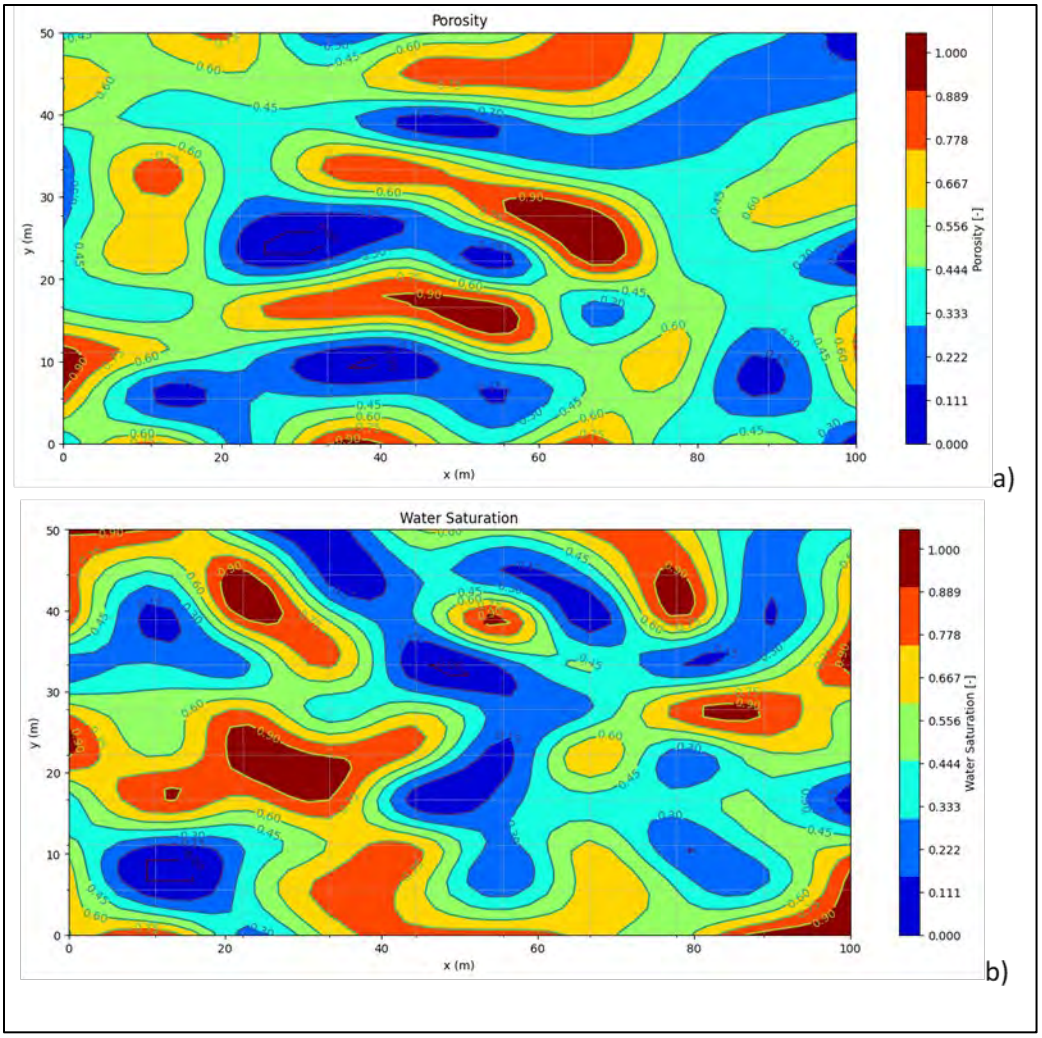

Figure 6: Porosity (a) and water saturation (b) distribution: Example 2.

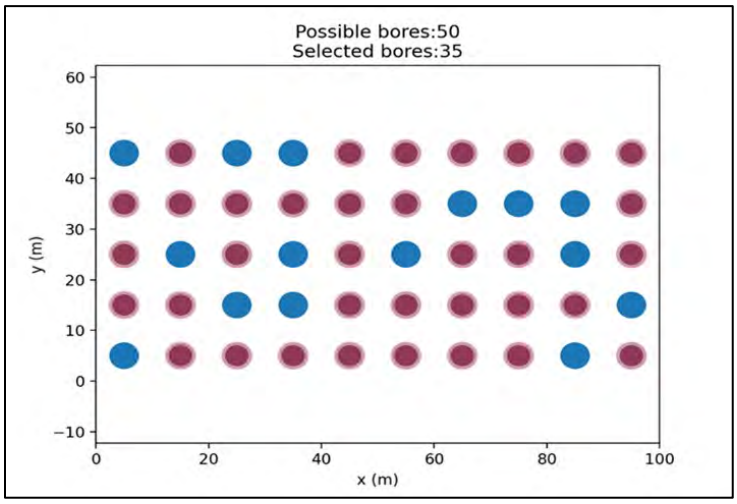

Figure 7: Locations and quantity of chosen boreholes optimizing the injected load: Example 2.

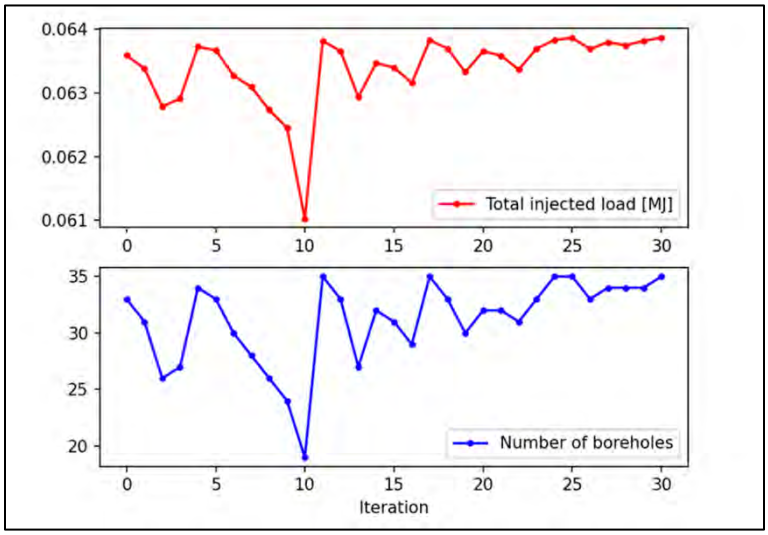

Figure 8: Variation in the injected load and the number of boreholes over the 30 annealing cycles: Example 2.

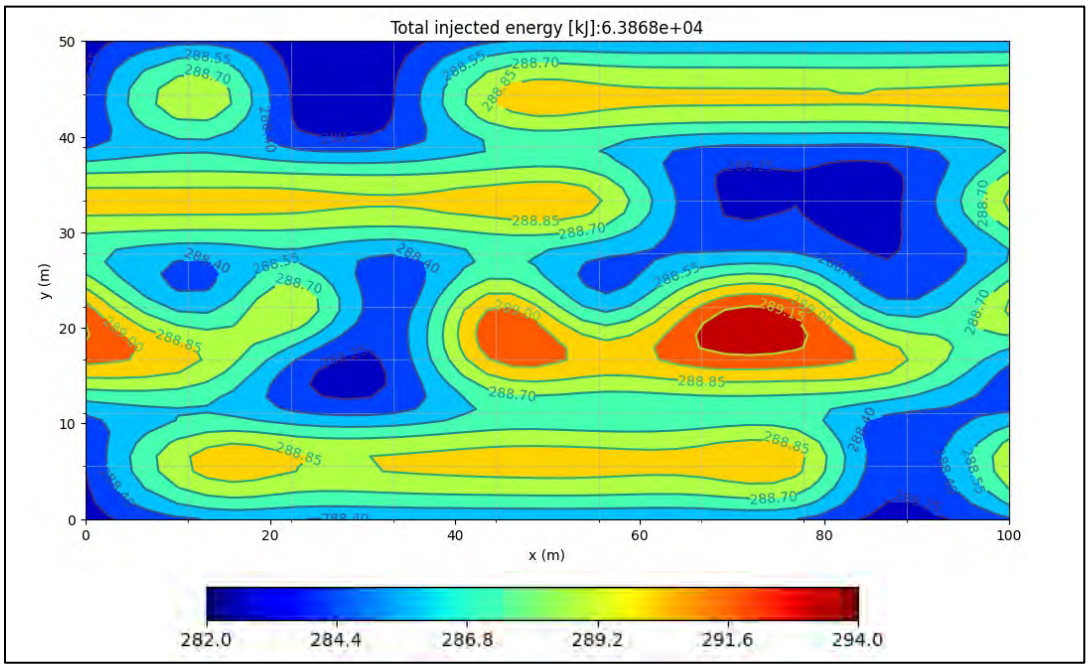

Figure 9: Temperature distribution of the configuration that maximizes the injected load: Example 2.

3.3 Example 3

In the final example examines a larger domain with a reduced separation distance between the boreholes on the x and y axes, set at 6 m. With a total domain length of 200 m and a height of 50 m, this allows for the installation of 33 boreholes along the x-axis and 8 boreholes along the y-

axis. This results in a potential total of 264 boreholes that could be installed, as illustrated in Figure 10. The properties of the domain are consistent with those in Example 1.

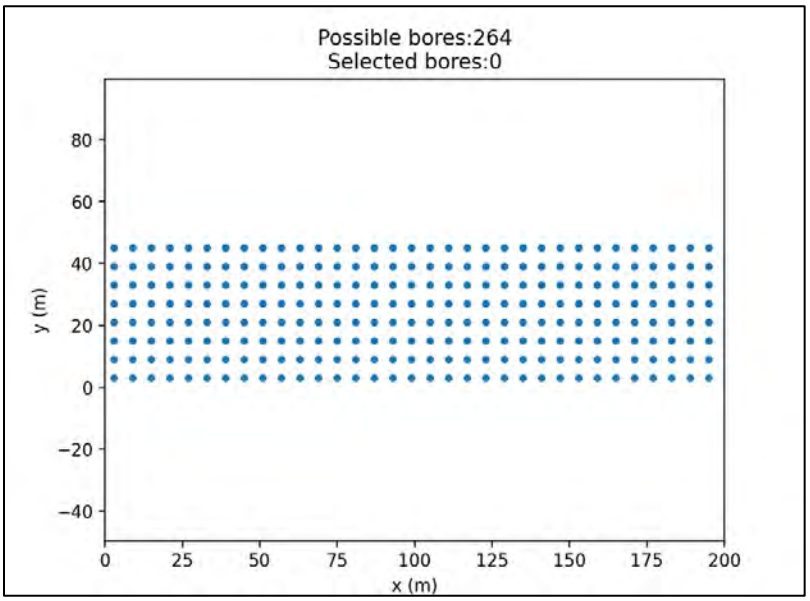

Figure 10: Domain illustrating the 264 potential locations for borehole installations: Example 3.

Investigating the variation of the total injected load and the number of boreholes during the annealing cycles, a significant difference from the previous examples is observed: an increasing injected load is accompanied by a decreasing total number of installed boreholes (Figure 11). This behavior arises because the high density of borehole installations hinders the dissipation of heat from the injected load. The maximum injected load is achieved by limiting the total installed boreholes to fewer than 70. Specifically, the maximum injected load of 0.067 MJ is attained with 63 boreholes installed.

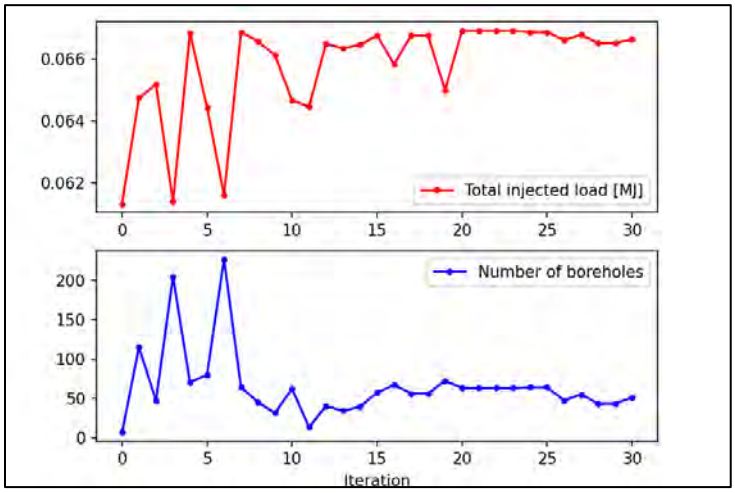

Figure 11: Variation in the injected load and the number of boreholes over the 30 annealing cycles: Example3.

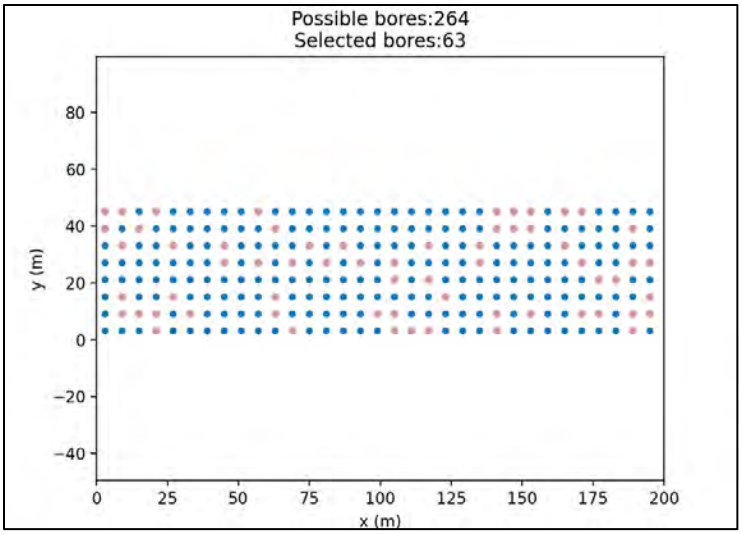

Figure 12: Locations and quantity of chosen boreholes optimizing the injected load: Example 3.

The locations of the 63 boreholes that maximize the injected load are shown in Figure 12. For reference, the temperature distribution with the optimal configuration is shown in Figure 13.

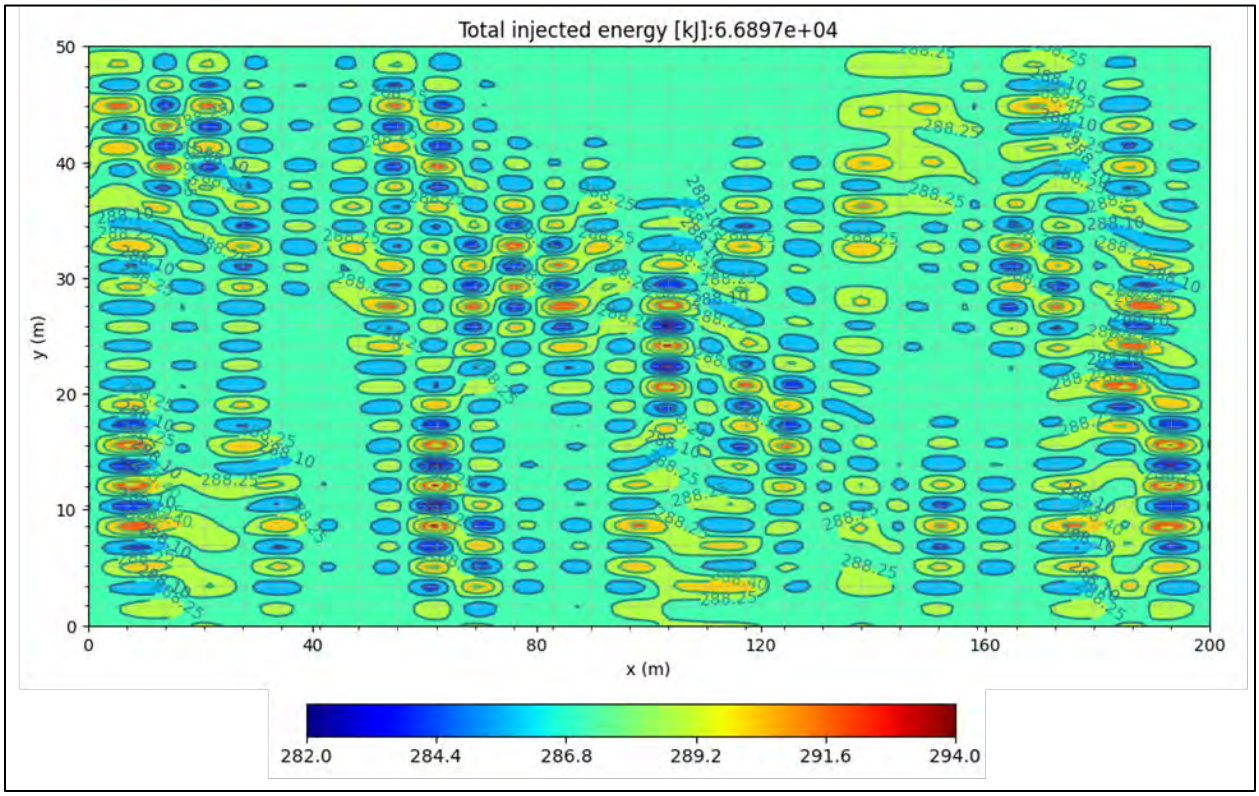

Figure 13: Temperature distribution of the configuration that maximizes the injected load: Example 3.

3. Summary and Future Work

This paper introduces a novel algorithm that utilizes simulated annealing to address the complexities of optimizing both the total number of boreholes and their spatial distribution in geothermal systems. The algorithm's efficacy was demonstrated through simulations across various geothermal reservoir scenarios, encompassing both homogeneous and heterogeneous conditions. It effectively determines the optimal configuration of boreholes in terms of number and placement to maximize the total injected load. This optimization task, due to its vast possible borehole location combinations, is otherwise daunting to solve. Notably, all simulations were completed within a few minutes on a standard PC. The study focuses on low Peclet numbers in the subsurface, assuming stagnant water with potential variations in saturation across the domain. Future work will incorporate groundwater flow effects to further examine its influence on borehole numbers and distribution. Objective functions to consider heating modes can be applied to design for optimal placement of boreholes for heating and cooling modes both occurring across the desired time domain.

Nomenclature

c_p	specific heat at constant pressure, ($J/kg \cdot K$)
E	energy
ΔE	difference in cost between the current design and the previous one
ΔE_{ave}	average value of the change in ΔE
D	distribution of boreholes
k	thermal conductivity, ($W/m \cdot K$)
N	number of boreholes to be installed
P	probability
Q	thermal energy, (J)
T	temperature, (K)
t	time, (s)
T_a	annealing temperature
x	distance, (m)
y	distance, (m)
ρ	density, (kg/m^3)
τ	simulation time
φ	porosity
Ω	computational domain

Subscripts	
b	borehole
w	water
s	soil
eff	effective

Math Symbols	
arg max	$\arg\max(f)$ is the set of values, a, for which $f(\alpha)$ is a maximum
exp	$exp(\alpha) = e^{\alpha}$
$\in$	belongs to/is element of (set membership)
$\forall$	for all (Universal Quantifier)

Keywords

Geothermal Collegiate Competition, Geothermal Technology, Students, Workforce, Outreach

ABSTRACT

In 2010, the U.S. Department of Energy (DOE) announced the launch of its inaugural National Geothermal Student Competition. The competition was open to all colleges, universities, and other post-secondary institutions in the United States, and was labeled as the first-ever to address geothermal education. The GeoVision, published in 2019 by the Geothermal Technologies Office (GTO), stated that improving geothermal energy education and outreach is critical in reducing risks and costs of geothermal technology deployment. The key actions included improving public education and outreach about geothermal energy and providing resources intended to attract and inform a skilled geothermal workforce. Student competitions in particular have the ability to increase awareness of renewable energy fields by engaging multi-disciplinary students in compelling design challenges to prepare them for careers in renewable energy.

GTO, in partnership with an administration team at the National Renewable Energy Laboratory (NREL), currently supports the Geothermal Collegiate Competition (GCC), with the main objective of advancing and cultivating collegiate student knowledge and career interest in geothermal energy. The administrating team works toward growing the number of students and collegiate institutions engaged, as well as diversifying the scope of the student design challenges. The main intentions of this publication are documenting the competition's evolution, setting a baseline for future GCC impact analysis and serving as a guide to other students' competition design committees looking for ideas to capture and increase the interest of students in collegiate competitions.

1. Introduction

The Geothermal Collegiate Competition (GCC) is part of the DOE funded competitions for students providing competitors the opportunity to get involve with a clean energy competition to help jumpstart a clean energy career. Through the GCC the DOE Geothermal Technologies Office

(GTO) encourages students to develop innovative solutions for geothermal energy application challenges and build career skills for the clean energy workforce.

In 2019, GTO published the GeoVision Report. The report highlights a general lack of awareness and understanding of geothermal energy's potential to contribute to the development of a clean energy future amongst policy makers and society-at-large. (DOE, 2019). The GCC helps to address this awareness gap by engaging multi-disciplinary collegiate students, faculty, industry mentors and communities into geothermal challenges.

Student competitors in the GCC gain experience solving relevant industry challenges that prepare them for careers in geothermal and related energy fields, while benefiting from mentorship, training, and collaboration. The GCC supports DOE's ongoing work to help grow the domestic geothermal industry and address employment gaps through experiential learning.

Ongoing goals of the competition include advancing and growing collegiate student knowledge and career interest in geothermal energy by increasing the number of students and collegiate institutions engaged, diversifying the scope of the challenges, engaging industry representatives in partnership roles, and raising the profile and outreach of the competition to a broader audience.

The information used in this publication was extracted from the competition's publicly available promotional material and press releases. The statistics were obtained from reports submitted to DOE by the competition administrators. Some competitions have incomplete or non-existent records, particularly the earliest years. All information about the competitions is open to revision.

2. History of the Geothermal Collegiate Competition

The GCC has origins going back over a decade. Since 2010, a total of 11 geothermal competitions targeting students to solve challenges relevant to technical and non-technical barriers for geothermal energy have been completed. Table 1 summarizes the geothermal student competitions from 2010 to 2023. The competition was not carried out in 2017 and 2018.

Notice the name of the competition has changed from 2011 through 2014 it was titled as the *National Geothermal Student Competition*, for competitions in 2016 and 2019 it was called the *Geothermal Design Challenge* and from 2020 to present is known as the *Geothermal Collegiate Competition*.

2.1 National Geothermal Student Competition 2011

GTO and NREL launched the National Geothermal Student Competition (NGSC) with 11 participant collegiate teams selected (Figure 1) after several U.S. colleges, universities, and postsecondary educational institutions participated in a competitive process. The NGSC was dubbed a first-of-its kind intercollegiate contest challenging students to conduct a comprehensive assessment of the geothermal energy potential of the Rio Grande Rift geologic province in southeastern Colorado and northeastern New Mexico. The competition objectives were to develop students' geothermal awareness and research skills, and expose participants to real world challenges (NREL, 2011). Detailed documentation about deliverables, evaluation process, winning teams and prizes was not found for this competition.

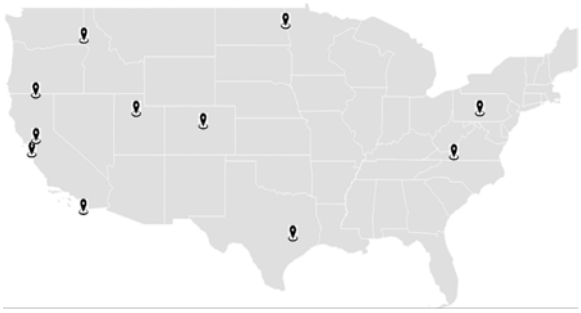

Figure 1: U.S. map showing 11 selected collegiate institutions for the NGSC 2011 (Colorado School of Mines, Oregon Institute of Technology, San Diego State University, Stanford University, Texas A&M University College Station, Pennsylvania State University, University of Utah, University of California Davis, University of Idaho, University of North Dakota, Virginia Polytechnic Institute and State University)

2.2 National Geothermal Student Competition 2012

This competition challenged undergraduate and graduate student teams to conduct a high-quality assessment of the Snake River Plain site in Idaho using innovative exploration technologies such as: geophysics, geochemistry, remote sensing, and geology. With eight teams as finalists, DOE announced Idaho State University as the winner of its NSGC 2012 with the project, "Development of an integrated, testable conceptual model of blind geothermal resources in the eastern Snake River Plain: application to the Newdale geothermal prospect" (ISU, 2012). Boise State University won second place, and Southern Methodist University Geothermal Laboratory finished third (Figure 2). Detailed documentation about deliverables, evaluation process, and prizes was not found for this competition.

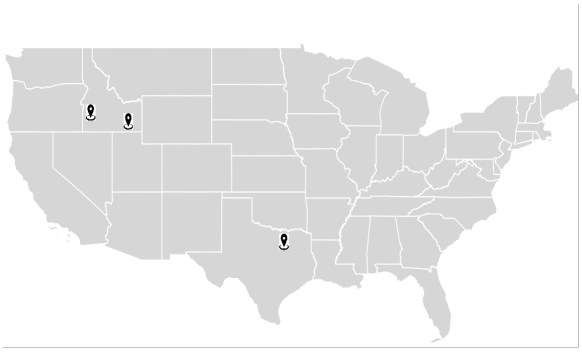

Figure 2: U.S. map showing three winning collegiate institutions of NGSC 2012 (Idaho State University, Boise State University, Southern Methodist University)

2.3 National Geothermal Student Competition 2013

In early May 2013, DOE announced the selection of four semi-finalists to advance to the final round (Figure 3) of the NGSC 2013. The competition challenged student teams to develop a business white paper on geothermal energy production and commercialization. Student teams submitted a concept paper containing technical analysis, budget plan and policy analysis sections

to compete. The evaluation criteria included completeness, clarity of project approach and methodology, technical viability, commercial viability and impact. The four semi-finalist teams received an award of $5,000 to complete their business plans, and $500 to be used to startup a geothermal club on their college campuses (UTRGV, 2013). Detailed documentation about deliverables and winning teams was not found for this competition.

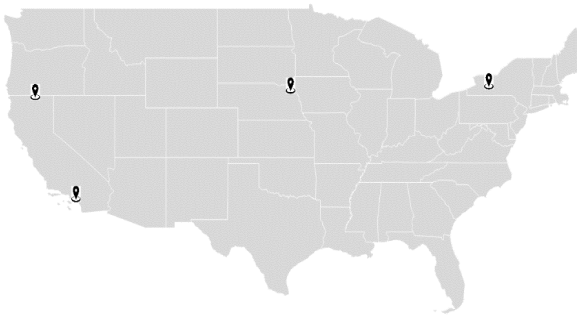

Figure 3: U.S. map showing four semi-finalist collegiate institutions of NGSC 2013 (University of Rochester; Oregon Institute of Technology; University of South Dakota – LTEC; California State Polytechnic University, Pomona)

2.4 National Geothermal Student Competition 2014

NGSC launched in 2014 with the title GeoEnergy Is Beautiful. The competition sought students interested in building and showcasing scientific research, communication and leadership skills to convey the role of geothermal energy as an important contributor to the nation's clean energy future via posters and visual aids.

The relative invisibility of geothermal energy renders it difficult to explain to a broad public audience. Graphics and infographics are frequently necessary to convey large quantities of data and complex information to facilitate insight, comprehend patterns, and understand complex messages while keeping text to a minimum.

Participating teams were asked to develop a powerful, robust, high-quality infographic explaining an aspect of geothermal power production and a communication and outreach strategy to disseminate the infographic to the public for maximum impact. Teams were required to have up to three students from graduate, undergraduate, and/or high school senior level, as well as a team sponsor such as professor, faculty member, post-doctorate or a teaching fellow. Teams could include additional sponsors from non-academic organizations.

The competition was comprised of two rounds. In round one, all participating teams were asked to submit the communications and outreach strategy and a mockup of their infographic; five applications were selected at the end of round one. In round two, the selected teams developed a full packet containing their final infographic and a final communications and outreach strategy.

Each team received a total award of $2,500, where $2,000 was expected to be used as stipend and $500 for the implementation of a component of their outreach strategy. The five teams were invited with paid expenses to the Geothermal Resources Council annual meeting 2014 to present their

infographic and meet geothermal stakeholders. During the meeting the top three teams were announced (Figure 4). DOE recognized Truckee Meadows Community College as the winner of first place, University of Texas Pan American (today part of University of Texas Rio Grande Valley) in second place, and University of Mississippi in third place (DOE, 2014).

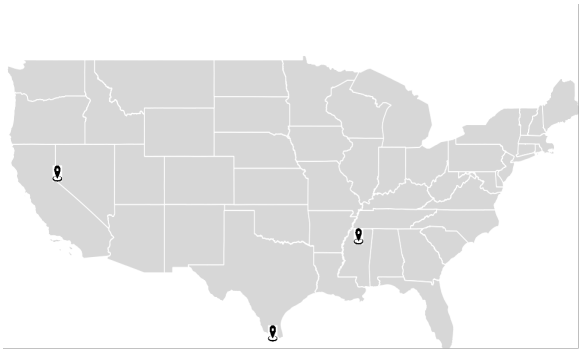

Figure 4: U.S. map showing three collegiate institution winning teams of NGSC 2014 (Truckee Meadows Community College, University of Texas Pan American, University of Mississippi)

2.5 Geothermal Design Challenge 2016

At the end of 2015, the competition launched another infographic challenge and trademark as the Geothermal Design Challenge. Students were invited to answer the question, "What is the future of geothermal energy and how will it impact you?". Five topics were recommended: History of Geothermal Energy, Workforce and Education, Science and Technology, Environmental Impacts, and Economics.

Students from high schools and universities were asked to form teams of two or three members and encouraged to find a team sponsor. For those students interested in participating but could not find the right team members, the competition provided an email contact to help their search for a matching team (INL, 2015).

The competition opened in December 2015, lasted eight months and contained three rounds. In round one, teams were asked to create a first draft of an infographic, and after a down select, round two teams refined and finalized their infographic. During the second round, teams received a one-on-one mentoring in geothermal energy and graphics arts. In the third and final round, teams selected, developed, and executed a social media campaign to promote their final infographics.

A team comprised of three students from Carnegie Mellon University's School of Design received the grand prize. They received $2,500 and an all-expenses paid trip to the Geothermal Resources Council annual meeting 2016 to showcase their work (CMU, 2016). Detailed documentation about deliverables, and finalist teams was not found for this competition.

2.6 Geothermal Design Challenge 2019

The 2019 Geothermal Design Challenge began in early January and concluded mid-April of the same year. The challenge asked teams to use actual data collected from the Frontier Observatory for Research in Geothermal Energy (FORGE) site in Milford, Utah, to create data visualization portfolios that answered the question, "Where do you target your next production well to maximize geothermal reservoir performance?". Specific datasets located in the Geothermal Data Repository (GDR) were provided for the challenge, including maps and well, drilling, temperature, surface, and reservoir testing data.

Teams from colleges and high schools were asked to imagine themselves as members of the FORGE project team tasked with placing a new geothermal well that would help researchers better understand Enhanced Geothermal Systems (EGS). Through data visualization techniques of their choosing and the data provided, teams were instructed to communicate an ideal subsurface location within the FORGE area to create a sustainable subsurface heat exchanger with minimal environmental consequences (FORGE, 2019).

The competition obtained 15 final submissions that were reviewed thoroughly by a panel of professionals. Three winning teams were selected: in first place, a joint team from DePaul University and Georgia Institute of Technology with the submission, "EGS Site Selection Using GIS and Machine Learning," was awarded $5,000; in second place, a team from Colorado School of Mines with the submission, "Open-Source Approach to 3D Communication," was awarded $3,500; and in third place, a team from Stanford University with the submission, "Want to Explore FORGE Data?," was awarded $2,500 (Figure 5).

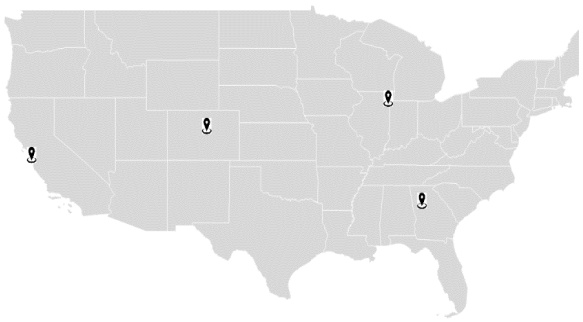

Figure 5: U.S. map showing four collegiate institution winners of Geothermal Design Challenge 2019 (DePaul University/Georgia Institute, Colorado School of Mines, Stanford University)

2.7 Geothermal Design Challenge Spring 2020

In 2020 the Geothermal Design Challenge Geographic Information System (GIS) Mapping competition focused on fostering understanding and sharing the benefits of geothermal technologies. Student teams were asked to research data, interpret information, and create a map (digital interactive or static print) showing how GIS could best communicate the benefits of geothermal technology. Through this deliverable, teams were asked to address the challenging questions, "How can geospatial mapping increase our understanding of this important renewable

energy resource? How can GIS improve how we visualize and communicate about geothermal energy?"

Registration for the Geothermal Design Challenge opened in January 2020, and submissions for the compliance review were due approximately three months later. Teams were required to pass an initial compliance review to advance to the final round of the competition. Some of the map requirements included that geothermal energy must be the primary theme, the analyzed data must be cited, it must include at least one dataset sourced from the Geothermal Data Repository (GDR), it should be technically accurate, and educational sponsor information should be included.

The challenge had a total of 78 registered students across 42 teams, including 31 from universities and 11 from high schools. Teams registered were in 25 U.S. states. The winning digital team, UW Cart Lab from University of Wisconsin-Madison titled, "The Rise of Geothermal," received a grand prize of $5,000. The winning print team, Flying Squirrels from Northern Virginia Community College titled, "Where to Tap Low-Temp Enhanced Geothermal Energy," also received $5,000 (INL, 2020). Five additional finalists were reported from Reykjavik University Iceland School of Energy (not shown in Figure 6), University of Alaska Anchorage, University of Montana, Stanford University and Bar Ilan University (not shown in Figure 6), and University of Maryland College Park (Figure 6).

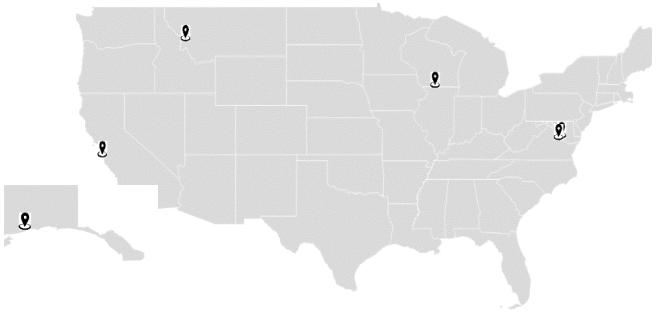

Figure 6: U.S map showing six collegiate institution finalists of Geothermal Design Challenge Spring 2020 (University of Alaska Anchorage, University of Montana, Stanford University, University of Maryland College Park, University of Wisconsin-Madison, Northern Virginia Community College)

2.8 Geothermal Design Challenge Fall 2020

GTO and NREL launched the Geothermal Design Challenge Fall 2020, where multidisciplinary teams of undergraduate and graduate students created robust, high-quality infographics illustrating aspects of geothermal energy production that were backed by technical data and accompanied by communications and outreach strategies to maximize impact.

The final deliverable package consisted of an executive summary, the infographic, communications or outreach strategy and a data appendix. The infographic should be innovative with a unique and compelling theme, be creative, be clear, contain relevant visual information and propose a relevant message. The communications and outreach strategy were evaluated for a clear approach and methodology, feasibility and impact with a broad audience.

The deliverables were submitted by participants in two phases via the HeroX platform, beginning with a progress concept submission followed by a final entry. Nine submissions were received from Antelope Valley College, Colorado School of Mines, Michigan Tech, Montgomery College, Texas A&M Corpus Christi, Tuskegee College, University of California Irvine, University of California Santa Cruz, and University of North Dakota (Figure 7).

The winning teams were: the first-place team Thermal Vision from University of North Dakota with the submission, "Geothermal Applications for the World," the second-place team Geo Slugs from University of California Santa Cruz with the submission, "Green & Unseen: The Future of Geothermal Power," and the third-place team from Antelope Valley College with the submission, "The Heat Beneath Our Feet." The competition did not provide monetary prizes (DOE, 2020).

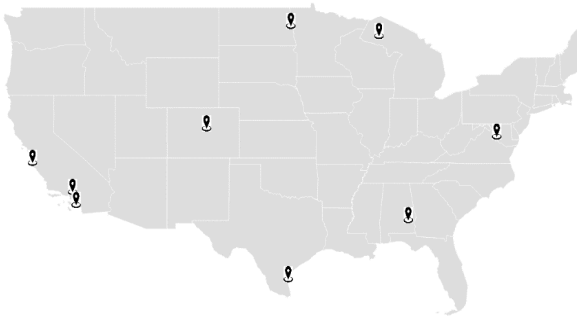

Figure 7: U.S. map showing nine collegiate institution finalists of Geothermal Design Challenge Fall 2020 (Antelope Valley College, Colorado School of Mines, Michigan Tech, Montgomery College, Texas A&M Corpus Christi, Tuskegee College, University of California Irvine, University of California Santa Cruz, University of North Dakota)

2.9 Geothermal Collegiate Competition Spring 2021

During the spring of 2021, GTO and NREL launched the Geothermal Collegiate Competition. This competition challenged students to identify a community or campus site to implement a direct-use geothermal energy system and conduct an initial resource assessment, load and usage determination, and preliminary economic feasibility analysis.

Additionally, teams were challenged to identify and interview relevant stakeholders for selected site to develop a stakeholder engagement strategy document. The strategy should contain key findings from interviews, materials to educate stakeholders about geothermal energy, a visual aid or tool to engage and educate local stakeholders about geothermal direct use case in their communities and a plan for sharing the tool more broadly.

Cash prizes of $1,000, $750, and $500 were awarded for first-, second-, and third-place winners, respectively. Honorable mentions were also awarded, with $250 for a well-done geoscience component and for an outstanding stakeholder engagement strategy.

Registered teams were required to submit deliverables in two phases: a mandatory progress submission and a final submission. The final submission was comprised of five scored sections: site identification, resource assessment, usage assessment, preliminary economic feasibility analysis, and stakeholder engagement strategy. The progress submission contained a subset of these sections.

The competition received 15 final submissions from 17 collegiate institutions (Figure 8). The winning teams were: University of North Dakota in first place, University of Oklahoma in second place, and Cornell University in third place. Additionally, the University of California Berkeley and Rutgers University received the honorable mention for their stakeholder engagement strategy and Colorado School of Mines for the geoscience's component (DOE, 2021).

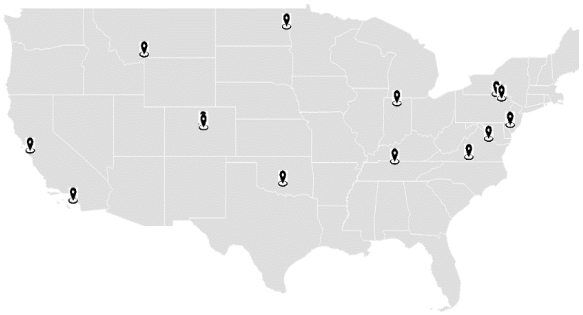

Figure 8: U.S. map showing 16 collegiate institution finalists of Geothermal Collegiate Competition Spring 2021 (Binghamton University, Colorado School of Mines, Cornell University, Cypress College, Liberty University, Montana State University, Northern Virginia Community College, Rutgers University, SUNY Broome, Temple University, UC Berkeley, University of Colorado, University of North Dakota, University of Notre Dame, University of Oklahoma, Western Kentucky University)

2.10 Geothermal Collegiate Competition Fall 2021 - Spring 2022

In its first full academic year version from fall 2021 to spring 2022, the Geothermal Collegiate Competition asked collegiate student teams to analyze geothermal technologies for a district energy application. The use case consisted of one or more commercial or multifamily buildings or an industrial or agricultural process with property access rights to geothermal resources. Student teams, required to be comprised of at least three students, developed a geothermal concept for an identified site working with real-world parameters, including actual energy load, utility rates, and subsurface data while designing their district-use project. Input from community stakeholders was required to obtain realistic project constraints and considerations.

As part of the competition strategy to support students, a series of training sessions were organized by NREL with topics from geothermal 101, technoeconomic analysis tools, 3D modeling software, systems design, and responsible stakeholder engagement. The videos were publicly posted and are available at the YouTube NREL Learning channel.

Main submission deliverables required the teams to include site identification, resource assessment, usage assessment, economic feasibility analysis, environmental impact analysis, stakeholder engagement strategy, and a stakeholder engagement event plan. Additionally, teams had to select two out of the following elective modules: curriculum supplement, conceptual geologic model, engineering design, and project development and solicitation.

The stakeholder engagement deliverables should include a list of stakeholders relevant to the project, a summary of engagements, a description of the possible community engagement event, and a letter of commitment from the prospective host of the event. The winning teams were required to execute the stakeholder event proposed in their projects. Additional funds were provided to the winning teams to execute the event within the following months after the winners' announcement.

Cash prizes were awarded for first place ($10,000), second place ($5,000), and third place ($2,500). The collegiate institutions of the first-, second-, and third-place teams each received a $10,000 University Support Cash Prize to be used in planning and implementing a local stakeholder engagement event.

Five full final submissions were received (Figure 9), including teams from Temple University, University of Colorado-Boulder, University of North Dakota and Reykjavik University, and University of Oklahoma (two teams). First place was awarded to the University of Oklahoma, second place to the University of North Dakota and Reykjavik University (not showing in figure), and third place to the University of Colorado Boulder (DOE, 2022).

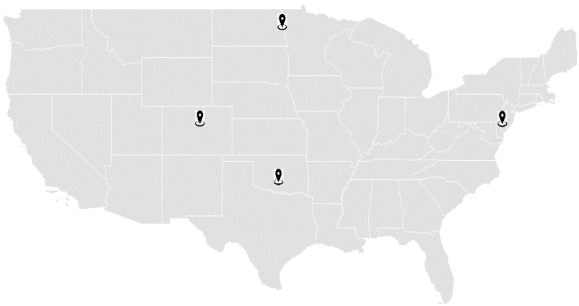

Figure 9: U.S. map of four collegiate institution finalists of Geothermal Collegiate Competition Fall 2021-Spring 2022 (Temple University, University of Colorado-Boulder, University of North Dakota, University of Oklahoma (two teams))

2.11 Geothermal Collegiate Competition 2023

The Fall 2023 Geothermal Collegiate Competition engaged student teams to develop and analyze forward-thinking geothermal heating and cooling concepts for a community or campus. Students were asked to assume the role of developer of a geothermal heating and cooling system for a district-scale application. In the interest of increasing diversity of disciplines, institutions, and applications, two types of tracks were designed for this competition cycle: the Technical Track and the Policy Track.

For the Technical Track, teams were asked to present a qualitative justification for deploying a geothermal district heating and cooling (GDHC) system in their proposed district (community or campus) and a conceptual design of a geothermal system based upon community needs, available resources, and prospective benefits to that community. Teams in the Policy Track were asked to present a qualitative justification for deploying a GDHC system in their proposed district including an analysis of the regulatory environment, financial incentives, and an economic assessment (DOE, 2023).

Three office hours sessions and two informational webinars were held for the competition. Teams were offered the option of registering early and being paired with an industry mentor, who supported their navigation of the competition; 19 teams took advantage of this offer.

Registration broke records. A total of 117 students formed 33 teams from 24 different collegiate institutions to propose innovative geothermal heating and cooling solutions for their communities. The competition engaged students from 14 states from a variety of disciplines, including mechanical and petroleum engineering, environmental policy, economy, finances, biology, city planning, architecture, dietetics, occupational therapy, supply chain management, and others.

For the final submission deadline, the competition received a total of 22 submissions from 18 collegiate institutions (Figure 10). Projects were comprised of diverse types of communities, such as campuses, low- and mixed-income residential buildings, and recreational infrastructure, the majority of which were located in rural areas.

The winners were announced via a live webinar on February 15, 2024. First- and second-place prizes were awarded in each track with $10,000 and $6,000 in cash prizes, respectively. Each first-place team also received $9,000 in additional funds for the purpose of planning and executing a stakeholder event in their project community. The first- and second-place winners of the Technical Track were awarded to the University of Oklahoma and the University of Tulsa, respectively. For the Policy Track, first place went to the Princeton University and Columbia University team, while second place went to the University of California, San Diego team.

Figure 10: U.S. map showing 18 collegiate institution finalists of Geothermal Collegiate Competition Fall 2023 (Aims Community College, California State University Bakersfield, Colorado School of Mines, Duke University, Massachusetts Institute of Technology, Norwich University, Princeton University and Columbia University, Smith College, Texas A&M University, University of California Davis, University of California San Diego, University of Colorado-Boulder, University of Michigan - Ann Arbor, University of Oklahoma, University of Tulsa, University of Wisconsin – Madison, West Virginia University)

3. Impact

More than 300 students participated in the geothermal competition from 2010 to 2023 as part of at least 101 finalist teams. Due to their professional expertise in the geothermal field, some GCC alumni are still involved as mentors or reviewers of current competitions.

A total number of 56 domestic collegiate institutions (Figure 11) from 30 states and two international universities have submitted entries to the competition. In the early years of the competition, when high schools were eligible to participate, about 11 institutions of that level registered to compete.

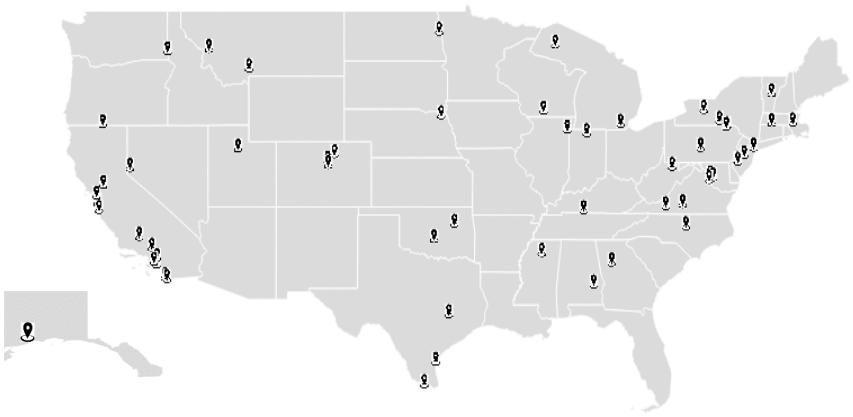

Figure 11: U.S. map showing 56 collegiate institution finalists of Geothermal Collegiate Competition since 2010

Out of the 56 collegiate institutions participating, eight are categorized as Asian American and Native American Pacific Islander Serving Institutions (AANAPISI), six as AANAPISI and Hispanic-Serving Institutions (HSI), five as HSI, one Historically Black Colleges and Universities (HBCU) and one Native American-Serving Non-Tribal Institutions (NASNTI) (Figure 12). All these categories are part of the Minority Serving Institutions (MSI) program.

Although community college participation has been low in the competition, it should be noted they had remarkable achievements. Truckee Meadows Community College won first place in 2014 for their infographic, and Northern Virginia Community College won first place in spring 2020 for the print-version GIS map titled, “Where to Tap Low-Temp Enhanced Geothermal Energy.”

Only five teams have participated in the competition including students from more than one institution. The competition reassures collaboration through encouragement of multidisciplinary teams as well as participants with various backgrounds to compete.

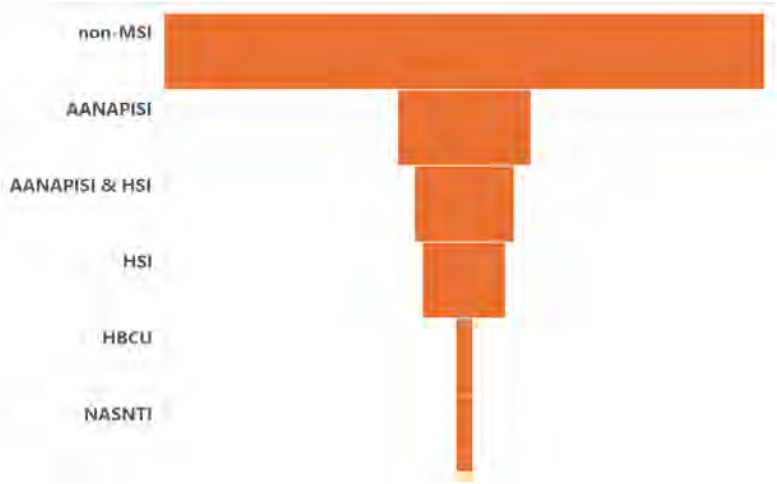

Figure 12: Distribution of non-MSI and MSI collegiate institutions in GCC from 2010 to 2023. MSI=Minority Serving Institutions (MSI), AANAPISI=Asian American and Native American Pacific Islander Serving Institutions, HSI=Hispanic-Serving Institutions, HBCU=Historically Black Colleges and Universities, NASNTI=Native American-Serving Non-Tribal Institutions

Historically the competition has targeted colleges with geothermal-related technical programs, such as geosciences and engineering. The addition of a new track with a policy focus in 2023, intended to increase participation amongst schools with policy, economics, and social programs. During registration for the 2023 competition, students were asked to list their major discipline; additional to the expected majors as geosciences and engineers, disciplines like: Finances, Business, City Planning, Architecture, Economics and Statistics, Energy Management, Industrial Technology, Public Affairs, International Relations, Social Sciences, and Supply Chain Management were listed. For the ongoing 2024 competition, the policy track is being offered again.

Currently, teams are not required to have a faculty advisor to participate in the competition; however, it is encouraged to connect with one. Over the years of the competition, it has been seen that teams accompanied by faculty are highly motivated to participate and win the competition. This might relate to the extra technical support an experienced faculty member can provide to the students. Some faculty make the competition challenge part of their class projects for their students. As an example, six teams from the same institution participated in the 2023 competition as the professor from their heat transfer class recommended the competition challenge as part of the fall semester program.

As part of the competition strategy to provide technical support to the students, a series of training sessions were recorded in 2021. The videos were publicly posted and are available at the YouTube NREL Learning channel.

Additional technical support and industry engagement has increased during the decade of the competition. Since 2020, the company Seequent has provided free student licenses and training for Leapfrog Energy®, a commercial software to evaluate geothermal resources. Another well-received initiative by the students was the mentor-team pairing, which started in the 2023 competition. Several geothermal experts were recruited from industry, academia, and national

laboratories to support student teams during the competition. Mentors' commitments included meeting with the student team regularly, discussing the progress of the project, and providing expert feedback.

The total cash prize has varied according to the recognition levels, sometimes by additional honorable mentions or supplementary prizes like paid attendance at key professional events, and funds to plan community stakeholder events. In figure 13, cumulative cash prizes are shown. Note for GCC 2022 the cash prizes were increased considerably; the injection of funds was made by DOE based on direct student feedback. Non-tangible prizes, like recognition on DOE and national laboratories' media channels, have been added to allow students and schools to promote their achievements publicly.

Figure 13. Cumulative cash prize pools and teams participating for the Geothermal Collegiate Competition from 2010 to 2023. Cash Prizes in thousands of dollars. Additional prizes, such as conference expenses paid, scholarships, and event funds, are not included. S=Spring. F=Fall

Since the spring 2021 competition, the technical topic has related to geothermal district heating and cooling for communities within the U.S. These types of projects have been proposed by the students on college campuses, tribal communities, low- and mixed-income communities, and community buildings such as school districts, local government offices, and federal facilities. Some exemplary applications for tribal communities were:

- The winning team of 2021-2022 created a prospect on gas well recompletion for geothermal district heating in Mandaree, North Dakota, located on the Fort Berthold Indian Reservation in the Mandan and Arikara nation. The project would generate heat as well as food through an integration of a direct-heated greenhouse. Judges praised this team for their exhaustive evaluation of the potential for geothermal direct heat using abandoned oil and gas wells.

- In fall 2022, the winning team designed and analyzed a system repurposing six abandoned oil and gas wells in Shawnee, Oklahoma to provide clean, renewable geothermal energy for more than 730,449 square feet of educational and municipal buildings, including sites within the Absentee Shawnee Tribe and Potawatomi Nation.

- For the GCC 2023, the newly introduced Policy Track winning team developed a proposal for a geothermal district heating and cooling system in Elim, an Alaska Native community on the Seward Peninsula. The team received the highest score due to their clarity and thorough research on applicable permitting and approval requirements, cost estimates based on well-sourced costs, and potential incentive options.

As previously mentioned, teams competing from 2021 were asked to develop a community engagement strategy including a stakeholder event plan. The goal of having student teams planning a stakeholder event was to get them involved with the communities benefitted and impacted by their proposed projects. Winners from the competitions of fall 2021-spring 2022 and 2023 have executed four stakeholder events with community participation and a variety of attendee backgrounds. For the sponsor and administrator teams, these events are currently the only in-person interaction opportunity with the student teams during the competition. The feedback received from the students, college personnel, community members, and participants about the events has been positive. It is noticeable that students put a significant amount of effort on the execution of the event.

4. Conclusions

The Geothermal Collegiate Competition challenges students to scale up geothermal technologies in a way that prioritizes the unique needs of individual stakeholder groups and communities. GCC's student competitors gain experience in solving real-world challenges while benefiting from mentorship, training, and collaboration. The GCC supports GTO's ongoing efforts to grow the domestic geothermal industry and address employment gaps through experiential learning.

From the beginning of the competition in 2010, more than 300 students have proposed innovative ideas for real-world problems with real-world solutions that benefit a diverse range of communities. In every version of the geothermal competition, GTO and administrators found innovative approaches to increase participation and to inspire students across the country to overcome real barriers of the geothermal industry. A few of many examples include creating non-technical tracks to motivate diverse disciplines, forming mentoring programs, providing free technical software access, creating elective modules, and increasing the national recognition of winning teams.

The maintenance of student competitions and a broad outreach beyond the typical disciplines from the geothermal field are critical to sustain a diverse pipeline for the sector's future workforce. Strategies to increase retention of current participating institutions and targeting minority serving institutions (MSI) are vital to reach the diverse backgrounds anticipated.

Based on participants' feedback, large cash prizes have a positive response from students considering participating in a collegiate competition. Additional prizes, such as attending professional conferences to present their projects, scholarships for short training programs, or certifications, are also worth evaluating as part of the prizes pool.

One of the goals of the competitions is to expose students to a hands-on learning experience and support them in getting skills applicable in an entry-level job. There is a great opportunity to increase the two-way interest between industry and students. Current geothermal internship programs vary largely; therefore, looking for a direct collaboration between student competitions and internship programs within the industry seems to be an interesting path to analyze in the short term.

Strengths-Based Bridges: Fostering Diversity, Inclusion, and Innovation in the Geothermal Industry

Brandy Brazell Obvintseva[1]

[1] Principal Strategist, Gallant Culture; Certified StrengthsCoach® Gallup

Keywords:

Diversity, Inclusion, Geothermal Energy, CliftonStrengths, Cross-Sector Collaboration, Renewable Energy, Cultural Integration, Gallup.

ABSTRACT

The advancement of the geothermal energy sector represents a critical frontier in the global shift toward renewable energy sources. A significant challenge in this endeavor is the integration of diverse industrial cultures, specifically those of the traditional oil and gas industry and the burgeoning environmental energy sector. This paper explores the hypothetical application of Gallup's CliftonStrengths framework to bridge this cultural divide, positing that leveraging individual and collective strengths can facilitate a celebration of diversity, inclusion, and varied perspectives. This examination proposes that understanding and applying these disparate sectors' inherent talents and strengths can enhance collaboration, innovation, and progress in geothermal energy development. By adopting the CliftonStrengths approach, the paper hypothesizes a scenario where the unique contributions of everyone are recognized and valued, fostering a more inclusive and productive dialogue between the traditional energy and environmental sustainability communities. This strengths-based strategy not only aims to accelerate the practical advances in geothermal technology and project execution but also seeks to establish a model for cross-sector cooperation rooted in mutual respect and shared objectives. Through theoretical analysis, this study illustrates the potential of the CliftonStrengths framework to act as a catalyst for uniting diverse groups, thereby contributing to the faster realization of geothermal energy's potential in the renewable energy landscape.

1. Introduction

The geothermal industry is at the forefront of the transition to renewable energy. Yet, it faces significant challenges in integrating the diverse industrial cultures of traditional oil and gas sectors with the emerging renewable energy community. The historical dominance of fossil fuel-based energy production has led to deeply entrenched practices and cultures that may not align with the values of the renewable energy sector. Diversity and inclusion (D&I) have been recognized as crucial for fostering innovation, enhancing problem-solving capabilities, and driving sustainable development in this sector.

1.1 Importance of Diversity and Inclusion

Diversity brings a variety of perspectives that can drive innovation and lead to more effective problem-solving. In geothermal energy, where technological challenges and environmental considerations are paramount, diverse teams are better equipped to develop innovative solutions. Inclusion ensures that all voices are heard and valued; creating a collaborative environment that leverages human potential. The integration of diverse perspectives not only leads to more robust solutions but also fosters a culture of mutual respect and understanding, which is essential for the long-term success of any organization.

1.2 Objective and Scope of the Paper

This paper investigates the potential application of Gallup's CliftonStrengths framework to bridge cultural divides and foster a more inclusive and collaborative environment in the geothermal industry. It explores how strengths-based approaches can enhance team performance, foster innovation, and promote a culture of inclusion. The focus is on integrating insights from traditional energy sectors and the growing renewable energy sector to create a cohesive strategy for advancing geothermal energy development. By examining the foundational principles of the CliftonStrengths framework and its application in various organizational settings, this paper aims to provide actionable insights for industry leaders.

2. Literature Review

2.1 Gallup's CliftonStrengths Framework

Gallup's CliftonStrengths framework emphasizes identifying and leveraging individual strengths to enhance team performance and organizational success. This framework is based on the premise that focusing on strengths leads to greater engagement, improved performance, and a more positive workplace culture. According to Gallup, organizations that adopt a strengths-based approach can significantly increase employee productivity and retention.

2.1.1 Basic Tenets of CliftonStrengths

The CliftonStrengths framework is founded on several key tenets:

- Strengths Identification: Recognizing that each individual has unique talents that can be harnessed for personal and organizational success.
- Strengths Development: Focusing on developing these strengths rather than solely addressing weaknesses.
- Strengths Utilization: Aligning tasks and roles with individuals' strengths to maximize efficiency and job satisfaction.
- Strengths Integration: Encouraging teams to leverage each member's strengths to foster collaboration and achieve collective goals.

2.1.2 Application in Organizational Settings

In organizational settings, the CliftonStrengths framework can be used to identify employees' unique strengths and align them with roles and responsibilities that maximize their potential. This approach fosters a culture of recognition and appreciation, where individuals feel valued for their contributions. It also encourages collaboration by highlighting complementary strengths within teams. These results in a more engaged and motivated workforce better equipped to tackle complex challenges and drive innovation.

2.2 Diversity in the Energy Sector

The energy sector, including geothermal energy, has historically struggled with diversity. According to a recent Boston Consulting Group (BCG) report, the energy industry is at risk of falling behind in terms of gender diversity, with women significantly underrepresented in technical and leadership roles. This lack of diversity can hinder innovation and limit the industry's ability to attract and retain top talent.

2.2.1 Gender and Ethnic Diversity Challenges

The BCG report highlights that the underrepresentation of women and ethnic minorities in the energy sector is a significant barrier to achieving a diverse and inclusive workforce. Women make up only 22% of the workforce in the traditional energy sector, and ethnic minorities are similarly underrepresented. These disparities are even more pronounced in leadership positions, where women and minorities often face additional barriers to advancement.

2.2.2 Benefits of Diversity

Diverse teams bring various perspectives that can lead to more innovative solutions. Studies have shown that companies with higher levels of diversity are more likely to outperform their peers regarding financial performance and innovation. In the energy sector, where complex technical challenges are common, diverse teams are better equipped to develop effective solutions and drive industry advancements. Moreover, team diversity enhances creativity and the ability to solve problems by providing a broader array of ideas and approaches to address issues.

2.3 Current State of Diversity in Geothermal

The 2022 GR DEI Paper highlights the efforts of Geothermal Rising to promote diversity, equity, and inclusion within the geothermal community. The paper discusses baseline demographic data and outlines strategies for increasing diversity and fostering an inclusive environment.

2.3.1 Demographic Data and DEI Initiatives

The 2022 GR DEI Paper presents demographic data from surveys conducted within the geothermal community. These surveys reveal significant diversity gaps, particularly in gender and ethnic representation. Geothermal Rising has implemented a range of DEI initiatives to address these disparities, including mentorship programs, diversity training, and targeted recruitment efforts.

2.3.2 Impact of DEI Efforts

The impact of these DEI efforts has been significant, with increased representation of women and ethnic minorities in the geothermal workforce. Geothermal Rising's initiatives have also led to a more inclusive workplace culture where employees feel valued and respected for their

contributions. This has contributed to higher levels of employee engagement and satisfaction and improved organizational performance.

3. Methodology

This whitepaper integrates qualitative and quantitative data from various sources to provide a comprehensive overview of the current state of diversity in the geothermal industry. Data were gathered from Gallup reports, industry publications, and internal surveys conducted within the geothermal sector. The analysis focuses on the potential application of the CliftonStrengths framework to enhance collaboration and innovation through a strengths-based approach.

3.1 Data Collection

Data were collected from various sources, including Gallup's workplace studies, industry reports from the Boston Consulting Group (BCG), and internal surveys conducted by Geothermal Rising. These sources provided a comprehensive overview of the current state of diversity in the energy sector and the impact of DEI initiatives on organizational performance.

3.2 Analysis Techniques

The analysis involved a combination of qualitative and quantitative techniques. Qualitative data were analyzed using thematic analysis to identify key themes and patterns related to diversity and inclusion. Quantitative data were analyzed using statistical methods to examine trends and correlations between diversity and organizational performance. The findings were then integrated to provide a holistic view of the current diversity in the geothermal sector and the potential benefits of a strengths-based approach.

3.3 Integration of Gallup's Framework

Gallup's CliftonStrengths framework was integrated into the analysis to explore how a strengths-based approach could enhance diversity and inclusion in the geothermal sector. This involved examining the alignment between individual strengths and organizational roles and identifying opportunities for leveraging strengths to drive innovation and collaboration.

4. Findings

4.1 Diversity in the Geothermal Industry

Like many sectors within the energy industry, the geothermal industry faces significant diversity challenges. The US Workforce Diversity Data report indicates that the energy workforce is predominantly male and lacks representation from minority groups. In the geothermal sector specifically, women and racial minorities are underrepresented, with significant disparities in leadership roles.

4.1.1 Gender and Ethnic Representation

According to the US Workforce Diversity Data, women make up only 25% of the workforce in the geothermal industry (up 3% since a 2022 paper was published by Geothermal Rising (see citation), and ethnic minorities are similarly underrepresented. These disparities are particularly

pronounced in technical and leadership roles, where women and minorities face additional barriers to advancement.

4.1.2 Barriers to Diversity

Barriers to diversity in the geothermal industry include unconscious bias, lack of mentorship opportunities, and limited access to networks and resources. These barriers can prevent women and minorities from advancing in their careers and contributing fully to the industry. Addressing these barriers requires targeted efforts to promote diversity and inclusion, including mentorship programs, diversity training, and recruitment initiatives.

4.2 Benefits of a Strengths-Based Approach

Gallup's CliftonStrengths framework enhances diversity and inclusion within the geothermal industry. Organizations can foster a more inclusive environment that values diverse perspectives and skills by focusing on individual strengths. This approach has been shown to improve team dynamics, increase innovation, and drive organizational success.

4.2.1 Enhancing Team Dynamics

A strengths-based approach can enhance team dynamics by encouraging collaboration and recognizing the unique contributions of each team member. By focusing on strengths, organizations can create a more positive and inclusive workplace culture where employees feel valued and motivated to contribute to their full potential.

4.2.2 Driving Innovation

Diverse teams that leverage individual strengths are more likely to develop innovative solutions to complex challenges. A strengths-based approach can drive innovation and accelerate progress in the geothermal industry, where technological advancements are crucial for sustainable energy production.

4.3 Case Studies and Examples

The State of the Global Workplace 2024 report provides several case studies highlighting successful diversity and inclusion initiatives in the energy sector. These case studies illustrate the positive impact of a strengths-based approach on employee engagement and organizational performance. Geothermal Rising's DEI initiatives serve as a model for organizations looking to enhance diversity and inclusion within their sectors.

4.3.1 Case Study: Geothermal Rising

Geothermal Rising has implemented a range of DEI initiatives to increase diversity and foster an inclusive workplace culture. These initiatives include mentorship programs, diversity training, and targeted recruitment efforts. As a result, Geothermal Rising has seen an increase in the representation of women and minorities in its workforce and higher levels of employee engagement and satisfaction.

4.3.2 Case Study: Global Energy Corporation

Global Energy Corporation, a leading energy company, has adopted Gallup's CliftonStrengths framework to enhance diversity and inclusion within its workforce. By focusing on individual strengths, the company has created a more inclusive environment that values diverse perspectives and encourages collaboration. This approach has led to higher levels of innovation and improved organizational performance.

5. Discussion

5.1 Challenges and Opportunities

The geothermal industry faces unique challenges in integrating a diverse workforce. However, these challenges also present opportunities for growth and innovation. A strengths-based approach can help overcome cultural barriers and foster a more inclusive environment that values the contributions of all employees.

5.1.1 Addressing Unconscious Bias

Unconscious bias is a significant barrier to diversity and inclusion in the geothermal industry. By promoting awareness of unconscious bias and implementing training programs, organizations can create a more inclusive workplace where all employees feel valued and respected.

5.1.2 Leveraging Diversity for Innovation

Diverse teams bring various perspectives that can drive innovation and lead to more effective problem-solving. By leveraging the unique strengths of each team member, organizations can develop innovative solutions to complex challenges and enhance their competitive advantage.

5.2 Implications for Policy and Practice

To achieve greater diversity and inclusion, the geothermal industry must adopt policies that support a strengths-based approach to workforce development. This includes providing training and development opportunities focusing on individual strengths and implementing policies promoting diversity and inclusion at all levels of the organization.

5.2.1 Policy Recommendations

Policy recommendations for promoting diversity and inclusion in the geothermal industry include:

- Implementing mentorship programs to support the career development of women and minorities.
- Providing diversity training to raise awareness of unconscious bias and promote inclusive behaviors.
- Establishing recruitment targets to increase the representation of women and minorities in technical and leadership roles.

5.2.2 Best Practices for Organizations

Best practices for organizations include:

- Conducting regular diversity audits to assess the representation of women and minorities in the workforce.
- Offering flexible work arrangements to support work-life balance and attract diverse talent.
- Creating employee resource groups to provide support and networking opportunities for underrepresented groups.

5.3 Future Directions

Future research should explore the long-term impact of strengths-based approaches on diversity and inclusion within the geothermal industry. Additionally, continued efforts are needed to develop and implement policies that support a diverse and inclusive workforce and measure the effectiveness of these initiatives over time.

5.3.1 Areas for Future Research

Areas for future research include:

- Examining the impact of strengths-based approaches on employee engagement and retention in the geothermal industry.
- Investigating the role of leadership in promoting diversity and inclusion within the geothermal sector.
- Assessing the effectiveness of diversity training programs in reducing unconscious bias and promoting inclusive behaviors.

5.3.2 Long-Term Impact of Diversity Initiatives

Future research should focus on the long-term impact of diversity initiatives on organizational performance and innovation. By measuring the outcomes of these initiatives over time, organizations can identify best practices and develop strategies for sustaining diversity and inclusion in the geothermal industry.

6. Conclusion

Integrating Gallup's CliftonStrengths framework can bridge cultural divides and foster a more inclusive and innovative environment in the geothermal industry. By focusing on individual and collective strengths, the geothermal sector can enhance collaboration, drive innovation, and accelerate the transition to renewable energy. The findings suggest that a strengths-based approach can play a crucial role in promoting diversity and inclusion, leading to a more sustainable and successful industry.

Canadian Policy Opportunities for the Geothermal Energy Industry (August 2024)

Alison Thompson; London Hillyer

The Canadian Geothermal Energy Association (CanGEA)

Keywords

Policy; Canada; Alberta; British Columbia; Geothermal; Incentives; Risk Mitigation; Regulatory; Permitting

ABSTRACT

Geothermal energy, despite its availability, has been largely untapped in Canada thus far. The industry has struggled to gain traction due to a lack of foundational support and strategic policy frameworks. This paper explores the existing federal and provincial policy landscapes to identify gaps and propose actionable recommendations to stimulate the geothermal sector. With strategic policy support and targeted investments, Canada has the potential to unleash its geothermal resources.

At the federal level, the promising Clean Technology Investment Tax Credit (ITC), now inclusive of geothermal heat and electricity, provides up to a 30% refundable tax credit. Further policy opportunities for the federal government to play its part to lay the foundation of the industry may include Heat Price Swapping Agreements (HPSAs) and establishing a clear framework for geothermal carbon offset projects and Carbon Contracts for Difference (CCFD). Further, a risk mitigation drilling fund would support geothermal developers by compensating unsuccessful projects and recycling funds from successful ones, thereby reducing financial risks and encouraging private sector investment.

In Alberta, targeted projects to fuel-switch industrial processes to geothermal heat can significantly reduce emissions while developing new energy sources. These demonstrations would prove the economic and technical feasibility of geothermal energy. Similar to existing incentives for petrochemicals and carbon capture, a dedicated geothermal incentive program would attract investment and accelerate industry development. On the regulatory side, extending surface access rights, addressing urban drilling regulations, ensuring exclusive rights to pore space, and considering electricity market reforms are areas for further policy reforms to catalyze the geothermal energy industry.

In British Columbia, introducing geothermal tax incentives similar to established mining and heat pump tax credits can attract investment and reduce the financial burden on developers. Introducing a geothermal portfolio standard in the CleanBC Industry Fund and as part of BC Hydro’s Integrated Resource Plan can facilitate the development of geothermal heating and electricity systems. Encouraging geothermal offset projects through the Fuel Switch Offset Protocol, reconsidering well classifications, exempting waste heat from regulation, and streamlining the permitting process can further remove barriers and expedite geothermal project development in the province.

Introduction

Canada represents a virtually new frontier for geothermal energy development with significant market and moderate resource potential. In our view, geothermal development has stalled because there has been an over-focus on electrification, as in the mid-2010s federal funding targeted electricity-generation, thus overlooking the foundations of the industry– direct-use of geothermal heat. Provinces on the other hand, have simply had other priorities, or have not been sufficiently educated or persuaded to recognize the potential and benefits of geothermal energy; however, this is beginning to change – as indicated by recent announcements such as the Alberta Drilling Accelerator.

The entire supply chain stands to benefit from industry-enabling legislation and regulations including developers, drillers, financiers, scientists and consultants, supply and service providers etc. Policy work has the potential to save millions ($) and save years on geothermal energy projects, enabling more projects to commence and finish, creating more sure and swift returns for developers and financiers. With a world-class energy sector and professionals to match, tapping into and commercializing geothermal resources in Canada could unfold rapidly with the right investments and policy shifts.

This paper will review the existing frameworks at the federal level, Alberta, and in British Columbia (BC) to recommend policy proposals from the perspective of geothermal energy stakeholders. There may be opportunities in other provinces as well, though this paper emphasizes Alberta and BC given that the bulk of geothermal industry stakeholders currently are developing projects and exploring potential projects in these two provinces, given the availability of Canada's highest quality resources in relation to market opportunities.

1. Federal

In Canada, geothermal permitting, leasing, project approvals and tenure is primarily handled at the provincial level, not the federal level. At the federal level, policy opportunities relate primarily to financial incentives and risk mitigation, as geothermal projects are not likely to be affected by proposed federal regulatory legislation, such as the Impact Assessment Act, which was initially struck down by the Supreme Court for encroaching on provincial jurisdiction (Killoran et al., 2023). Natural Resources Canada, a federal agency, funds various programs related to natural resource development, and under the current government, prioritizes clean resources, technologies, and emissions-reducing projects.

1.1 Investment Tax Credits (ITCs)

<u>The Clean Technology ITC</u>

This ITC represents not a policy gap, but a policy win. The 2022 Fall Economic Statement introduced the initial details of the Clean Technology ITC. Mentioned eligible clean technology equipment included systems relating to storage, heat pumps, nuclear, and solar—notably absent was geothermal energy. Immediately, CanGEA began a campaign to ensure geothermal energy systems would be included in legislative drafts of the Clean Technology ITC. After a series of half-a-dozen meetings with both sides of the aisle and dozens more communications beginning in late 2022, in the Spring of 2023, Environment Minister Guilbeault announced the expanded

eligibility of the Clean Technology ITC to include geothermal energy systems, as is also contained in Budget 2023.

The Clean Technology ITC is a refundable tax credit of up to 30% of investments in eligible property acquired on or after March 28, 2023. Eligible equipment includes, *"(v)equipment used exclusively for the purpose of generating electrical energy or heat energy, or a combination of electrical energy and heat energy, solely from geothermal energy, that is described in subparagraph (d)(vii) of Class 43.1 in Schedule II to the Income Tax Regulations, but excluding any equipment that is part of a system that extracts fossil fuel for sale"* (Parliament of Canada, 2023). If labour requirements (prevailing wage and apprenticeship conditions) are not satisfied, the tax credit rate would drop by 10 percentage points.

This ITC was introduced in the House of Commons on November 30, 2023, as part of a broader package (C-59) to implement provisions of the Fall Economic Statement and as of summer 2024, is available to claim in an updated Schedule 31 ITC form for corporations.

CCUS Investment Tax Credit Parity and Hydrocarbon Co-production:

Our industry may receive up to 30% via the Clean Technology ITC, whereas the CCUS Investment Tax Credit provides up to 60%. We are grateful for geothermal energy's eligibility under the Clean Technology ITC, though 60% would of course be preferred over 30%.

Hydrocarbon Co-production:

Furthermore, the ITC legislation specifies that— *"equipment used for geothermal energy projects that will co-produce oil, gas or other fossil fuels would not be eligible for the [Clean Technology Investment Tax] credit."* Geothermal projects that may co-produce hydrocarbons will still reduce net emissions and should not be excluded from the Clean Technology ITC.

Conclusion

Although there are still ways to improve the Clean Technology ITC for geothermal energy, such as raising the percentage points to match CCUS and accommodating for hydrocarbon co-production, we commend the Government for their forward-thinking approach to our energy future and would encourage energy developers across Canada, and abroad, to consider adding Canadian geothermal projects to their portfolio, considering this new incentive to develop geothermal energy.

1.2 Renewable Heating Portfolio Standard (RHPS) and Heat Price Swapping Agreements (HPSAs)

Although the Federal Government in Canada cannot mandate a Renewable Portfolio Standard (RPS) for public utilities (which would fall into provincial jurisdiction), they can mandate a RPS for federal agencies. RPS mandates in the U.S., such as Executive Order 13514 and 13693, have led to the power purchase agreements (PPAs) of geothermal energy by federal departments, such as by the Department of Defense (DoD).

Although PPAs are well established and proven effective, the geothermal industry is not yet at the maturity level in Canada to generate electricity in a competitive market – thus PPAs would need

to be adjusted to pay premiums for baseload renewable energy. A more necessary (and novel) policy market mechanism at this time would be the idea of Heat Price Swapping Agreements (HPSAs), given that direct-use of geothermal heat is the low hanging fruit of the industry, and will serve as its foundation. Heat cannot be dispatched onto a grid, and it loses energy rapidly if it is transported across even small distances; therefore, at the federal level in Canada, to enable government buildings and/or agencies to purchase geothermal heat, the government could implement a HPSA Program to meet the targets of a Renewable Heating Portfolio Standard (RHPS).

The Government of Canada is the single largest building owner in Canada (Efficiency Canada, 2024). Under the HPSA Program, a government building customer would swap the price they pay for heat (natural gas) with a customer located near a geothermal heat resource. The government customer would continue to receive their existing heating source but pays the price for geothermal heat. Meanwhile, the customer near the geothermal resource would receive geothermal heat but pay the usual price of the government customer's conventional heat. By purchasing geothermal heat in place of natural gas, carbon emissions would be reduced, local air quality would improve, and energy security would be enhanced.

The Canadian Gas Association (CGA) has likewise proposed procurement of renewable natural gas (RNG) for the heating of the federal buildings, which calls for a 5% and 25% blend of RNG by 2025 and 2030 respectively (Canadian Gas Association, 2021). However, opting for geothermal heating instead would enable the Federal Government to eliminate virtually all GHG emissions from these buildings rather than only by 110,000 tonnes/year by switching to RNG. This will help to reduce the Government of Canada's 11.2 million GJ/yr of natural gas reliance, either directly or through renewable heat credits, which is equivalent to taking 124,500 homes/year from fossil fuels (Canadian Geothermal Energy Association, 2021).

The cost of RNG quoted at $18/GJ by the CGA is a premium over the current natural gas rate. Once established, geothermal heat prices are extremely economic, competitive, virtually immune to commodity price fluctuations, and would likely be much lower than the price of RNG. Locking in geothermal heat at a fair price over a long-fixed period would not only help the federal government reduce GHG emissions but would secure a sustainable rate for these buildings. Additionally, while a geothermal power facility would create approximately 17 times as many full-time jobs as a comparable natural gas facility, CanGEA (2014) posits that would be a comparable ratio to a geothermal heating system versus a natural gas burning system.

An HPSA Program could lead to a cascading effect of geothermal heating sites across Canada, as waste heat from an initial industrial customer can then feed into nearby district heating infrastructure. As the Federal Government invests in building greater geothermal heating infrastructure, further growth within other communities through greater knowledge capacity will be enabled. Moreover, the infrastructure created for geothermal projects has a long-life cycle and is extremely resilient relative to conventional combustion heating infrastructure, enhancing energy security.

A white paper may be necessary to explore the feasibility of the HPSA Program. The paper would determine the capability and outcomes of acquiring geothermal heat for hundreds of Government of Canada federal buildings. As well, the project will develop a deeper understanding of the implications of an RHPS policy in Canada and how creating a renewable heating credit trading

system would assist the Federal Government in the procurement of geothermal heating for their federal buildings and to meet GHG reduction goals. The HPSA Program would promote a stable foundation for the geothermal industry and establish its infrastructure and supply chains.

1.3 A Clear Framework for Geothermal Carbon Offset Projects and Geothermal Carbon Contracts for Difference (CCFD)

The proposed federal regulations to cap emissions in the oil and gas sector present a substantial opportunity for the geothermal energy industry. Establishing a clear framework for geothermal carbon offset projects can maximize this opportunity, ensuring that the benefits persist regardless of political changes. This framework should include Carbon Contracts for Difference (CCFD) specific to geothermal projects, providing the financial certainty necessary for long-term investments.

Additionally, the framework should facilitate credit trading among emitters and enable collaboration on offset and emission-reducing projects, including projects that would switch from combustion fuels to direct-use geothermal heat. Emitters contributing to emission-reducing projects offsite should still receive credits for these reductions, even if their own emissions are not directly decreased. This approach encourages investments in emissions reductions wherever they can be most effectively achieved, promoting national solutions over localized ones, and recognizing contributions to broader emissions reduction goals.

The Federal Government should establish a comprehensive framework that would accommodate geothermal energy Carbon Contracts for Difference (CCFD). Although some individual CCFD deals have been signed with specific companies in other industries (Department of Finance Canada, 2023), there is no broad framework in place. CCFDs guarantee the future price of carbon, offering financial stability for geothermal energy investments. Without a robust CCFD framework, the future of large-scale geothermal projects could be jeopardized if political support wanes after the upcoming federal election. Establishing this framework would provide certainty and encourage sustained investment in geothermal projects, securing their role in Canada's clean energy future.

1.4 Geothermal Exploration Risk Mitigation Drilling Fund

Heat customers with existing assets who are interested in switching to geothermal heat face significant financial and technical risks in making the transition. Developers aiming to sell electricity also confront drilling risks and the potential challenges of not finding quality resources at economic costs or lacking sufficient capital to develop resources that are cooler or more difficult to access. A risk mitigation insurance program, where unsuccessful projects are compensated and successful ones pay back premiums to the program, would minimize risks for both the government and the private sector. This government-backed initiative would encourage private sector participation by providing a safety net for developers, reducing the financial risks associated with geothermal projects.

A revolving risk mitigation drilling fund would be immensely beneficial for the geothermal industry. Access to this fund would likely be competitive, with bids evaluated based on project feasibility and potential impact. Initial funding allotments would be awarded to kick-start projects, with subsequent disbursements provided on a milestone basis. This phased approach ensures that funds are allocated efficiently, and projects are monitored for progress and viability.

Successful developers would repay the investment, effectively recycling the funds back into the program. Conversely, unsuccessful developers would be forgiven and have no obligation to repay, thereby minimizing financial risks for both developers and the government. Thus, the program provides grants (forgiven loans) as well as loans that are eventually repaid. This model ensures that successful projects offset the costs of unsuccessful ones, maintaining a balanced and effective risk management strategy, and ensuring the sustainability of the fund and continuous support for new projects.

Key features of the proposed risk mitigation program:

- Projects would compete for initial funding based on their feasibility and potential impact.
- Initial allotments to start projects, with subsequent disbursements contingent on meeting specific milestones.
- Successful developers repay the loans, recycling funds back into the program for future projects.
- Unsuccessful developers are forgiven, reducing financial risks for all parties involved.
- The program supports all geothermal technologies, both for electricity generation and direct-use heat applications, excluding ground source heat pumps.

This structured and balanced approach to risk mitigation and funding would significantly reduce the barriers to entry for geothermal projects. The program could also be replicated and proposed at the provincial level.

2. Alberta

Alberta represents a virtually new frontier for geothermal energy development with significant market and moderate resource potential. Hydrothermal resources are immediately accessible for relatively low-risk development with already existing and mature technologies, not necessarily for power generation, but more readily for direct-use, which will in turn access and collect critical data from deep aquifers, de-risking them for later electricity generation.

With more than 600,000 oil and gas wells already drilled in Alberta, we have enough data to determine that approximately 4,000 of them may be geothermally interesting (CanGEA, 2023). Critical to achieving the emissions reduction and energy resilience goals of Alberta, is the utilization of every readily available energy resource. It is geothermal heat that is readily and immediately available, and this heat happens to be baseload, abundant, renewable, and low-emitting.

With a world class energy sector and professionals to match, tapping into and commercializing geothermal resources in Alberta could come to fruition rapidly with the right strategy, investments, and policy developments.

2.1 Fiscal: Industrial Fuel-switching to Direct-use of Geothermal Heat Demonstration Projects

There is a great fit between the heat demand of Alberta's industries (large final emitters) and Alberta's geothermal potential to supply— a few projects are already in the early stages of

development, such as the Canfor Geothermal Wood Kilns Project near Whitecourt and the Latitude 53 Project near Hinton. The development of our geothermal energy resources for direct-use of heat could reduce emissions by about ⅔ in our heavy industry sectors, or 18.9 MT/year (Borealis Geothermal, 2023). In addition, land impacts are extremely minimal and do not disrupt natural water cycles or ecosystems. The ideal geothermal temperatures needed to satisfy the demand for heat in industrial processes such as food processing, pulp and paper manufacturing, vegetable dehydration, dairy and sugar processing, aquaculture, and greenhouses etc. exist in Alberta. Processes such as these cannot be fully or efficiently electrified, thus renewable thermal energy is the only way to sustainably decarbonize these energy intensive essential industries. Crucially, many of these operations are already proximate to accessible geothermal resources. There is an additional economic opportunity to harness the cascading or waste geothermal heat from these industrial customers to feed into municipalities for district heating.

To stress the efficiency of direct-use, the direct transfer of geothermal heat avoids the inefficiencies and energy losses associated with generating and transmitting electricity and then converting electricity into heat. Furthermore, geothermal resources maintain a nearly constant temperature throughout the year, providing a reliable and stable heat supply that is not subject to weather variations nor requires combustion. Geothermal installations are also characterized by their long operational lifespan, typically ranging from 25 to 50 years, with minimal degradation in performance. Finally, maintenance and operational costs are low – virtually unmatched in the subsurface energy industry.

Critical to the rapid development and commercialization of geothermal direct-use is the existing technical and drilling expertise, infrastructure, and supply chains that exist in Alberta's world class energy workforce. These jobs are highly transferrable to the geothermal industry and would require little-to-no retraining. More broadly speaking, a developed geothermal industry could create tens of thousands of jobs including temporary and construction jobs (Borealis Geothermal, 2023). Additionally, it would protect 73,000 existing heavy industry jobs that may be threatened by federal emissions reduction strategies (Borealis Geothermal, 2023).

Although the risk of accessing the geothermal resource is low, potential industrial customers of direct-use (large final emitters) are wary of the risks associated with retrofitting/replacing their combustion systems with geothermal energy systems. Heat customers with existing assets that are interested in switching to geothermal heat have to somehow justify the financial and technical risks of making the switch. A risk mitigation insurance program where unsuccessful projects are compensated, and successful ones pay back premiums to the program would minimize risk for both the government and the public sector. The private sector would also be emboldened by government sponsorship of the initiative.

2.2 Fiscal: Geothermal Incentive Program

Following the establishment of the foundation of the industry with direct-use pioneer projects, to further catch the eye of investors, fruition of a 12% geothermal incentive program akin to the

Alberta Petrochemicals Incentive Program and the Alberta Carbon Capture Incentive Program, as directed in the mandate letter to the Energy and Minerals Minister to catalyze the industry will rapidly scale the industry to the next level of maturity. Broadened eligibility to include geothermal-hydrocarbon co-production would partially compensate for the omission of such projects from the Federal Clean Technology ITC.

2.3 Fiscal: Expanded Scope of the Alberta Drilling Accelerator (ADA) to Include Subsurface Data Collection

The ADA represents a massive public policy win and opportunity for the geothermal industry, given that the "geothermal component" of the accelerator has been given priority order. However, the current focus of the ADA is to advance and accelerate drilling technology, as per the geothermal policy mandate from the Alberta Emissions Reduction and Energy Development Plan. As a result, the scope of the project includes only limited reservoir testing (e.g. wireline logging to determine the lithology, fluid and porosity of the strata from the base of the surface casing to total well depth, as mandated by the regulations); completions are not considered as part of the initiative.

After the geothermal drilling component, later stages of the ADA would assess the integration of other drilling techniques for industries such as CCUS, helium, and rare earth minerals. In Alberta, these emerging industries are generally interested in targeting a similar pore space – deep basal sediments in the Western Canada Sedimentary Basin. Unfortunately, there is a dearth of information associated with these deep basal sediments because most information of Alberta's subsurface comes from decades of data collected from oil and gas reservoirs that are found in shallower formations. Further understanding of the characteristics of these poorly tested reservoirs would be extremely helpful for advancing emerging subsurface industries, including geothermal.

While advances in drilling are important components for accelerating the aforementioned industries, there is an opportunity to leverage the ADA initiative and include funding support for reservoir testing. Drilling through the basal sediments could test both basal sediments and the basement itself, collecting critical data for emerging subsurface industries in the province, including geothermal. It is in the interest of the geothermal industry to socialize this opportunity with stakeholders, the public, and the Governments of Canada and Alberta, to ensure that the ADA is fully leveraged and expanded to catalyze evolving subsurface industries within the province.

The reservoir testing aspect of the ADA could include:

- Core samples and permeability/porosity measurements.
- Drill Stem Tests (DST), H_2S measurements, water samples.
- Wireline logs (including standard gamma ray, resistivity, sonic, and neutron/density logs as well as detailed temperature measurements).
- Injection/production tests (when possible).
- Diagnostic Fracture Injection Test (DFIT) to determine formation pressure, permeability, and fracture closure pressure.

To get the most value out of the data collected during the testing program it is imperative that locations of high geothermal/lithium/helium/CCUS potential are targeted as test drilling locations

by the ADA. Furthermore, the selected drilling contractor must be equipped to properly execute the testing program.

2.4 Regulatory: Surface Access Rights

The Surface Rights Act allows oil and gas developers to appeal to access land in cases where developers and landowners cannot reach an agreement. Section 2.3 of AER Directive 089 expressly excludes geothermal from the same right-of-entry mechanisms under the Surface Rights Act. Given that most geothermal development is likely to occur on private land, this creates a significant barrier to geothermal resource development, as landowners can simply refuse access and geothermal has no recourse, presenting complexities, costs, and risks for geothermal developers and investors that do not exist in other provinces—namely BC and Saskatchewan which do provide equitable surface access rights to geothermal.

In Alberta, there exists political sensitivities with respect to landowner rights; as such, a reasonable compromise to protect landowners may entail a public interest test by restricting geothermal surface rights to locations that matter—aligning with provincial objectives to responsibly develop resources and cut red tape. For a geothermal project to be eligible for surface access, criteria may be set such as a minimum emissions reduction threshold, job creation and retention, and demonstration of good faith efforts to fairly compensate and negotiate with landowners.

2.5 Regulatory: Urban Drilling in the Presence of sour gas (H_2S)

In collaboration with the private sector, regulator, and the relevant ministries, it is critical we find a safe regulatory solution to enable geothermal drilling in the presence of sour gas (H_2S) near communities. Current H_2S regulations (Directive 56) require drilling to be distant from population centres. This might not be a problem for hydrocarbons, but for geothermal, it makes sense to be near the heat customer. There are also other rules pertaining to rigs, drilling mud, backup equipment, and training that may be unnecessarily stringent for our industry. The actual hazard presented by drilling through H_2S reservoirs, on the way to sweet geothermal reservoirs, has largely been managed without incident for decades now. This necessitates changing the regulations to reflect geothermal drilling and production.

2.6 Regulatory: Exclusive Rights to Pore Space

Pertaining to pore space hierarchy, it is critical that where geothermal and other subsurface rights coexist, geothermal projects are ensured to commence first with exclusive pore space rights, to access the resource before it is sterilized by other subsurface developments. This will significantly increase investor confidence in geothermal projects.

2.7 Regulatory: Electricity Market Reform

Alberta is known for its longstanding energy-only market, in which electricity generators are only paid for the power they provide to the market. As a longer-term objective to scale up the electricity market share of geothermal sources by assuring developers of a profitable price for geothermal electricity that is well worth the risk, it would be necessary to make common sense reforms to the Alberta electricity market.

In response to rising strains on the grid, Alberta's Premier has been calling for the need for reliable sources of baseload power, openly criticizing the unreliability of Alberta's intermittent renewable resources. In late 2023, a grid alert came in the wake of a "deep freeze," in which increased demand took most of the blame for the shortage. A later alert on April 5, 2024, cannot be blamed solely on increased demand, rather, intermittent resources were generating at very low capacities and many gas generators were not running that morning (Doering, 2024). It has also become increasingly discussed that providers may be shutting down generation to inflate and manipulate the price. Perhaps an overhaul of Alberta's energy market is past due.

The government has touted its commitment to *"protecting Alberta's grid and ensuring our province continues to generate reliable baseload power both now and in the future."* It is becoming increasingly apparent that market measures are needed to lay the groundwork for the public and private sectors to work together to unleash baseload geothermal megawatts onto Alberta's grid. Such measures may be a capacity market that pays for both energy and the baseload capacity (availability) of geothermal, as AESO recommended in a 2016 report. Another option would be for Alberta to encourage geothermal power by creating a public utility that pays a premium for baseload dispatchable power, similar to a first-of-its-kind Clean Transition Tariff (CTT) that Google and a Nevada public utility introduced to enable private sector giant customers to pay a higher rate for clean baseload power.

2.8 Regulatory: Update Directive 060 to Mandate the Utilization of Geothermal Waste Heat

Alberta's AER Directive 060: *Upstream Petroleum Industry Flaring, Incinerating, and Venting* provides guidelines and requirements for the flaring, incinerating, and venting of gas in Alberta's upstream petroleum industry. The directive requires industry to harness flare gas, implementing practices to reduce flaring and venting volumes through conservation, utilization, and minimizing gas releases. Operators must monitor flaring, incinerating, and venting activities and report data to the AER, enabling effective oversight and enforcement of regulations. An additional provision of the directive to mandate the utilization of geothermal waste heat from oil and gas operations could be developed.

Co-produced wastewater from oil and gas operations is sometimes hot enough to be used for power generation in binary geothermal power plants. If able to be produced, this electricity can be used to decarbonize the oil and gas operation and/or provide clean energy to the grid. More significantly, co-produced wastewater from oil and gas operations is nearly always hot enough for direct-use heating. In theory, co-produced water with temperatures as low as 40°C could be used to economically heat a greenhouse. District energy systems used for space heating and commercial activities are viable options for communities and entrepreneurs in the areas surrounding oil and gas operations.

Many oil and gas wells may produce approximately less than 10% hydrocarbons and greater than 90% water –co-produced (Kemp, 2014). Co-produced water, at a minimum temperature and volumetric threshold, should be mandated to be used for economic and environmental benefit in much the same way that the AER Directive 060 has mandated the utilization of flare gas. A co-produced water analogue to AER Directive 060 would result in the maximization of the utility of the drilled well and the associated land disturbance. Furthermore, the implementation of a co-produced water analogue to AER Directive 060 will reduce the costs and risks associated with geothermal energy development by using already existing infrastructure such as roads, well pads,

and electrical connections, thereby encouraging the growth of Alberta's nascent geothermal industry.

3. British Columbia

The Province of British Columbia boasts some of the highest quality geothermal resources available in Canada. British Columbia has the resource, market, and political conditions to follow the pathway to geothermal development set by states such as California, as there are notable parallels. Although GHG reduction policies set by the BC government are encouraging the search for clean power sources, permitting red tape, regulatory disparities, and lack of up-front targeted capital, are inhibiting the initial takeoff of geothermal energy projects within the province.

3.1 Fiscal: Tax Incentives

Parity with existing mining tax credits.

The BC Government has established the 20% Mining Flow-Through Share (MFTS) tax credit, and a 20-30% the B.C. Mining Exploration Tax Credit (METC), to encourage investment in critical resources. Eligible expenses may include prospecting, geological surveys, and drilling. Given BC's clean electricity and GHG reduction goals, a similar Geothermal Energy Tax Credit for electricity generation and direct-use would be in line with provincial objectives.

Carbon Tax Credits for Direct-use Geothermal Investments.

To build out the foundations of the geothermal industry, it is logical to go after the low hanging fruit—namely hydrothermal resources for direct-use applications—and tailor initial incentive policies around this opportunity. Geoscience BC's 2016 report titled *Direct-Use Geothermal Resources in British Columbia* featured a tax incentive proposal called the Carbon Tax Credits for Direct-Use Geothermal Investments. Incentivizing the use of geothermal would equate to reduced electricity and natural gas demand, which is exactly what the province is looking for.

3.2 Fiscal: Funding Parity

Carve-out for geothermal energy in the Clean BC Industry Fund.

Currently, as standalone greenfield projects, geothermal energy projects do not fall under any eligibility stream of CleanBC funding, unless a geothermal developer partners with a large emitter. An additional stream to fund greenfield clean energy projects, including geothermal, would enable fuel-switching away from emitting fuels, thus contributing to the goals and purpose of CleanBC programs. For example, geothermally heated greenhouse projects, whether new projects or retrofit projects, should be included as an eligible project type under the CleanBC Building Innovation (CBBI) Fund. Also, a geothermal portfolio standard could be paired with the Fund whereby a portion of funding would be dedicated to a minimum threshold of geothermal heat as the carbon offset mechanism.

Direct public investments into geothermal district heating.

BC has recently announced an investment of up to $151 million toward the Federal Oil to Heat Pump Affordability (OHPA) program. Additionally, The CleanBC Better Homes program provides incentives for homeowners to install a heat pump for cooling and air filtration.

Geothermal heat can also be used directly to heat and cool municipal districts even more efficiently than heat pumps or natural gas, and thus should receive equivalent public investment or eligibility under existing heat pump funding streams. District heating systems could also provide the infrastructure needed to hook up geothermal stoves – which could be paired or consolidated with the existing Community Wood Smoke Reduction Program.

3.3 Regulatory: Encouraging Geothermal Offset Projects

The Fuel Switch Offset Protocol (FSOP) in British Columbia, established in 2018, enables offset projects that reduce emissions through energy conservation, energy efficiency, and switching to lower-carbon fuels. The FSOP is currently under review to assess its alignment with the Greenhouse Gas Industrial Reporting and Control Act (GGIRCA) and ensure it continues to deliver real, quantifiable, verifiable, permanent, and incremental emissions reductions. Given the potential of geothermal energy to significantly reduce greenhouse gas emissions, it is an opportune time to advocate for its inclusion and consideration in the revised FSOP, to ensure that geothermal development is encouraged as an offset project option for developers and emitters seeking to meet GHG reduction mandates. Additionally, consideration and flexibility of geothermal as offset projects in connection to BC's developing new Output-based Pricing System and Net-zero New Industry policies would be helpful to raise awareness of the geothermal opportunity in connection with these various GHG reduction policies and initiatives in BC.

3.4 Regulatory: Reconsider Geothermal Well Classifications

Currently, the Geothermal Resources Act serves to regulate all activities associated with the exploration for and production of geothermal resources above 80 °C. While the Geothermal Resources Act lends itself well to regulating Hot Sedimentary Aquifers (HSA) geothermal resources, it is not optimized to regulate the development of fault controlled geothermal resources that require exploration – the vast proportion of BC's geothermal resource portfolio. Geothermal well classifications should be reconsidered under the Geothermal Resources Act. In particular, the BC Government should reconsider the creation of a well classification for 'Thermal Gradient Wells' for fault-controlled resources under the Geothermal Resources Act, built to the standards of Geotechnical Wells licensed under the Water Sustainability Act.

3.5 Regulatory: Exempt Waste Heat from BCUC Regulation

We recommend that heat as a by-product <u>not</u> be regulated by the BC Utilities Commission and/or be granted an exemption from regulation. As illustrated in Figure 2, below, an individual geothermal energy application often uses only a portion of the available energy. As such, a portion of the energy remains and can be used in other applications (i.e. cascading energy use) such as greenhousing, aquaculture and crop drying. It is this by-product heat, also known as 'waste heat,' that should not be regulated. This recommendation would increase investor confidence and aligns with one of BC's clean energy objectives, "to reduce waste by encouraging the use of waste heat," as stated in the Clean Energy Act.

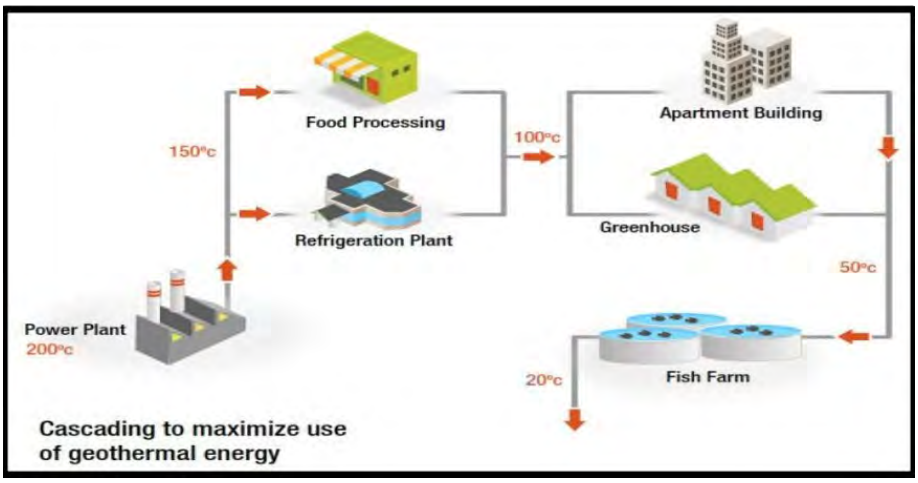

Figure 1: An example of cascaded energy use

3.6 Regulatory: Streamlined Geothermal Permitting

There are a series of measures that could be observed to smooth out the geothermal permitting process in BC.

1. Increasing the number of available geothermal permits to encourage more players to enter the market, sparking competition and innovation. BC is falling behind Alberta in this regard, as BC has only issued one permit to Alberta's 32 in the same time period, as measured by the Canadian Geothermal Energy Association (CanGEA).
2. A redesigned and simplified geothermal-specific permit application portal. Currently, geothermal developers have to apply through a non-tailored application management system, which is arduous and unintuitive. The portal could be redeveloped to be more user-friendly and tailored to the unique needs and characteristics of geothermal energy projects, as Alberta has done, making it less time-consuming and more cost-effective for new and existing geothermal energy providers.
3. That BC budget greater resources to the Energy Policy and Regulation Branch to enable increased staff to accelerate geothermal permit and lease processing.

<u>Cost Recovery</u>

In the United States, proposed federal permitting reform legislation has been complemented with cost-recovery provisions, namely in H.B. 7422 and S. 4753 In the United States, legislative cost recovery provisions would authorize the Bureau of Land Management to charge developers for the cost of streamlined permit processing to ensure the agency possesses the staffing resources needed to complete reviews.

In BC, the equivalent agency is the BC Energy Regulator (BCER), and we likewise propose a compromise of a balanced legislative package to streamline permit processing inclusive of a cost recovery provision to bolster the staffing capabilities of the Regulator. Staff who process geothermal applications should have a minimum technical knowledge of the industry necessary to understand the nuances and risks (or lack thereof) of an application. It may also be necessary for

the Regulator to create or reform training materials necessary to bolster staff knowledge of geothermal energy and streamline application processing.

We would like to see cost recovery as a temporary measure until both the Regulator and applicants have established a repeatable process with clear expectations and consistently streamlined outcomes. The key to any cost recovery is the determination of what is a reasonable cost. For instance, lawyers splitting hairs for the sake of it may be great for their billable hours but may not be fully recoverable or efficient. In other instances, it may be advisable for the Regulator to bring in consultants from developer companies. These personnel may advise on regulatory design – but not on specific project approvals—to avoid a conflict of interest.

Cost-recovery could also be launched in Alberta to likewise bolster the permitting capacity of the Alberta Energy Regulator.

3.7 Regulatory: A Geothermal-Procurement Standard

When Regulators identify new technologies, or generation sources that will improve service quality, e.g., improvements of reliability and cleanliness, the Regulator can order utilities to acquire certain types of energy or install certain technologies (BCUC, 2019). BC Hydro is already directed to seek out approximately 3,000 GWh/year of additional clean energy as early as late fall 2028 (BC Hydro, 2024). Although it would be unreasonable to mandate a public utility to purchase geothermal power from generators that is not yet available, setting a minimum standard or goal for geothermal power acquisition as part of BC Hydro's Integrated Resource Plan would compel the BCER to accelerate permit approvals and the Minister to create incentives for energy developers to add geothermal projects to their portfolios.

3.8 Regulatory: Periodic Legislated Reviews of Geothermal-related Legislation

From the perspective of members of the Canadian Geothermal Energy Association (CanGEA), there are series of potential legislative reforms in the BC Geothermal Resources Act that would improve the development landscape for geothermal energy projects, either for direct-use or power generation. Furthermore, as the industry develops, qualms and issues which have not yet arisen are nearly certain to arise. It is critical that legislation be flexible to the needs of the evolving industry. For example, BC's Environmental Assessment Act (EAA) requires a mandatory review and industry stakeholder engagement every four years. It would be in the interest of the geothermal industry that the Geothermal Resources Act (and Alberta's Geothermal Resource Development Act) also be subject to periodic mandatory review and industry consultation.

A few areas for potential review in the BC EAA are outlined below:

<u>Timeline Certainty:</u>

Currently, it is unclear when developers can expect a decision to be made on their permit applications. Timeline certainty is needed to reduce cost, risk, and investor uncertainty in geothermal projects in the province of BC. Lack of deadlines for the BC Energy Regulator (BCER) to finalize assessments represents a gap in the Geothermal Resources Act.

Decision Appeals:

Section 5(1) of the Act states, *"The minister may issue or refuse to issue a permit, whether or not the requirements of this Act have been complied with, and the refusal is final."* CanGEA proposes that an appeal mechanism instead be put in place, which represents a protection of public rights and interest.

Grounds for Refusal:

Section 12(1) states, *"Subject to the regulations, the regulator may issue, subject to conditions, restrictions and stipulations considered necessary or desirable, or may refuse to issue, a well authorization."* It would reduce uncertainty for industry and investors for the Legislator and/or Regulator to clarify grounds and criteria for refusing a well authorization.

Conclusion

Geothermal energy holds immense potential for transforming Canada's energy landscape, providing a stable, renewable, and low-emission source of power and heat. However, the industry has faced significant challenges due to policy gaps and lack of targeted support. By addressing these challenges through strategic policy and legislative reforms at both federal and provincial levels, Canada can unlock the full potential of its geothermal resources.

Federally, introducing clear frameworks for carbon offset projects, enhancing tax credits, and establishing supportive market mechanisms such as Carbon Contracts for Difference (CCFD) can provide the necessary financial stability and incentives for geothermal development. Additionally, a risk mitigation drilling fund would reduce the financial and technical risks for developers, encouraging more investments in geothermal projects.

In Alberta, the opportunity lies in leveraging existing resources and expertise to develop direct-use geothermal heat projects. Fiscal incentives, such as a dedicated geothermal incentive program and demonstration projects, can stimulate initial development. Regulatory reforms, including granting surface access rights and addressing urban drilling regulations, are essential to create a favourable environment for geothermal exploration and production.

British Columbia, with its high-quality geothermal resources, requires targeted fiscal incentives and funding parity to attract investments. Regulatory adjustments, such as encouraging geothermal offset projects, reconsidering well classifications, and streamlining the permitting process, can remove barriers and accelerate the deployment of geothermal technologies.

Ormat Technologies Inc, Reno NV, USA

Keywords

Ormat, Technical Career Path

ABSTRACT

Ormat Technologies Inc (Ormat) has recently developed and deployed a geothermal-specific Technical Career Path, covering the roles of Geology, Geophysics, Geochemistry, Reservoir Engineering, Reservoir Modeling and Drilling Engineering.

This paper will discuss the: development process, considerations and challenges that went into the Technical Career Path, the deployment process, key learnings, and, future considerations. Twelve categories were developed and new job titles determined, and the requirements of each will be shared in full in this paper to enable other organizations to benefit from this work.

1. Introduction

Ormat has one of the largest geothermal resource teams globally with over forty scientists and engineers. This paper discusses the development and deployment of a Technical Career Path for the resource team. Benefits of a department-specific Technical Career Path includes attracting talent, encouraging professional development, boosting job satisfaction, strengthening competitive advantage, and supporting succession planning. All these benefits have the benefit of improving the geothermal industry's ability to attract and maintain a strong technical workforce. It was determined to publish a paper on this process to assist other organizations in implementation of a Technical Career Path, and to assist with standardization of job titles within the industry.

2. Development of a Technical Career Path

At Ormat, prior to commencing the development of a Technical Career Path existing titles used (but not limited to) included: Chief Discipline (e.g. Chief Geologist), Principal Discipline (e.g. Principal Reservoir Engineer), Senior Discipline (e.g. Senior Geologist), Staff Discipline (e.g.

Staff Geophysicist), Discipline (e.g. Geochemist), with Staff Discipline and Discipline interchangeable depending on the technical function.

The Technical Career Path was initially developed to cover the main Geothermal Resource technical disciplines of Geology, Geophysics, Geochemistry, Reservoir Engineering, Reservoir Modeling and Drilling Engineering.

The following sections discuss the development process of the Technical Career Path.

2.1 Initial Feedback

The idea to improve the promotion process and implement a technical career path came after increasing feedback channels between management and the technical staff. Feedback channels included monthly 1-on-1's with feedback forms and anonymous surveys. Key items that came out of feedback from both 1-on-1's and a team engagement survey were:

- There was a desire to have a Technical Career promotion process
- There was a lack of clarity on the way that people are promoted, with perceptions that those closest to management were preferentially treated or those that pushed hard for themselves
- There was a lack of clarity on titles, in particular what does "Staff" mean and "Resource Engineer", and what is the relevancy of job titles to associated industries (mining, oil and gas)
- That promotion and performance needs to be linked to all the key areas in the technical career path
- The singularity of the Chief title is perceived to cap an individual's possible development
- There was a lack of clarity regarding roles/responsibilities for particular titles (i.e. expectations and accountabilities)
- Technical authorities (higher level technical roles) haven't had clear sign-off or decision-making delegation of authority.
- The expectation of coaching/mentoring between experience levels was unclear and not aligned.
- Higher level technical roles haven't been expected to help improve systems
- There was a lack of incentives or motivation to align technical roles with business objectives specifically around driving excellence or advancing workflows
- Overall we need to formalize expectations

Key items that came from feedback acquired through collaboration with other geothermal operators or professionals associated with previous major geothermal operators:

- Any technical career path needs to be specific enough to enable development planning, but not specific that it limits or achieves the wrong overall outcomes
- There is a need to prevent box-ticking that goes against the intention of wholesome development of individuals
- Recommended incentivization of specialization for individuals that delivers good team outcomes. For example, filling capability gaps within the team and not having everyone specialize in one space

- We need to ensure consistency across assessments for promotion, which is best done as a panel of technical managers to prevent inconsistencies across the team or misinterpretations
- It is important to give feedback to individuals out of assessments to give guidance for where there needs to be continued development
- Managers need to ensure they don't set expectations of promotions, to prevent false-hope and to prevent undermining the technical career assessment panel
- Ahead of getting to Senior, it is recommended to consider 3 levels to acknowledge the required progression. Having two levels prior to senior can result in a feeling of stagnation early in ones career
- Implementing a career path should be paired with a positive team-culture to prevent hierarchy becoming an issue within the group and getting in the way of collaboration and team outcomes
- There is a need to ensure collaboration, team building, coaching/coachability etc. are part of the technical career path
- Wherever possible align the technical career path with established company processes, such as training and technical career processes, however care needs to be made to ensure company processes do not work against the intent of technical development

2.2 Forward Progress

A selected group (the "foundation group") was assigned to determine a path forward to develop a Technical Career Path based on collected feedback. This group included all the functional managers and group managers across the technical disciplines of Geology, Geophysics, Geochemistry, Reservoir Engineering, Reservoir Modeling and Drilling Engineering, as well as representation from Human Resources.

Key items to determine for the group were:

- Working out how to consult with the wider team and when feedback would be sought, and how to both act on, and close-out, that feedback
- Determining the Categories/Areas that we wished to define parameters within a career path
- Determining the number of levels in the Technical Career Path
- Determining the titles that go with each level in the Technical Career Path
- Working out how and who to consult within upper management across these disciplines and Human Resources.

2.3 Development of Categories

Evaluation of other Technical Career Paths that were shared from within the geothermal industry and from associated industries, such as oil and gas, resulted in the following categories to create a comprehensive and balanced career path.

A general concept was established early that technical development alone is insufficient to capture all elements required for career development and career advancement and that other areas needed to be measured. These included 'soft-skills' and the recognition of the impact that soft-skills have on career growth, personal development, team culture, and business impacts. The resulting categories are shown in Table 1.

Table 1: Categories with specific Breakdowns for the Technical Career Path

Categories	Breakdown areas
Behaviors	• Level of Initiative & Latitude • Problem Solving • Elevating Culture
Technical	• Breadth of Knowledge • Depth of Knowledge (core competencies) • Accuracy & Relevant Application
Interpersonal Skills	• Leadership • Coaching, Mentoring & Training • Communication
Impacts	• Sphere of Influence • Business Alignment & Relevancy • Systems & Processes

2.5 Development of Levels and High-Level Measures

By being a global company it was noted that there are variabilities across some countries (whereby some cultures value a title change itself very importantly) and that some smaller start-up type companies have less issues with providing title changes (less system-impact concerns). There were concerns that to customize a system for one country that it could cause issues elsewhere that we needed to be considerate of. As the majority of our technical staffing is based in the United States of America, it was determined that the framework should be structured primarily for this market and made to have slight adjustments to factor in cultural considerations for our technical team in Indonesia.

Factoring in feedback, it was determined we would have three levels prior to Senior with a purpose of enabling development steps and measuring progress at a reasonable timeframe. This was the primary driver, however a consideration was made to prevent risk of overt hierarchy and that perhaps the external facing title would stay similar.

As part of the determination of the levels, the foundation group worked to develop simplified high-level measures which are noted in Table 2.

Consideration was made if there was a need to have either one or two levels above Senior, and in the end it was determined to have two. This was for two reasons:

1) There were already Principal and Chief titles within the organization, thereby to some level there was already establishment of two levels above Senior
2) Feedback from other companies felt that if there is only one level above Senior, then the obtaining of Senior may be challenging and perception related to other companies or industries that the granting of the title will be late. This increased the risk of staff turnover if this was to occur.

Table 2: Levels of the Technical Career Path with simplified High-Level Measures

Level	High Level Measures
7	• *Industry title level of Chief, Head, Advisor or Senior Advisor etc* • Regarded as absolute industry-leader across broader geothermal and discipline • Significant track record of mentoring, training, adding significant business value, guiding business strategy
6	• *Industry title level of Principal* • Limited routine project work, or significantly reduced levels. Major focus on mentoring, processes, reviewing etc, and special projects • Regarded industry-wide, internal technical leadership group
5	• *Industry title level of Senior* • Can lead a joint-venture or acquisition process from a technical perspective factoring in business and cultural considerations • Mentoring others consistently occurring, wide-ranging influence in business • Fully developed capability across all core disciplines
4	• Sphere of influence increasing • Within company regarded for specialization within a core competency of the discipline, continued advancements of all core competencies and broader knowledge across all disciplines
3	• Technical knowledge and ability across all core competencies has developed, broadening knowledge across all associated disciplines • Given projects to be primary on without extensive oversight
2	• Entry level for roles from University (or early career), even with Masters or PhD, extensive mentoring and direction provided • Developing core competencies, developing broad knowledge across all disciplines
1	• Entry level for fixed-term internships

It was important to also note internships, which at this stage have not been factored into the matrix to-date as it is relatively self-explanatory.

2.5 Development of Titles

Titles were initially proposed as per Table 3, which was to use the existing titles wherever possible and to try a new title in place of Chief to remove the association with this being a singular title.

One of the existing titles within Ormat was the title of Staff (e.g. “Staff Geologist”) which was beneath the Senior title and was used for some technical disciplines and not others. Within associated industries and within Ormat, the title of Staff had different feelings associated with it. In some cases, it sat beneath a straight discipline title, and sometimes it sat above Senior. Therefore, it was noted that the title of Staff was confusing in-particular when advertising for recruitment purposes. A more appropriate title was proposed, and this was the title of “Project”. This was felt to be more relevant, as we have numerous operational and exploration projects.

In consultation on moving the title from Chief to Advisor, it became apparent that the title of Advisor has a connotation with sitting outside a team to a certain level and that this role isn’t so much within the workflows and only provides advice. Therefore, the existing title of Chief was retained and there was a re-definition that the title is not intended to limit to one individual per discipline. As a part of the implementation, a promotion was made within one of the disciplines that resulted in the appointment of a second Chief which further reinforced the lack of singularity. It should be noted that not every discipline has a Chief, and that the integrity of the Technical Career Path matrix takes precedence over desires of titles through guiding and informing progression within the framework.

Table 3: Connection of Technical Career Path Levels with the Titles

Level	Titles as Initially Consulted	Titles Implemented
7	Advisor	Chief
6	Principal	Principal
5	Senior	Senior
4	Staff II	Project II (external facing - “Project”)
3	Staff I	Project I (external facing - “Project”)
2	Discipline	Discipline
1	Intern	Intern

One of the other items that was changed was that all “Resource Engineers” had a job title to “Reservoir Engineer” to align with external companies and associated industries. It was felt that this change would increase the relevancy of job advertisements and the likelihood of getting suitable candidates.

2.6 Development of Matrix

A matrix was developed that is in the Tables and Pages that follow this section. Key components of the development of this matrix were:

- The matrix was initially put together by one member of the foundation group and then there were multiple sessions to review this by the whole group, whereby the initial member didn’t participate in the initial review. This was to get alignment and ownership by the rest of the group and to enable a meaningful review.
- That there needed to be a continuum and evolution through the levels. For example, under “Level of Initiative & Latitude” was going from received direct guidance, detailed review

and supervision (Discipline) through to having significant autonomy to ensure the team and company is a world leader in its work and outcomes (Chief). This is consistent with good people management approaches around Autonomy as covered in Pink (2009).

- There was a need to balance the level specificity with broad outcomes to prevent box-ticking activities whereby people chase a promotion and not necessarily the development itself.
- At the Discipline and Project levels there is a general focus on: investing in your own development; achieving positive results; showing improvements and closing gaps; and, aligning behaviors with expectations.
- At the Senior, Principal and Chief levels there is a general focus on: investing in other team members development and growth; supporting achievement of the company's goals; growing standards and ways of working; and, being a role model for behaviors to all team members.
- It was acknowledged that improvements would be made to the matrix over time after each promotion review round factoring in feedback from the review group.

		Level - Title					
	Category	**2 - Discipline**	**3 – Project I**	**4 – Project II**	**5 - Senior**	**6 - Principal**	**7 - Chief**
Behaviors	Level of Initiative & Latitude	- Receives guidance and detailed review on many aspects of work - Requires mentoring and supervision of work products - Ensures completion of work assignments consistent with basic knowledge - Initiates routine procedures and seeks out mentors as needed for progress	- Receives moderate guidance from mentor(s) and peers - Capable of being the Project lead and will proactively check in with technical mentor(s) - Proceeds on own initiative or judgement with occasional supplementary coaching and progress reviews	- Complete assignments based on general objectives - Proactively proceeds on work with complete ownership - Responsibilities requires high dependability for being on-top of all elements of work and delivering work outputs, without follow-up being required - Utilizes resources, stakeholders, and technical mentors appropriately and proactively	- Demonstrates consistency in providing information and data - Ensures team and direct management are well informed - Deliverables include strong and accurate technical recommendations - Takes the initiative to organize technical work for appropriate distribution to all stakeholders	- Consistently proactive, with a high level of initiative to independently determine work objectives for self and team - Focuses effort of self and team for accuracy of impact	- Autonomy to ensure the team and Company is a world leader in its work and outcomes
	Problem Solving	- Capable of supporting others with working through problems - Can provide and process data/information that supports the team or objective	- Capable of defining problem statement and putting together a proposed method to approach problem - Able to identify resources required and their availability and actively seeks these resources as-required	- Capable of complex problem solving - Demonstrates creativity in managing problems to reach a solution	- Robust in using first principal approaches when problem solving - Utilizes both internal and external resources as appropriate - Introduces external best-practices based on industry knowledge and standards	- Guides wider team(s) to correct problem solving approaches and tools - Conducts problem solving for highly complex problems with high-impact - Develops solutions to problems where few precedents exist	- Track record of problem solving with high-impact across the Company
	Elevating Culture	- Maintains a learning mindset - Able to give and receive feedback in a constructive manner - Must be a consistent collaborative member of their team - Contributes to harmonious team culture	- Actively participates and contributes to team discussions - Develops and engages in understanding international cultures that facilitates teamwork and partnership - Cultivates a positive team environment in all situations - Actively interested in others work and how their work affects others	- Is consistently highly proactive - Delivers outcomes and results consistently	- Maintains team standards and consistently provides timely, specific and constructive feedback to others - Leads conversations within team settings, no matter the composition of the team - Supports onboarding new staff - Celebrates success and provides appropriate recognition	- Complete awareness of team-wide work activity and culture - Comes in at the right time and level with an appropriate style for the situation - Sets and maintains high team standards	- Presence on staff is highly-regarded industry-wide and is favorable for recruitment of employees

		Level - Title					
	Category	**2 - Discipline**	**3 – Project I**	**4 – Project II**	**5 - Senior**	**6 - Principal**	**7 - Chief**
Technical	Breadth of Knowledge	- Learning company ways and fundamentals of the industry - Training in the use and application of basic principles, techniques, and tools as assigned - Developing proficiency with appropriate software applications, computing tools, and other tools associated with the role - Clearly understands the role & responsibility of others and their importance to add value and achieve company objectives	- Maintains and expands technical knowledge through practical application - Able to compile, organize, and interpret data - Familiarity with Project management frameworks (e.g. PMI – PMBOK) - Clear understanding of roles and responsibilities and interface with business partners and stakeholders	- Capable of being relied upon as part of any due diligence activities within their technical area - Broad knowledge of all associated disciplines - Has conducted basic project management training and now possess a high familiarity with Project frameworks and operates seamlessly within this framework	- In-depth knowledge of key components of all associated disciplines - Experience across the full value chain of geothermal (exploration, development, and operations) - Capable of leading a multi-disciplinary team for any due diligence or joint-venture activities - Capable of handling work or assignments that are not part of one's normal work routine - Solid understanding and practice of project management, able to produce PM documentation, e.g., business cases, work programs, project summary presentations and project lookbacks	- Deep understanding of more than one geographic area (with significant working experience) - Functional experience working across multiple geothermal reservoir types - Wide understanding of all geothermal reservoir types and intimate knowledge on how that impacts ones own discipline as well as broad knowledge on impacts on other discipline areas	- In-depth global knowledge of geothermal resources across all geological types - Knowledge of all disciplines associated with Geothermal
	Depth of Knowledge	- Maps out core competencies to address gaps for development and learning plan - Commences taking proactive steps to learn and develop core competencies - Converts data into information under supervision	- Has developed understanding of core competencies and demonstrates ability to operate independently within own discipline, with frequent check-ins and feedback from technical mentors - Clearly understands limitations of current knowledge of core competencies	- Continued development of core competencies - Increased trust and reliance on the delivery of technical work - Has developed specialization of at least one core competency that is regarded as being company and industry leading	- Full development of all core competencies - Able to teach and train core competencies either internally or externally (e.g. to new staff)	- Ensures the correct methodologies are applied for analysis within the team - Creates new tools and methods as required to develop a world class team - Considered industry expert within discipline	- Develops innovative tools and methods to ensure Company deliverables when no other approaches are known
	Accuracy & Relevant Application	- Dependable and uses sound judgement in all activities - Discusses approach in-advance and consistently checks in on it	- Utilizes technical knowledge to achieve measurable and relevant outcomes	- Delivers quality work and high throughput - Recognizes and captures uncertainty and risk in work	- Successfully leads work activities that are multi-disciplinary in nature - Applies knowledge that results in meaningful value to the Company	- Consistently demonstrates results with innovative application of knowledge, resulting in exceptional value to the Company	- Recognized internally & externally for ensuring analysis or problem solving is always conducted with world-leading approach

		Level - Title					
	Category	**2 - Discipline**	**3 – Project I**	**4 – Project II**	**5 - Senior**	**6 - Principal**	**7 - Chief**
Interpersonal Skills	Leadership	- At all times represents the company positively in alignment with company values - Working towards taking on primary roles on projects	- Has responsibility on specific projects as a technical project lead - Organizes and achieves progress on projects that are under their responsibility	- Leads members of other disciplines and departments towards project outcomes - Proactively works with peers to achieve objectives on projects as a team, even if not within own direct responsibility	- Demonstrates leadership in creating new projects and business opportunities - Resolves and manages technical conflict amongst peers - Acts in an ethical manner and delivers a presence of professionalism and role modeling	- Leads major technological advancements with significant added impact - Prioritizes time availability for the benefit of others - Changes approach and style to the situation successfully - Reviews technical work in a timely, appropriate, and proactive manner - Inspires and holds team accountable for technical standards and outcomes - Consistently acts as a leader no matter the setting	- Cultivates relationships and ensures a highly ethical team relationship - Highly respectful relationships in all settings, based on style and track-record - Seen internally and externally as a true leader for their track-record in lifting both the Company and Industry
	Coaching, Mentoring, & Training	- Willingly works with more senior technical peers to receive coaching, mentoring and training - Proactively participates and works through internal training opportunities - Able to give and receive feedback in a constructive manner	- Seen to be significantly improving in all aspects through actively engaging with coaching, mentoring & training.	- Capable of providing formal training in a particular areas of expertise - Recognizes opportunities to train and mentor, and acts upon them - Can oversee interns successfully	- Motivates and develops team utilizing effective training & mentoring - Prioritizes team development and learning over providing the direct answer themselves	- Major focus on targeted & efficient broader team training - Works with management to develop training plans within the team - Trains and develops other stakeholders to achieve business objectives - High awareness of team and individual competencies to identify gaps and to rectify these	- Ultimately provides confidence to upper management that the capability of the team is world-class, through ensuring appropriate coaching, mentoring & training is conducted within the wider team across all competencies
	Communication	- Can prepare technical insights in a suitable communication method - Can prepare and deliver an effective presentation - Asks insightful questions - Correctly utilizes company templates for communication	- Able to provide clear recommendations in a suitable communication method for the audience - Ensures details are correct in any communication method - Can prepare and deliver logical, well-supported presentations to peers, management and immediate stakeholders - Consistently professional in all communication channels - Communicates to the right stakeholders consistently	- Consistently utilizes the right communication channel and approach for the situation in a timely manner to achieve an outcome - Capable of writing conference-level technical papers and reports	- Ability to communicate complex technical matters to general audiences and influence thinking - Reviews others work and provides impactful feedback to improve communication - Ensures transparency through timely and appropriate communication by self and to the team	- Continued development in ability to communicate highly technical matters to appropriate audience - Able to provide board-level communication (e.g. papers and presentations) - Capable of writing journal-level technical papers	- Commands clear communication and presentations to any audience type or level (e.g. general population, board, highly technical forum etc.)

		Level - Title					
	Category	**2 - Discipline**	**3 – Project I**	**4 – Project II**	**5 - Senior**	**6 - Principal**	**7 - Chief**
Impacts	Sphere of influence	- Limited to manager and immediate work group	- Sphere of influence expands to peers in other work groups within technical realm - Acts as a primary point person for projects to other business units (e.g. Business Development or Operations)	- Sphere of influence internally increasing wider to key stakeholders	- Influence extends to industry and relevant professional bodies - Regularly represents the Company at industry or stakeholder meetings	- Regarded highly by industry and professional bodies - Well known and respected by executive management internally with a track record of performance and results	- Known and highly respected by other major geothermal operators - Proven track record that commands respect instantly both internally and externally
	Business alignment & relevancy	- General awareness of business drivers - Basic understanding of economics and financial drivers	- Applies basic economic/risk analysis to projects. Can produce a simple economic analysis - Possess basic knowledge of projects and power plant operations, - Understands the impacts of own work on project schedule, cost and quality - Prioritizes work to align with Company objectives	- Can produce economic calculations - Factors in risk and uncertainty consistently into work conducted - Understands impacts of own discipline to other projects, power plant operations, Business Development, etc; and vice-versa	- Work and projects fully consider risk and uncertainty - Utilizes economic calculations factoring in risk/uncertainty to prioritize work - Driving decisions to optimize project schedule, cost and quality	- Utilizes economic calculations, factoring in risk/uncertainty, to align Company objectives with opportunities identified - Understands how new and evolving technologies impact business unit and Company objectives	- Consistently drives business strategies in the right direction - Consistently drives industry, education organizations, agencies and others towards business objectives
	Systems & processes	- Gains knowledge of business systems & processes	- Uses business systems & processes (including tools) consistently and correctly - Identifies areas for improvement within own business unit's systems & processes	- Drives improvements of systems & processes within own business unit - Ensures engagement to deliver results in a high-quality manner	- Accountable for the use of systems & processes correctly - Technical authority within certain processes (e.g. drilling) that requires accuracy and relevance - Innovates to improve and build tools to improve business systems & processes, with reason and logic - Documents processes & systems clearly in a high-quality manner	- Proactively benchmarks systems & processes used against other geothermal companies and related industries to ensure Company is world-class with foresight to upcoming trends and implications to Company - Takes ownership within group of particular systems & processes and ensures continued relevancy	- Track record of consistent delivery implementing systems & processes that result in meaningful impacts

2.7 Technical Career Path – Promotion Review Process

A promotion review process occurs twice per year. Some key components to note are:

- The technical review group is made up of all the functional managers of the disciplines, even if no nominations have been made for their specific function/discipline
- Observing the process, and ultimately signing off on the outcomes are the Vice President(s) of the two groups: Exploration & Resource Management; Drilling.
- Nominations would be made by managers ahead of the review process
- Nominations can be made by any manager of any individual within the process, to prevent bias against any particular individuals
- An in-person review process is held, and discussion is made on each individual throughout the matrix. Consideration is made for comparisons to others throughout this process to ensure consistency in application. This review process has been found to take at least half a workday of time.
- Active debate is encouraged within the technical review group, as this group is there to balance bias that is overly critical or overly generous. Oversight from the Vice President(s) helps ensure the process is consistent and biases are not in-play.
- There needed to be achievement of all twelve categories of the Technical Career Path Matrix to enable promotion to occur.
- Notes are captured to enable development conversations for those who do not achieve a promotion, and feedback is then provided afterwards to the individual. This is to be fed back into the individuals development plan.

A key learning has been the need to have 6-monthly reviews to prevent bias towards providing a promotion for the lower levels in the Technical Career Path. In addition, one promotion round should be conducted around the company annual review process. Considerations for higher roles such as Senior, Principal and Chief should realistically only be done around the annual review process.

3. Learnings and Future Considerations

As a high-level sign of success, the following year's engagement survey resulted in no comments related to the Technical Career Path, with focus on other items instead. This is considered a success.

Key learnings include:

- It is important to get organizational buy-in to the deployment of a Technical Career Path. As part of this, having the need clearly articulated through something such as an engagement survey assists in achieving buy-in.
- The development, deployment, and on-going utility of a Technical Career Path takes significant effort and drive, and that the easy path is to not do it. There is a balance point whereby the size of the team covered by this makes the effort worthwhile.

- Review processes need to be 6-monthly to prevent bias towards providing a promotion for the lower levels in the Technical Career Path
- Changes to job titles, with the removal of Staff and the implementation of Project has worked well. The movement from Resource Engineer to Reservoir Engineer has also resulted in more relevant applicants during hiring processes.
- Attempting to keep the Project title external facing and to behind the scenes track Project I and Project II has been difficult with issues throughout the HR systems, job descriptions, pay benchmarking etc.
- Updating of job descriptions with inputs from the Technical Career Path is essential to ensure full alignment of expectations for each level.

Future considerations include:

- Improve how to determine when someone is ready for consideration for promotion, i.e. should there be a self-evaluation of readiness, or should nominations only come from management? Ideally we would have some form of 360˚ evaluation.
- Adding specific training requirements, which can be conducted within your organization to the matrix is important. An example is that there has recently been deployment within the company of things such as: the Project Management Institute's project management processes and associated PMP® or CAPM® qualifications; and, the Blanchards SLII® leadership model.
- Not all technical disciplines within the business, such as engineering, have a structure such as this, and there are abilities to widen the scope in a more meaningful company-wide manner.
- A need to align Behaviors and Interpersonal Skills with a company-wide competency model, with provision for learning and training options.
- There is a need to widen the scope of the Technical Career Path for other disciplines, such as technician roles or smaller disciplines such as Artificial Lift.

Acknowledgement

The authors would like to thank all those involved in the process of consultation and deployment of the Technical Career Path, with special thanks internally to Shimon Hatzir, Liza Tavori and Nidia Rivera for their support and sponsorship. Lauren Riemenschnitter was instrumental in enabling this work. Thanks also go to those who were available for industry history of Technical Career Ladders or Paths from other companies, in particular to Bill Cumming, Lutfhie Azwar and Ian Richardson.

ABSTRACT

The geothermal community is well established with long-standing events, organizations, and tools that are known across the geothermal community. But many of these tools and resources are located behind pay walls, require memberships, or are otherwise difficult to find, especially for people looking to join the geothermal community. These barriers to access can prevent outsiders from discovering valuable geothermal resources, limiting the geothermal community's potential for collaboration with other communities, such as clean energy entrepreneurs looking to expand into geothermal energy. The Department of Energy's (DOE) GeoBridge serves to bring these communities together by acting as a single, publicly accessible, searchable portal that facilitates easy access to available geothermal knowledge and information. It works to expand and diversify the pool of geothermal stakeholders by providing in-roads to geothermal information and community resources. It helps build a stronger geothermal community; one inclusive of individuals and groups from a variety of different backgrounds, including potential investors and start-up companies looking to accelerate innovation in geothermal technologies.

By linking communities to geothermal information, analysis and expertise, GeoBridge serves as a launch point, directing interested parties to existing data and tools, events, educational resources,

STEM programs, permitting and regulatory information, and other resources that can be used to evaluate, promote, and discover geothermal opportunities.

1. Introduction

Geothermal technologies such as Enhanced Geothermal Systems (EGS) and Ground Source Heat Pumps (GSHPs) have been gaining national attention over the last several years, boosted in part by high-profile projects like Google's project with Fervo Energy (McDermott 2023). As more people become interested in geothermal, many of them, especially those in professions adjacent to geothermal technologies or in other industries, are finding it challenging to get connected to the resources they need to join the geothermal community.

The National Renewable Energy Laboratory (NREL), working with the Department of Energy (DOE) and an advisory board comprised of geothermal experts from many different segments of the geothermal community, have identified the need for an aggregate information portal to address gaps in information that are making it difficult for some communities to get started in geothermal. A cursory analysis identified 9 user communities facing notable information gaps. In some cases, the information they seek is simply not available, while in others, it is hidden behind membership or pay walls, invisible to search engines, or otherwise undiscoverable.

DOE's GeoBridge facilitates easier access to geothermal knowledge and information by making it universally accessible to all, and by bridging knowledge gaps that exist between the established geothermal community and the 9 user communities identified below. (GeoBridge 2024).

GeoBridge works to expand and diversify the pool of geothermal stakeholders to help build a stronger geothermal community; one inclusive of individuals and groups not traditionally linked to geothermal research and analysis, including potential investors, municipalities interested in geothermal and start-up companies looking to accelerate innovation in geothermal technologies.

2. Origins of GeoBridge

An early example of the need for GeoBridge came from the DOE Geothermal Data Repository (GDR), which provides free, universal access to geothermal data. Each dataset on the GDR has a primary Point of Contact (POC) listed to allow users to ask detailed questions about the data contained with the dataset, such as the conditions and methods used to acquire the data, any assumptions made, or other questions critical to understanding the data. The GDR also has links that allow users to "Contact GDR Help" to ask questions about the GDR platform itself or request technical assistance with data submission (Weers et al 2022). However, recent inquires to both these communication channels have illuminated potential gaps in information that could be making it challenging for outsiders to join the geothermal community. The GDR Help team along with numerous dataset POCs and other geothermal subject matter experts have reported fielding a growing number of questions unrelated to their established communication channels.

GDR Help, for example, has recently been receiving questions such as, *"What colleges or universities should I be considering if I want to have a career in geothermal energy?"* and *"What events should I attend to meet geothermal professionals or learn more about emerging geothermal technologies?"*

While the answers may seem obvious to many, it's important to recognize that the geothermal community is well established with long-standing events that require little-to-no advertisement to garner participation. Events like the Geothermal Rising Conference (GRC) and the Stanford Geothermal Workshop are well known to those already in the community. Their cadence and locations are stable, predictable, and familiar to those that have been before. However, these events and others are not easily discoverable through conventional means, including internet searches. This is but one example of an information gap identified by the GeoBridge team. Additional gaps are listed in *Section 3: Identified Information Gaps*.

2.1 Information Accessibility and Discoverability

It is important to fully recognize and appreciate the likely journey an information seeker has undertaken prior to emailing the GDR Help team. On the road to answers, people asking questions like those above do not start with an email to the GDR Help team. More likely, they begin their journey at a search engine or by asking their question to an Artificially Intelligent (AI) chat bot; in both cases expecting an instant response. Yet, at some point in their search, these information seekers are arriving at the GDR, finding the GDR Help email (located under the Help menu or in the footer of each page), opening an email program, typing their question in an email to an unfamiliar recipient and then awaiting a response. This is not an efficient way to get information in the modern world. Sending an email to GDR Help is often a last resort, the (presumably) final attempt of a desperate information seeker.

The questions above, and many more like them, are indicative of larger gaps in the availability of relevant geothermal information. Whatever the answers may be, we can assume that they are not easily discoverable through conventional means.

2.2 Community Engagement

The GeoBridge team reached out to geothermal subject matter experts across the geothermal community to identify information gaps. Many of the experts had recently fielded similar queries from students, job seekers, startup companies, regulators, utilities and more. The people in these communities were clearly struggling to find answers to their questions and were otherwise unable to engage the geothermal community.

The primary objective of GeoBridge is to bring these communities together to improve diversity in geothermal energy and bridge the gap between established geothermal communities, emerging startups, and the next generation of the geothermal workforce. To fulfill that objective, the GeoBridge team established an Advisory Group consisting of experts and representatives of many different aspects of the geothermal community.

2.2.1 Formation of the GeoBridge Advisory Group

The GeoBridge Advisory Group was formed in early 2024 and contains members from industry, non-profit organizations, universities, DOE, national labs, international associations, installers, state energy offices, and the Women In Geothermal (WING) network. The group is also representative of the many aspects of geothermal technologies, with experts in EGS, GSHPs, direct use, low temp, analysis, policy, and development. The GeoBridge Advisory Group was selected to be representative of the geothermal community at large and tasked with assisting the GeoBridge team with the identification information gaps and the prioritization of efforts to address those gaps.

3. Identified Information Gaps

The following information gaps have been identified and prioritized by the GeoBridge team through conversations with the GeoBridge Advisory Group and interviews with industry professionals, geothermal experts, and other stakeholders. These gaps are organized by community along with examples of their respective needs and described in the sections below:

Section	Community
3.1	**Entrepreneurs** looking to introduce their technology into the geothermal space
3.2	**Professionals** looking to find and build a career in geothermal including work force development and training for the next generation of geothermal workers
3.3	**Homeowners and Businesses** interested in learning how heat pumps can save them money
3.4	**Students** looking for studies programs that will set them up for a career in geothermal
3.5	**Organizations** looking to generate more interest in geothermal projects and job openings
3.6	**Teachers** looking to integrate geothermal learning into their lesson plans
3.7	**Policy Makers** looking to introduce geothermal into their communities and educate their constituents
3.8	**Utilities** looking for guidance on how to incorporate geothermal energy into their future plans
3.9	**Regulators** looking for assistance and best practices for approving and monitoring geothermal systems

Table 1. Identified information gaps organized by communities and their respective needs.

3.1 Entrepreneurs looking to introduce their technology into the geothermal space.

DOE initiatives such as GEODE (DOE GTO 2024) are helping to address technology and knowledge gaps in geothermal through the transfer of technology, expertise, and best practices from the oil and gas industry. Many other efforts already bridge the gap between geothermal and oil and gas, however there are numerous other industries, both established and emerging, with geothermally relevant technologies that are struggling to make a connection. The GDR Help email has received inquiries from startup companies specializing in high temperature electronics, special cements, and advanced sensing technologies such as Distributed Acoustic Sensing (DAS), each looking to expand into geothermal energy, but unsure of who to talk to, what events to attend, or how to get connected with geothermal experts.

3.2 Professionals looking to find and build a career in geothermal

It is difficult for outsiders with geothermal-relevant skills to discover opportunities in the geothermal industry. This is especially relevant to GSHP companies who are struggling to find certified installers and technicians (IGSHPA 2024). Many people aren't aware that their existing skills are applicable to geothermal technologies while others are searching for ways to advance their careers in geothermal. Increasing awareness of training and certification programs can help with workforce development. Additionally, links to prominent geothermal employers and their job boards can provide additional pathways for others to advance their geothermal careers.

3.3 Homeowners and Businesses interested in learning how heat pumps can save them money

Interest in GSHPs has grown considerably in recent months. Searches for GSHP incentive programs, average costs and the feasibility of installation by region have increased by as much as 1,200% in the last two years (Google Trends 2024). However, an in-depth analysis of the search terms used and the resources available indicated that homeowners and businesses alike were failing to find the unbiased information they need to make informed decisions. The GeoBridge team found that members of these communities are often turning to Reddit forums, friends, neighbors, and other unvetted sources to find answers to their questions. Furthermore, incentive programs for GSHPs can be difficult to find as they often toe the line between energy efficiency and green building programs and will appear inconsistently in lists of one or the other depending on region and funding source.

3.4 Students looking for studies programs that will set them up for a career in geothermal

Many of the inquiries received by the GDR Help team were from high school students and undergraduates interested in a career in geothermal, wanting to know which schools are the most involved in the geothermal community and which degree programs are most likely to be valued by hiring organizations.

3.5 Organizations looking to generate more interest in geothermal projects and job openings

Geothermal organizations frequently share their progress, project updates, and job openings during popular geothermal events, but these announcements often do not reach beyond the established geothermal community. GeoBridge is built upon OpenEI's wiki making it easy for others to contribute to topics and provide additional information. Users can leverage this structure to advertise their projects and successes to a broader network and connect with new audiences and communities to help fill open positions.

3.6 Teachers and educators looking to integrate geothermal learning into their lesson plans

Energy education is critical for the adoption and acceptance of new and innovative technologies. However, geothermal is typically only a small piece of renewable energy education. While geothermal energy appears to be easily understood within the confines of a textbook, it is difficult to illustrate in hands-on activities. GeoBridge includes a variety of resources for teachers and educators such as hands-on activities and lesson plans broken down by appropriate grade level, with examples of standards and corresponding materials (e.g., Next Generation Science Standards).

3.7 Policy Makers looking to introduce geothermal into their communities and educate their constituents

Policy makers, including state and local energy offices, are struggling to find the information they need to affect long term changes in their energy grid, including the adoption of geothermal technologies. Even in communities where there is considerable motivation to adopt geothermal technologies, community leaders still need assistance crafting effective policies and regulations, and educating their constituents on the benefits, economics, and potential job opportunities of geothermal technologies.

3.8 Utilities looking for guidance on how to incorporate geothermal energy into their future plans

Utilities interested in geothermal energy are struggling to find the information they need to make informed decisions. They are finding it difficult to sort through the multitude of tools and resources available, to identify information that is current and relevant to their service territories.

3.9 Regulators looking for assistance and best practices for approving geothermal systems

The classification of GSHPs varies from state to state, with some states classifying them as water wells, requiring additional permits and restricting proposed locations. The approval of new geothermal projects in these areas often depends on the limitations of outdated or potentially unrelated regulations, and in some areas can prevent GSHP wells from existing beneath residential structures (Gergely et al 2023). The regulations, best practices and lessons learned from communities with high GSHP adoption rates could help expedite the adoption of geothermal technologies in other areas.

Similarly, as EGS technologies begin to expand to other regions across the country, states less familiar with regulating geothermal technologies are seeking technical assistance and information on regulatory best practices.

4. Bridging the Gaps

GeoBridge is working to bring these communities together by acting as a single, publicly accessible, searchable portal that facilitates easy access to available geothermal knowledge and information.

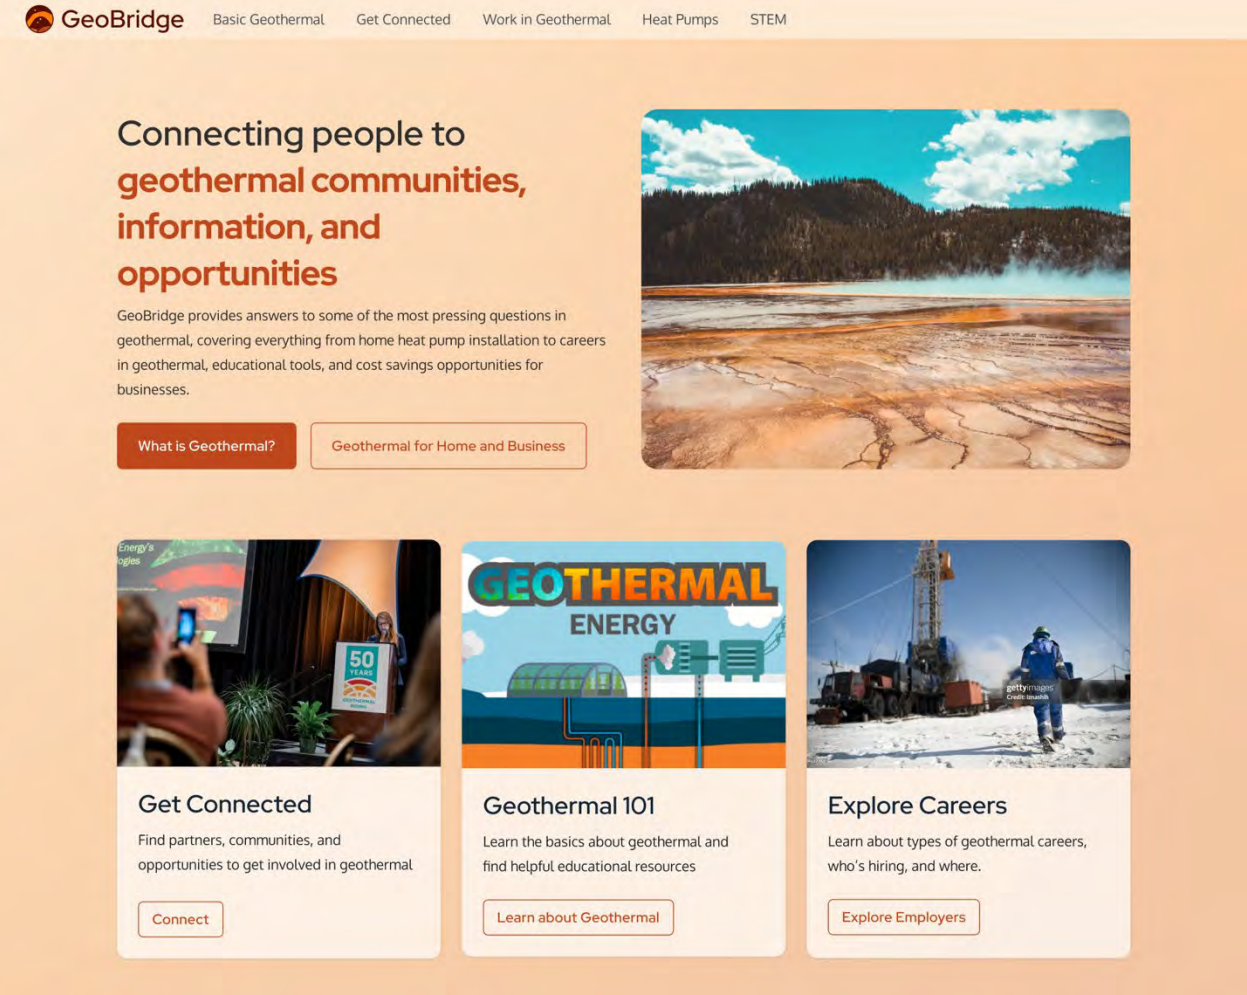

Figure 1 GeoBridge home page and main site navigation.

The GeoBridge site has been organized around the needs of the communities and information gaps identified in Table 1. The collective needs of these communities were clustered into common themes, which formed the basis for the main navigation. Additional pathways to information are featured in tiles on the homepage (Figure 1), which have been designed to align with common questions about geothermal pulled from recent inquiries to the GDR team and an analysis of search terms being used on major search engines.

In addition to the homepage and main navigation, GeoBridge features focus pages tailored to information from each of the common themes identified across the target communities. For example, a page on how to get connected within the geothermal industry (Figure 2) helps entrepreneurs, businesses, students, and aspiring professionals find the events, resources and connections they need. These content pages were prioritized by the GeoBridge team and the Advisory Group based on community engagement and outreach efforts and are designed to maximize the impact of GeoBridge's efforts to bridge the information gaps identified above.

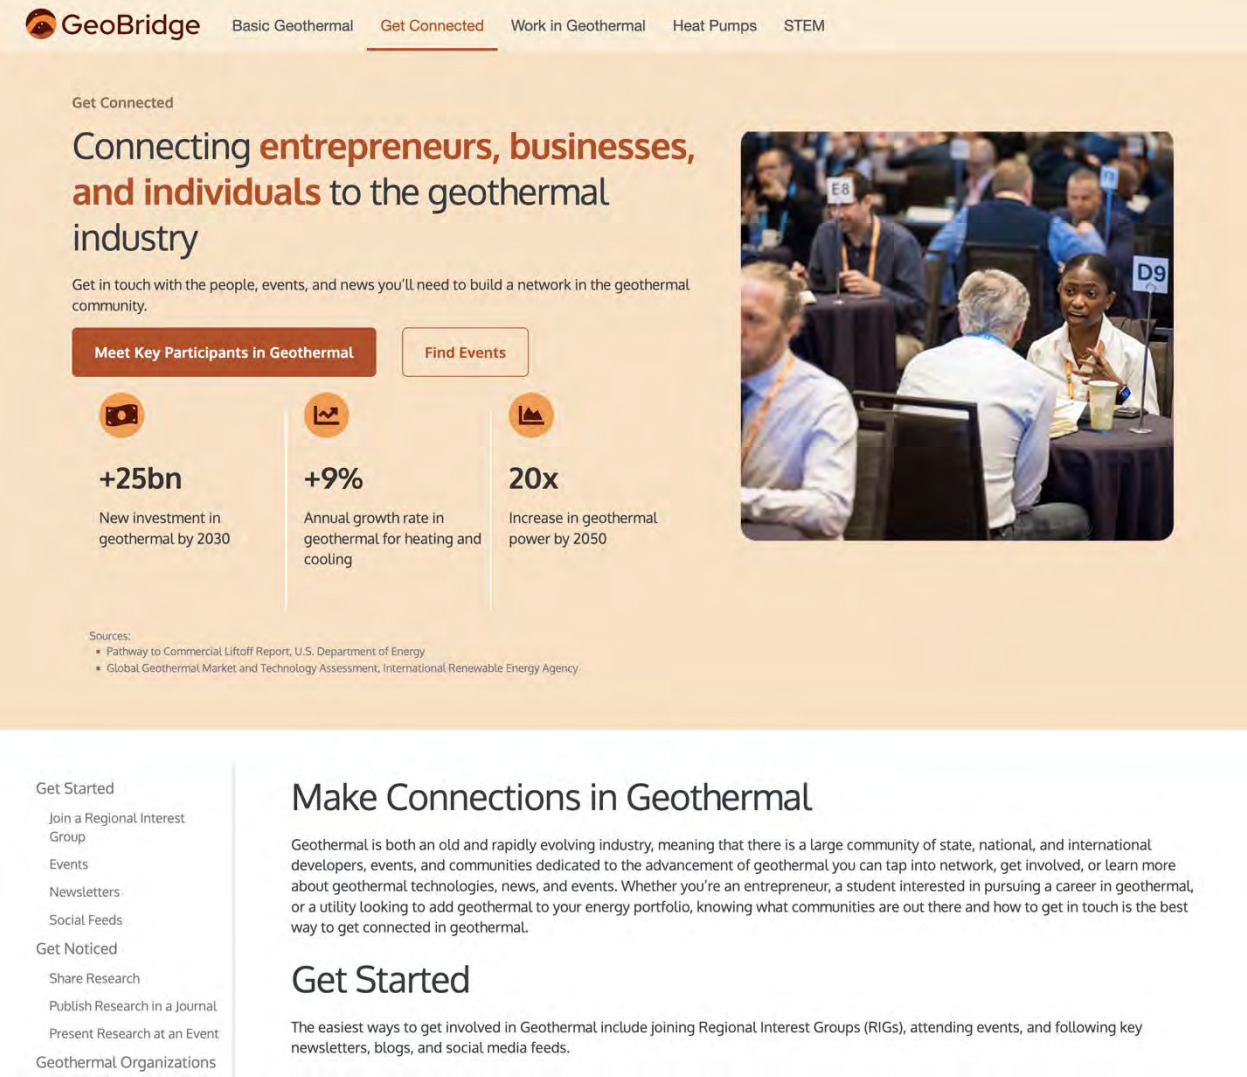

Figure 2 GeoBridge focus page for entrepreneurs, businesses, students, and aspiring professionals looking to make connections in the geothermal industry.

4.1 Content Roadmap

Content development and organization activities included in the initial launch of GeoBridge were outlined in a Content Roadmap developed from the gap analysis and prioritization efforts of the GeoBridge team, DOE, and the Advisory Group. The Content Roadmap also outlines future development efforts planned for Federal Fiscal Year 2025 (FY25), which include providing additional information and resources for:

1) Entrepreneurs looking to accelerate the development of their technologies, seek additional funding, or collaborate on new projects with existing geothermal teams.
2) Homeowners and businesses interested in GSHPs looking for an impartial, reliable source for information on the cost and feasibility of GSHPs in their local area.

3) Professionals seeking careers in geothermal or looking to apply their skills toward geothermal ventures.
4) Students interested in geothermal-relevant graduate programs.
5) Teachers looking for resources and experiences outside of the classroom such as geothermal field trips.
6) Work force development resources and additional information on training and certifications needed to become GSHP installers, technicians, and other supporting trades.

4.2 Built on OpenEI: Open Energy Information

GeoBridge has been developed in the OpenEI wiki, enabling quick and easy content updates and allowing the geothermal community to assist in keeping resources and links up to date. OpenEI uses a Semantic Mediawiki hosted in a secure cloud environment to provide universal access to energy information. Launched in 2009 as part of the White House Open Government Initiative (Brodt-Giles 2009), information on OpenEI is freely available and is accessible online through web browsers and numerous Application Programming Interfaces (APIs), making it a powerful and effective information dissemination engine. It is currently home to over 50,000 content pages and more than a dozen energy-related data and analysis applications.

By leveraging the OpenEI platform, GeoBridge content is easily discovered by search engines and is automatically disseminated to dozens of other sites.

4.3 Avoiding Duplication of Effort

GeoBridge helps users find the information they need without generating duplicative content. In cases where pertinent information already exists online, GeoBridge points to the best sources for that information. For resources with difficult to discover information, such as information behind membership or pay walls, GeoBridge acts as a guide providing users with the additional context needed to access the information they seek.

The GeoBridge team coordinates closely with the GeoBridge Advisory Group, which includes operators of other geothermal information portals, who help ensure that GeoBridge efforts are complimentary to the ongoing and future efforts of other sites. The GeoBridge team is working closely with Geothermal Rising, IGSHPA, and state energy offices to address these gaps across the geothermal information space and to serve the needs of the communities identified above without being duplicative.

5. Conclusion

Users of GeoBridge are able to answer their questions, make connections, and find useful inroads into the established geothermal community through links to existing knowledge hubs, databases, and websites from a variety of sources, including other national labs, energy.gov, Geothermal Rising, the International Geothermal Association (IGA), state and local geothermal hubs, and more.

GeoBridge creates pathways to information not currently available or easily discoverable and makes it easier for outsiders to find information and opportunities within the geothermal industry. It helps to expand and diversify the larger geothermal community by bridging gaps to geothermal

information and community resources. As a result, it helps build a stronger geothermal community; one inclusive of individuals and groups from a variety of different backgrounds, including potential investors, clients interested in geothermal and start-up companies looking to accelerate innovation in geothermal technologies.

Downhole Logging

Innovative E-line Intervention Solutions for Geothermal Wells

Garry Andrews, Mark Satre

Welltec

Keywords

E-line interventions, wellbore remediation, mechanical interventions, well integrity, wellbore clean-out

ABSTRACT

E-line interventions play a crucial role in maximizing the productivity and lifespan of geothermal wells. Geothermal energy is an important renewable energy source with significant potential for global energy sustainability. However, geothermal wells present various challenges, including scaling, corrosion, and mechanical issues which necessitate periodic interventions to maintain or restore their optimal performance. E-line interventions offer a versatile and efficient method for diagnosing, evaluating, and resolving these issues.

The main E-line intervention categories can be categorized into two main approaches: logging, and mechanical interventions. Logging interventions involve the deployment of various tools to acquire real-time data on well conditions to diagnose and evaluate well performance and assist in decision-making for subsequent interventions. Mechanical interventions, on the other hand, employ e-line conveyed tools to directly address issues in the wellbore such as wellbore clean-out, scale removal, casing repair, pipe recovery, and fishing operations, thus contributing to enhanced well performance and prolonged lifespan. A description of the mechanical intervention solutions will be detailed in the paper with the objective of broadening knowledge of the extensive applications.

1. Introduction

With its ability to provide a constant and reliable energy supply, geothermal energy is increasingly becoming a focal point for energy sustainability initiatives worldwide. However, the operational efficiency and longevity of geothermal wells are often compromised by challenges such as scaling, corrosion, mechanical failures, and reservoir depletion. Addressing these challenges necessitates periodic well interventions.

E-line intervention solutions have emerged as a pivotal technology in maintaining and enhancing the productivity of geothermal wells. By leveraging advanced diagnostic and mechanical intervention tools, e-line technology offers a robust and efficient approach to tackle the myriad of issues that can afflict geothermal wells. This paper delves into the specifics of e-line intervention methodologies, with a particular focus on mechanical interventions, illustrating their applications and benefits in the context of geothermal energy production.

2. E-line Intervention Methodologies

E-line interventions are broadly categorized into two primary methodologies: logging interventions, and mechanical interventions. Each serves a distinct purpose in the maintenance and enhancement of geothermal well performance.

2.1. Logging Interventions

Logging interventions involve the use of various diagnostic tools deployed via an electric line to gather real-time data on well conditions. These tools provide critical insights into the well's performance, enabling operators to make informed decisions about necessary interventions.

Common logging tools include:

- Temperature and Pressure Gauges: Monitor real-time well conditions
- Caliper Logs: Measure the diameter of the wellbore to identify restrictions
- Corrosion Logs: Measure the extent of corrosion in downhole tubulars
- Cement Bond Logs: Assess the quality of cement around the casing
- Flow Meters: Evaluate the flow rate and distribution within the well

2.2. Mechanical Interventions

Mechanical interventions utilize e-line conveyed tools to address and rectify physical issues within the wellbore. These interventions are essential for maintaining the well's structural integrity and operational efficiency. Common mechanical interventions in oil and gas wells that can be applied in the geothermal setting include:

- Wellbore clean-out and scale removal
- Casing repair
- Fishing operations
- Annulus leak repair
- Workover and abandonments

3. Benefits of E-Line Interventions vs Other Intervention Methods

Electric line (E-line) mechanical interventions offer several distinct advantages over coiled tubing and slickline operations in oil and gas wells, and one of the primary benefits is the precision and control afforded by the technology. E-line tools can deliver real-time data and feedback, enabling operators to perform highly accurate and targeted interventions. This real-time capability allows for immediate adjustments and optimization of downhole operations, which can significantly reduce intervention times and enhance overall efficiency. Additionally, E-line interventions are

typically less invasive and produce a smaller footprint from equipment compared to coiled tubing, making them more suitable for operations in constrained or complex environments. Unlike slickline, which lacks the capability to transmit real-time data, E-line can power and communicate with sophisticated downhole tools, enabling a wider range of mechanical tasks such as milling, high-force actuating for fishing or swaging, and tubular punching and cutting with greater precision. Furthermore, the ability to deploy advanced robotic and electric-powered tools on E-line can lead to more effective problem resolution, reduced non-productive time (NPT), and enhanced safety by minimizing the need for heavy mechanical operations. Overall, the versatility, precision, and efficiency of E-line mechanical interventions make them a highly valuable option for maintaining and optimizing well performance.

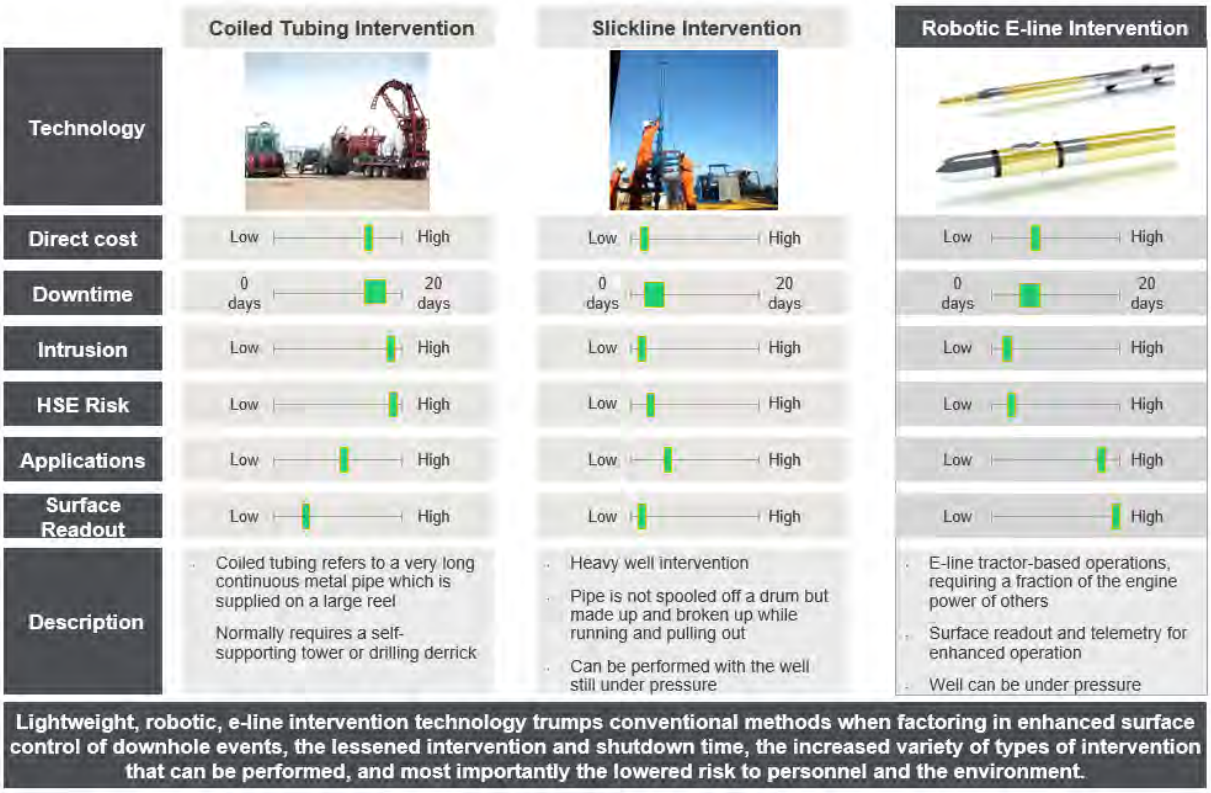

Figure 1: Comparison of coiled tubing, slickline, and e-line intervention methods (ref. SPE-203064-MS)

4. Overview of E-line Bottom Hole Assemblies – Standard BHA

A standard BHA for an e-line mechanical will include the following tools and configurations:

- Cable head with mechanical weakpoint – backup means of releasing from a stuck BHA with fishing neck for later retrieval.
- Surface command release device – primary means of release from a stuck BHA with fishing neck for later retrieval.
    - Multiple surface command release devices can be run in the BHA
- Correlation device – CCL or GR/CCL
- E-line tractor (optional) – for conveyance in deviated or horizontal wells or for providing weight on bit for milling operations.

- Principal objective tools
  - Downhole actuator for fishing or casing repair
  - Suction tool for the removal of loose debris
  - Milling tool for the removal of scale, cement, or consolidated deposits
  - Mechanical, non-explosive cutting and punching tools

Figure 2: Example e-line mechanical intervention BHA showing individual components.

5. Electric Line Mechanical Interventions Solutions

5.1. Wellbore Clean-out

E-line suction tools are highly effective for wellbore clean-out operations in geothermal wells, offering a sophisticated solution for removing debris and obstructions that can impair well performance. These tools are deployed via an electric line, allowing precise placement at the target depth where they create a powerful vacuum to extract loose debris such as sand, and other particulates. The ability to operate efficiently under the high-temperature conditions of geothermal wells makes e-line suction tools particularly advantageous. Real-time data transmission and surface control capabilities enable operators to monitor and adjust the clean-out process dynamically, ensuring thorough debris removal without causing damage to the wellbore. This method not only enhances the efficiency and productivity of geothermal wells but also minimizes downtime and reduces the need for more invasive and costly intervention techniques.

These tools operate by means of downhole electric motor driving a hydraulic pump creating a differential pressure and suction. This suction pulls both the wellbore fluid and debris into bailer sections, with the fluid then passing through filters and back out to the wellbore.

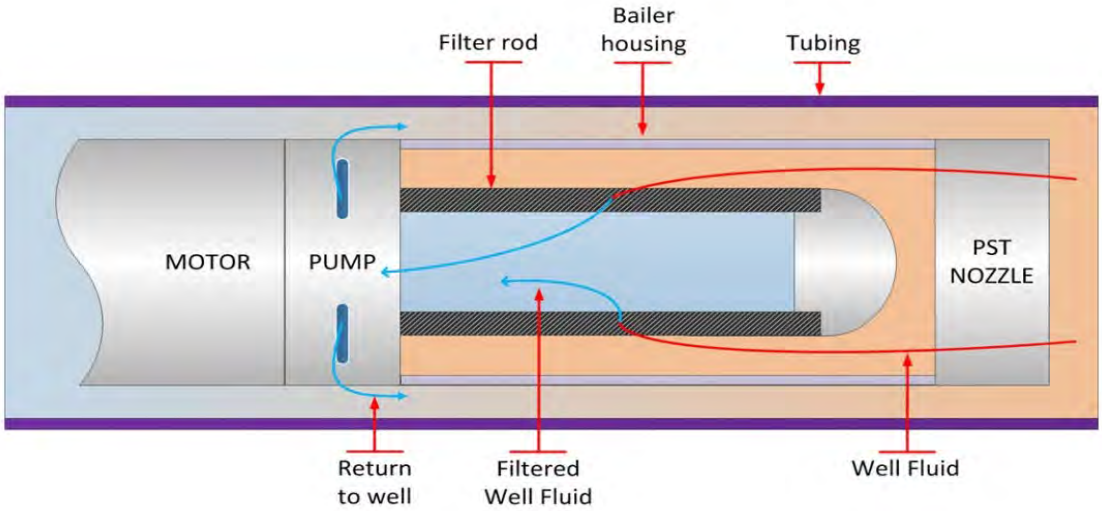

Figure 3: Diagram of e-line suction tool cross section showing fluid and debris paths.

5.1.1. Wellbore Clean-out Capabilities

Several sizes of tools are available for applications in different wellbore sizes with 2.125”, 3.125” and 4.25” outer diameter (OD) tools. These base tool sizes can then be configured with varying ODs of bailers for increased debris recovery e.g. the 3.125” tool can be run with 3.125”, 3.5” or 4” OD bailers. The maximum possible recovery is with the 4.25” tool is 21gal per run when the tool is configured with seven bailers.

5.1.2. Wellbore Clean-out Considerations

As with most of the e-line tools mentioned in this paper, the temperature and pressure limitations are 300°F and 20,000psi. respectively. Some of the solutions mentioned here do have the ability to run in 350°F and 25,000psi.

Expected debris also needs to be taken into consideration ensuring that the correct filters and nozzles are utilized ensuring maximum recovery possible per run. If the debris makeup is unknown, these configurable parts can be changed between runs refining the clean-out approach when a debris sample is collected.

5.1.3. Wellbore clean-out Case Story

An Australian operator wanted to explore options for wireline conveyed sand bailing in one of their offshore platform gas producing wells. The objective was to remove twenty-six meters of sand fill inside the 9.625" production casing, with an internal diameter (ID) of 8.681". Due to the landing nipple at the end of the tubing, the minimum run-in-hole restriction of the production tubing string was 3.987".

To limit the number of clean-out runs, the latest technology in e-line deployed suction tools with a 4.25" OD was chosen, which provided increased recovery volume over its smaller cousins, plus real-time surface control and monitoring. Because of the tool's overall diameter, the landing nipple also required milling to allow access. Therefore, a specially designed 4.412" mill bit was manufactured and run on a milling tool – a tool requiring tractor conveyance to provide weight-on-bit and counter the reactive torque.

As the well had low deviation, the subsequent clean-out toolstring was run standalone (without tractor). One of the key factors governing the feasibility of conducting this operation on e-line was the overall toolstring lengths, where the lubricator height was limited to approximately 16 meters.

The e-line deployed milling technology – which produces a grinding action rather than cutting – successfully milled through the landing nipple and a ball catcher in four runs, thus increasing the ID sufficiently to allow access for the clean-out toolstring. A well fluid column of approximately 7 bar is required to enable operation of the suction tool. The clean-out tool was configured with three bailer sections (seven max) for the first run, to determine sand recovery optimization. Three different sizes of micron bailer filters are provided; prior knowledge of debris particle size is therefore advantageous. In this case, a slickline bailing sand sample had been recovered, which immediately aided filter choice. Seventeen bailing runs were conducted over five days (with the number of bailer sections increased to six), successfully recovering a total of 918 liters of sand,

equating to about 2.4 tons. Ultimately, the process enabled perforation of two additional gas zones to increase production.

The e-line toolstring, consisting of six different sensors and robotic tools, made this a more controllable and inherently safer operation than coiled tubing methods, as well as having a smaller footprint with reduced environmental impact.

5.2. Scale Removal

E-line milling tools are a viable option for addressing the prevalent issue of mineral scale buildup that can obstruct fluid flow and reduce well efficiency in geothermal wells. These tools, deployed via an electric line, allow for precise navigation and positioning at the site of scale deposits. Once in place, the milling tools utilize high strength cutting elements to grind and remove the hardened scale, restoring the wellbore's ID and enhancing fluid conductivity. The E-line deployment provides continuous power and real-time data transmission, enabling operators to closely monitor the milling process and make necessary adjustments to ensure thorough scale removal. By using these advanced tools, operators can significantly improve the operational efficiency and longevity of geothermal wells, minimizing downtime and maintenance costs.

5.2.1. Scale Milling Capabilities

Two options of milling tool are available for the removal of scale: one being tools with milling *only* capability, the other being those with combined milling and suction capability. The milling and suction option can be applied when there is no flow path in the well, with the tool itself creating a fluid circulation for the movement and collection of cuttings. The milling only tool requires either fluid production or bullheading to move the cuttings produced. With both options, a tractor is required to be run above the milling tool to both provide weight on bit and to hold back torque from the rotating head.

The evolution of milling technology has also increased the parameters in which scale can now be milled out to with BHA's allowing up to 8.5" OD milling bits to be deployed on e-line.

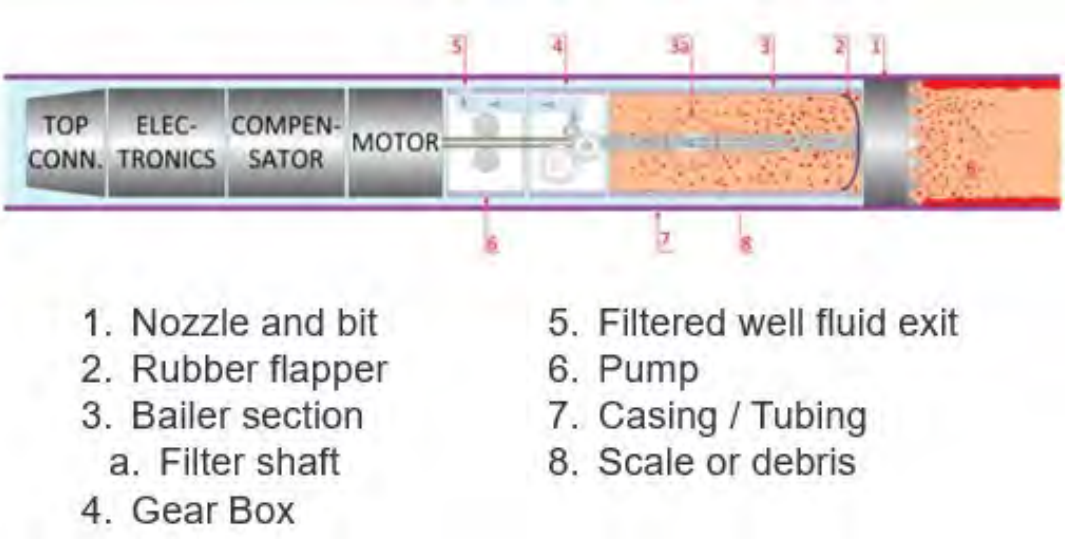

Figure 4: Diagram of e-line milling and suction tool cross section.

5.2.2. Scale Milling Considerations

When planning a scale milling operation, the main considerations to ensure a successful operation are expected scaling interval, expected scaling extent (as to whether the flowpath is fully closed or only restricted) and required (resulting) wellbore ID (dependent on if the original wellbore ID is required or only a sufficient ID for subsequent well operations).

If the scale interval is expected to be long but there is still a flow path, the preferred method is with the milling only tool. In a geothermal application, fluid bullheading is recommended as this will both move the cuttings from the bit face but also quench the well allowing for more favorable operating conditions. The wellbore sump then must be factored in to ensure there is sufficient volume below the milling interval for the cuttings generated. These will be forced to the toe of the well to later be produced or removed via further e-line runs.

5.2.3. Scale Milling Case Story

A dual completion oil producer offshore Malaysia had been having CaCO3 scale buildup problems since it was put on production in 2004. By mid-2008, the scale had accumulated severely in the short string of the well, almost choking oil production. The 3-1/2” x 9.2 lbs/ft tubing internal diameter had been reduced from 2.992” to approximately 1.50” all the way to the end of tubing. Due to the scale, Q oil from the short string had been reduced from an average of 2,000 bbl/day to almost 70 bbl/day.

Mechanical milling of the scale by coiled tubing was not an option due to the limited deck space and crane capacity on the platform. The operator chose milling on electric wireline utilizing a combination of the e-line tractor and miller with a customized 2.70” outer diameter scale milling bit because of a permanent minimum restriction of 2.813” in the well.

During the scale milling operation, the well was being flowed with a choke size of 22/64 equivalent to a flow rate of approximately 120 bbl/day to flow the debris to surface as well as for heat dissipation purpose at the mill bit.

The operation achievements include:

- A total of 5,350 ft CaCO3 scale interval was milled (vertical scrapping and rotational milling)
- Total time from rig up-rig down: 14 hours
- Time savings: approx. 4 days (compared to coiled tubing)
- A path with an internal diameter of 2.70” was obtained
- Increased oil production: 36 bbl/day (Immediate additional gain post scale milling)

The open path enabled further slickline operations such as tubing broaching to scrap remaining scale in the tubing or maintain the open path for the remaining production life of the well followed by changing out the gas lift valve. Q oil is expected to be further increased by another 300 bbl/day after changing out the gas lift valve.

5.3. Casing Repair

E-line mechanical intervention technology is highly effective for performing casing repairs, addressing issues such as deformation and buckling that can compromise well integrity and ultimately production. Using tools like an e-line stroker and swaging tools, these interventions can be precisely deployed to the damaged section of the casing via an electric line, which provides both conveyance and power. The stroker tool applies controlled mechanical forces to realign and stabilize the casing, while the swaging tool presses against the casing walls, reshaping and reinforcing them to restore their structural integrity. This process is monitored in real-time through continuous data transmission, allowing for immediate adjustments to optimize the repair. This approach not only extends the operational life of the well but also minimizes downtime and avoids the need for more invasive and costly repair methods.

Figure 5: Casing swage shown connected to the bottom of an e-line stroker

5.3.1. Casing Repair Capabilities

With the increase in downhole tool capabilities and new e-line stroker tools now being able to push / pull 100klbs (3.5” OD) and 28klbs (2.125” OD), this allows these surface-controlled tools to be applied to more operation types normally the remit of heavier intervention methods like coiled tubing or snubbing. With 100klbs of force available at depth, swaging is now possible via e-line with these operations being considered standard for collapsed or buckled intervals up to 10ft in length. A surface command release device will be run between the stroker and swage as a backup means to release in the vent the swage become stuck.

5.3.2. Casing Repair Considerations

A caliper is always recommended prior to performing a swage operation, to understand the extent and length of collapse. This would then inform planning on the well specific approach when it comes to swage size and swage OD step up per run.

An SIT is always recommended for any tubulars not yet swaged with one of the SIT objectives being to record tool surface readout, force required and planned swage OD approach. These parameters would then be used during the operation as a guide for completing the objective.

5.3.3. Casing Repair Case Story

A US land operator scheduled intervention work on an existing well to retrieve a packer with sand screen assembly. A casing collapse above and below salt formations in three intervals prevented the retrieval of the packer. The 7" 32# P110 casing deformation ranged from 5.67" ID to 5.8" ID, with lengths ranging from 3' to 6' with the packer having a 5.875" OD and 7.6' length. An SIT was performed with the well-specific casing showing the e-line stroker and swage as a viable option to recover casing ID.

An intervention was then planned based on the results of the SIT, with the objective of enlarging the area/s with casing restrictions enough to allow packer retrieval. The e-line stroker with 100klbs force 312 expanded the three restrictions in a single run with a 5.9" OD swage. A subsequent run with caliper data confirmed a baseline ID of 5.85" – 5.9" ID throughout the Charles salt formation section of the well. Swaging was performed in a single day (daylight operations) with the operator ultimately being able to successfully retrieve the packer and return the well to production. The application of e-line mechanical tools also meant the avoidance of a heavier and costlier intervention method, such as coiled tubing.

5.4. Fishing Operations

E-line stroking tools are essential for efficient downhole fishing operations and can be applied to geothermal applications. These tools are conveyed via an electric line and once correlated on depth will use sophisticated mechanical actions, such as surface command gripping and latching combined with high force stroking, up and down, to effectively dislodge and retrieve the stuck or stubborn items. The electric line system provides continuous power and real-time data transmission, allowing operators to monitor the fishing process closely and make real-time adjustments to optimize the operation. These adjustments can be an increase in pulling force or release and relatch mid-run. This capability not only minimizes operational downtime and reduces the risk of further damage to the wellbore but also enhances the overall efficiency and safety of fishing operations. By utilizing these advanced tools, operators can achieve successful fishing interventions, ensuring the continued productivity and longevity of geothermal wells.

Figure 6: Example E-line Fishing BHA with Surface Command Latch Tool and 100klbs Force

5.4.1. Fishing Capabilities

With the ever-increasing force of e-line stroker tools, these e-line options are now becoming the first choice for fishing operations. Downhole forces now available are 28klbs for slimhole, and 100klbs available for larger completions and casing. These forces are bi-directional, controllable from surface and can be stepped up and down in 500lb increments. The surface readout and surface control mean what is happening downhole is being monitored real-time at surface and the approach can be changed on the fly based on what is happening downhole.

The high force tools in combination with surface-controlled latching tools adds another level of capability over conventional fishing methods, where a fishing can be latched and unlatched multiple times in one run. This ability can be used to incrementally increase the latch area allowing for higher overpull.

Whilst the bi-directional stroker tools and surface command latching tools provide the primary and secondary means of release from a fish which cannot be retrieved, a surface command release device can also be included in the string as a tertiary means to recover the e-line BHA to surface.

5.4.2. Fishing Considerations

Surveillance runs should be performed in advance of any fishing run to confirm the fishing neck or fish stickup is clear from any debris or absent of damage. These can take the form of LIB, camera or gauge runs.

E-line specifications should also be planned for to ensure the tensile strength of the cable is sufficient for the recovered fish. Along those same lines, if pressure control equipment is required, the lubricator section should be of sufficient length to both hold the main BHA *and* items retrieved from the wellbore.

5.4.3. Fishing Case Story

A strong offshore oil producer well was shut down after an unsuccessful slickline plug-retrieval operation, which led to the slickline toolstring and isolation plug becoming stuck at a shallow depth. Heavy-duty fishing was performed using electric wireline self-anchoring hydraulic stroking tool. While pulling, 100Klbs of force was applied to free the slickline toolstring from the plug. This paper is written to share the experience gained while planning, preparing, and executing this high-profile job.

After reviewing all available options, it was decided to use the high-capacity version of the electric wireline hydraulic stroking tool, rated to 100,000 lbs. The approach to the job was to retrieve the slickline toolstring either as one piece or break it into parts by applying maximum force and retrieving via multiple runs. After fish retrieval, a further plan was to retrieve the isolation plug using slickline. The preparation phase included a function test at the base with full reconstruction of the well situation to confirm the approach as correct.

The base function test was performed to determine if the high level of force from the electric wireline hydraulic stroking tool would break the slickline toolstring or release it from the plug. For the test, the exact fish components, including the plug, were set up in a horizontal tubing. A long overshot was designed to swallow the jars in the slickline toolstring. It took five upward strokes, up to 100,000 lbs, to release the slickline toolstring from the plug's fishing neck. The ring of the fishing neck sheared from isolation plug.

Following the base function test, equipment was mobilized offshore. The heavy duty overshot was installed on the fish using Slickline. The electric wireline hydraulic stroking tool was then rigged up on, run-in-hole, and latched onto the overshot. After two strokes of up to 100,000 lbs, the slickline toolstring released cleanly from the fishing neck of the plug (similar to the base function test).

The plug was successfully retrieved and the well was brought back onto production. Using the electric wireline hydraulic stroking tool allowed a rigless intervention, in a cost-effective, safe and time-controlled manner.

5.5. Workover and Abandonments

The advent of non-explosive pipe cutting and pipe punching tools has revolutionized e-line mechanical intervention services, particularly in high-risk environments like geothermal wells. These advanced tools provide a safer, more controlled alternative to traditional explosive methods, significantly reducing the risk of accidental detonation and subsequent damage to the wellbore or surrounding formations. By eliminating the need for explosives, non-explosive tools enhance operational safety and simplify logistics, as there are fewer regulatory hurdles and transportation restrictions. Additionally, the precision of non-explosive cutting and punching tools ensures cleaner cuts and more accurate perforations, which are crucial for subsequent intervention tasks such as casing repairs, fluid circulation, and pressure equalization. The ability to deploy these tools via an electric line allows for real-time monitoring and dynamic adjustments, further improving the efficiency and success rate of intervention operations. Overall, the integration of non-explosive technologies in e-line mechanical interventions has led to safer, more efficient, and environmentally friendly well maintenance and repair processes.

5.5.1. Workover and Abandonment Capabilities

The introduction of e-line non-explosive pipe punching and cutting intervention tools allows the operator to have real-time confirmation of a successful cut and/or punch. The e-line cutters with tool ranges from 3.5” to 9 5/8” tubulars produce a beveled cut which does not require subsequent dressing. These cuts can also reliably be performed in compression with no impact on cutting time. Reach of the cutting arms can also be limited to protect tubulars outside of the target pipe.

The e-line non-explosive punchers also provide a real-time confirmation of successful punch, a known flow path area, a limit to the punch depth of penetration and do not leave burrs on the OD of tubing or casing. The current tools available can punch from 2.825” tubing out to 10.75” casing. Punch direction can be oriented to punch on the high side or provide full coverage holes.

The above tools can be combined allowing a one run cut and punch solution, further saving rig time.

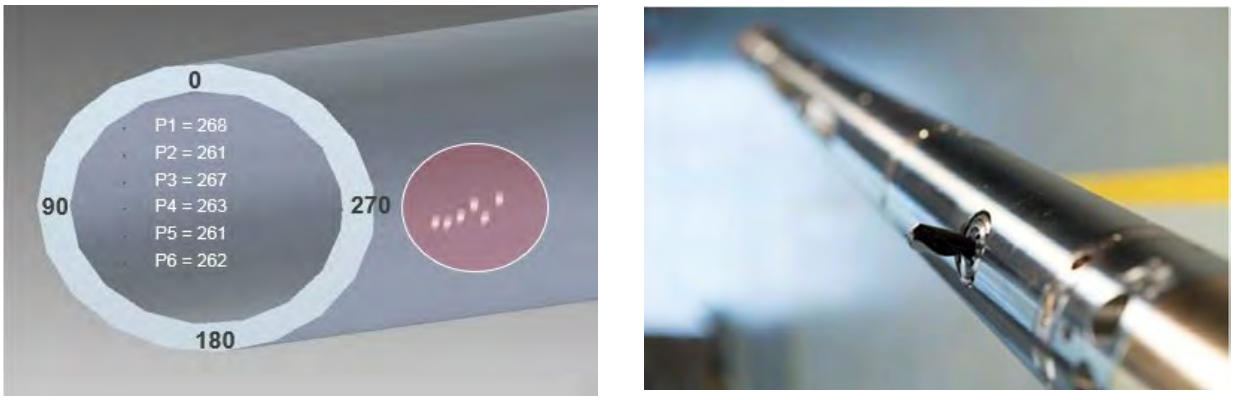

Figure 7: Example of tubing punch operation with the orientation defined for the e-line mechanical puncher.

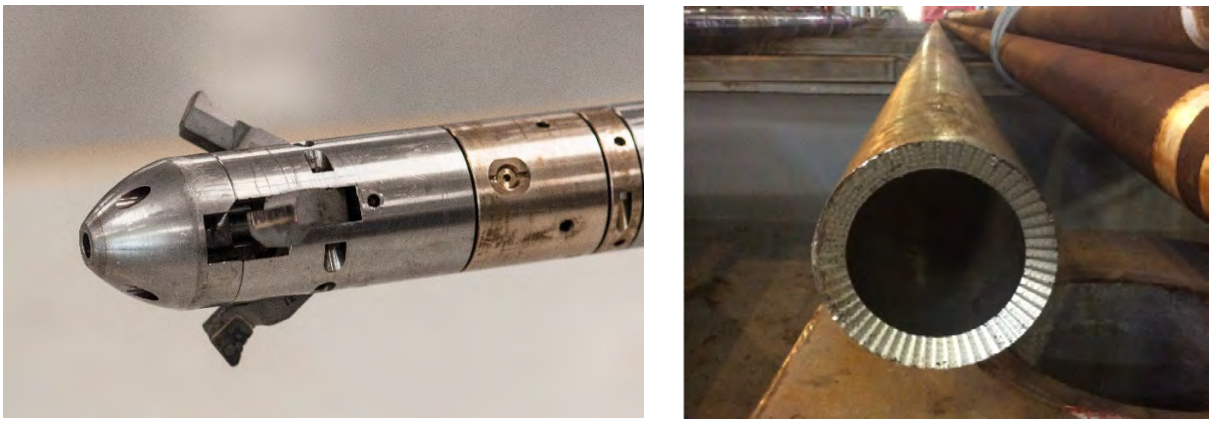

Figure 8: Example of pipe cutting operation showing a clean cut performed in compression on heavy walled tubing.

5.5.2. Workover and Abandonment Considerations

For the utilization of either the e-line mechanical puncher or cutter, there has to be confirmation of previously cutting the tubing or casing. If the target pipe has not been cut or punched, an SIT must be performed to confirm toolstring setup. The surface readout recorded in the SIT will then be utilized in the operation as a guide. Again, for either tool, the limiter for the cutting arm reach, or puncher bit reach, has to be predetermined as this involves the installation of a mechanical stop/no-go.

5.5.3. Workover and Abandonment Case Story

During a subsea remote-operated vehicle survey in a North Sea field, an operator discovered that three wells had leaks in their horizontal Christmas trees. It was therefore imperative to undertake workover interventions to remedy these leaks as soon as possible. The operator evaluated the need for replacing the Christmas trees, as well as the upper completion, in each well. As part of the work scope, it was necessary to punch and cut the 7”, 32 ppf tubing just above the production packer.

The selection criteria for the cutter tool included the following parameters:

- Tool must run on electric line (e-line).
- Tool must be able to cut tubing in compression.
- Tool must not cause damage to the outer casing.
- Tool must leave a clean, beveled edge after the cut, allowing for safer entry in the lower part of the completion on subsequent runs.

The operator found a precision tool that satisfied the above criteria: an electrohydraulic e-line pipe-cutting tool.

Unforeseen challenges emerged, however, when a ballistic puncher was used prior to cutting. The first attempt to punch made by the ballistic puncher failed to achieve fluid circulation. Luckily, the operator also mobilized a recently developed electrohydraulic pipe-punching tool run on e-line as a contingency. This tool can be oriented such that it drills holes sideways, maximizing the potential for successful fluid circulation. The electrohydraulic puncher tool was given a green light. It drilled 16 holes, performing as expected. It was followed by the e-line cutting tool, which made a clean

cut. Thus, all operational objectives were met. The well was recompleted successfully, and two more wells followed.

6. Conclusion

E-line intervention solutions represent a transformative approach to addressing the complex challenges faced by geothermal wells, ensuring their operational efficiency, and extending their productive lifespan. By utilizing proven advanced diagnostic and mechanical intervention tools, e-line technology offers precise, safe, and efficient methods to mitigate issues such as scaling, corrosion, and mechanical failures. This paper has explored the specific methodologies and applications of e-line mechanical interventions, highlighting their significant benefits in maintaining and enhancing geothermal energy production. As the global focus on energy sustainability intensifies, the role of e-line interventions in optimizing geothermal wells will become increasingly crucial, supporting the broader adoption and reliability of geothermal energy as a sustainable power source.

NOMENCLATURE

E-line	-	electric line
BHA	-	bottom hole assembly
NPT	-	non-productive time
OD	-	outer diameter
ID	-	inner diameter
SIT	-	systems integration test
PPF	-	pound per foot

inliSAMP, a Modularly Designed Fluid Downhole Sampler for Deep Geothermal Applications - Proof of Concept

Gawan Berentelg, Stefan Dietze and Veit Hagenmeyer

Institute for Applied Computer Science IAI

Karlsruhe Institute of Technology KIT

Keywords

downhole fluid sampler, geothermal borehole logging, in situ temperature and pressure, monitor and record

ABSTRACT

The fluid sampler inliSAMP is being developed for remote controlled downhole sampling in deep geothermal boreholes. inliSAMP is designed based on the system platform for downhole tools hotToolKIT. It is a follow-up development to the inliCAM. Thus, both probes are built up from modular components of the construction kit. A new sampling and storage concept is developed and realized in a functional demonstrator (sampling volume 480 cm^3). The sampling process was tested and proven to work under laboratory conditions up to 90 bars. The demonstrator sampling system is remotely controlled via wireline using real time data. Temperature, pressure in different locations of the sample chamber, and electronic components are permanently monitored and recorded. In the design, most electronic components such as a highly efficient power supply, motor drivers and control units are placed inside a supply probe Dewar flask. The in-situ storage of the monophasic sample is being realized by an adaptive hydraulic and heating control system. The hydraulic components are developed for high dynamic loads and small installation spaces. Furthermore, the functional demonstrator fulfils the requirements of the design standard downhole logging tools (T = 200 °C, p = 60 MPa, harsh and corrosive fluids). Currently, the mechanic units such as the sample chamber, sensors, and hydraulic power pack are mounted on a socket in a demonstrator housing and are tested under realistic conditions on a test rig at the Karlsruhe Institute of Technology (KIT) in preparation for a borehole deployment. The functional tests of the sample procedure include descent of the probe, the sample intake, maintenance of sample temperature, and dispensing at changing ambient temperatures on a test rig. The focus of the research is on temperature monitoring, control, and operation management of in situ downhole sampler. This paper gives an overview over commercially available fluid sampler, the development process, a test rig for fluid samplers, explains the technical details of the complete system and presents the results of the proof of concept and the quality measure of sample temperature and pressure.

1. Introduction

This paper presents a novel fluid sampling concept for remote in-situ downhole sampling, the design of the inliSAMP probe and a proof of concept on a test rig. inliSAMP stands for "in situ live sampler". It is designed for remote-controlled sampling in deep boreholes and was developed at the Karlsruhe Institute of Technology. It is a modular build up tool based on the system platform for downhole tools hotToolKIT (Holbein et al., 2018) and a follow-up development of the video inspection probe inliCAM (in situ live camera). As a conventional downhole sampling probe, inliSAMP is lowered on a wireline in the completed borehole, and it collects a fluid sample from the borehole fluid at formation conditions. The probe stores and maintains the fluid sample nearly in situ conditions until it is transferred to a transport container at the surface.

Providing insights to downhole fluids are a crucial for the evaluation and exploitation of underground resources such hot water, crude oil, CO2 storage, and shale gas (Hsieh et al., 2021). The increasing number of projects in exploitation of geothermal energy from a reservoir or carbon storage injection of supercritical CO2 “require accurate geochemical analyses of formation water and gas samples for chemical characterization and monitoring purposes” (Wolff-Boenisch and Evans, 2014), (Lund et al., 2022), and (Ayliffe, 2022). Merely representative downhole fluid samples provide important information for aqueous chemistry, isotopic composition, and gas characterization analyses as “the physical and chemical properties of geothermal water that is at or close to equilibrium with host rocks in water-dominated reservoirs change from their initial state to the surface sampling condition during the up flow of the fluid along the wellbore” (Akın and Kargı, 2019).

The data of a downhole sample and its dissolved gases are important information for geothermal use, exploitation and research, e.g. the assessment of the operation conditions, the heat transfer and mineral scaling (Hsieh et al., 2021) and (Wolff-Boenisch and Evans, 2014). In application of mineral carbon storage, a representative sample of injection conditions is needed to evaluate the hydro-geochemical pattern and proportions of *CO*2 mineralization of the aquifer (Alfredsson et al., 2016). In another application, "dissolved gas concentrations in groundwater are useful environmental tracers that can be used to determine groundwater residence times, understand geochemical processes, monitor contamination plumes, and identify mineral, oil, and gas reserves" (Eddie W. Banks et al., 2017). Further, in the oil and gas industry, representative formation fluid analyses are essential as precipitates of paraffins and asphaltenes are examined. In groundwater studies, which also detect volatile tracers such as SF6 in samples (Wolff-Boenisch and Evans, 2014).

"The main processes that change the reservoir water chemistry in the wellbore are the boiling of water, degassing of dissolved gases and the consequences of adiabatic cooling and mineral scaling. The combined effects of the increase in dissolved species concentration (boiling), decrease in temperature, rise in pH (degassing) and redistribution of bulk compositions among species (speciation) cause mineral scaling in the wellbore" (Akın and Kargı, 2019). These effects appear due to change in the formation pressure and temperature, as the mineral saturation is further dependent on temperature (Lowenstern et al., 2012). Precipitation occurs in the sample chamber with at alterations of its environmental conditions such as pH, temperature, and pressure changes (Wolff-Boenisch and Evans, 2014).

Obtaining a representative water sample, means to preserve technically the physical conditions of the downhole reservoir in the water sample, ongoing the time the sample is collected, during transport out of the borehole until it is transferred to a transport container at the surface.

Well sampling techniques distinguish between downhole (in-situ) and uphole (ex-situ) sampling. Today, available commercial downhole samplers and specific field-tested samplers are lowered to the target depth in the borehole. A positive displacement sampler (PDS) are systems, which is described in (Wolff-Boenisch and Evans, 2014) and still state of the art, for example the Single-Phase Reservoir Sampler of Schlumberger (Schlumberger, 2020). Other in situ technologies as vacuum and flow through samplers are here not considered, as they have no pressurization of the collected sample (Conaway et al., 2016). A PDS consists in principle of a housing with cable head connected to a wireline, a sample chamber and a time-controlled valve. It works with a prefilled pressurized displacement fluid that first exerts a piston on the closure and second, when a timer sets the valve open, it controls a slow displacement while existing differential pressure to the formation. A pressurized gas such as Nitrogen can be used to keep in the sample above reservoir pressure, while cooled from outside down during uplift and transportation. "Deployment of a PDS or keeping the well over pressurised can produce a single-phase fluid, which requires the sample extraction line to be operated under overpressure with respect to the formation or the bubble point and the introduction of a well-defined sampling loop to acquire a representative sub-sample."(Wolff-Boenisch and Evans, 2014)

The following state-of-the-art examples show the variety and current usage cases: The Positive Displacement Sampler PDSshort provided by Leutert for example has a sample capacity of 600 cm^3, an operating temperature of 180 °C and a sample pressure of 1035 bars. With a preloaded pressurized chamber, it retrieves a representative sample in a single-phase condition to the surface (Leutert, 2021). The sampling of deep geothermal wells and CO_2 reservoirs with the Leutert positive displacement sampler (PDS) is well documented in many publications, for example in (Kampman et al., 2013) and (Regenspurg et al., 2010). The Armada® SPS-A Single-Phase Sampler by Halliburton operates at similar conditions and has the additional feature to preload scavenger fluid. Further, the sample chamber material is designed for detection of trace elements such as H_2S (Halliburton, 2022).

The GTFSampler is composed of a shut-in valve, maximum thermometer, a filter, check valve and a sampling cylinder with noble gas as Nitrogen. It is designed for temperatures up to 200 °C and pressures up to 77 to 226 bars. It is made for the retrieval of geothermal fluids (water, vapor, and gas) with a sampling volume of 500 cm^3 (Hsieh et al., 2021). The Multi-Temperature Fluid sampler (MTFS) is designed for fluid sample 1000 cm^3 with operation temperatures up to 190 °C, non-gas tight and to connect different probes in a row in the Deep Sea Drilling Project Hole 504B. It uses a syringe style design of the sample chamber and a "mechanical trigger that utilizes the thermal-response properties of a shape memory alloy (SMA)" (Wheat et al., 2020). The MTFS can be deployed with the elevated temperature borehole sensor (ETBS) tool in the borehole (International Ocean Discovery Program, 2022).

The downhole sampler of the project SECURe-Subsurface Evaluation of Carbon capture and storage and unconventional Risks is made for retrieval of integer fluid samples (water, oil, gas) with any contamination and leakage to the surface. The analyzation of geochemical composition of the fluid sample is done in a laboratory on site. The probe transmits measured data via the wire line (Ricroch et al.). The variation in the products is the quality of the fluid sample as pressurization

sample while intake, storage, the product specification and fluid sample volume. Most of the probes have a countdown timer to open the inlet valve and use a pressurized displacement fluid and gas. Furthermore, most probes do not transmit real-time data about the status of the sample, temperature and pressure, as they operate purely mechanically. Findings from current research projects are the need of more downhole data of the sampling process (Ricroch et al.), sample pressurization and verification further reservoir information to the taken sample such as downhole pressure and temperature.

Commercially available samplers today only partially have remote control and monitoring of the sampling process as well as active control of the samples taken. This issue is to be addressed by developing a remotely controllable and monitorable sampling probe. To improve the integrity of a representative fluid sample, it is crucial to log the full sampling process. The quality of the fluid sample can be enhanced with a remotely operated opening and closing unit. Further, an adaptive control and monitor system is used to maintain the formation pressure and temperature inside the sample chamber. The quantity of samples can be increased with a shorted preparation time at the surface and faster sampling, as well as by multiple sampling at different depths. How is an automatic sampler downhole probe designed, and how is the procedure to remotely controlled collect and retrieve a fluid sample from a deep borehole at nearly in situ conditions?

The novel inliSAMP probe has remote controlled actors and sensors for intake, storage, and retrieval of the sample. A steerable hydraulic unit and a resistance heater are used as actuators for an adaptive pressure and heating system. With the developed sampling procedure, a fluid sample can be stored and maintained under nearly in situ conditions, without the need of a displacement fluid and pressurized nitrogen. The mission of the downhole fluid sampler inliSAMP is to take a sample larger than 450 cm^3 from the borehole at an arbitrary depth and retrieve a single-phase sample to the surface at in situ downhole conditions with logging data. In this research, a novel sampling procedure is being developed and implemented in a demonstrator probe inliSAMP. The demonstrator is a simplified hardware version of the borehole probe. This involves the experimental investigation of the sampling process, the temperature distribution in the sample chamber and the sample pressure during the process.

The main focus of the research is to develop a solution for keeping the sample temperature and pressure constant during the ascent at a changing ambient temperature. For this purpose, a constructive solution, extended sampling procedures and the use of a temperature control with limited heating power are combined. The demonstrator with the sampling procedure is tested on a test bench. Chemical analysis and measurement of dissolved and undissolved gases in the sample are not performed.

Moreover, inliSAMP is specially designed to meet the requirements of most geothermal boreholes in Central Europe. The main requirements are an operating temperature of 200 °C, a maximum thermal water pressure of 60 MPa, and resistance against very corrosive and harsh environments (Spatafora et al., 2019). The specifications are consolidated in the so-called hotToolKIT requirements. At the Karlsruhe Institute of Technology, within the workgroup Geothermal Energy at the Institute for Automation and Applied Informatics was developed an open-source platform for geothermal borehole tools and probes to enhance and innovate the information quality and integrity of deep geothermal applications. The hotToolKIT platform is the renaming and commercialization of the ZWERG modular system and the two downhole probes inliCAM (working title GeoKAM) and inliSAMP (working title WASAM) (Holbein et al., 2018).

hotToolKIT links the requirements of deep boreholes, electronic hard- and software, a design construction kit. Standardized testing is applied for variable uses such as a video inspection system GeoKam (Spatafora et al., 2019), a permanent cooling system (Holbein, 2019) and a new downhole sampling system (Isele et al., 2015b) and (Berentelg et al., 2020).

2. Novel fluid sampling method for deep boreholes

HotToolKIT is a modular system for design, construction, and operation of downhole tools and high-temperature applications. The general operating parameters of the environment condition for all probes are listed in Table 1. The tool and technology development are structured by applying a repetitive modular design. Development costs and the risk of errors are thus significantly minimized (Holbein et al., 2017).

The module-based probes consist of universal modules and task-specific application modules. The universal modules include all components such as a housing and thermal insulation, which each type of probe requires. The application module is developed task-specific and is made of assemblies, actuators, and sensors. Special electromechanical couplings enable the individual modules to be connected and combined (Isele et al., 2015b).

The sampling probe inliSAMP structure is build up from standards of the hottoolKIT. inliSAMP is composed of an application module: the sampling unit and various universal modules such as a hydraulic power pack, insulation, power supply unit, and a communication board. The probe consists of two sections, a high-temperature section with the sample unit and hydraulic power pack with a coupling (Holbein et al., 2017) and an insulated section for temperature sensitive electrical components. A suitable Dewar tube from hotToolKIT is used for the thermal insulation of the electronic components. Control circuits boards, as HiTES, communication electronics, and power electronics are installed to operate and monitor the probe (Dietze, 2020). The module groups are each protected by a stable housing tube which is screwed to the coupling (Spatafora et al., 2016).

The sampling unit, the application module for the task of downhole sampling and fluid storage, is a new development. It consists, in principle, of an insulated and heated pressure vessel named the sample chamber attached to a hydraulic cylinder (Berentelg et al., 2020). The hydraulic cylinder is actuated by a hydraulic power unit. The container is closed by two axially movable pistons which are directed over a rod. The distance between the pistons corresponds to the volume of the sample to be taken up in the so-called sample chamber.

The developed fluid sampling procedure is simplified by a five-phase principle: descending the probe, sample taking, closing, pressurization, temperature control, and sample dispensing. The phases are illustrated in Figure 1 showing a Pressure vessel with an Inlet hole, Heating, mechanical Stops, and a Sample piston and Valve piston. The sampling concept is based on the function of a syringe and a valve. Each piston, shown, has seals on both sides and can only be shifted axially by fluid pressure or the piston rod force:

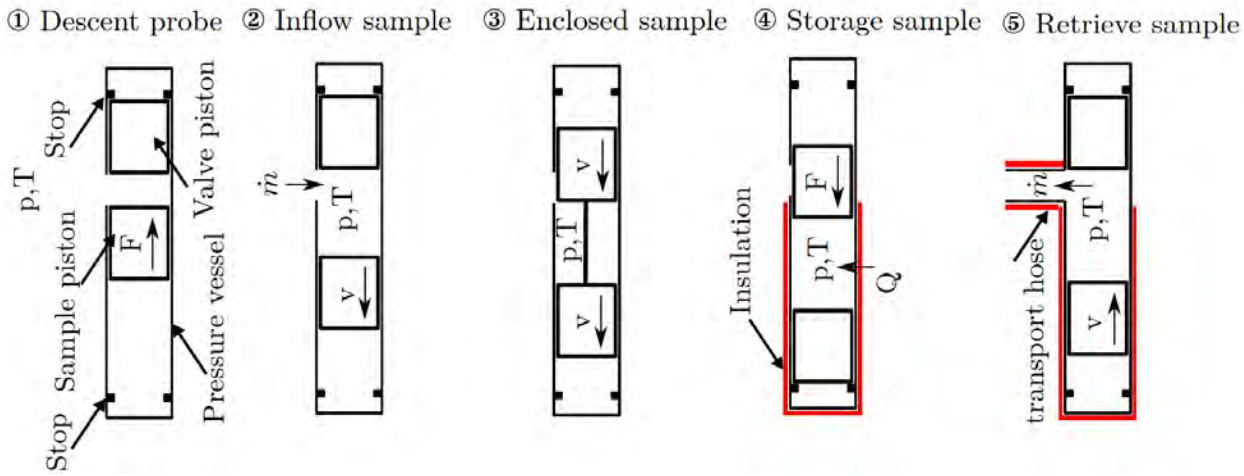

Figure 1: fluid sample principle in five phases: ①descent probe: The probe is submerged into the borehole to a selected depth. The Sample piston is held in place as the sample container closure is open. The Valve piston pushes against a Stop. The sensor system measures temperatures outside and inside and the pressure. ② As the Sample piston is released, the fluid enters the sample chamber. ③ the defined sample volume in the sample container is enclosed by the two pistons, and everything is moved until the Valve piston closes the inlet. Then the sample is sealed. ④During emergence and at the surface, the sample pressure is controlled by the Valve piston force and the sample temperature is controlled by an electric heater. ⑤When dispensing via a hose, the Sample piston presses the Valve piston against the upper Stop and the sample is transferred to a transport container with minimal loss.

①*Descent probe*

The probe is submerged into the fluid-filled borehole to a selected depth via the wireline. The rising pressure pushes the Valve piston constantly against a Stop, and rising temperature heats up the probe slowly. The Sample piston is held in place by the piston rod force *F* as the sample container closure is open. The sensor system measures temperatures inside *T_in* and outside *T_out* and the ambient pressure *p*.

②*Inflow sample*

At the selected depth, the piston retention force is set lower than the force on the piston. As a result, the piston moves and fluid flows into the sample vessel. The inflow velocity is determined by the velocity of the piston rod.

③*Enclose sample*

The stroke of the piston rod determines the volume of the fluid sample. The collected sample is shuttled between the Sample piston and the Valve piston, and thus the system is in a state of equilibrium. Piston force is used to move the system until the Valve piston closes the inlet. Then the sample is sealed yet can still be moved axially in one direction.

④*Storage sample*

The temperature *T_in* and pressure *p* of the sealed sample are kept constant by an adaptive control of piston force and heating power. During emergence and at the surface, the ambient temperatures are lower than in the sample and the sample chamber. The sample pressure *p* is dependent on the true sample temperature and can be manually controlled by the Valve piston force.

⑤*Retrieve sample*

When dispensing via a hose, the Sample piston presses the Valve piston against the upper Stop and the sample is transferred to a transport container with minimal loss. To avoid a drop in temperature in the out flowing sample, the fittings, hose, and transport cylinder are preheated up to sample temperature.

Table 1: Environment condition and requirements for sampler and downhole probes, taken from (Spatafora et al., 2019)

Borehole depth	5 km
Diameter open hole	approx. 220 mm / 8 ½ inch
Diameter Housing tube	<95 mm
Ambient Temperature	<200 °C
Ambient pressure	<600 bar, 60 MPa
Sample Volume	> 450 cm3
Pressure keeping & record	+20 bar
Temperature maintain & record	± 5 K
single phase sample, CO2, *uGT*	slow sampling, heat control

2.1 Enhancement of temperature control

In the sampling principle, the sample chamber temperature is assumed to be equal to the ambient temperature at all times downhole. Thermal inertia, heat transfer, temperature stratification in the sample and in the sample chamber is neglected. In reality, there are temperature differences between the outside and inside the probe, as the deployment time is reduced. Generally, these differences are summarized by the Φ-factor. The Φ-factor or thermal inertia is the ratio of the mass times the heat capacity of the sample to the sample container. The closer this is to value 1, the more representative the sample is (Ekkehard, 2020). For a more representative sample in the sampler, the following procedures are recommended: Preheat the sample chamber to ambient temperature with a dummy sample. The heat transfer across the shell surface is reduced by an insulating layer. Furthermore, by forcing natural convection in the sealed fluid sample, temperature stratification is avoided.

3. Design demonstrator probe inliSAMP and sampling procedures

3.1 Design and layout of mechanical components inliSAMP

The proof of concept demonstrated the implementation of the novel sampling method, illustrated in Figure 1. The inliSAMP probe was engineered and constructed as a demonstrator for this purpose. A specific sampling procedure was developed for inliSAMP, which was then deployed

on a borehole test rig under laboratory conditions. The sampling procedure was successfully tested with the demonstrator. The demonstrator inliSAMP is built according to the hottoolKIT standards. It consists of two high-temperature modules: the task specific sampling unit and a universal hydraulic power pack. The two modules are built up and installed in a housing tube, see Figure 2. The electronics boards required for the remote operation of the demonstrator are outside the housing tube and are supplied by laboratory power supplies. The setup is shown schematically in yellow on Figure 3. Components and assemblies used from the modular system and new designed parts for the borehole probes, are at different stages of product readiness and have different material requirements. For the sample unit, mainly stainless steel 1.4313 QT900, 1.4307, and 2.468 (Inconel® Alloy 718) were selected.

3.1.1 Hydraulic power pack

The hydraulic power pack is a module from the construction kit (Holbein et al., 2017) for down-hole tools. The hydraulic power pack consists of a 4-3-way valve, a high temperature pump, a high temperature motor, an oil tank and a lowering brake valve on the secondary side. Table 2 lists all purchased parts that were used. Figure 3 shows the hydraulic circuit diagram.

Table 2: Used purchased parts in the demonstrator inliSAMP

Item	Product	Producer
Electric Motor	EC-4pole 32 brushless 480 Watt | Heavy Duty	Maxon motor AG
Motor control board	EPOS4 CoMPact 50/8 CAN	Maxon motor AG
Fixed displacement micropumps	PB33	Hydro Leduc
4/3 Directional spool valve solenoid operated	WK06E-01	Tries GmbH & Co. KG
Lowering brake valve	SJ 00 G	HAWE Hydraulik SE
Heating mat	RS Pro Silicon Heater Mat, 80 W, 200 x 400mm, 12 V dc	RS Components GmbH
Pressure sensor	Series 7 LHP Inconel®Alloy 718	KELLER AG
Temperature sensor	PT 1000 Class B 1.0 x 3.0 mm	Farnell GmbH
Temperature sensor	PT 1000 Class B 1.7 x 1.7 mm	RS Components GmbH
Hydraulic fluid (fire resistant)	AeroShell Fluid 31	Shell Deutschland GmbH

3.1.2 Sampling unit

The sampling module comprises a sample chamber and two double-acting hydraulic cylinders arranged in tandem, as shown in enlargement in Figure 2. Connecting the hydraulic cylinders in parallel increases the piston rod force for both extension and retraction strokes. Both cylinders are equipped with a pressure sensor to monitor the force transmission over the piston rod. Pressure sensor P 3 measures the extension pressure (PUSH) and P 2 measures the retraction pressure (PULL) refers to Figure 3. The hydraulic fluid pressure data is crucial to operate and control the

sampling process remotely. The measured pressure rise in the cylinder tube is important information for determining the piston position in the sample chamber.

The sample chamber is a heatable pressure vessel insulated over the circumferential surface, see Figure 2. The connection between the housing tube and the sample chamber is implemented with a small inlet flange and bushing. This is radially connected to an axially and radially movable sleeve, which is around the inlet bore of the sample chamber (Berentelg et al., 2020). The sample chamber tube has an inner diameter of 55 mm and a stroke of 305 mm; thus, the sample volume is approximately 480 cm^3. The sample volume can be easily increased by using a longer stroke and longer tubes. The piston rod diameter is 20 mm in the sample chamber and 22 mm in the hydraulic cylinder due to buckling. Standard fine pitch threads of M20 X 1.5 are used for coupling and end stop. The assemblies are connected by a special gland and a multi-part piston rod.

As shown in the concept in Figure 1, the water sample is taken between the Sample piston and the Valve piston. In the design shown in Figure 2, both pistons are axially mounted movable on a piston rod. The piston movement is controlled between both stops. They are equipped with O-rings (material Fluorocarbon (FKM)), back-up rings (material Polytetrafluoroethylene (PTFE)) and guide rings (material PTFE with bronze) on the piston seal and rod seal. The sealing clearance between the tube and the piston is approximately 2/10 mm.

Technical cleanliness in the sample chamber is provided through the design, preparation, and the sampling process. At the beginning of sampling, when the cleaned probe is lowered, the two pistons are in contact on the face and the inlet port is filled with demineralized water. Due to the vertical position of the hole of the inlet and length and small diameter of the pipe, little substance exchange takes place through the water inside and outside. This could be further reduced by the use of a push-off cap. Due to the small axial stroke of 65 mm at sample termination, it is feasible to equip the moving piston with a pressure sensor and a short and a long resistance temperature sensor probe using flexible, high temperature pre-bent wires. The pressure sensor records the ambient pressure in the borehole and, after closure, the sample pressure in the sample chamber. Two immersion temperature sensors measure the temperatures in the sample chamber. A longer temperature sensor (immersion depth 20 mm) measures the sample temperature, defined *T1*. while the short sensor (immersion depth 1 mm) measures the boundary layer temperature between sample and piston, defined *T2*. Furthermore, the borehole temperature and the outside temperature are recorded with an external temperature sensor, defined as T inlet flange *T_IF* on the nose of the probe. When the probe is lowered downhole (descent probe), the water pressure pushes the Sample piston (lower piston) on the piston rod against a Nut, the lower Stop. The upper Stop for the Valve piston is a short, thick-walled pipe. The hydraulic valve is closed, and the pump is at a standstill, hence the retention force from the Sample piston is transferred to the hydraulic cylinder via the piston rod.

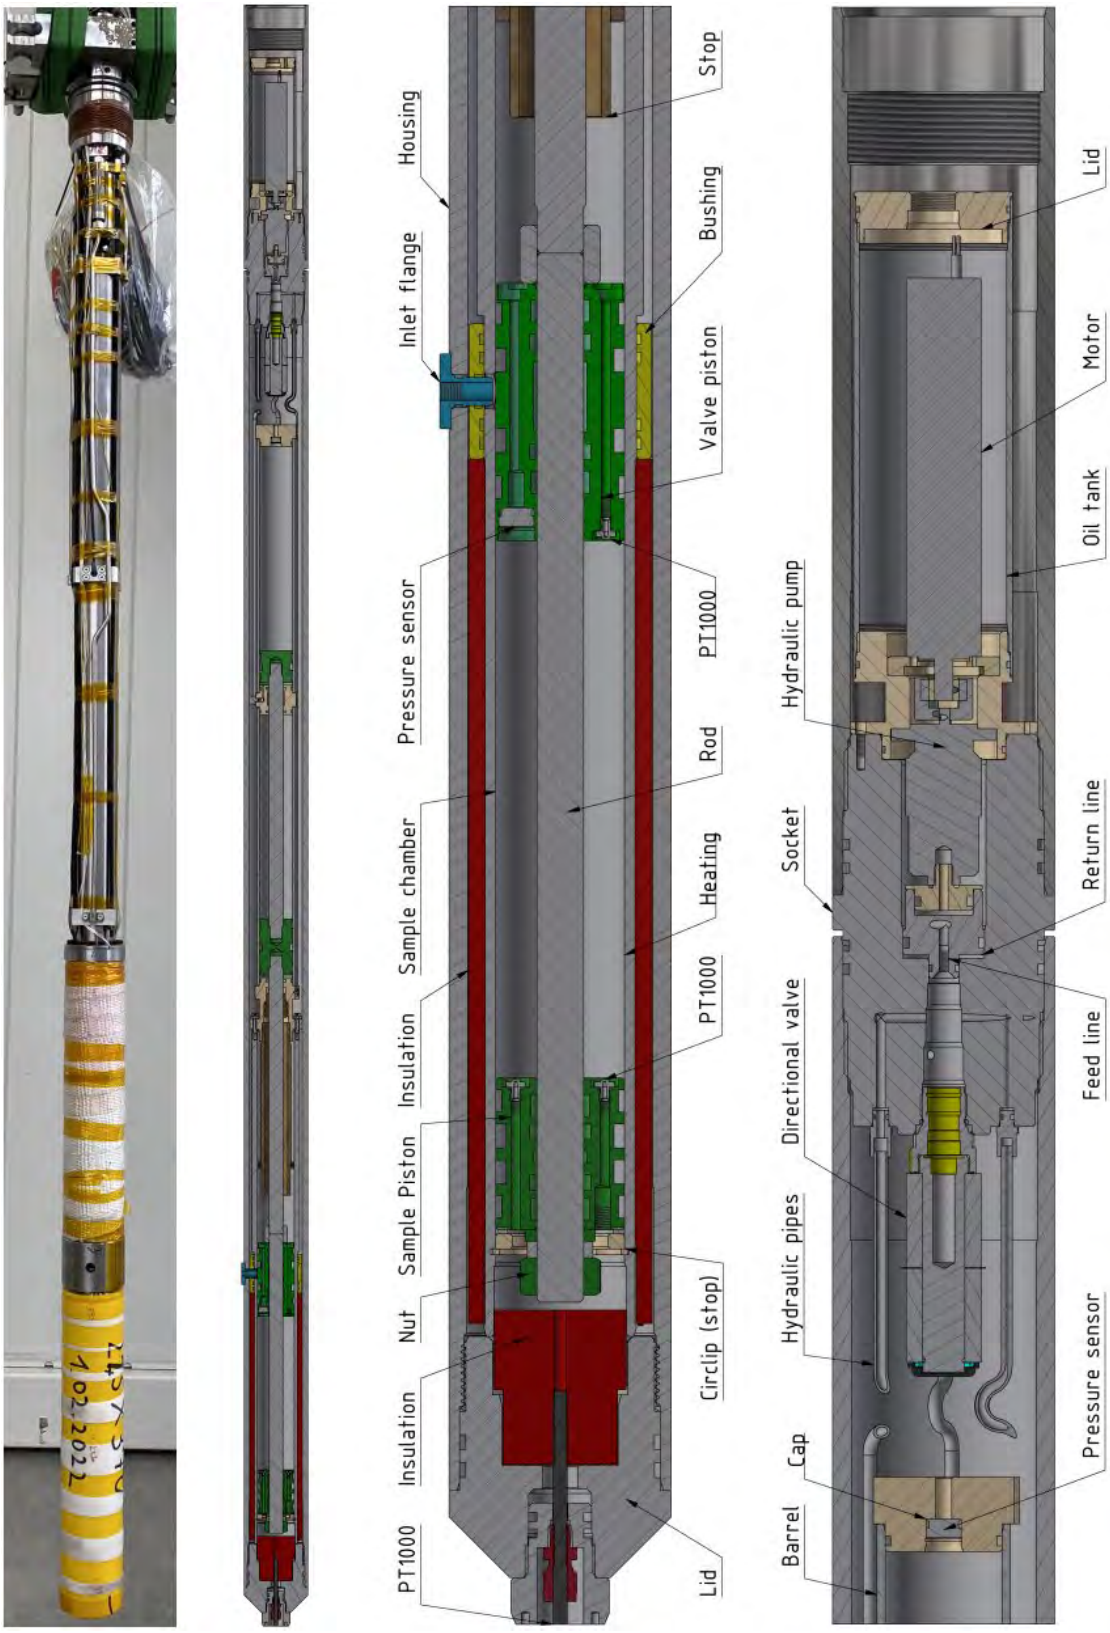

Figure 2: Left to right: photo of demonstrator inliSAMP used in test rig, CAD model borehole probe inliSAMP, enlargement: sample chamber, hydraulic power pack.

To initiate the inflow sample under load (inflow sample), the valve opens the retraction cylinder and hydraulic oil flows through a lowering brake valve to the tank. The lowering brake valve enables a set constant flow rate, largely disengaged of the load, and is used to adjust the sampling time according to the application requirements. Simultaneously, the pump transports oil on the extension side without back pressure. The process is terminated by contact between the Valve piston and the collar on the tie rod at the end of the stroke. A force equilibrium (enclosed sample) is created, and the movement of the Sample piston stops immediately. Thus, only little fluid power is required to move the Sample piston, the fluid sample and the Valve piston to the lower Stop, a heavy retaining ring. The retaining ring is seated in a groove in the pressure vessel tube and the exact position is adjusted by spacers.

The sample is sealed when the lower O-ring of the Valve piston has passed over the inlet bore. This initiates the storage phase, in which pressure and temperature are kept constant. The pressure in the sealed hot sample is temperature-dependent and must not fall below the borehole pressure. The pressure can be increased or decreased by changing the heating power, or more precisely, changing the global sample chamber temperature.

In case of leakage, deviation, or temperature drops, the sample pressure can be manually increased as required by fluid power through the piston rod and the Valve piston without changing the sample temperature. The heating of the sample chamber carries out three functions, heating the sample chamber and dummy sample before sampling in a hotter environment, keeping the temperature of the sample constant at colder outside temperature and to avoid shrinkage of assemblies. The resistance heating mat is glued onto the sample chamber up to the bushing and insulated towards the outside (see Figure 2 left). During storage phase, the outside temperatures are below the sample temperature and required heating power depends on the outside temperature.

The heating and insulation design of the sample unit is adapted from everyday objects such as an electric kettle. During storage phase, the heat source is at the bottom and the heat sink, the coldest point, is at the top. Thus, the different density of the fluid creates a static buoyancy. Natural convection leads to a homogeneous permeability and temperature distribution in the sample chamber. Before sample dispensing (retrieve sample), the inlet flange and outer housing is heated externally with a heating jacket (Leutert, 2021). In addition, the lower Nut on the piston rod must be manually readjusted. This reduces the pressure drop during sample dispensing.

3.2 Wireline power supply unit, control and communication board

3.2.1 Power supply requirements and layout for inliSAMP

The probe is powered by a DC power supply. Unlike the inspection tools such as the inliCAM probe, the expected consumption of the probe is much higher (Dietze, 2020). The embedded system and the communication systems are using about 10 W. The expected power consumption for the heat and motor control is approximately 400 W. In addition, the valves require 10 watts, and the maximum power is calculated as 420 W. It is recommended to use the theoretical maximum power transfer at the impedance matching point, where the output voltage is the same as the voltage over the cable and thus the probe voltage is half of the supply. For the coax cable of inliCAM, about 4.2 km long, and including a higher cable resistance to heat, a power supply with 520 Volt DC is needed. When less power is needed, nearly the maximal voltage applies to the entrance of the DC-DC converters at the probe. Therefore, special DC-DC converters operating at

high volt are needed. For inliSAMP an additional circuit converter for use of long cables and storage functionality was invented. It operates in a Dewar flask with cooling reservoir (Dietze, 2020). Alternatively, a larger cable diameter with more copper can be used, but this will increase the weight and require larger winding equipment. A coaxial cable is usually very heavy in itself. The maximum length should be short enough with a reserve, before tearing itself off from weight. For example, the inliCAM cable weighs 1125.6 kg (in air), which is about 25% of the cable strength. Holding a probe with additional 150 kg is acceptable in water (RochesterWireCable., 2012).

3.2.2 Communication and embedded system

Communication, modems, and processing system were designed and developed for a universal use in borehole probes (Holbein et al., 2018). The main board of the embedded system, High Temperature Embedded System (HiTES), has as main chip a Field Programming Array (FPGA), which allows an implementation of algorithms for data modulation and demodulation in a suitable flexible way.

The wireline cable communication system was developed by an external partner and is presented in (Schubert et al., 2015) The communication system consists of plug & play software and hardware and further a Softcore-CPU for control and monitoring. The whole communication system is the same as the one successfully used for the inliCAM project, including the filter amplifier boards. The host modem, which is connected to the host PC via Ethernet, is a HiTES - system too, identical as for all wireline connected probes.

3.2.3 Electronics for measurement and control technology

To get access to the peripheral sensor and actors of inliSAMP, an IO-plugon-Board for HiTES has been developed, handling several measurement inputs and digital outputs. A motor control board for the hydraulic motor with a suitable size for the probe Dewar (Spatafora et al., 2016) was obtainable from Maxon™ (EPOS4 CoMPact 50/8 CAN, see Table 2). A Power IO board (PIO), which enables control of valves and heaters, as well as inputs for temperature sensors (Resistance thermometer, PT1000) and pressure sensors (piezoresistive pressure transducers), was built and installed. The layout of the circuit fits the mounting bars of the main board in the Dewar tube.

3.2.4 Information management

The host-PC software from hotToolKIT (Isele et al., 2015a), named “GeoGUI” is a workbench where forms can be composed with gadgets, which are connected to values to the probe or sending commands. InliSAMP has several forms and is designed with a GUI for full live control of the system. GeoGUI is connected to an SQL database and for example has the ability to replay a session at different speeds. Additional database export features were implemented for InliSAMP: Sensor data, valve position, motor control values, please refer to Figure 3.

3.2.4 *Control and monitoring of pressure and temperature in the sample chamber*

For the operation, partly automatized procedures have been implemented to HiTES Firmware to make remote control easier: To handle pressure, a "Wait-until-P_set-raise" and "maintain-P_set", where P_set is selectable out of the measured pressures in the inliSAMP. The procedures compare the measured P_set with a demand pressure and, if necessary, drives the motor of the hydraulic

pump with a demand velocity. Heating of the probe is done by supplying the heat mat with 28 Volt and up to 18 Ampere.

Table 3: Sampling procedure: actions, monitoring, and measurements as positions of sensors are in Figure 3 and Figure 4.

operation	Phase principle	environment borehole test rig	Function for the probe operator or computer	Monitoring Measuring data in the probe
descent	①descent probe	p increase TIF increase	valve CLOSED preheat sample chamber motor 0 rpm.	P1 increase TIF; T1 increase P2, P3 = 1 bar
dummyIN	②inflow probe	p const TIF const	valve Port PUSH (B) heat sample chamber motor 4500 rpm	P1 const T1 increase P2 increase, as a braking element
dummyOUT	⑤outflow probe	p const TIF const	valve Port PULL (A) heat sample chamber motor 2500 rpm	P1 const T1 const P2 increase

enclose	③enclose probe	p const TIF const	valve Port PUSH (B) control heat sample chamber motor 2500 rpm	P1 const T1 const P2 and P3, decrease to balance
storage	④storage sample	p decrease TIF decrease	valve Port PUSH (B) control heat sample chamber motor 1500 rpm	P1 const T1 const P3 increase
sampleOUT	⑤retrieve sample	p = 1 bar T air = 14 °C	valve Port PULL (A) control heat sample chamber motor 2500 rpm	P1 const T1 const P2 increase

The use of a software of pulse-width modulation (PWM) with a cycle of two seconds and a minimal time slot of 20 milli seconds results in a demand of X % PWM of the maximal power of 504 watts. To heat up the sample chamber (demand temperature T_{demand} increase of the water sample), the nominal power is approximately 400 watts, this is defined for 100 % PWM heating power. For temperature control, a PI-Algorithm is provided with a cycle period of 100 milli seconds: The bias X of demand and curing temperature T_{cur} is calculated in Equation 1.

$$x_d(t) = T_{demand} - T_{cur}(t) \qquad (Equation\ 1)$$

$$x_{sum}(t) = k_{s0}x_{sum}(t-1) + k_{s1}x_d(t) \qquad (Equation\ 2)$$

$$y(t) = k_p x_d(t) + k_i x_{sum}(t) \qquad (Equation\ 3)$$

The sum for integral part is done in Equation 2. But additionally, because of the lack of negative output, there is no cooling possible, the integral sum is kept positive or set to zero. The vanish

factor k_{s0} should be greater than zero and less than 1.0. Equation 3 shows the addition of the P- and the I-Part creating the output y. For example, the P-factor k_p is default set to 5.9. With ignoring the I-Part the maximum y = 100 % PWM is then reached when $T_{cur} < T_{demand} - 17$ K and defines a linear working range of 17 K below the demand temperature.

3.3 Sampling procedure

The sampling procedures are the sequences of operations the operator or the program runs through. It includes 7 operations steps and is listed in Table 3. These are the execution of the 5 different fluid sample principles, see Figure 1. The function at system level is not explained. It involves the operation of the control elements in sequence as given in the Table 3 and observation of the measurement data by the operator or a program. Below are listed the controls and measuring sensors for the execution and monitoring of the fluid sampling. The positions of the sensors and actuators are shown in Figure 3 and Figure 4.

- Control element:
  - hydraulic directional valve, status flow: Port PULL (A); CLOSED; Port PUSH (B)
  - electric motor rpm, user selectable: 1500 to 6000 rpm
  - heating, user selectable or controller max. 400 watts: 0 to 100 % PWM heat power
- Monitoring system
  - sample chamber temperature, Valve piston: T1, T2; Sample piston: T3.
  - borehole environment temperature outside inliSAMP: TIF
  - sample pressure: P1; pressure hydraulic pull; P2 pressure hydraulic push: P3.

The sampling procedure listed in Table 3 and actions are started and ended by predefined measured values and predefined states. Before sampling or testing, the preparation includes a surface pressure test, use of clean and rinsed equipment, connection check, and power supply review. At "**descent**" of the probe in the borehole the ambient pressure P1 and temperatures TIF, T1 increases with depth, the sample chamber is empty and heated up in accordance to TIF. The valve is at status CLOSED and motor on stop. At planned depth, temperature, formation pressure or some other point, the operation **dummyIN** starts, the hydraulic valve opens Port PUSH (B) and the motor set to 4500 rpm. It is finished when P2 decreases. Then the full sample chamber with T1 is heated up to TIF. In the next operation **dummyOUT** the hydraulic valve opens Port PULL (A) and the motor set to 2500 rpm, and it dispenses the dummy sample. It is finished when P1 rises up. The sample chamber temperature T1 is kept constant at TIF using the heating. At sampleIN the hydraulic valve opens Port PUSH (B) and the motor set to 4500 rpm. The sample is taken and the chamber temperature T1 is heated up again to TIF if necessary. It is finished when P2 decreases. To enclose the fluid sample, the hydraulic valve again opens Port PUSH (B) and the motor set to 2500 rpm. It is finished when P1 rises a little up the hydraulic cylinder are in equilibrium as the sample is confined between Sample valve and Piston valve. The sample chamber temperature is kept to T1. To store the fluid sample, the hydraulic valve opens Port PUSH (B) and the motor set intermittent to 1500 rpm and finished when P1 rises up a little in a hysteresis loop. The control of the chamber temperature and pressure is achieved via the T1 control. This may be used as an alternative method. At surface conditions, the sample dispensed "sampleOUT" with hydraulic valve opens Port PULL (A) and the motor set to 2500 rpm. At first, the system is in balance, hence only small force is required. When the sample chamber is connected to the transport cylinder, the full mechanic load has to be applied. The heat control heats the sample chamber to T1. The operation is completed

when P1 rises up. The procedure was carried out in the proof of concept experiment in section 5. A detailed protocol of the experimental demonstration can be sent on request.

4. Setup test environment demonstrator inliSAMP

4.1 Test rig characteristics for fluid sampling

The functioning of sampling procedure and quality of measurements outputs of the demonstrator inliSAMP are evaluated on a test rig under laboratory conditions. The test rig simulates the environmental conditions in the borehole at a specific depth. Only demineralized water in the liquid state is used as downhole fluid. By varying the parameters of pressure and temperature of the water, different virtual depths can be reached. Heating and cooling sequences simulate the descent and ascent of the probe. This is essential for mapping the heating and cooling processes inside the probe. The test rig delivers a flow of water at a constant temperature and pressure. The sample is taken from a heated pressure vessel (preheater). In a real downhole application, the sample from the borehole is dispensed into a transport cylinder (Leutert, 2021). In this test rig, the sample is returned to the preheater at the end of the sampling procedure. The probe mechanism sets the flow rate. To maintain the aggregate condition of the water, the design of the test rig has to be failure safe. To fulfil the boundary conditions of taking samples up to 200 °C, all components have to be temperature rated. For safety measures, the sample pressure is scaled from 600 bars to 60 bars. This is possible as the isobars are adequately close to each other in the liquid state (Huber et al.). Demineralized water is used to prevent rust.

4.2 Test environment for hot water deep borehole

The test rig is shown in Figure 3 for the execution and monitoring of the fluid sampling procedure described in subsection 3.3. The demonstrator inliSAMP stands upright on a support and is permanently connected to the test rig. The test rig consists of a commercial standard hydraulic double-acting cylinder (DAC) with fastenings, a heatable pressure vessel (preheater) and a heating hose. The DAC is grabbed by a lifting hook at the head. Test weights (2.1 t) equivalent to 88 bars are attached to the rod of DAC. The retracting port of the DAC is connected with a hose via a check ball valve to the lower port of the preheater. A commercial flexible heating hose connects the upper port of the preheater to the inlet flange of the demonstrator inliSAMP. The demonstrator inliSAMP and the preheater are mounted vertically to obtain convection in the vessels. Tap water is used to cool the outer housing tube of the demonstrator. A pressure gauge and transmitter, and a lower and upper thermocouples type K monitor the pressure. Pressure *P* 4 and temperature, *T_Ph* and *T_IF* are logged by a computer. All hot hoses and connections are insulated and heated externally. The laboratory power supply units for the heaters are regulated manually. For testing, the demonstrator inliSAMP is equipped with additional temperature sensors that provide information about the operation of the probe and help gain a better understanding of the sampling processes and effects in the probe. For easier handling in test operation, the lower lid is also not used, see Figure 4. Hence, temperature *T_Ph* and *T_IF* represents the borehole temperature in the test rig. The outer temperature sensor *T_IF* is mounted on the inlet flange to the sample

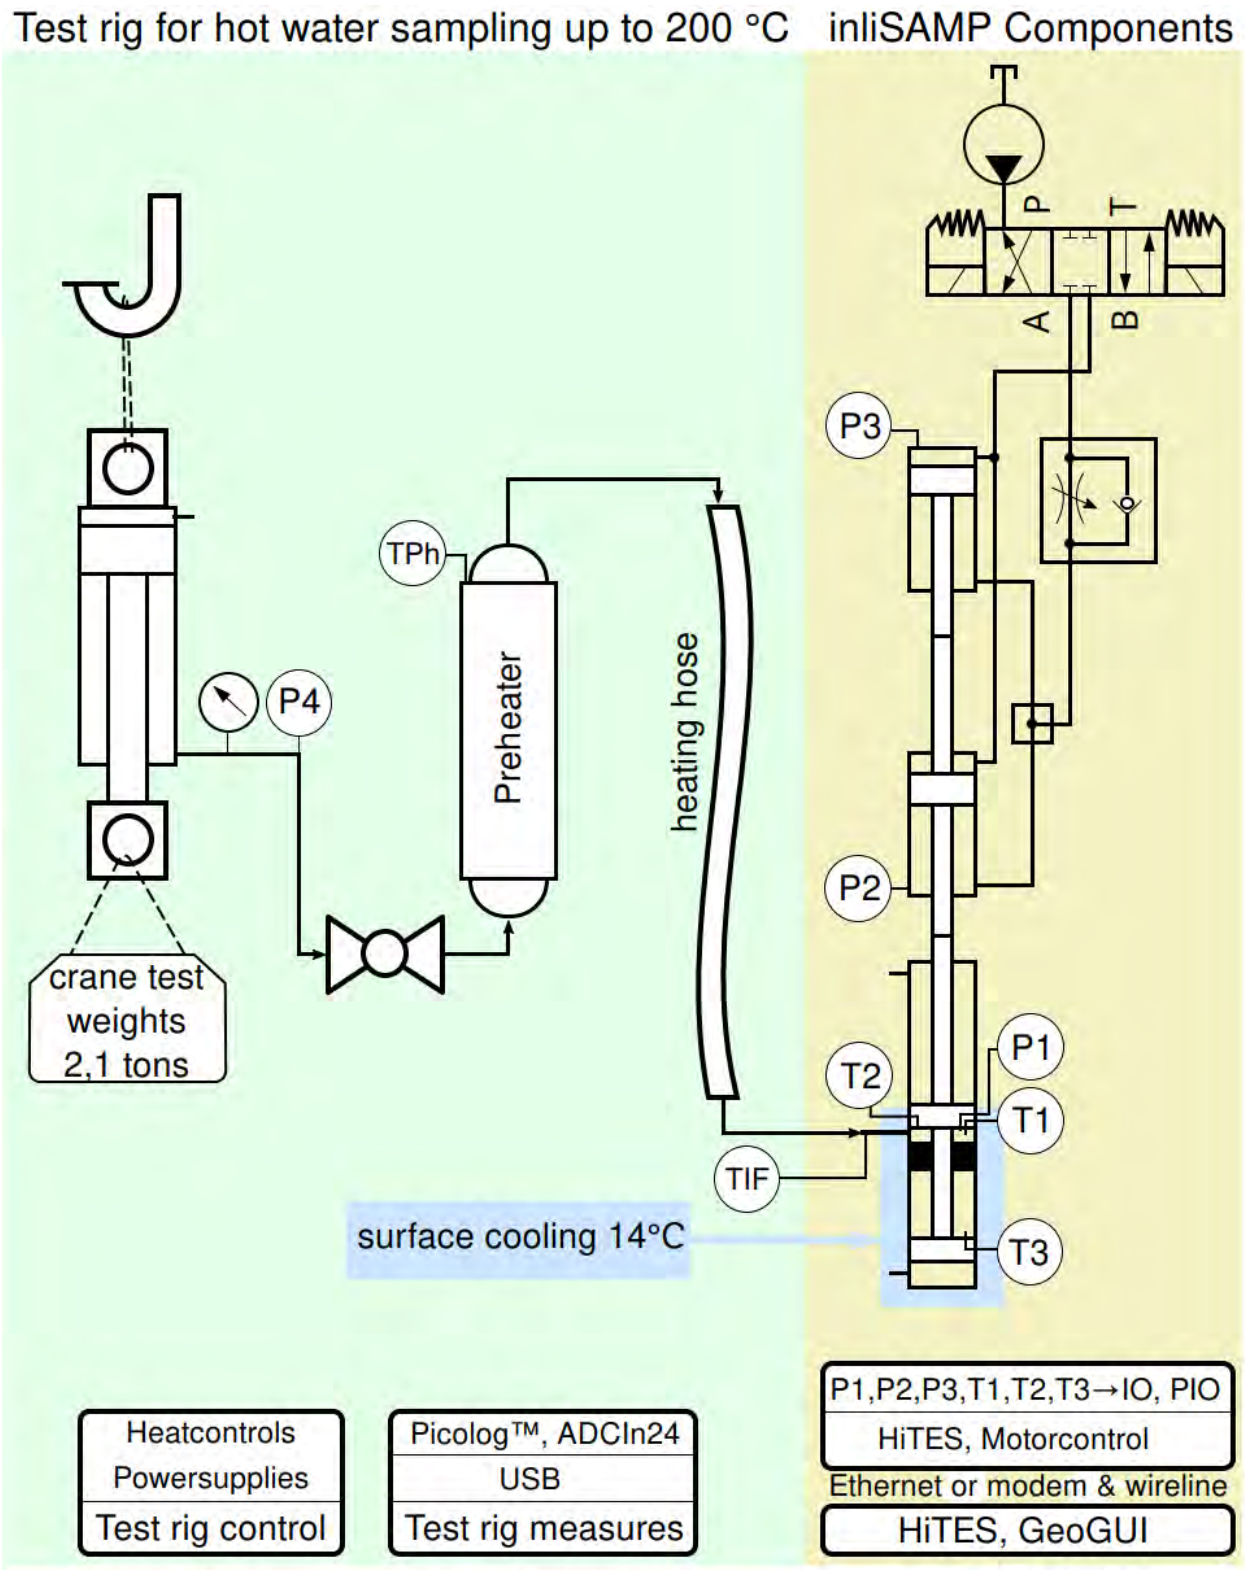

Figure 3: green: Test rig for hot water sampling up to 200 °C; yellow: hydraulic circuit diagram of fluid demonstrator inliSAMP.

chamber and important during the **descent** and **storage** operations as well while dispensing the sample. On the probe *T_HM* is on the internal heating mat. It monitors the maximum heating temperature placed on the tube at a lower heat flux. *T_SC*2 is positioned in the centre of the sample chamber tube and provides information about the heat transfer to the housing and the sample chamber. *T_SC*2 is near the inlet flange and bushing, it monitors the heat flux over the thermal bridge of the demonstrator. The immersion temperature sensor *T*3 in the Sample piston, together with temperature sensors *T*1 and *T2*, monitors the temperature stratification in the fluid sample over the height of the sample chamber.

4.3 Test run fluid sampling procedures

The planned tests involve going through the full sampling procedure (see Table 3) using the test rig and the demonstrator inliSAMP. The objective is to test the sampling process applied with the demonstrator and evaluate the temperature curves and pressure maintenance over the full sampling procedure. The sampling history data are proof for the quality of the water sample. In addition, the following issues are to be answered by the experiment: Required heating power during different operations and in transition, heat up and temperature regulation in a cold environment, stability of pressure and temperature of the sealed sample, temperature stratification and natural convection in the sample, behaviour of the temperature curve, during sample taking and dispensing.

5. Results proof of concept demonstrator

5.1 Test execution Sampling procedure

In the **descent** probe operation, the probe housing tube was heated up to 200 °C with a detachable heating band, as well as the test rig components such as the water-filled preheater, and the heating hose. Inside, the PWM heating power preheated the empty sample chamber to 200 °C. The sample pressure was set by the ambient pressure at approximately 88 bars (see Figure 4). A heated fluid sample was taken in the sample chamber. After **dummyIN** operation, the dummy sample was deliberately overheated by the PWM heating power up to 204 °C, to avoid a temperature drop in the next operation. The other temperatures were manually controlled to be constant at about 200 °C. While dispensing the dummy sample at **dummyOUT** the PWM heating power was maintained in the sample chamber temperature. After short stabilization of the reference temperature, at **sampleIN** the final sample was taken at 200 °C. During **enclose** the sample was enclosed by the moving Sample piston and Valve piston and was heated up with the PWM heating power to 200 °C. Briefly, after sealing the sample at **storage**, the external heaters are switched off and only the PWM heating power was used to maintain the sample temperature. The heating hose is removed. The housing tube and the inlet flange are cooled down to 14 °C with faucet water. The PWM heating power is used to maintain the sample temperature and pressure remotely. The hydraulic system was being additionally used to manually increase the pressure. For the retrieval of the sample into the preheater at **sampleOUT**, the heating hose was reconnected to the inlet flange and the heating band heats up the housing tube. The PWM heating power was reduced to avoid overheating and overpressure while heating from outside. At constant temperatures at the inner and outer vessels, the sample is dispensed to the preheater.

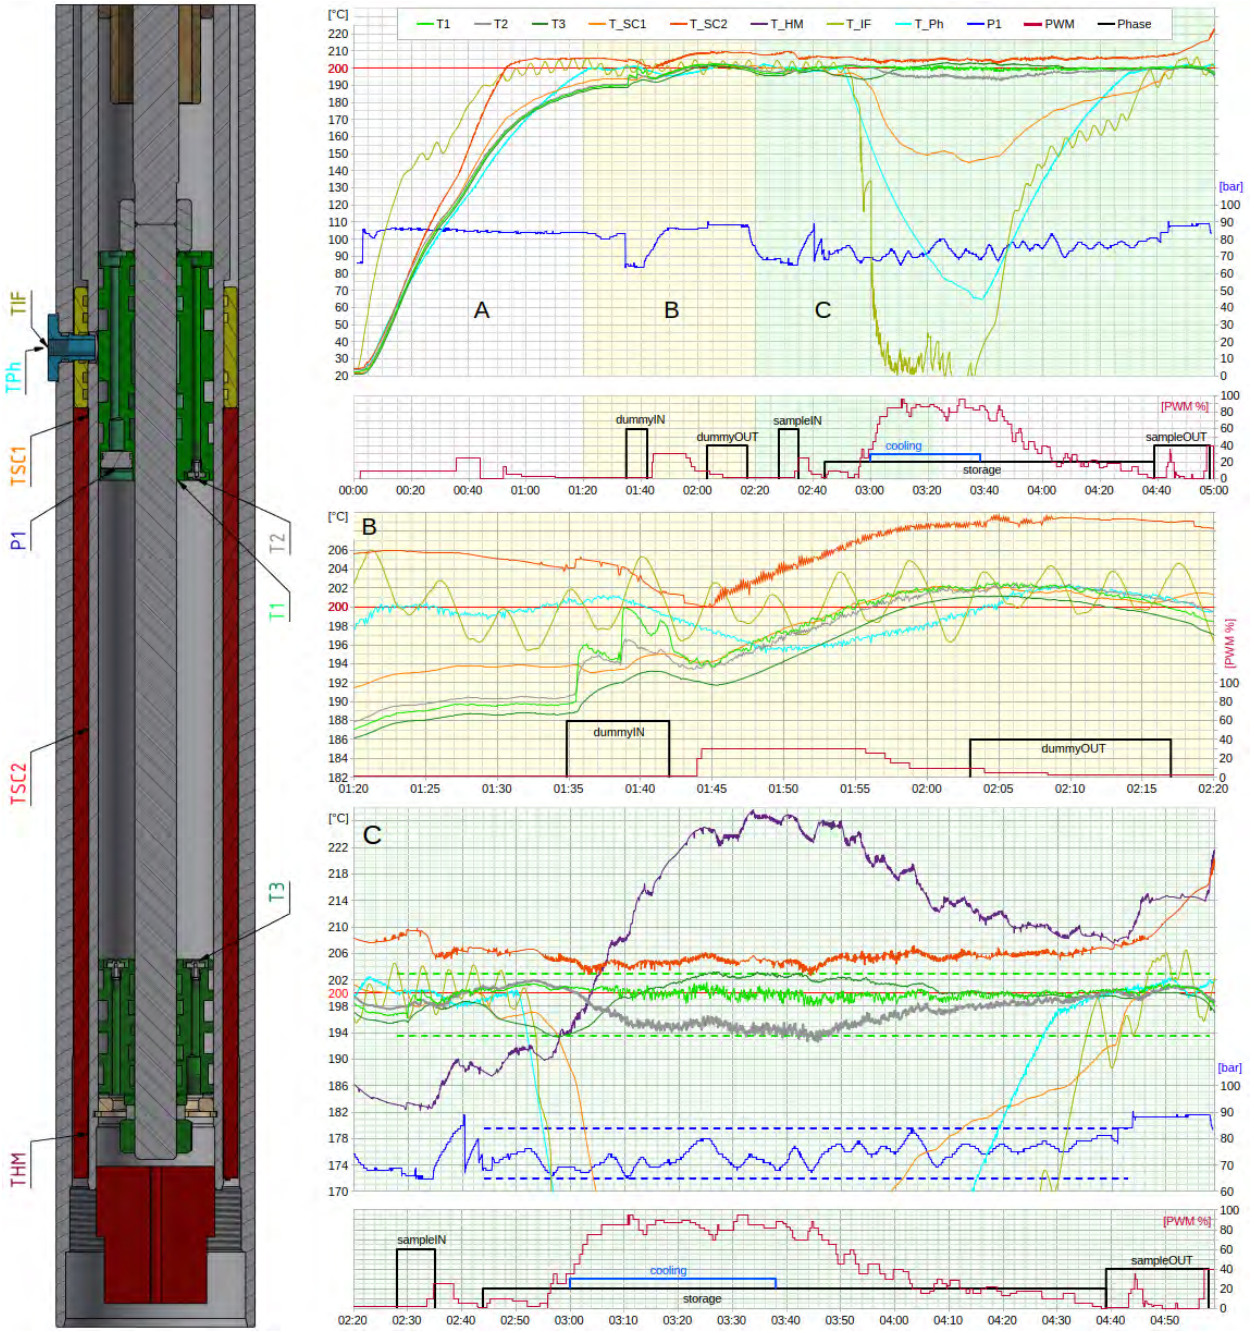

Figure 4: Left: sample chamber with temperature measuring points and pressure sensor (P1). Right: Data of test run with a dummy sample and representative water sample. The upper diagram is an overview of all measured values and operations. Section B shows dummy sample inflow (dummyIN), heat up and stabilize, dummy sample output (dummyOUT), Section C shows sample inflow (sampleIN), heat up and stabilize, sample output retrieval (sampleOUT).

5.2 Results and data of the demonstration run

The measured values of the sensors from the test are shown in Figure 4. The upper section is the overview of all data and performed operations over a demonstration run. The temperature data is shown on the left ordinate and the pressure data is shown on the right ordinate. On the abscissa,

the time of experiment and additionally the steps of sampling procedure and PWM heating power of heating are listed. Section B shows the intake, heat up and dispensing of the dummy sample, and section C shows the intake, storage and dispensing of the representative sample in greatly enlarged form. The accurate representation of the data is intended to facilitate the presentation of thermodynamic effects of the different operations and to show the quality of the equipment.

5.2.1 Result descent probe: heat up and pressure monitor in Figure 4 section A

During heat up, the temperatures *T1, T*2, *T*3 and *T_SC*1 increased slower than the middle outer sample chamber temperature *T_SC*2. At 01:00 *T_SC*2 stabilized with 205 °C, at a utilization rate of 14% PWM heating power, illustrated in the upper Figure 4 section A. At the end of this operation the curve of *T1, T*2, *T*3 and *T_SC*1 flattened, and they have reached a plateau at 190 °C, the temperature difference is 3 K. Temperatures *T_IF* and *T_Ph* showed oscillations and were on average about 200 °C hot. As the fluid sample was open until the **storage** operation, the surrounding pressure was dependent on the test rig. First, the surrounding pressure *P*1 was above 65 bars. During the heating period, the pressure increased to 88 bars due to thermal expansion and the resulting static friction forces in the cylinder. These can be explained by the design of the test setup. The temperature data showed that the heat transfer from the outer housing tube to the sample chamber varies in vertical (axial) direction. In the area from the inlet flange the heat transfer is high, and at the lower part of the sample chamber vessel to the piston it is low. It is limited by the maximum operation temperature of the heating mat and sealing. It is monitored with *T _HM* in section C. Therefore, the empty sample chamber can only be slowly preheated from the outside and inside.

5.2.2 Result dummy sample: inflow, heat up and outflow in Figure 4 section B

During the inflow of the hot sample (*T_Ph*=201 °C), temperatures *T1, T*2, and *T3* increased immediately at 01:35 shown in Figure 4 section B. After taking the sample, *T_SC*2 decreased from 205 to 200 °C at 01:45 evenly. Due to thermal inertia and thermal gradients, the taken sample temperature *T1, T*2, was 194 °C, 5 K below the reference temperature of 200 °C. The reference temperature *T_Ph* decreased after the sampling as cold-water flows into the preheater, this does not affect the demonstration. With 30% PWM heating power from 1:45 to 1:55, the dummy sample was overheated *T_SC*2 at 210 °C, so fluid temperatures *T1, T*2 increased to 202 °C, with *T3* reached only 201 °C at 02:05. After dispensing the dummy sample, *T1* decreased to 197 °C, whereas *T2* was approximately 1 K above. Temperature *T*3 decreased to 195 °C at 2:20. Despite minimal PWM heating power, *T_SC*2 remained at 210 °C.

As a finding, the 200 °C hot water dummy sample from the preheater heats up the upper part of the sample chamber and the pistons. In summary, the fluid sample becomes slightly colder, as the heat is distributed in the probe. Due to the increased heat transfer in a fluid loaded sample chamber, the system can be PWM power heated more homogeneously and faster to reach equilibrium with the reference temperature.

5.2.3 Results sample: inflow, heat up, storage and retrieval, sampleOUT in Figure 4 section C

After preheating with the dummy sample at 2:20, the temperatures at the different temperature measuring points are much closer to each other. At the beginning of the operation Temperatures **sampleIN** at 2:30 *T3, T1, T2* were at 196 °C to 198 °C represented in the Figure 4 section C. The

PWM heating power with 10 to 20% was used to maintain the taken sample *T1* and *T2* at 200 °C at 02:40, however, temperature *T3* did not increase consider-ably. Before the sample is drawn and enclosed the heating controller starts maintaining the sample temperature, represented by a dashed green line in Figure 4 section C. Since the pressure in the sample *P* 1 was dependent on the total fluid temperature, it also ramps up until 90 bars.

At 02:44 after the **enclose** operation the fluid sample was sealed and thus the sample probe is disconnected from the test rig. The operation **storage** has been started and can be controlled by the operator. From this moment, the fluid sample in the sample chamber was separated from the pressure compensation of the test rig. Due to the closed sample chamber, the pressure *P*1 was directly dependent on the actual temperature. This state is marked by a dashed blue line. Furthermore, the dashed line blue and green represent the range of minimum and maximum values of pressure and temperature in the **storage** operation. Small temperature changes of the inert mass of fluid sample and sample chamber result in large pressure changes, as the pressure values went up and down. It had the lower boundary at inlet pressure 65 bars and upper boundary at 83 bars (blue dashed line), as the given procedure allows only positive elevations.

At 02:50 all external heaters were disabled, and *T_Ph* began to decrease slowly to 65 °C. The housing tube and inlet hole *T_IF* were cooled below 20 °C, first with air and then with faucet water. Hence, the temperature at the inlet flange *T_SC*1 decreased to 145 °C, simultaneously *T1, T*2 decreased and stabilized at 201 °C at 02:56. Temperature *T3* dropped to 194 °C, the lower boundary of the temperature range.

Next, the PWM heating power was ramped-up to 90% to maintain *T1* at a constant value. At 02:58 at temperature lines intersection point the lower piston temperature *T3* and *T_SC*1 started to rise and stabilized to 203 °C at 03:26 the upper boundary value. Concurrent *T2* over time decrease to 194°C with small aberration. As well, *T1* wobbled around the target temperature with ± 1 K difference.

During the **storage** operation and extensive *cooling*, temperature *T_SC*2 decrease evenly to a minimum of 204 °C, although the PWM heating load was at peak. Further, the curve *T_HM* showed a maximum temperature of 227 °C at 03:40, indicating the activity of the internal heat mat. At 03:40 the detachable heating band, preheater and heating hose were set back and heated up to a reference temperature of 200 °C of the test rig. The PWM heating power was reduced accordingly. The fluid sample temperatures *T1, T*2, and *T3* slowly converge nearly to 200 °C, beginning at 03:45 until 04:39. When the sample was half retrieved *T1, T*2 rose to 201 °C. After sample dispensing *sampleOUT*, the *T1, T*2, *T*3 dropped to a minimum of 198 °C, while *T_IF* and *T_Ph* fluctuated slightly. During sample dispensing, the pressure increases to 88 bars to overcome the frictional forces in the cylinders.

The results and data show that after dispensing the dummy sample, temperatures in the sample chamber dropped 2 K because of cooling effects in the sample chamber. This small value indicates that the temperature is evenly distributed. Next, the incoming hotter sample heats up slightly the sample chamber, as *T*1 and *T2* rose. After the additional heating with the PWM heating of the chamber, there was subsequently a temperature stratification due to cooling processes and an inhomogeneous temperature distribution in the sample chamber. During the **storage** operation and cooling stage, the top of the sample chamber and inlet flange is colder as the bottom (see design of the probe Figure 2). As shown in the measurement data applying the heating power to the lower

part of the sample chamber, leads to a reversal of the thermodynamic system and the temperature stratification dissolved (follow *T3* from 2:56 to 3:35). This result is an inversion of the temperatures. At the lower Sample piston, the highest temperatures are measured, and at the boundary layer at the Valve piston the lowest. The temperature *T1* immersed in the fluid remained approximately constant but gets many small jumps. In addition, the sample chamber wall temperature *T_SC*2 decreased while heating power is high. The effect can be explained by the occurrence of natural convection, as the chamber is cooled at the top and heated at the bottom. The coincident heating and cooling of the sample chamber leads to vertically different temperatures in the fluid sample. Thus, a flow is created by different temperatures of layers, which affects the density. This leads to a steady temperature exchange, increased cooling of the sample chamber tube, and mixing of the sample.

After the water cooling was disabled, the heating power was reduced accordingly. Simultaneously, the vertical temperature difference in the sample decreased. Due to the homogeneous temperature distribution in the sample chamber and the successful mixing of the sample, the temperatures converged towards 200 °C.

As the experiment shows, an electrical heating power of 400 watts, insulation and good design of the sample chamber is sufficient to maintain the temperature in the sample chamber permanently. Furthermore, the seals (O-ring) kept the pressure in the sampling process without leakage on the demonstration run. Materials FKM and FFKM were used. The experience with these materials under the given conditions at 200 °C and 60 to 100 bars is the failure of the O-ring after passing through the radial inlet bore several times. A revision of the design is necessary here.

Furthermore, the housing tube of the demonstrator housing is made of steel. A housing tube of the same dimension made of Inconel® Alloy 718 has a lower thermal conductivity, and the system would be cooled and heated more slowly by the environment.

6. Discussion

The findings from the experiment show that, under laboratory conditions, a fluid sample can be taken, stored and dispensed using the demonstrator inliSAMP in the test rig. The quantitative results from the experiment show that with the execution of the fluid sampling procedure, the sample temperature and pressure in the sample chamber deviates only slightly from reference fluid in the preheater. Thus, proof of concept has shown that a fluid sample can be collected and stored in the inliSAMP demonstrator under nearly in-situ conditions.

First, a water dummy sample with 200 °C and 65 bars was taken from the preheater. In the cold sample chamber inside the probe, it was heated up to the target temperature of 200 °C and dispensed back in the preheater. Second, the actual sample was taken from the preheater and stored in a clean, warmed-up sample chamber. When the sample was stored in the demonstrator, the heating hose was disconnected. The outer housing was cooled down to 14 °C. The sample temperature and pressure were maintained by the sample chamber heater control and hydraulic piston force. Only small pressure overshoots were allowed. Natural convection is used to keep a homogeneous sample. At the end, the sample was dispensed into the preheater at nearly 200 °C and 88 bars.

The inliSAMP demonstrator consists of a stable housing with the sample unit and a hydraulic power pack and electric supply. The parts are developed accordance to the HottoolKIT standards and taken from the modular system. The sample unit was developed for undisturbed and pressure-constant sample collection, storage, and dispensing. The high-performance hydraulic unit was engineered for high temperature operation and for usage in very small, round installation spaces. The associated communication and power supply was provided via a high temperature circuit board HiTES and power supply units in the laboratory.

The sampling procedure was developed for the inliSAMP demonstrator with the aim of obtaining a representative fluid. A key feature is the preheating of the sample chamber by a dummy sample, mixing and adaptive temperature control of the sealed sample during uplift and transportation. The test rig provides preheated water with a permanent pressure control. Also heating jackets and a heating band for thermal simulation of a borehole environment. The total power consumption of the demonstrator was also derived from the experiment. The power requirement is approximately 470 Watts for inliSAMP (see section 3.2), 400 Watts for heating at an ambient temperature of 14 °C in water, 50 Watts for the electric hydraulic motor, 10 Watts for the alternately powered valve and 10 Watts for permanent power for embedded and communication. Thus, for industrial available cables, the maximum cable length or operation depth can be calculated. A coax cable of 5 km length and 500 V DC capable, with a bit thicker wire than the cable of video probe inliCAM is required.

The quality of the fluid sample taken with the demonstrator has been assured by various technical measures such as the use of an adaptive intake and sealing mechanism, temperature controllers and temperature monitoring. Sample temperature and pressure, and sample status can be directly monitored and logged. Before the storage operation the temperature can be increased manually by the operator. The sample pressure can be increased manually as often and as high as desired during storage.

The temperature distribution in the sample is monitored at three measuring points and adjusted by an internal heating control according to the predefined procedure. The temperature gap between the sample chamber and the borehole is reduced by preheating. With a dummy sample, the temperature difference is reduced to 6 K at 200 °C during 3 hr testing. Convection dissolves the temperature stratification and permanently mixes the sample in the storage operation. Processes such as over heating, cooling, degassing, mineral perception which result in an alteration of the sample are suppressed by these measures. The pressure in the sample chamber is identical to the formation pressure until sealing. Moreover, the sample is collected slowly, independent of the load. Due to the simple sealing mechanism, the formation pressure or a higher adjustable sample pressure is in the sample chamber. Hence, there are no pressure differences and processes such as flashing and adiabatic cooling does not occur. The overpressure is to ensure no alteration of the sample, the maximum range value is 20 bars plus, due to thermal expansion.

Similar temperatures to the test bed and demonstrator at 190 – 197.5 °C were measured downhole in geothermal wells using the GTFSampler (Hsieh et al., 2021). After the probe has cooled down to about 20 °C, the sample pressure is 25 bars, The aqueous composition of the sample is verified by a simulation and the geochemical characteristics provides knowledge about the geothermal reservoir. Hence, downhole procedure of full pressurization at formation pressure and pressurization above dissolved gas pressure should be further investigated. A similar result is provided by the in-situ sampling (150 °C, 45 MPa) in Groß Schönebeck, Germany with the Leutert

system (Regenspurg et al., 2010) from the borehole. Here, no results of the measurement of pressure and temperature at the surface are measured, as only downhole fluid from the borehole analysis is existent. In addition, the inliSAMP demonstrator could provide temperature and pressure data over the wireline.

The integrity of the fluid sampler inliSAMP demonstrator is maintained by a representative fluid sample, a measurement log of the entire sample process history, real-time monitoring and remote control. The log contains data from the sample chamber (fluid temperature and pressure), borehole temperature, and operating data from the hydraulic power pack. The operating data provides important information about the status of every operation of the sampling procedure, the sampling time and the success of the sampling. In the SECURe project the sampler provides temperature and pressure data from downhole and volume. In the deployment, a pressure of 41.5 to 42 bars is measured, which is in the same magnitude to the experiment. Temperature and pressure are not maintained, so that no data is available during uplift to the measuring station (Ricroch et al.). However, it would be interesting to compare the sensor data accuracy and sample function with the inliSAMP demonstrator, as both probes can transfer real time data to the operator.

The inliSAMP demonstrator reduces the sampling time in the borehole, since no displacement fluid and pressurization fluid are required. Furthermore, repeatability of the sampling procedure is easily possible with the electrical and mechanical components. In the future, this will also include sampling with several probes or sample chambers. As preparation at site, a rinsing of the sample camber, check of the functions and filling of demineralized water is required. To obtain a representative sample from the borehole, the following fundamental requirements for temperature and pressure management as well as cleanliness of the sampling procedure and design were met. The experimental results and findings on the behaviour of the developed sampling procedure and inliSAMP demonstrator show progress in the field of in situ sampling tool development.

7. Conclusion

Extensive investigations have been carried out for the development of a novel sampling procedure, the sample chamber design and the implementation of a sampling module in the inliSAMP demonstrator. The overall objective was to develop a sample unit with controls and actors to retrieve a representative sample from downhole to surface with monitoring and control in real time data. The sampling module was mounted in a demonstrator housing and the developed sampling procedure was performed on a test bed under laboratory conditions. The investigations were mainly focused on design calculations of the sample chamber, the sample intake, and closing mechanism plus the sampling procedure with a minor temperature distribution in the sampler and a permanent pressure maintenance. Standards, experience with materials, and component developments were adopted and/or further enhanced from the hotToolKIT construction kit.

The main investigations and results of the proof of concept test showed:

- With the sampling procedure the fluid sample is taken, stored and delivered near in-situ downhole conditions.
- With a two-piston mechanism and operation hydraulic force, the sample is taken up without flashing, sealed without pressure change, recompressed if required and released again. Pressure change occurs during the storage and dispensing of the sample.

- In the sample chamber, the temperature distribution in the sample is monitored and logged over time at three positions. A tube heating mat is used to preheat the sample chamber, maintaining the temperature of the fluid sample and mix the sample due convection flows. Small deviations occur when the sample is let in and out.
- The inliSAMP demonstrator is monitored, supplied and operated with real time data via the wireline. Thus, a free choice of operations is possible. Additional operations could be performed such as sampling repetition, dispensing of any fluid downhole, multiple sampling and extended measurements.

During the proof of concept demonstration run and previous runs of the test rig, the pressure range is plus 20 bars in the storage operation during uplift and the temperature range is about 6 K during the sample intake in a preheated sample chamber. Thus, the in-situ conditions of the formation fluid a nearly maintained. The pressure increase could be reduced by improved automatized control of the temperature. For each process operation, a controller should also be developed to simplify remote operation by the operator and to partially automate sampling. A further test would be of importance with brine including dissolved gases in the test rig and a subsequent fluid and gas analysis. Furthermore, a revision of the design of the inlet hole and the seal is necessary to increase the lifetime of the sealings. For deployment of a prototype probe in the borehole, electronic components such as a power management system and power supply are under development. Many existing solutions such as the Dewar tube, cold reservoir and communication unit can be adopted from the inliCAM. This research on the inliSAMP probe has focused intensively on the sampling process and the maintenance of in situ downhole conditions in the sample chamber, as well as the enhancement of the integrity of the sampling data.

Keywords

Geothermal well testing, deflagration, temperature transient analysis, pressure transient analysis, temperature derivative.

ABSTRACT

Geothermal well test analysis is an essential tool for understanding reservoir behaviour and determining the parameters of fluid flow dynamics such as reservoir permeability, skin effect, wellbore storage and reservoir boundaries. Traditionally, only the pressure transients are analysed, while temperature transients are often overlooked despite their sensitivity to the changes in the wellbore and reservoir conditions. This work presents the temperature and pressure transient analysis conducted during the pre and post-deflagration testing of well BR064 in the Ohaaki geothermal field, New Zealand. The study uses a novel numerical framework to investigate temperature and pressure data resulting from the well-testing, matching them with their respective derivatives (temperature and pressure). Analysing temperature gives additional information about the reservoir and enhances the conventional pressure transient analysis. Through the temperature derivatives, it is possible to understand the complex heat transfer phenomena in the wellbore and obtain further information from existing well test data that are typically not considered.

1. Introduction

Deflagration is a stimulation method that uses subsonic high-pressure gas generated through an explosive charge that cleans the perforated linear and enhances the skin zone permeability of the wellbore (Zarrouk and McLean, 2019). The deflagration method has been used in different geothermal fields to improve well performance without conclusive results (Ohren et al., 2011; Sigurdsson, 2015; Bixley et al., 2016; McLean et al., 2016). Bixley et al. (2016) pointed out that an increase in the production flow rate indicates that deflagration was successful. However, this can take several months because the temperature, fractures, and well flow need to stabilise.

Completion well testing is usually carried out to assess the deflagration efficacy, which typically examines pressure and flow rate data (pressure transient analysis, PTA) to estimate reservoir, skin zone and wellbore properties such as permeability, skin factor and boundaries/faults (Zarrouk and McLean, 2019). The completion well testing involves the injection of cold water into the

geothermal well employing different rates, whilst the pressure, temperature, and spinner (PTS) sensor tool records the changes along the geothermal well.

Conventional analytical PTA considers constant fluid temperature (isothermal conditions) (Sidorova et al., 2014). However, this approach can prompt inaccurate results because it neglects the effects of temperature (Benson and Bodvarsson, 1986; Zarrouk and McLean, 2019). Nowadays, the numerical PTA methods can account for non-isothermal conditions, but they are not yet widely incorporated into the analysis.

The temperature transient analysis (TTA) investigates the temperature data from well testing under transient thermal conditions (Rangel-Arista et al., 2023). Therefore, TTA is an ideal complement to PTA, providing further insights (Ramazanov et al., 2010; Palabiyik et al., 2016).

Several works have investigated the supplementary application of TTA alongside PTA approaches. For instance, Palabiyik et al. (2013) developed a non-isothermal reservoir simulator for single-phase liquid-dominated geothermal systems. Onur and Palabiyik (2015) presented an analytical model to compute temperature and pressure at the sandface during constant-rate production tests. Panini and Onur (2018) proposed a TTA-PTA analytical model for a vertical oil well in a radial composite reservoir. Rangel-Arista et al. (2022) updated McLean and Zarrouk's (2017) geothermal framework for numerical pressure analysis, incorporating temperature conditions. Rangel-Arista et al. (2023) utilised Rangel-Arista et al.'s (2022) updated framework to investigate the non-isothermal effects of downflow in the Well CHI-8A (El Salvador) during pressure falloff.

The previous works investigated the deflagration process only by analysing the pressure response (Ohren et al., 2011; Sigurdsson, 2015; Bixley et al., 2016; McLean et al., 2016). Meanwhile, the works involving the temperature response analysis focused on wells without deflagration (Palabiyik et al., 2013; Onur and Palabiyik, 2015; Panini and Onur, 2018; Rangel-Arista et al., 2022; Rangel-Arista et al., 2023).

Therefore, we selected the BR64 dataset for this work to evaluate the effectiveness of deflagration through both temperature (TTA) and pressure (PTA) analysis, using data from injection tests performed pre and post deflagration.

2. Case Study: BR064

Figure 1 shows the casing profile of geothermal well BR064, a single-phase (only liquid) wellbore in the Ohaaki geothermal field, New Zealand. The well has a total depth of 2057 m, with a reservoir thickness of 864.5 m. Based on pressure, temperature, and spinner (PTS) sensor tool data, a pay zone of 400 m is estimated, with the remaining reservoir thickness composed of impermeable rock.

Figure 2 shows BR064 well testing parameters, pre (Pre-D), during and post (Post-D) deflagration: pressure, temperature, sensor tool depth, and injection flow rate. During Pre-D phase, water injection causes wellbore cooling (Figure 2) for approximately 123633 s (34.34 hours) from the beginning to point A. Prior to reaching Point A, pressure and temperature fluctuations occur because the PTS sensor tool travels up and down along the wellbore (Figure 2). Before point A, the injection flow rate experiences incremental increases in three steps: 10, 21 and 31.7 kg/s.

Moments before point A in the Pre-D (Figure 2), the sensor tool reaches the target depth, leading to a decrease in flow rate from 31.7 kg/s to 2.91 kg/s, commencing a non-zero pressure falloff (Zarrouk and McLean, 2019) for the Pre-D period (A-B). During this time, temperature buildups from 67.3°C to 137.85°C (ΔT∼70.55°C), whilst pressure falls off from 129.72 to 121.91 bar (ΔP∼7.81 bar). The pressure falloff period lasts for 36,301 s (10.08 hours).

Once the Pre-D falloff period is over (Figure 2, A-B), the PTS tool travels to the bottom of the well (B-D). Then, the injection flow rate increases (C-D) to 29.16 kg/s for additional wellbore cooling. Next, the flow rate drops (E-F). During period D-G (Figure 2), deflagration occurs as the downhole PTS sensor is removed from the wellbore. At point G, the PTS sensor tool re-enters the well, travelling downward to the target depth. Afterwards, the PTS tool travels up and down the well to identify loss zones (Zarrouk and McLean, 2019) (G-H), prompting temperature and pressure peaks (Figure 2). Simultaneously, the injection flow rate exhibits two incremental increases (G-H): 21 and 32.16 kg/s. Before point H, the sensor tool returns to the target depth (Figure 2).

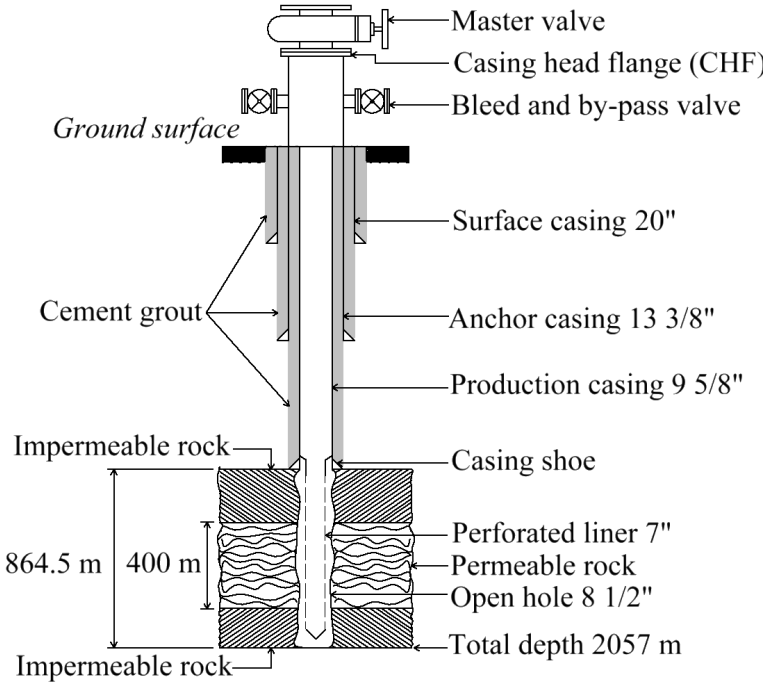

Figure 1: Well BR064 casing diagram.

At point H (Figure 2), the injection flow rate drops (2.91 kg/s), prompting the Post-D non-zero pressure falloff period (H-I), which lasts 31,771 s (8.82 hours). During this time, the temperature increases from 60.74°C to 127.86°C (ΔT∼67.12°C), whereas the pressure decreases from 135.23 bar to 122.43 bar (ΔP∼12.8 bar).

Figure 3 shows the pressure and temperature responses during pressure falloff for Pre-D and Post-D. The pressure responses remain transient without reaching full equilibrium (Figure 3), although the falloff period lasted more than 8 hours for both cases. This can indicate a low reservoir permeability with possible damage in the near wellbore zone.

The temperature increases rapidly during the first moments because of the drop in the injection flow rate (Figure 3). The cooling effect diminishes as the flow rate declines, prompting the sudden temperature increase until the new injection flow step stabilises. The temperature rises gradually after the rapid growth (Figure 3) because of the cooling effect induced by the low injection flow rate (2.91 kg/s). The rapid pressure fall and temperature rise seen in Post-D indicate a stronger (enhanced) connection between the wellbore and reservoir.

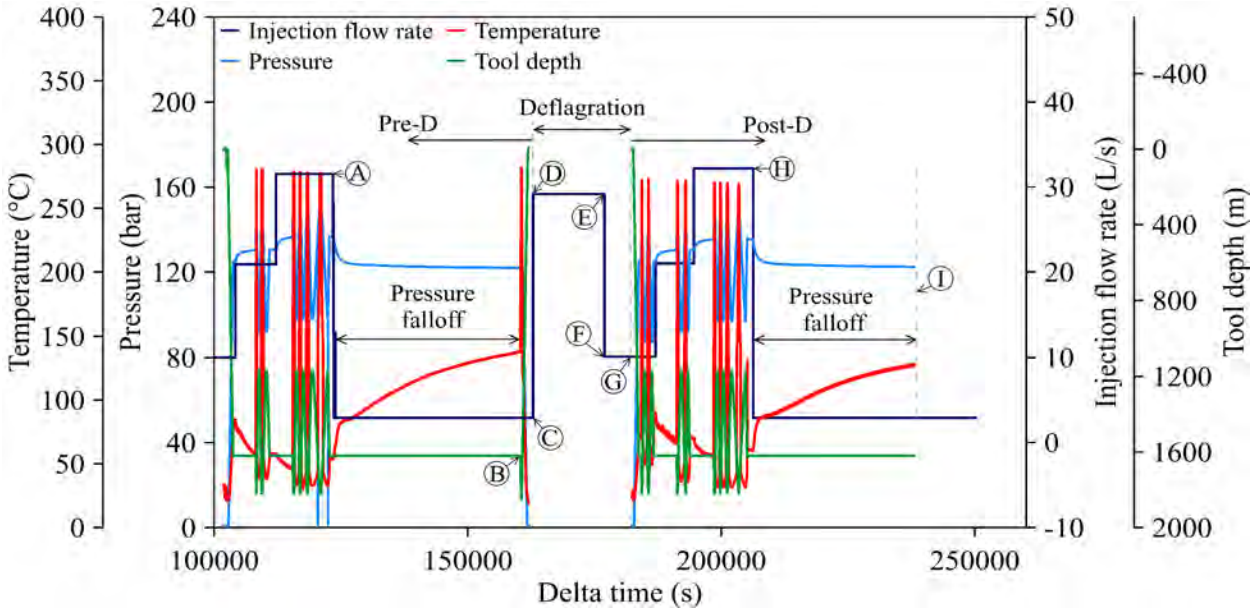

Figure 2: Pre (Pre-D) and post (Post-D) deflagration well testing.

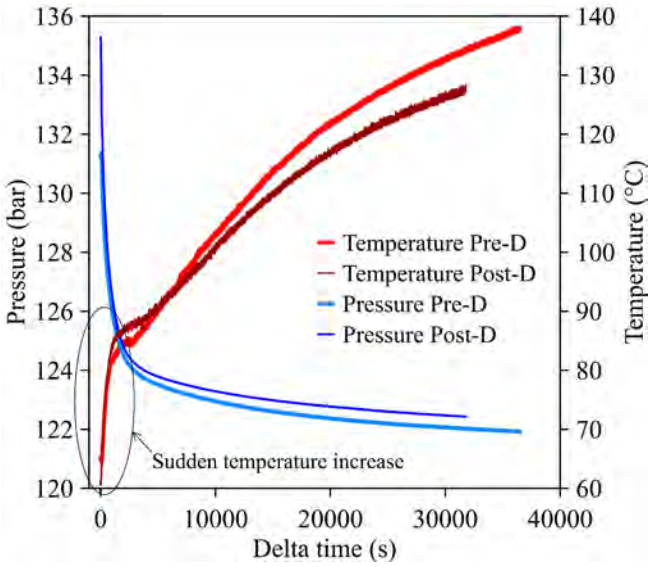

Figure 3: Temperature and pressure during pressure falloff, pre (Pre-D) and post (Post-D) deflagration.

Figure 4 shows the pressure difference ($dP = P_i - P$) and pressure derivative (dP') for Pre-D and Post-D. The duration of the wellbore storage effect (unity slope straight line response) is shorter

during Post-D than Pre-D. This shows improvement in the connection between the wellbore and the reservoir post-deflagration.

Then the transient effect prompts a large hump (Figure 4), indicating damage in the skin zone (positive skin). After the skin effect, a 0.4 unit slope appears, probably indicating the presence of a boundary.

Figure 5 shows the temperature difference ($dT = T_i - T$) and temperature derivative (dT') for Pre-D and Post-D. Multiple prominent peaks appear at the beginning (1st zone) and middle (2nd zone) because of the small temperature changes. Some peaks are more significant, indicating that almost constant temperature occurred, prompting the temperature derivative to tend to zero (Rangel-Arista et al., 2023). Two flattening zones appear for both derivatives, containing peaks with slight changes (Figure 5).

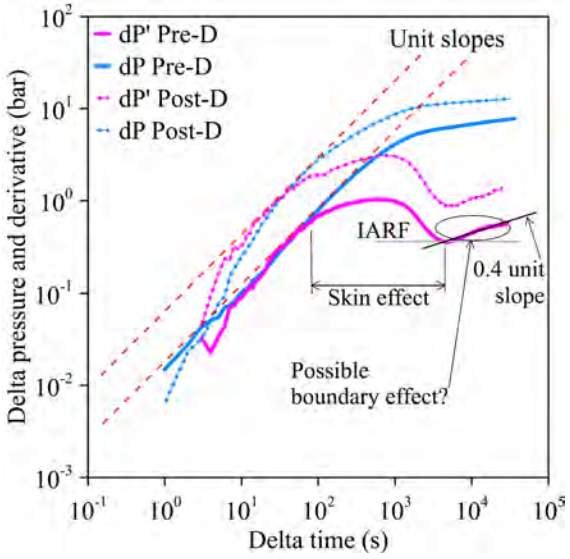

Figure 4: Pressure derivative, pre (Pre-D) and post (Post-D) deflagration.

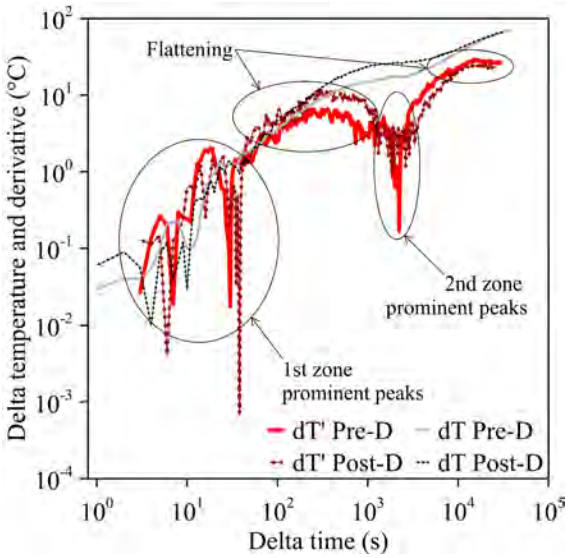

Figure 5: Temperature derivative during pressure falloff, pre (dT' Pre-D) and post (dT' Post-D) deflagration.

3. Well Test Framework Set Up

We used Rangel-Arista et al.'s (2022) numerical modelling framework, which updated McLean and Zarrouk's (2017) numerical framework for analysing the transient pressure to include the transient temperature. Rangel-Arista et al. (2022) demonstrated that matching the TTA along the PTA will result in a more accurate reservoir parameter estimations while unlocking additional information about the reservoir.

Rangel-Arista et al.'s (2022) framework employs AUTOUGH2 and PyTOUGH. AUTOUGH2 is a reservoir simulator based on TOUGH2 (Pruess et al., 1999), a general-purpose simulator to model subsurface fluid and heat flow in geothermal reservoirs. PyTOUGH manages AUTOUGH2, handling grid construction, data files, plotting and analysis of results, as well as the implementation of initial and boundary conditions and physical parameters (Croucher, 2020).

The framework uses a grid geometry that consists of three radial layers with multiple blocks in the radial direction to capture the changes in temperature in the vertical and radial directions more efficiently (Figure 6) (Rangel-Arista et al., 2022). The blocks are spaced logarithmically, representing the wellbore, skin zone and reservoir. The central cylinder blocks represent the wellbore, while skin zone blocks extend from the wellbore radius up to 5 m. Reservoir blocks extend from the skin zone to 20000 m. The pay zone, 400 m thick, is represented (Figure 1) by three layers, each 133.33 m thick.

3.1. Numerical Modeling Framework: Pressure Response

The pressure response was analysed according to McLean and Zarrouk's (2017) framework, which employs the fractional dimension model (Zarrouk and McLean, 2019) to represent the fractured reservoir in dynamic conditions (Barker, 1988). This method simulates complex fractured reservoirs better without explicitly considering rock mechanics (Zarrouk et al., 2007).

The fractional dimension theory considers assigning a number that ranges from one to three, typically involving non-integer values (fractional numbers). Number one represents a linear flow along a plane (fracture wall). Two represents radial flow converging in the well, forming a round disc. Three represents flow from all directions converging in the well, creating a spherical flow (Zarrouk and McLean, 2019).

3.2. Numerical Modeling Framework: Temperature Response

The underground heat transfer involves conduction, convection and advection processes, occurring simultaneously (Zarrouk and McLean, 2019). The new PTA and TTA modelling framework (Rangel-Arista et al., 2022) simplifies the heat transfer mechanism by assuming that only conduction (thermal diffusion only) takes place, achieved by artificially changing the Péclet number.

This simplification is necessary due to the complex heat transfer between the wellbore and reservoir throughout the feed zones, where hot and cold fluids enter and leave the well through a complex network of fractures within the reservoir. The full representation of this process would require a detailed mapping of all the feed zones with multiple sensors along these areas, which is impractical due to the cost and high temperatures involved.

In our approach, we assumed that the Péclet number averages conduction, convection, and advection within the wellbore and skin blocks, changing for each step to match the temperature response. A Péclet number close to one reflects that most heat transfer is due to conduction. Higher Péclet numbers denote dominant convection, meaning a more significant interaction between the injection flow (cold) and hot fluid (from the reservoir and feed zones).

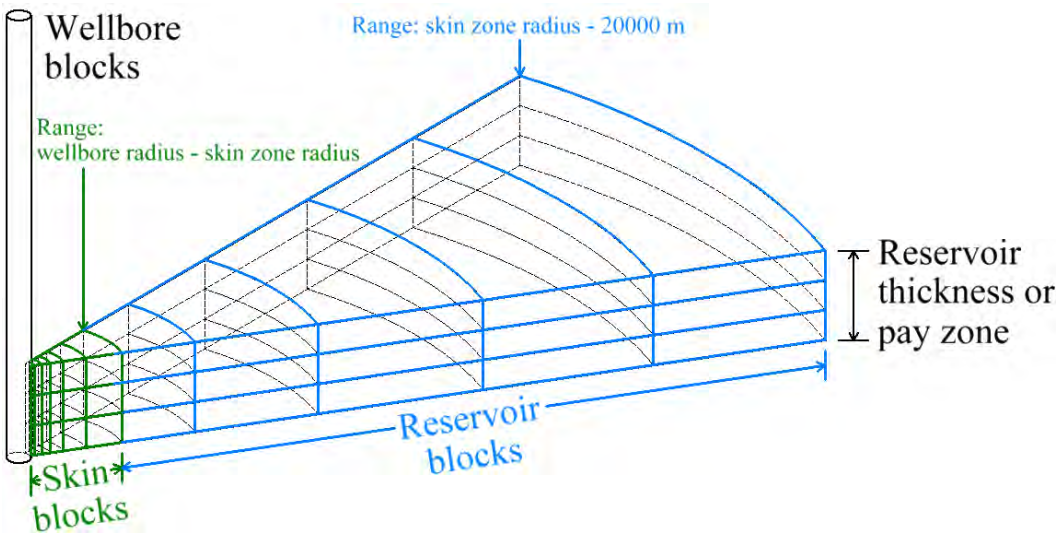

Figure 6: Grid geometry.

3.3. Numerical Modeling Framework: Parameters and Solution

Table 1 shows the parameters used to set up the geothermal numerical framework. Wellbore volume, pay zone, and wellbore radius correspond to the actual dimensions of well BR064. We utilised 40 and 60 blocks per layer for the skin zone and reservoir, respectively (based on our experiments to calibrate the geothermal TTA-PTA framework).

The modelling time is divided into multiple steps to match the temperature and pressure responses. The Péclet number and fractional dimension are the only parameters changing in each step. The remaining factors related to the wellbore, skin zone, and reservoir maintained the same values throughout the simulation.

Table 1: The geothermal well testing framework sets up initial parameters for Well BR064.

Model parameters	Input
Well volume (m^3)	75
Pay zone (m)	400
Well radius: r_w (m)	0.10795
Model radial extent (km)	20
Number of layers	3
Layer thickness	133.33
Skin zone blocks per layer	40
Reservoir blocks per layer	60
Injectate temperature (°C)	67
Reservoir porosity (dimensionless)	0.1

Reservoir permeability: $k \times 10^{-15}$ (m^2)	10
Reservoir temperature (°C)	290
Skin zone radius: r_s (m)	4
Skin factor: s (dimensionless)	6
Skin zone permeability: $k_s \times 10^{-15}$ (m^2)	3.76

4. Results

Figure 7 shows the temperature and pressure history matches between field data and models for the Pre-D (Figure 7a) and Post-D (Figure 7b). Both show very good matches between the model and field data.

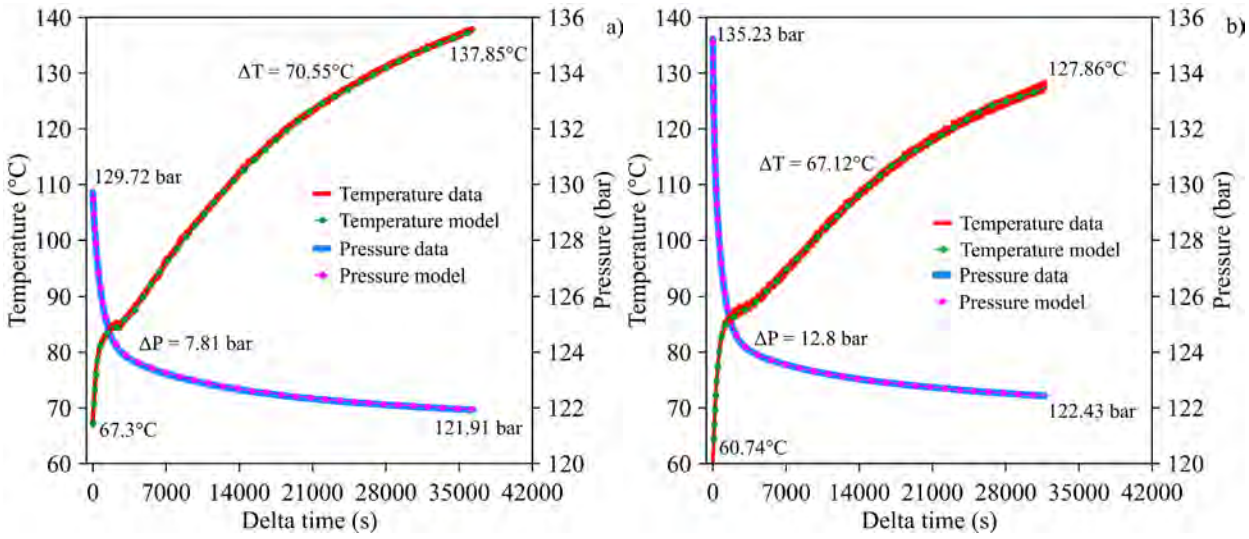

Figure 7: Temperature and pressure matches, a) pre and b) post deflagration.

Figure 8 shows the Péclet number changes needed to match the temperature response for Pre-D and Post-D. During period A (Figure 8), the Péclet number starts with high values, gradually decreasing over time because the last injection flow step effects (31.52 kg/s) are still present but diminishing for both Pre-D (Figure 8a) and Post-D (Figure 8b). This indicates a transition from convection to conduction because the amount of injection fluid is less (the cooling effect of the injection diminishes), prompting the sharp temperature rise for both periods (Pre-D and Post-D). Simultaneously, although hot fluid comes from the reservoir, its impact on the wellbore and skin zone is smaller than the cooling effect caused by the last injection step.

The Péclet number (Figure 8) rises during period B for both cases (Pre-D and Post-D). The increase is more noticeable for Pre-D (Figure 8a), where the heat transfer occurs mainly in the wellbore and skin zones (indicating lower permeability or connection with the reservoir). For the Post-D (Figure 8b), the reservoir zone interacts slightly more (more permeability or connections with the reservoir), reflecting a less significant increment.

The effects of the new injection period (2.91 kg/s) at the end of period B (Figure 8) are less noticeable than the last injection period (31.52 kg/s), prompting the lowest Péclet number. This indicates that convection decreases, tending to conduction, although convection prevails.

The new injection flow rate (2.91 kg/s) is entirely stable at the beginning of period C (Figure 8). Simultaneously, the hot fluid from the reservoir 'kicks in' according to the new injection flow rate (2.91 kg/s), increasing the Péclet number for Pre-D (Figure 8a) and Post-D (Figure 8b). Then, it stabilises for both cases (Pre-D and Post-D), with slight variations up to the period C end. The Péclet number is slightly more significant for the Post-D case (Figure 8b) along period C, indicating that more hot fluid comes from the reservoir (permeability increase), creating a considerable temperature rise rate for Post-D (Figure 7b) than for Pre-D (Figure 7a).

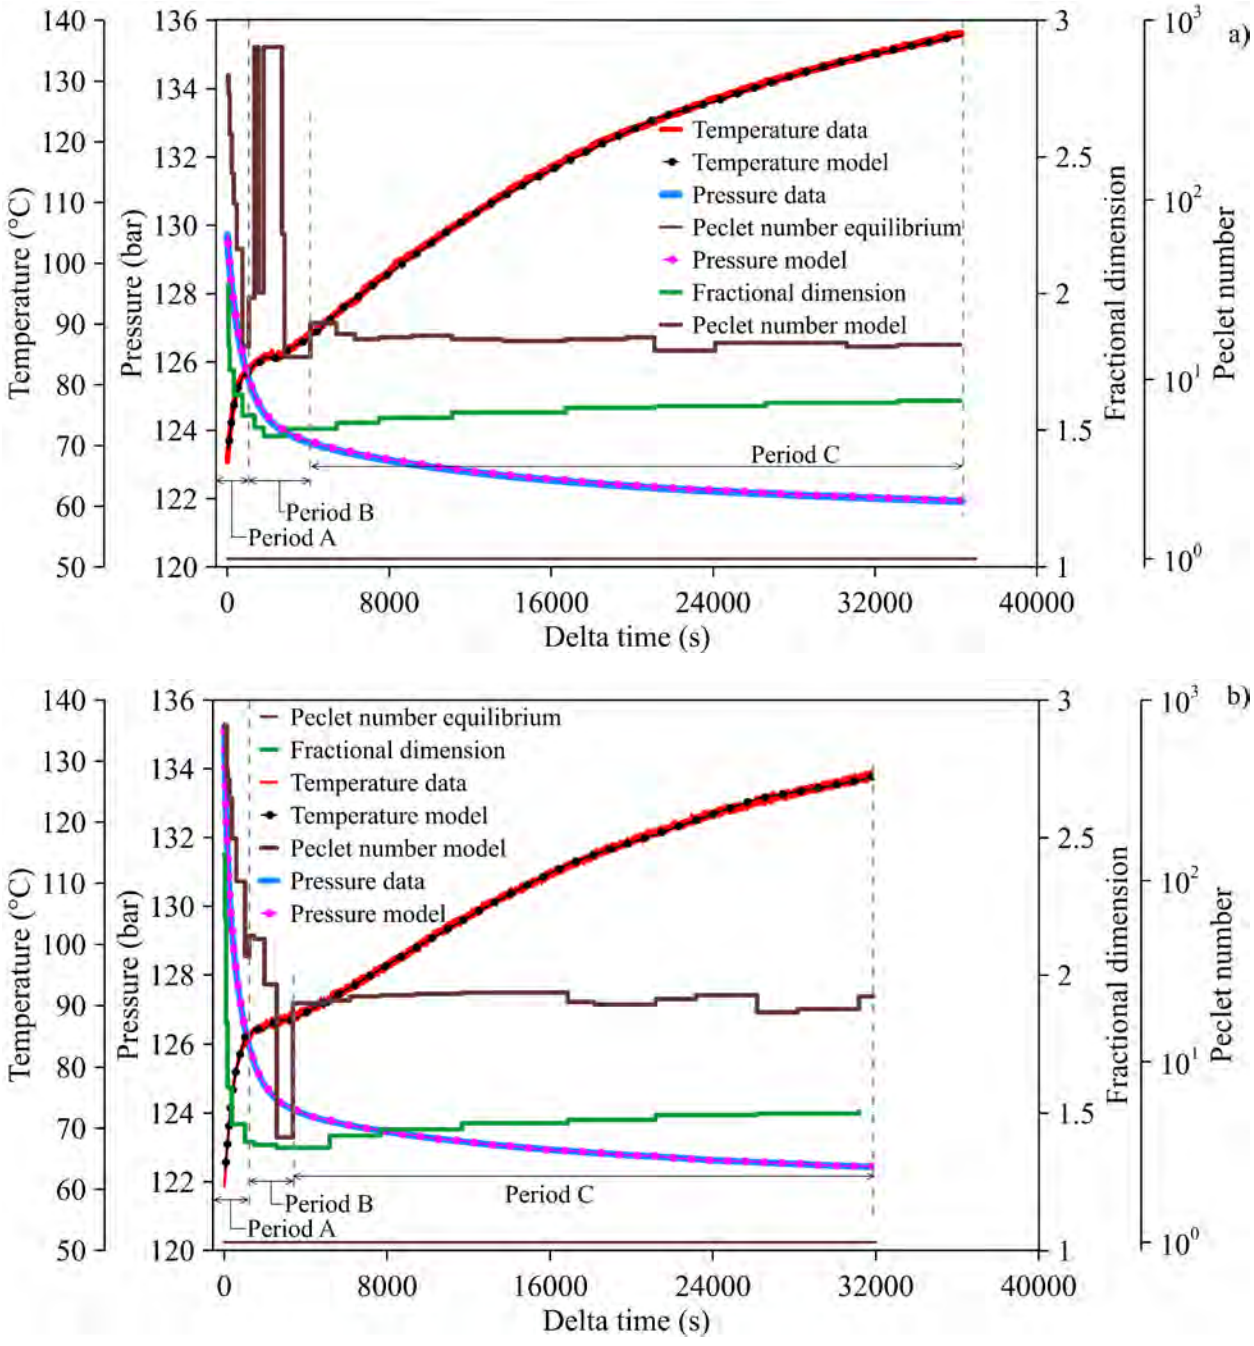

Figure 8: Temperature match and Péclet number, a) pre and b) post-deflagration period.

Figure 9 shows the pressure derivate match for Pre-D and Post-D. Both cases show a smooth match along the falloff during the wellbore storage effect, skin zone (transient zone) and reservoir response. We are unable to discuss the possible presence of the boundary (Figure 9) because of the lack of field information.

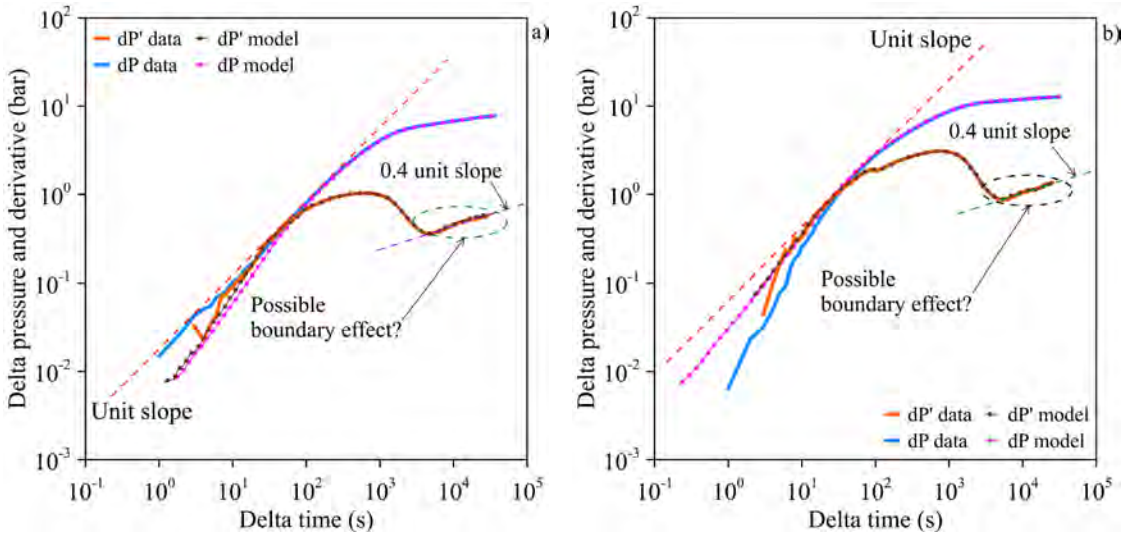

Figure 9: Delta pressure (dP) and pressure derivative (dP') match, a) pre and b) post deflagration period.

Figure 10 shows the temperature derivative match for the Pre-D and Post-D, displaying the same periods as the temperature match (Figure 8). Prominent downward peaks appear at the beginning of Period A (Figure 10) before the flattening. The peaks represent less notable temperature changes that almost reach constant Temperature, prompting the derivative to tend to zero.

After these initial peaks (Figure 10), the trend flattens in period A, accompanied by slight oscillations in the temperature derivative, reflecting the water injection process. Next, in period B (Figure 10), the last injection step (31.52 kg/s) effects vanish entirely. Simultaneously, the new injection flow step (2.91 kg/s) starts producing effects, and the hot fluid from the reservoir rises. At the end of period B (Figure 10), the new injection flow rate (2.91 kg/s) is fully developed.

The Pre-D case (Figure 10a) shows the temperature stabilisation point (Period B), where an almost constant temperature is reached, prompting the derivative to tend to zero. Then, hot fluid 'kicks in' according to the new injection flow step (2.91 kg/s).

During period B, in the Post-D case (Figure 10b), a temperature stabilisation zone appears instead of the temperature stabilisation point (Figure 10a). This indicates that the temperature changes are more significant in Post-D than for Pre-D, suggesting a connection improvement between the wellbore and reservoir. In Pre-D, slight temperature changes almost reach constant temperature, prompting the temperature derivative to approach zero (Figure 10a). In Post-D, more considerable temperature variations occur, resulting in the absence of a constant temperature and preventing the temperature derivative from approaching zero (Figure 10b).

During Period C (Figure 10), the temperature derivative rise reflects the temperature increase, which is almost similar for Pre-D (Figure 10a) and Post-D (Figure 10b). Flattening occurs at the

end of Period C because of the injection flow step effect for Pre-D (Figure 10a) and Post-D (Figure 10b).

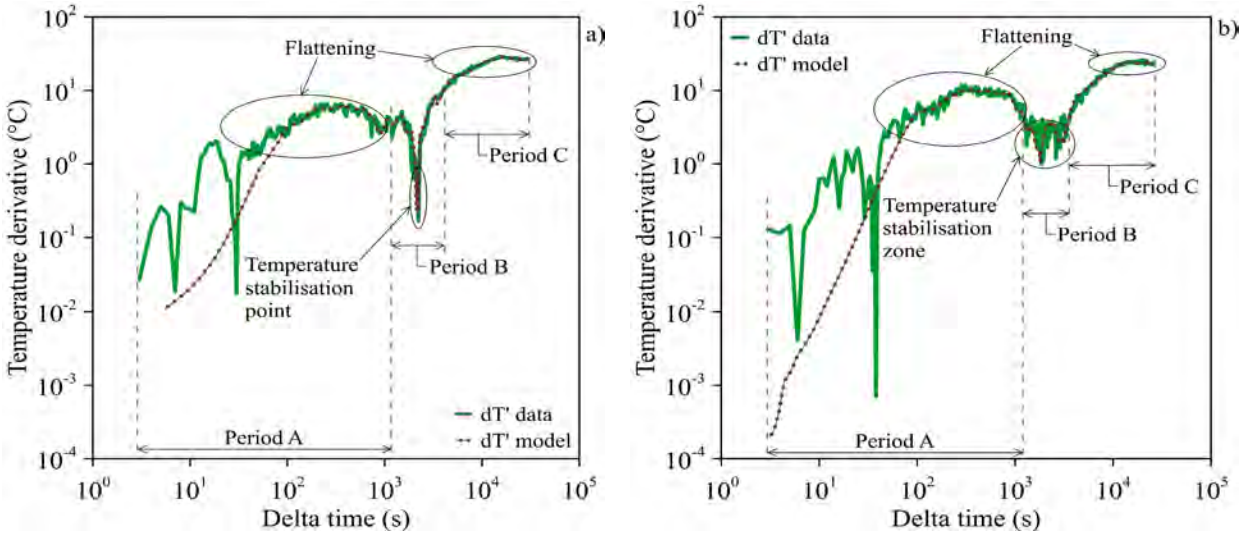

Figure 10: Temperature derivative (dT') match, a) pre and b) post deflagration period.

Table 2 shows the changes observed in the Pre-D and Post-D cases. The remaining parameters maintained the same values as shown in Table 1. A slight permeability rise occurs at the skin zone, increasing by 4.62 mD. The skin factor decreased by one unit, indicating that the damaged area improved because of deflagration, enhancing the connection between the wellbore and reservoir.

Table 2: Parameters affected by deflagration.

Parameters	Pre deflagration	Post deflagration
Skin factor: *s* (dimensionless)	6	5
Skin zone permeability: $k_s \times 10^{-15}$ (m^2)	3.76	8.38

5. Conclusions

The deflagration process resulted in a minor improvement in the skin zone permeability and a reduction in the skin factor. This confirms the findings of previous studies indicating that deflagration has a limited impact on the well performance as it only improves the near wellbore part of the reservoir. Despite the improvements, the skin zone in well BR64 remains positive Post-Deflagration, indicating that the skin damage still exists in this well. The cause of skin damage can be further investigated, and other solutions, such as chemical treatment, can be put in place to stimulate the well.

The temperature transient analysis proved to be helpful in interpreting the well-testing data. In this case, the effects of deflagration caused an improvement in the wellbore-reservoir connection, displaying a faster temperature rise Post-D compared to Pre-D. This is evident in the temperature derivatives at period B. The temperature stabilisation zone is less noticeable for Post-D compared

to Pre-D, indicating a quicker stabilisation following the transition between injection flow steps and the influx of hot fluid from the reservoir after deflagration.

Our analysis captured the complex heat transfer dynamics by accounting for thermal diffusion and Péclet number, providing insight into the multiple interactions between the injection flow steps and hot fluid flow from the reservoir.

Our study demonstrates that the temperature derivative is a sufficiently sensitive tool to show various complex heat transfer interactions, allowing the identification of distinct zones corresponding to the multiple interactions. This capability enhances the interpretation of temperature data, providing an additional layer of understanding of the heat transfer process occurring within the well.

ABSTRACT

The exploration and exploitation of vapor dominated geothermal reservoirs present unique challenges due to their complex subsurface dynamics and elusive fluid behaviors. This abstract proposes a novel approach of utilizing and testing of advanced high temperature and high-pressure subsurface wireline conveyed tooling to enhance the characterization and understanding of such reservoirs and the wellbore environment. Traditional techniques often struggle to accurately capture these properties, leading to suboptimal resource utilization and operational inefficiencies. In response, this testing study advocates for the integration of cutting-edge subsurface tool testing methodologies and leveraging state-of-the-art technologies to provide comprehensive insights into reservoir characterization.

Through the development of advanced downhole tools equipped with high-resolution sensors and high-temperature mitigation techniques, new approaches to sub-surface wireline conveyed cased hole and open hole logging aim to capture data including temperature gradients, pressure differentials, steam flow profiles, feed-zone identifications, and wellbore integrity. By obtaining and analyzing this data in conjunction with existing reservoir models and geological data, geologists, reservoir engineers, and seismologists can optimize feed-zone characterization models, refine placement strategies, and improve reservoir management practices. Furthermore, the

continuous monitoring enabled by these tools facilitates early detection of reservoir and wellbore anomalies and enhances the efficiency of reservoir surveillance programs.

The continued development of this technology offers significant potential for the geothermal industry by enabling more informed decision-making processes, reducing operational risks, limiting operational non-productive times, and maximizing resource recovery. Furthermore, the insights gained from these tests can contribute to the advancement of geothermal energy as a sustainable and reliable source of clean energy, thus supporting global efforts towards mitigating climate change and transitioning towards a low-carbon future.

1. Introduction

Located in Lake and Sonoma County, California, The Geysers Geothermal Steamfield epitomizes humanity's quest for sustainable energy sources and the formidable power of Earth's geological dynamics. Encompassing over 44 square miles, this expansive complex of steam vents, hot springs, and bubbling pools stands as the world's single largest geothermal electrical operation. Beyond its natural allure, it serves as a crucial energy resource powering millions of homes and businesses while minimizing environmental impact. Exploring the depths of The Geysers reveals not only the intricacies of geothermal energy production but also the delicate equilibrium between harnessing Earth's resources and conserving its natural splendor for future generations.

With 316 active production wells and 53 active injection wells spread across the vast steamfield, each requires subsurface maintenance and monitoring to meet regulatory standards, ensure wellbore integrity, and sustain steamflow reliability. Essential to these efforts are advanced wireline tools and equipment, including Pressure, Temperature, and Spinner tools (PTS), 15-arm Kinley Casing Calipers, "bridge busters" for chisel broaching, and downhole cameras. Engineered to thrive in the challenging conditions typical of The Geysers, where reservoir temperatures average 371ºF, these tools are designed for durability and optimal performance.

As drilling technology continues to advance and wells within the geothermal field deepen, temperatures in the wellbores are expected to rise. This progression underscores the critical need for ongoing enhancement and innovation in subsurface tools and equipment capable of withstanding escalating environmental demands. Calpine is actively evaluating newly developed tools suitable for the rigorous geothermal environment. These collaborations also offer invaluable insights to tool developers and manufacturers, who rigorously test tools in diverse environments over extended periods, focusing on durability, precision in data collection, and operational efficiency.

2. Kaldera PTS-XY Bi-Directional Caliper Logging Tool Testing

The Kaldera, LLC. founders have been manufacturing and supplying tools specifically designed for geothermal fields for over three decades. During this time, they have observed a growing need for devices that enhance operational efficiency to reduce costs.

High-temperature logging tools that can record well pressure, temperature, and flow rates (PTS tools) have been crucial in helping geothermal fields maintain high production levels. However, these tools do not provide information on changes to the internal diameter caused by natural scale buildup over time.

In the oil and gas industry, XY Caliper logging tools have long been a standard part of an operator's toolbox. Unfortunately, typical temperatures in geothermal operations are roughly double those in oil and gas, making the temperature rating of XY Calipers designed for oil and gas unsuitable for most hot geothermal wells, which usually exceed the tool's nominal 350 degrees Fahrenheit rating.

The lack of a suitable XY Caliper tool for geothermal operations left operators with a few options. They could lower multiple gauge rings of different diameters to various depths to get a rough idea of the internal diameter, a time-consuming and costly process. Alternatively, they could cool the well and then use a lower-temperature XY Caliper tool designed for oil and gas. However, cooling the well may be both costly and risky.

Even when using an XY Caliper tool designed for higher temperatures, the ability to simultaneously record pressure, temperature, and flow allows operators to save time by eliminating the need of an additional PTS survey run.

Due to the required length of both an XY Caliper and a PTS tool, coupling the two together presents a challenge for wireline operators, who must source a sufficiently long lubricator and crane.

Kaldera decided to integrate the PTS sensors and a high-temperature geothermal XY Caliper into a single tool with a single electronic section. This integration reduces the total length compared to combining two tools in one run, thus lowering operational costs.

PTS/XY Caliper tools have been sold and operated in Central America and Asia. These tools help eliminate the need for running multiple gauge rings before logging services, record the full profile of scale buildup in the internal diameter of the casing and liner, and better understand calcite buildup. This information helps determine the chemical dosage required during the maintenance of geothermal wells. Kaldera's patented PTS-X/Y combination tool is the only tool designed for the geothermal market that records inside diameter, pressure, flow, and temperature.

2.1 General Specifications & Basic Theory

2.1.1 Tool Specifications

Characteristics	**Specifications**
Pressure Range	Up to 8,500 psi
Pressure Accuracy	0.05% FS
Temperature Range	325ºC/617ºF (Caliper) 350ºC/660ºF (PTS)
Temperature Accuracy	±0.15ºC
X-Y Caliper Range	2.75" to 13 3/8" Casing
X-Y Caliper Accuracy	±0.25"
Tool Length	121.5"
Tool Weight	80 lbs
Spinner Range	10 to 20,000 rpm
Sampling Frequency	Up to 8 Hz (Adjustable)

Figure 1: Image of a Fully Assembled Kaldera PTS-XY Caliper tool in combination.

2.1.2 Basic Tool Theory

The tool incorporates high-temperature electronics and a vacuum flask for electronic protection, alongside modular and proprietary sensors for detecting mechanical diameter changes. It consists of four main sections. Firstly, the Electronics Section comprises a vacuum flask, serving as a heat shield to safeguard all electronics. The Pressure and Temperature Sub-Assembly follows, crucial for monitoring external temperature and pressure to assess well conditions accurately. Next, the XY Caliper features four naturally open arms equipped with roller wheels, ensuring constant contact with the well's inside diameter. Fully closed, the tool maintains an outside diameter of 2.75 inches, enabling passage through 3-inch restrictions and measurement of casing diameters up to 13-3/8 inches, facilitating versatile use across a wide range of geothermal wells. Finally, the Spinner, situated at the tool's bottom, measures flow rate, delivering essential data on well performance.

2.2 Kaldera XY Caliper Durability Testing

Kaldera collaborated with Calpine to assess the XY Caliper's resilience in the open hole segment of a wellbore. This partnership aimed to enhance steam flow calculations for Calpine’s reservoir engineers and gain insights into formation anomalies, all while minimizing wireline operational time. The test's primary objective was to evaluate the tool's functionality and durability in the demanding open hole environment. Although no electronic measurements were taken during the test, the X-Y Bi-Directional Caliper, equipped with roller wheels, was designed to hover above the casing or open hole surface. Its spring-loaded arms offered flexibility to navigate obstructions or narrow holes while ensuring contact with the wall surface for accurate diameter measurements.

While starting to run in the well, the Wireline Operator monitored the tension meter for any deviations. The X-Y Caliper performed admirably, with tension deflections occurring as anticipated at specific depths, including the crossover points between different casing strings and through the milled window. The tool exhibited smooth movement within both the casing and open hole sections, meeting expectations regarding its performance and detecting tension changes indicative of varying hole sizes.

Upon retrieval, the caliper showed significant wear, with most roller wheels worn down by at least half and missing pins that held the upper arm together. Scratches and abrasions adorned the arms, despite the drilling of a 10 5/8” hole size. Some arms displayed substantial wear, nearly compromising the integrity of the keep pin holding them together.

Despite the wear and tear experienced during the open hole run, the Kaldera X-Y Casing Caliper Tool performed admirably, fulfilling its intended purpose of casing ID measurements. While the test revealed wear and damage, the tool endured without failure, marking the test as a success overall.

2.3 Kaldera XY Caliper Full Function Field Testing

The XY Caliper underwent comprehensive field testing at The Geysers geothermal resource in Northern California. This resulted in the successful execution of the inaugural downhole field trial for the fully assembled Kaldera geothermal PTS/XY Caliper, representing a pivotal moment in affirming the functionality and deployment viability of this cutting-edge technology. The trial served as a testament to the robustness and effectiveness of the Kaldera PTS/XY tool, showcasing its ability to meet the demands of real-world geothermal operations.

Figure 2: Figure of the Kaldera PTS-XY Caliper Tool being removed after the completion of the test at The Geysers.

The field test was conducted within a well comprising both 11 ¾” and 13 3/8” casings, presenting a relatively simple and controlled geological environment. Notably, the instrumentation exhibited impeccable functionality, evincing a conspicuous absence of discernible physical anomalies during its traverse within the wellbore casing. Furthermore, the casing caliper adeptly captured and meticulously documented bi-directional data, as vividly depicted in the accompanying graphical representation. Noteworthy achievements include the accurate identification of pivotal

transitions, such as the 13 3/8” to 11 ¾” crossover, alongside the discernment of numerous casing collars and rugosity dispersed throughout the spatially intricate wellbore environment.

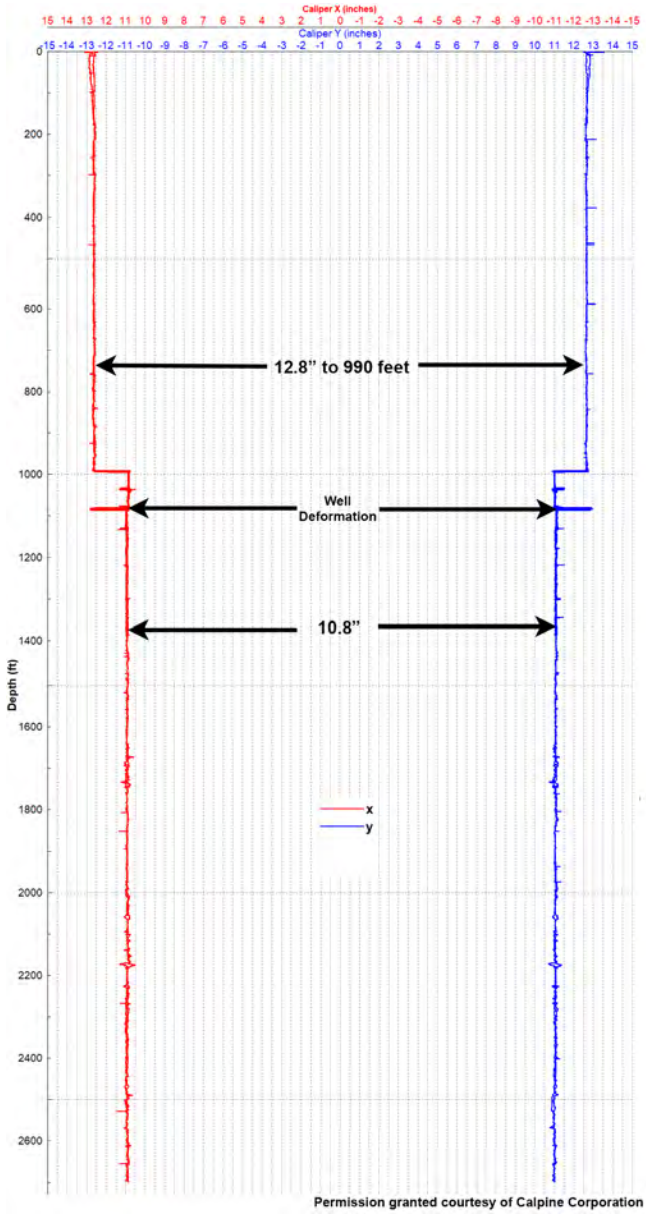

Figure 3: Figure showing the graphical results of the of the Kaldera PTS-XY Caliper Tool full functional field test clearly indicating the 11 ¾” & 13 3/8” crossover.

3. Rapid Prototypes, LLC Ultra-High Temperature Logging Tool (UHTLT)

The Ultra-High Temperature Logging Tool (UHTLT) was developed as part of the Department of Energy’s HeroX design challenge, sponsored by the Geothermal Technologies Office. This challenge aimed to showcase the potential of additive manufacturing to advance the geothermal industry.

The logging tool relies on additive manufacturing (AM) as a core manufacturing capability that allows for optimal geometric design to reduce thermal conductivity and radiative heat transfer between the electronics and the geothermal reservoir (well). By reducing heat transfer flux from the outside of the tool to the sensitive electronics equipment in the center, increased exposure times at higher temperatures can be achieved without the need for expensive and complex ultra-high temperature electronics.

In this approach, the prolonged and costly avenue of researching and developing 400°C electronic modules has been bypassed. Instead, the team utilized well-documented and field-proven 200°C electronic components from the Oil and Gas industry and created a more effective packaging system through AM.

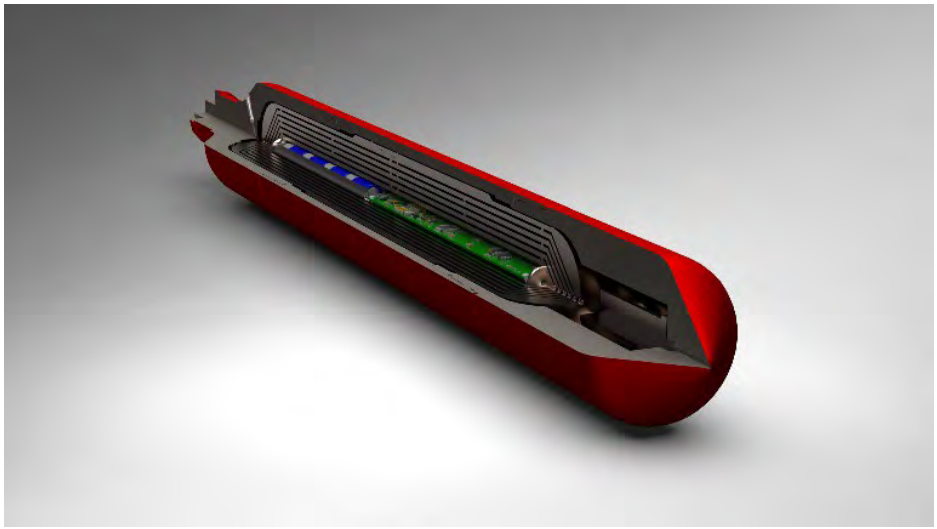

Figure 4: Computer Rendering of the cross-section view of the UHTLT design concept.

The heat sink was manufactured using Powder Bed Laser Fusion (PBLF). The Oak Ridge National Lab (ORNL) team, supported by the HeroX voucher, underwent four iterations to manufacture the internal components shown on the right side of Figure 5. These iterations were necessary to ensure adequate support for internal components and geometric features, and to optimize the powder application and removal processes. Following manufacturing, the AM components were removed from the build plate and forwarded to the team for machining and assembly.

Figure 5: Final components of UHTLT.

Internally, the Ultra-High Temperature Logging tool electronics were designed for operation up to 200°C with a safety margin of 10°C. Passive components were selected in accordance with high

temperature design considerations and overrated in terms of power, voltage, etc., to provide an additional safety margin.

The PCB implemented for the field trial was tested to 210°C. With continued testing, the expected maximum temperature is approximately 220°C.

The design of the printed circuit board (PCB) was based upon industry standards for downhole, high temperature circuit board design with the following design choices made to mitigate the risks of high temperature exposure.

Partial & final assembly is shown in Figure 7 & Figure 8.

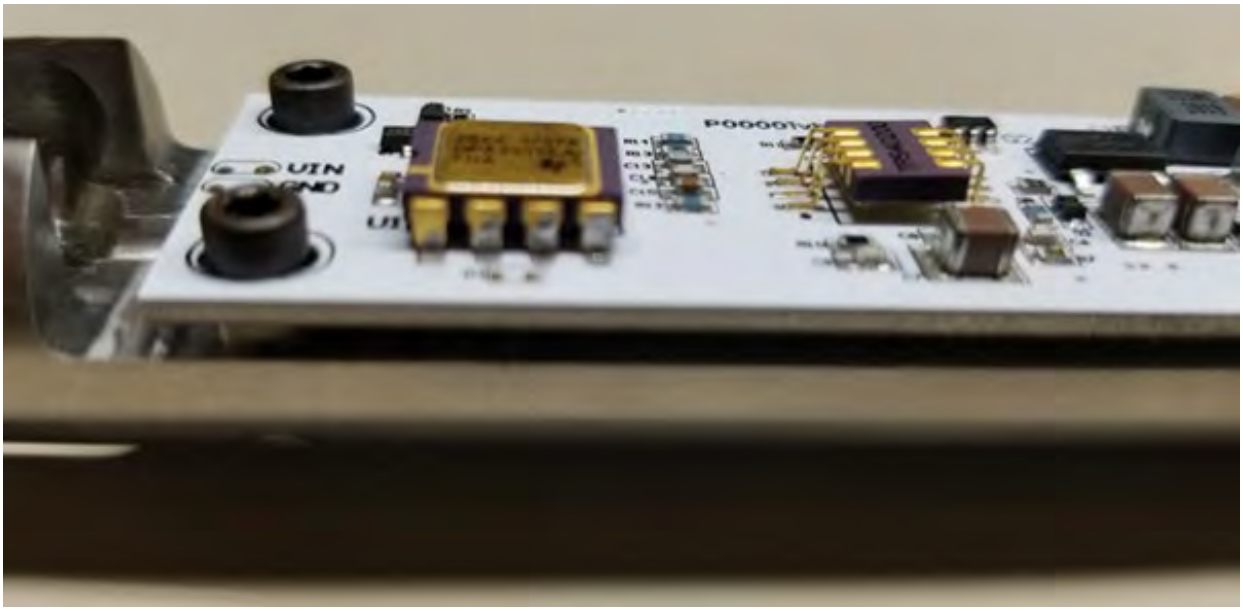

Figure 6: Image of the electrical components indicating optimization of materials selection, component orientation, mounting & traces.

Figure 7: Partially assembled tool with housing removed to show internal heat sink.

Figure 8: Fully assembled tool.

3.1 General Specifications & Basic Theory

3.1.1 Tool Specifications

Operational Description	**Specification**
Tool OD	4.5” / 114.3mm
Max Tool Length	15ft / 4.57m (prototype is 40 inches)
Max Temperature	400°C / 752°F
Max Pressure	15,000PSI / 1034Bar
Max Time at Temperature	10 hours
Well Fluid Compatibility	2% H_2S, HCl, 20% NaCl Brine, pH≥2
Measurements	Well Temperature, Well Pressure, Inclination, Orientation, Electronic Temperature
Electrical Description	**Specification**
Max Temperature	200°C / 392°F
Max PCB Width	0.71” / 18mm
Max PCB Length (incl batteries)	3.28ft / 1m
Pressure Measurement Range	0 – 15,000PSI / 0 – 1207Bar
Pressure Measurement Accuracy	10PSI / 0.69Bar
Pressure Measurement Resolution	1PSI / 0.07Bar
Temperature Measurement Range	-55 - 450°C / -67 - 842°F
Temperature Measurement Accuracy	1°C / 1.8°F
Temperature Measurement Resolution	0.1°C / 0.18°F
Inclination / Orientation Accuracy	2°
Inclination / Orientation Resolution	0.5°
Sampling Frequency	Programmable | <10Hz
Data Storage	Onboard – non-volatile
Data Recovery	Serial retrieval
Mechanical Description	**Specification**
Tool OD	4.5” / 114.3mm
Max Tool Length	15ft / 4.57m (prototype is 40 inches)
Cable Connection	1-1/16 – 10 UN
Max tensile strength	20,000lbsf / 89,000N
Max compression strength	20,000lbsf / 89,000N

3.1.2 Basic Tool Theory

In the development of the UHLTL, several geometric and material combinations were investigated. The optimal design uses a series of annual spaces fabricated with stainless steel and vacuum sealed. The combined effect of mitigating conductivity and radiation heat transfer leads to a tool of >32 hours at <200C for the electronics package, as shown in Figure 9.

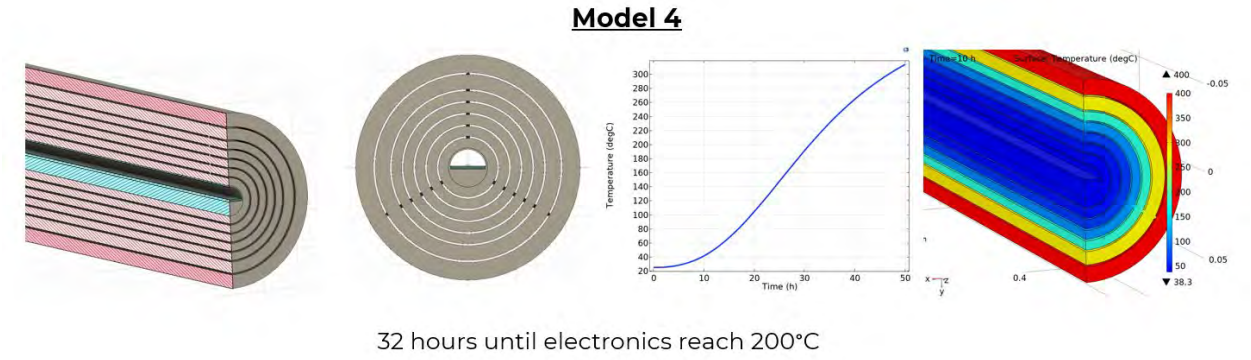

Figure 9: Modeled mitigation of conductivity and radiation heat transfer.

As the thermal energy is absorbed in the tool pressure housing, the temperature of the pressure housing quickly reaches the temperature of the surrounding fluid. This thermal energy is then transferred to the outermost concentric layer of the heat sink via radiation and conduction. The thermal energy transfer from layer to layer is driven primarily by radiative heat transfer since both conductive and convective modes have been minimized in the design of the tool. The time it takes to increase the temperature of the concentric layers is determined by the rate of thermal energy transfer driven primarily by the surface emissivity and specific heat capacity of each layer.

3.2 Performance Testing in Geothermal Wellbore Conditions at The Geysers

The testing in the well was instrumental in testing the performance of the tool in a real-world scenario. This provided conditions that were not attainable in the lab such as well fluid heat capacity, humidity and fluid flow as the tests were conducted in a live well.

Four tests were conducted in this well and are described below:

3.2.1 Test #1

Test 1 was conducted on August 1, 2023. The objective of Test 1 was to deploy the UHTLT into the well for a guaranteed safe duration. The bottom hole temperature of the well was unknown as the last attempt to log the well failed due to wireline and tool failure.

The maximum external temperature the electronic module observed downhole was 216°C while the maximum internal temperature only reached 155°C. The log file of the recorded temperature data from Test 1 as recorded by the UHTLT is shown in Figure 10.

During Test 1, the tool was set to begin logging when the electronic module reached 70°C.

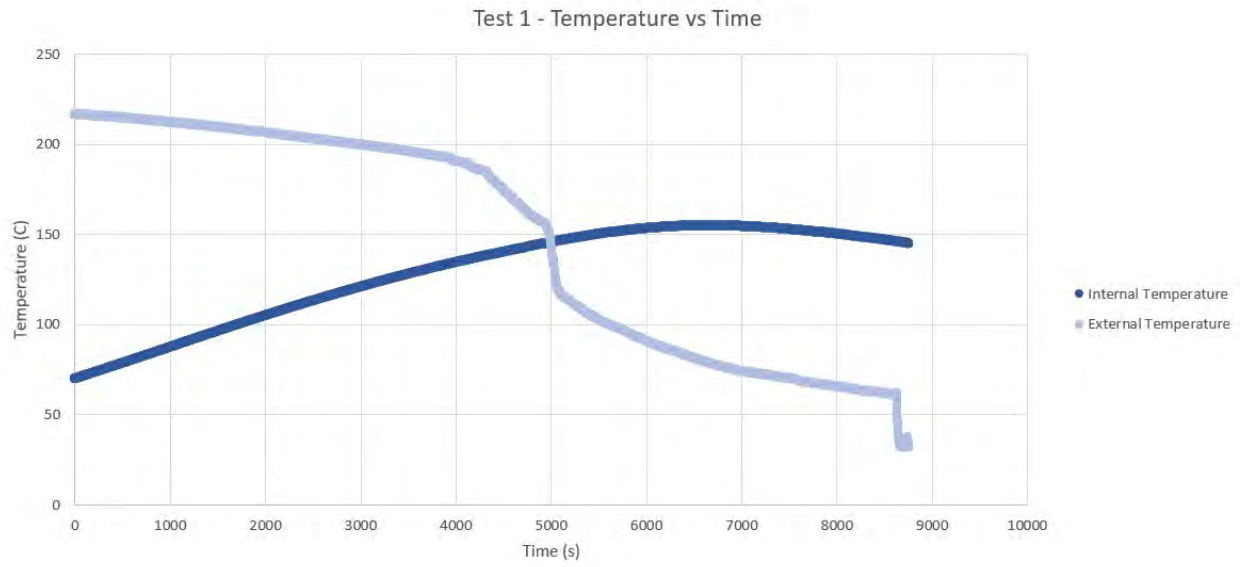

Figure 10: Test 1 data.

As seen in Figure 10, the tool was POOH when the logging began indicating that the tool was in the well for over 60 minutes before the internal temperature reached 70°C. It is also noteworthy that the internal temperature continued to rise after the tool was removed from the well, as highlighted by the rapid decrease in external temperature. This behavior was anticipated.

3.2.1.1 Test Parameters

Characteristics	Specifications
Run-In-Hole Speed	100 ft/min
Total Depth	4500 ft
Pull-Out-Of-Hole Speed	50 ft/min
Dwell Time at Depth	15 minutes
Total Time in Well	2.5 hours

3.2.2 Test #2

Test 2 was conducted on August 2, 2023. The objective of Test 2 was to deploy the UHTLT into the well for an increased dwell time to validate the model generated during the SNL test while still maintaining a safety margin to prevent approaching the temperature limit of the battery pack. The test plan for August 2, 2023 was to perform 2 runs during the day which is more representative of the operational requirements for Calpine to have an interest in the UHTLT as a commercially viable product.

During Test 2, the UHTLT was assembled and prepared for the runs ”on-site” using the tailgate of the rental pickup as a mobile workbench. This was used to highlight the field operational maturity of the tool; i.e. the tool does not need to be assembled by a team of highly trained personnel in a clean lab which would not be commercially ideal any wireline operator.

The tool firmware was also updated to begin logging after the internal temperature of the tool reached 50°C for 10 minutes, a decrease from the previous 70°C threshold. This was implemented to capture more data while downhole as it was observed from Test 1 that the UHTLT did not begin logging until the tool was being POOH and at an approximate depth of 2900ft. With the increased dwell time as well as the decreased internal temperature threshold, the UHTLT began logging earlier in the run and at TD.

The log file of the recorded temperature data as recorded by the UHTLT for Test 2 is shown in Figure 11.

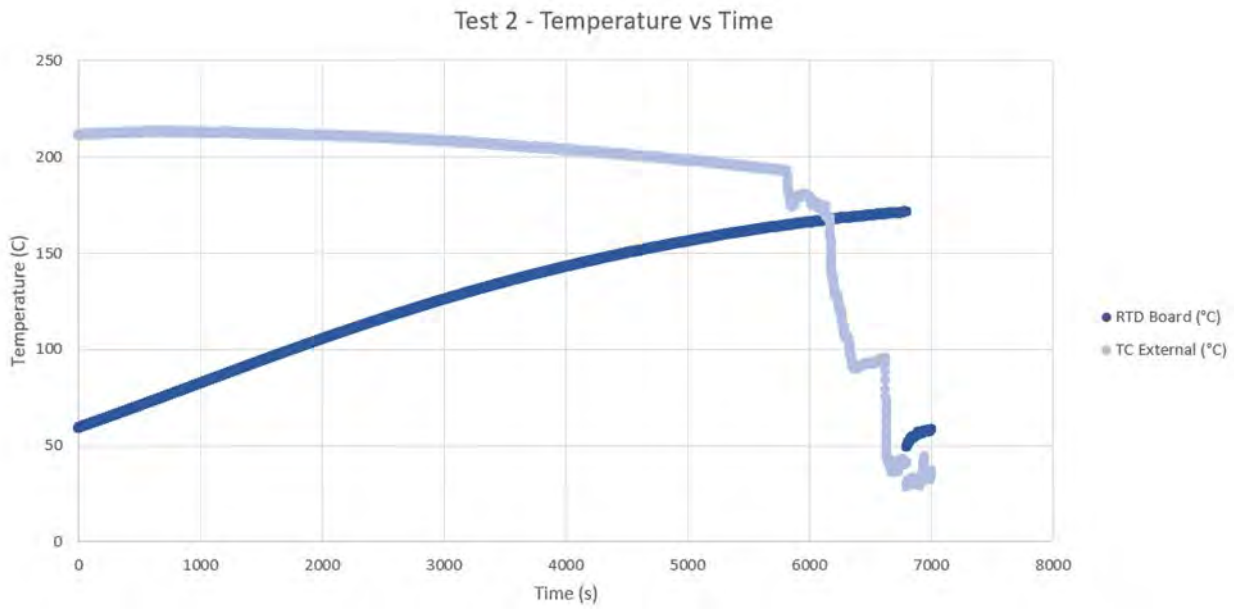

Figure 11: Test 2 data.

As seen in Figure 43, the maximum external temperature of the UHTLT was measured after the tool began logging in contrast to Test 1 where the UHTLT began logging with a decreasing external temperature. The downhole temperature of the Prati-4 well was measured at 213°C.

It can also be seen from Figure 43 that the internal temperature reached a maximum temperature of 171°C and decreased dramatically. This was due to a new procedure to cool the tool which was implemented during Test 2. The tool was rigged down and placed on a bed of ice to rapidly cool the external housing of the tool to allow for safe handling temperatures to be reached within minutes.

3.2.2.1 Test Parameters

Characteristics	Specifications
Run-In-Hole Speed	100 ft/min
Total Depth	4500 ft
Pull-Out-Of-Hole Speed	50 ft/min
Dwell Time at Depth	30 minutes
Total Time in Well	2.75 hours

3.2.3 Test #3

Test 3 was also conducted on August 2, 2023 with Test 2. The objective of Test 3 was to deploy the UHTLT into the Prati-4 well at a high rate of speed to test the vibration resilience of the tool while under real temperatures and pressures.

As previously stated, a secondary objective was to perform 2 runs during the day to showcase the ability of the UHTLT to maintain the wireline deployment schedule setup by Calpine.

During Test 3, the tool began the operational run at an elevated temperature due to the heat sink temperature being cooled to 50°C after Test 2. This allowed the UHTLT to begin logging during the pre-run vacuum. This allowed the well temperature to be captured while RIH as well as POOH.

The log file of the recorded temperature data as recorded by the UHTLT for Test 3 is shown in Figure 12.

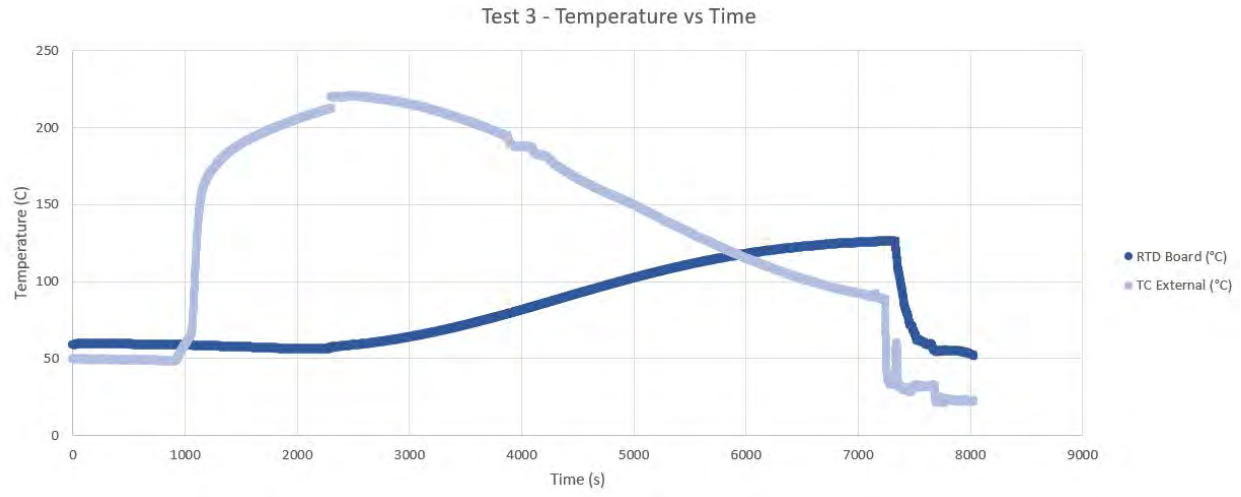

Figure 12: Test 3 data.

As seen in Figure 12, the internal temperature of the UHTLT continued to cool for approximately 20 minutes after the tool was inserted into the steam flow of the Prati-4 well. The rapid increase in temperature highlights the high temperatures measured not only at TD, but throughout the well as the steam temperature decreases by a small amount between TD and exiting the well into the steam collection system.

As this run was RIH and POOH very quickly, coupled with a short dwell time, the maximum internal temperature was very low at only 126°C. The maximum external temperature measured during Test 3 was 220°C. Contrary to Test 2, the UHTLT was placed in the back of the rental pickup and driven to the wireline workshop while still on and cooling. The tool was removed from the well at approximately 4000 seconds in Figure 12 as indicated by the temperature transient. At the time the UHTLT was removed from the well, the internal temperature was measured to be 82°C.

Test 3 was an important test for the UHTLT as it highlighted a different use case of the UHTLT. Currently the main objective of the UHTLT was an increased dwell time at 400°C. The use case

discussed with Calpine at the close of Test 3 was to use the UHTLT as a TD temperature measurement tool when RIH and POOH quickly using low temperature batteries to negate the delay in the logging data capture. With this test, it can be shown that by using low temperature batteries such as low-cost AA alkaline batteries, pre-cooling the heat sinks to -20°C and having a minimum dwell time at TD, the UHTLT can be used to go into a well of any temperature as long as the mechanical integrity of the tool is not diminished.

3.2.3.1 Test Parameters

Characteristics	Specifications
Run-In-Hole Speed	200 ft/min
Total Depth	4500 ft
Pull-Out-Of-Hole Speed	200 ft/min
Dwell Time at Depth	10 minutes
Total Time in Well	55 minutes

3.2.4 Test #4

Test 4 was conducted on August 3, 2023. The objective of Test 4 was to test the control heat sink in a comparison run with Test 2. This would allow the effects of the ultra-high polished internal layers to be tested in a real-world environment.

Test 4 took over 2 hours to prepare for vacuum, approximately 4 times longer than using the UHTLT with the nominal heat sink. The UHTLT was prepared in the wireline workshop and would not be able to be assembled in the field as had been done during Test 2 and Test 3. It is noteworthy to highlight that due to a mechanical interference fit issue, the ceramic balls used to separate the external layers with the housing of the UHTLT were removed which would decrease the dwell time of the UHTLT with the control heat sink.

The log file of the recorded temperature data as recorded by the UHTLT for Test 4 is shown in Figure 13.

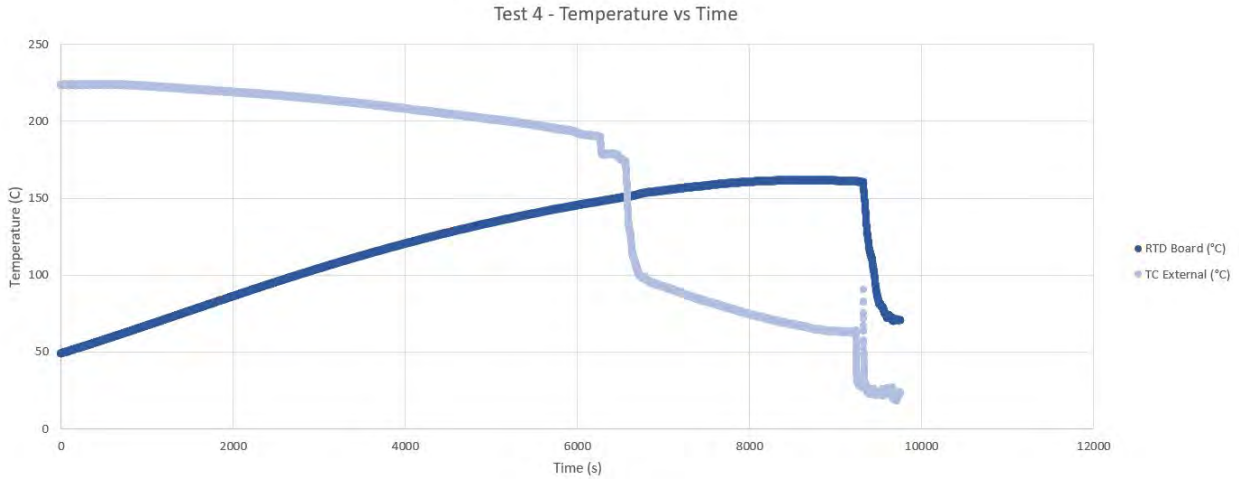

Figure 13: Test 4 data.

As seen in Figure 50, the UHTLT began logging after the maximum temperature had passed indicating that the tool was being POOH when the tool began acquiring data. The maximum internal temperature measured during Test 4 was 161°C, and the maximum external temperature measured was 224°C.

After the UHTLT was rigged down, the tool was placed in the back of the rental pickup truck and transported back to the wireline workshop for disassembly.

3.2.4.1 Test Parameters

Characteristics	Specifications
Run-In-Hole Speed	100 ft/min
Total Depth	4500 ft
Pull-Out-Of-Hole Speed	50 ft/min
Dwell Time at Depth	30 minutes
Total Time in Well	55 minutes

3.2.5 Comparison of Test #2 & Test #4

As seen in Figure 50, the UHTLT was exposed to a slightly higher external temperature in Test 4 at 224°C in comparison with the maximum external temperature of Test 2 at 213°C. The maximum internal temperature of the UHTLT during Test 4 was measured at 161°C while the maximum internal temperature of the UHTLT during Test 2 was measured at 171°C. Given the similarity of the test in terms of RIH speed, dwell time and POOH speed, the test showed a marginal improvement of the control heat sink. Therefore, the additively manufactured heat sink will not require a high degree of internal polishing to perform, however a path to polishing the AM heat sink will be continued in 2024 to gain performance.

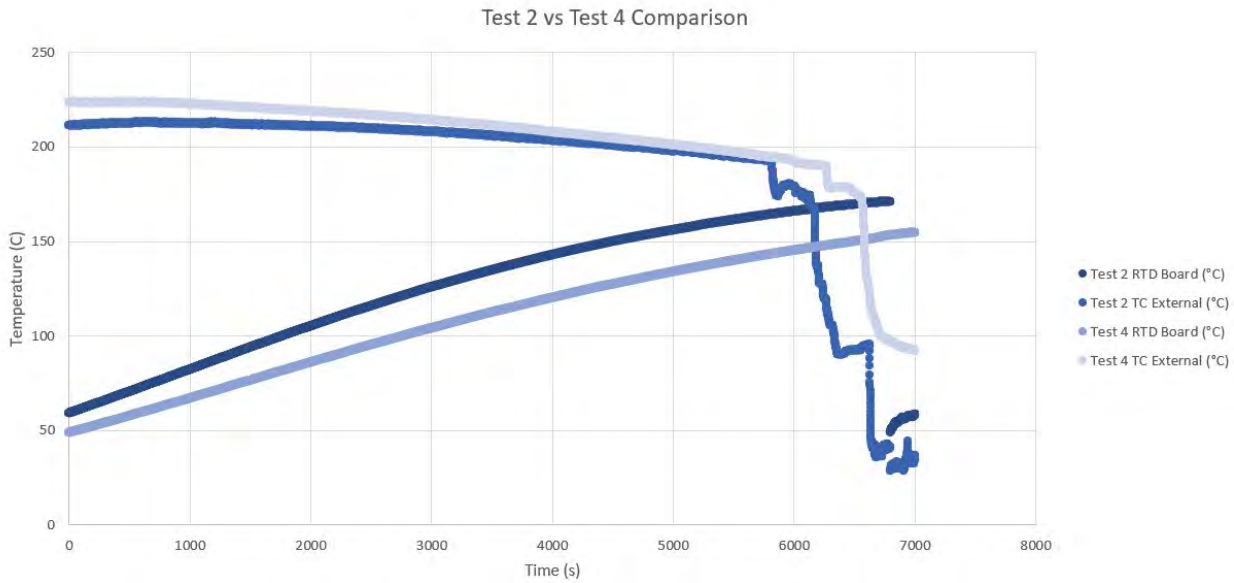

Figure 14: Test 2 & Test 4 data.

3.3 Post-Field Testing Developmental Tool Improvements

Rapid Prototypes, LLC plans to continue developing the tool with low-temperature, lower-cost electronics and battery requirements in preparation for additional testing as a "screening tool". By eliminating expensive electronics, they aim to significantly reduce the tool's cost and enhance its usability for customers, thereby improving operational efficiency. Additionally, they intend to investigate the impact of vacuum versus non-vacuum tools to streamline operator assembly and preparation time.

The ultimate objective is to design a tool that field crews can set up, test, operate, and download data from in an efficient and straightforward manner, thereby reducing operational costs and minimizing training requirements for technicians.

Due to the tool's simplicity and durability, there is perceived market potential as a rapid screening tool capable of measuring bottom hole temperatures up to 650°C. Through pre-run cooling procedures, it is anticipated that the tool can operate in wells with higher temperatures than any other currently available tool, provided that runs are kept under 1-2 hours.

4. Future Field Verification of Scientific Drilling International’s MFT-40 Casing Caliper at the Geysers

Scientific Drilling International (SDI) has stood as a cornerstone of the oil & gas industry since the mid-1970s, continually evolving through acquisitions, expansions, and achievements. Over the years, SDI's commitment to innovation has extended beyond oil & gas, benefiting the geothermal sector, particularly in drilling and subsurface wellbore assessment. Among the array of casing calipers tested at The Geysers, the MFT-24 stands out, initially tailored for oil & gas applications.

However, the MFT-40 emerges as a testament to SDI's dedication to progress, stemming from the MFT-24 but reimagined for the demanding environments of geothermal wellbores. This evolution showcases enhanced mechanics, electronics, and software).

Already validated and operational across diverse global locales, from southern California to Europe and the Far East, the MFT-40 now faces the distinct challenge posed by The Geysers. Conducting field verification within the intricate wells of The Geysers steamfield, the MFT-40 must prove its mettle in varying conditions while capable of seamless integration with non-conductive wireline systems, all while ensuring steadfast reliability amidst fluctuating temperature ranges.

4.1 Tool Specifications

Characteristics	Specifications
Tool Length	Caliper – 5.58’ Centralizer (2) – 3.19’ Total – 11.98’
Weight	215 lbs
Measurement Range	5.5” – 15.5”
Maximum Temperature	343ºC (650ºF)
Measurement Sample Rate	50 samples/sec
Horizontal Accuracy/Resolution	Radially ±0.02”/0.001”
Vertical Resolution	0.12”
Inclinometer/High-Side Resolution	± (5-355º) rotation & inclination
Maximum Pressure	12,000 psi
Construction Materials	Corrosion resistant throughout

Figure 15: Image of the SDI MFT-40 Casing Caliper with caliper arms retracted prior to running in the well.

4.2 Field Verification Calpine Benefits

The Vulcan™ MFT 40 is equipped with advanced features specifically designed to streamline casing inspection processes. Featuring a finger sensor positioned every 9°, high-speed electronics, and generous memory capacity, it boasts a sampling rate of 50 times per second, thereby yielding detailed results within a matter of hours rather than days. Its capability to log multiple casing sizes in a single operational pass minimizes production interruption, eliminating the need for multiple runs. Functioning optimally at ultra-high temperatures of up to 650°F/343°C, it facilitates rapid decision-making with prompt data turnaround. Its innovative design facilitates on-site maintenance, while its robust electronics package ensures reliable logging even in high-temperature environments. Additionally, the Vulcan™ MFT 40 provides comprehensive data delivery, including reports featuring statistical joint-by-joint analysis, logs of finger radii raw and centered, cross-sections, and selected 3D images, thus enhancing overall operational efficiency and decision-making processes.

4.3 Proposed MFT-40 Field Verification at The Geysers

The thorough validation regimen of the MFT-40 spans across five separate wellbores within the Geysers, serving as a methodical examination of its precision, dependability, and resilience for sustained operational deployment. These wellbores, comprising four designated for production and one allocated for injection purposes, present a diverse array of challenges that scrutinize the MFT-40's capabilities. These challenges encompass a gamut of complexities, ranging from navigating intricate casing profiles, inclusive of scab liners, to withstanding the severe conditions prevalent in high-temperature wellbores, where temperatures exceed 500°F. Moreover, the prospect of encountering casing deformations or damage further underscores the necessity to evaluate the MFT-40's resilience in authentic operational scenarios. Its extensive array of caliper arms and its ability to curtail lost production time could position it as an indispensable asset in the perpetual upkeep and oversight of geothermal wells within the field, thus ensuring sustained operational efficacy and reliability in the long term.

5. Conclusion

The successful field trials and operational deployments of these advanced tools underscore their role in optimizing operational efficiencies, curbing expenditures, and enhancing the precision of data acquisition. Moreover, the collaborative synergy between technology developers and operational partners like Calpine operations at The Geysers underscores a proactive strategy aimed at surmounting challenges and pushing the boundaries of what is feasible in geothermal exploration and production. In the future, sustained research and development endeavors will be pivotal in further refining these tools and broadening their capacities to meet the dynamic demands of the geothermal sector.

Chloride concentration, Fracture Inflows, Utah FORGE, EGS, Chloride, Single-Phase

ABSTRACT

This paper presents the ongoing development of a chloride-based wireline tool designed to detect and quantify inflows from feed zones in geothermal wells. The tool aims to characterize stimulation events in EGS wells at Utah FORGE (Frontier Observatory for Research in Geothermal Energy) and other EGS sites. Successful development of the chloride tool would greatly improve production monitoring of the fractures and enable proactive prescription of additional stimulations over the life of the field, thus helping to improve EGS commercial feasibility.

The recent developments of the chloride tool have focused on preparing for and conducting the field deployment at the Utah FORGE site. The field-scale tool assembly features a FORGE sensor package housing the Ion Selective Electrode (ISE), a pH electrode, and a reference electrode, as well as a Mitco PTS sensor package for secondary downhole measurements. A high-temperature logging tool has been developed and tested to capture and transmit data from the chemical sensors to the surface through a 7-conductor wireline cable. Alongside the development of the field-scale tool, flow experiments were carried out in the artificial well system at the Stanford Geothermal Lab. These experiments provided crucial insights into how the chemical tool responds to different variables, including the chloride concentration in the feed zone, its vertical positioning relative to the feed zone, and the presence of other chemical species in the feed zone fluid. The results highlight the tool's sensitivity to various parameters, underscoring the potential of using chloride concentration measurements as a method for inferring feed zone inflow rates in geothermal wells. The tool was successfully deployed at the Utah FORGE site using a wireline truck in the vertical well 58-32 and the directional production well 16B(78)-32.

1. Introduction

Enhanced Geothermal Systems (EGS) use artificial fractures to increase fluid extraction in less permeable geothermal reservoirs (Huenges, 2016). Artificial fractures are created through hydraulic stimulation and may close over time, reducing the productivity of the EGS wells (Fei et al., 2023). By monitoring the productivity of artificial fractures, operators can prescribe mitigation techniques such as restimulation. Timely interventions can help to keep the fractures open and flowing throughout the geothermal plant's lifetime, which typically lasts between 30 and 50 years (Sullivan et al., 2010).

The pressure-temperature-spinner (PTS) tool is commonly used to measure inflow rates from feed zones, with the spinner part determining the flow rate (Sisler et al., 2015). PTS tools show limitations in wells with low fluid velocity, low enthalpy, and large diameters (Acuña and Arcedera, 2005). The study found that there was an overestimation of the inflow rate in the vertical section compared to the nonvertical section of the well. Furthermore, changes in hole diameter outside of slotted liners will influence spinner rotation, which could be misinterpreted as an actual change in flow rate.

A geochemistry-based alternative to the PTS tool has been developed by Sandia National Laboratory and the Stanford Geothermal Program as part of the Utah Frontier Observatory for Research in Geothermal Energy (FORGE) project. This tool uses an ion-selective electrode to measure chloride concentration in the well fluid via electrical voltage between a sensor formed from a combination of pressed AgS and AgCl powder and a reference electrode formed from pressed AgCl powder (Hess et al., 2014). Chloride concentration readings around the feed zone can be used to calculate the feed zone inflow rate. In this paper, this tool is referred to as the "chloride tool", the tool assembly is shown in Figure 1-1. A major advantage of the chloride tool is that it does not require knowledge of the hole diameter, which is a limitation of PTS tools.

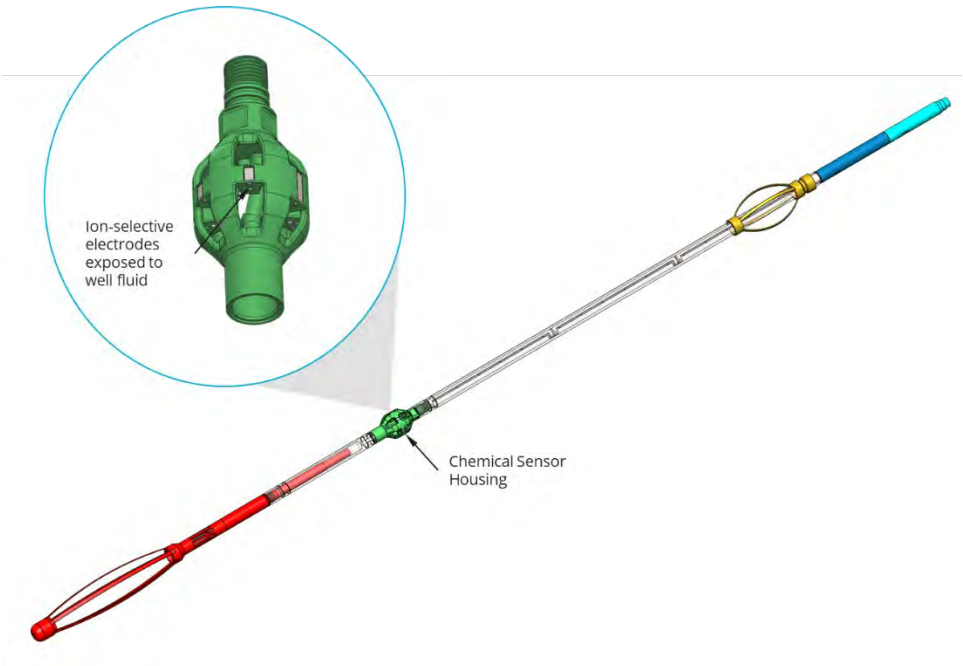

Figure 1-1: Field-deployable chloride tool assembly with close up of chemical sensor housing.

This study expanded on a previous investigation by Gao et al. (2017), which used a similar chloride tool prototype developed by Sandia National Laboratory (Cieslewski et al., 2016; Corbin et al., 2017). In the preliminary study, the team used measurements from the ion-selective electrode to estimate the enthalpy of the feed zone. They targeted chloride concentrations because chloride is consistently present in the liquid phase of geothermal reservoirs. (Sausan, 2023). Building upon that previous research, the current study aimed to develop a field-deployable version of the chloride tool to be used at the Utah FORGE project, which features EGS wells with single-phase fluid and multiple feed zones. This study focused on estimating the feed zone inflow rate, specifically in single-phase flow conditions, rather than enthalpy. The ultimate goal is to leverage insights from the Utah FORGE field trial for broader applications across various EGS sites. More importantly, this study explored a wider role of geochemistry, indicated by the chloride species concentration change, in determining fluid flow patterns in geothermal wells. Typically, the practical application of geochemistry in the geothermal industry revolves around estimating enthalpy or using tracer studies. However, this wider use of geochemistry could enhance our comprehension of the behavior of geothermal wells and fields.

This study employed a multifaceted approach, integrating analytical methods, numerical simulations, laboratory experiments, data science techniques, and field trials. Previously reported progress can be found at Sausan et al. (2021**,** 2023) and Judawisastra et al. (2022, 2023). This paper highlights the latest progress involving field-scale tool fabrication and testing, laboratory setup improvements, and numerical simulations involving the field-scale tool housing and at Utah FORGE temperature and pressure operating conditions. Finally, the successful deployment of the tool at the Utah FORGE site is described.

2. Tool Development and Assembly

2.1 Chloride Tool Assembly

The field-deployable chemical tool assembly incorporates the Mitco PTS sensor package and a tip centralizer at the leading edge of the tool. This is used for secondary downhole measurements to compare the geochemistry-based alternative method to the commonly used PTS measurements. A wire guide component was developed to adapt the PTS tool to the FORGE chemical sensor housing. The sensor wires from both the Mitco PTS tool and the chemical sensors pass through a wire feedthrough in the chemical sensor housing to the high-temperature logging tool in the electronics housing. The electronics housing connects to the wireline via a 4-conductor feedthrough that is adapted to a 7-pin conductor feedthrough that matches the wireline connection. The full assembly schematic is shown in Figure 2-1.

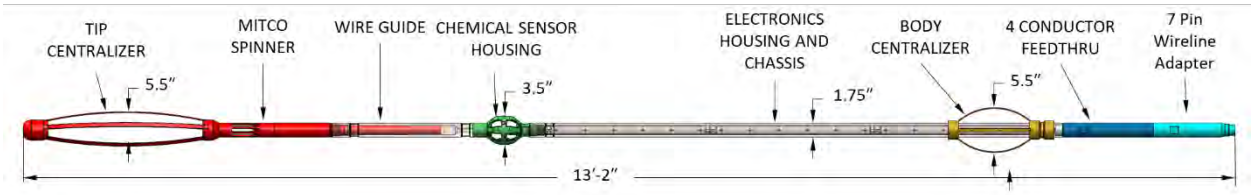

Figure 2-1: Field-deployable chloride tool schematics, including an existing PTS tool adapted to the chloride-based wireline tool and high-temperature developed by Sandia National Laboratory.

2.2 Chemical Sensor Fabrication and Testing

The chloride tool developed by Sandia National Laboratory consists of an ion-specific electrode coupled with a reference electrode. The constituent materials used to develop the ion-selective electrode and reference depend on the ion of interest. The ion-specific electrode probe generates a voltage proportional to the chloride concentration in the fluid, while the reference electrode provides the reference potential for the pair.

The Ion-Specific Electrodes (ISE) probe consists of a pellet formed from an equal part by a mass mixture of Silver Sulfide powder and Silver Chloride (AgS/AgCl) powder. The powder is weighed and transferred to a ¼" diameter die press and compressed to 4000 lbs. and held at constant pressure for 15 minutes. The pellet is then transferred to a preheated oven at 200°C for one hour and then cooled to room temperature.

A CuAg plated pellet wire adapter was fabricated to centralize a high-temperature nickel-plated copper wire on a conductive surface. The CuAg plated pellet wire adapter was attached to the pellets using a high temperature conductive epoxy and cured in a mold to keep the wire adapter centralized on the pellet. The assembled pellets and wire adapters are shown in Figure 2-2. The assembled sensors were then coated with Gagekote #1, a protective coating rated up to 455°C. This configuration of sensor design can then be sealed in the tool assembly using a commercial compression seal feedthrough bulkhead (rated up to 870°C and 10ksi) and allow for multiple sensors to be tested in the same tool.

Figure 2-2: ISE and reference sensor assemblies before application of Gagekote.

To demonstrate the ruggedness of the chemical sensors under High-Pressure, High-Temperature (HPHT) conditions, a laboratory test was conducted using the Sandia autoclave. The sensors and

bulkhead connection design were submerged in 225°C brine at 5000 psi for 24 hours and showed stable measurements. This provided confidence that the chemical sensor design could survive at the Utah FORGE conditions.

To demonstrate the capability of the sensor performance in the chemical composition of the brine at Utah FORGE, samples of flowback water from Utah FORGE Well 16A (78)-32 and 16B(78)-32 were collected and tested using the ISE electrode sensors. The chemical composition of the samples is shown in Table 2-1. Figure 2-3 shows the calibration fit of the well samples in comparison to various molarities of Potassium Chloride (KCl) in distilled water. The voltage measurements of the samples from the flowback in both wells are in good agreement with the measurements of the KCl solution, with lower correlation to the fit line at the lowest chloride concentrations.

Table 2-1: Chemical composition of well samples from Utah FORGE Wells 16A(78)-32 and 16B(78)-32

DATE TIME	LOCATION	Major (mg/l)									
		pH	Na	K	Ca	Mg	B	SiO_2	Cl	SO_4	HCO_3

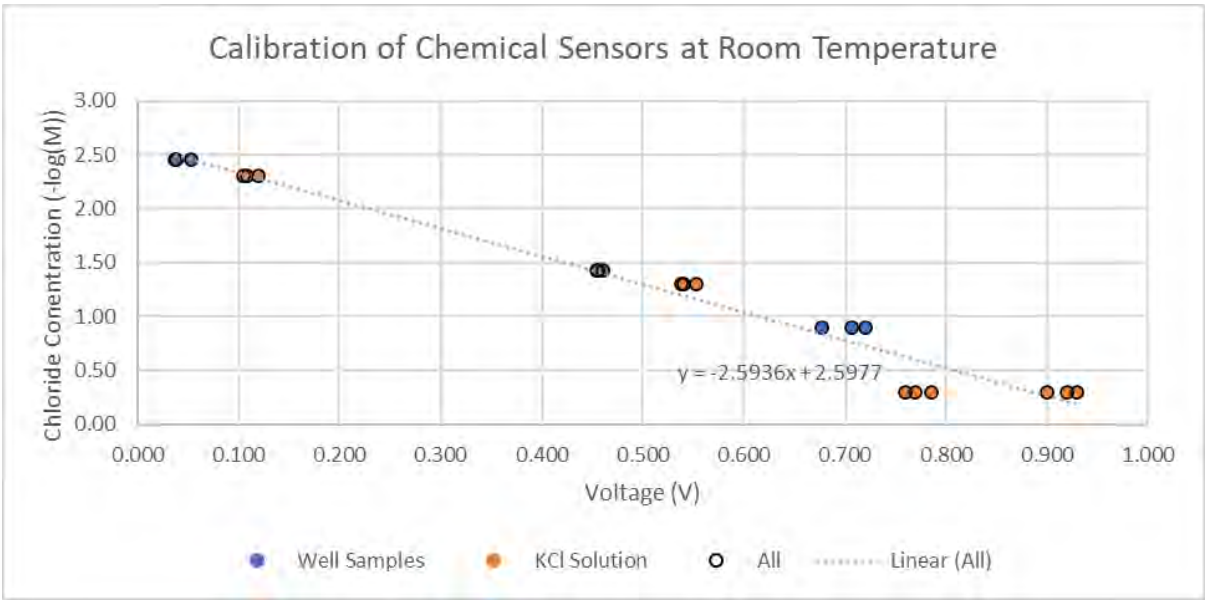

Figure 2-3: Calibration of chloride sensors in KCl solution and samples from wells 16A and 16B for sensors deployed in Utah FORGE Well 16B.

2.2.2 Chemical Sensor Housing

The chemical sensor housing has been designed and developed to enclose the ion-selective chemical sensors, pH Sensor, and the reference electrode sensor. The sensor housing was designed to allow flow to pass through the housing and interact with the chemical sensors uniformly. The housing includes retainer slots to incorporate three Ion-Selective Electrode (ISE) sensors, one reference electrode sensor, and two pH sensors. The sensors are routed through a wire feed-through and sealed using a Conax Compression Seal Fitting. In the current setup, the Conax Compression Seal Fitting can hold up to four wires, this allows for two ISE sensors, one pH sensor, and one reference electrode, the remaining retainer slots are left empty. The housing also includes a wire feed-thru to accommodate the downstream Mitco PTS sensor used for secondary measurements. The unique feature combinations (internal tube, pellet slots) are enabled through metal additive manufacturing. Three sensor housings were manufacture and tested to ensure they are pressure safe and leak resistant. A sensor housing with installed sensors is shown in Figure 2-4.

Figure 2-4: Fabricated sensor housing populated with installed sensors and bulkhead fitting.

2.3 High Temperature Logging Tool

Two versions of the High-Temperature (HT) Logging Tool have been developed and assembled to capture and transmit data from the chloride sensors and PTS spinner tool through the wireline to the surface. The primary version incorporates a modified and previously deployed and tested HT electronics package. The system is composed of three main boards: 1) a digital board featuring a Honeywell HT HT83C51 microcontroller, a Sandia custom high-temperature Application-specific Integrated Circuit (ASIC), and memory, 2) an analog board equipped with an analog to digital converter (ADC), multiplexer, and operation amplifies for the pressure and temperature inputs, and 3) a buffer board that includes a Chemical Buffer Amplifier (CBA) designed to convert the chemical sensor's high input impedance to low impedance. Two full assemblies of the primary HT logging tools have been assembled and tested to confirm operation (see Figure 2-5). The secondary logging tool was constructed to serve as a backup for contingency in the field. This electronic system uses the EV-HT-200CDAQ1 High-Temperature Data Acquisition Reference Design Platform from Analog Devices Inc as an alternative to the digital and analog board in the first system. All three logging tools have been tested to confirm they can accurately capture readings from the chloride and pH sensors, record measurements from the Mitco PTS module, and relay the information through the wireline cable.

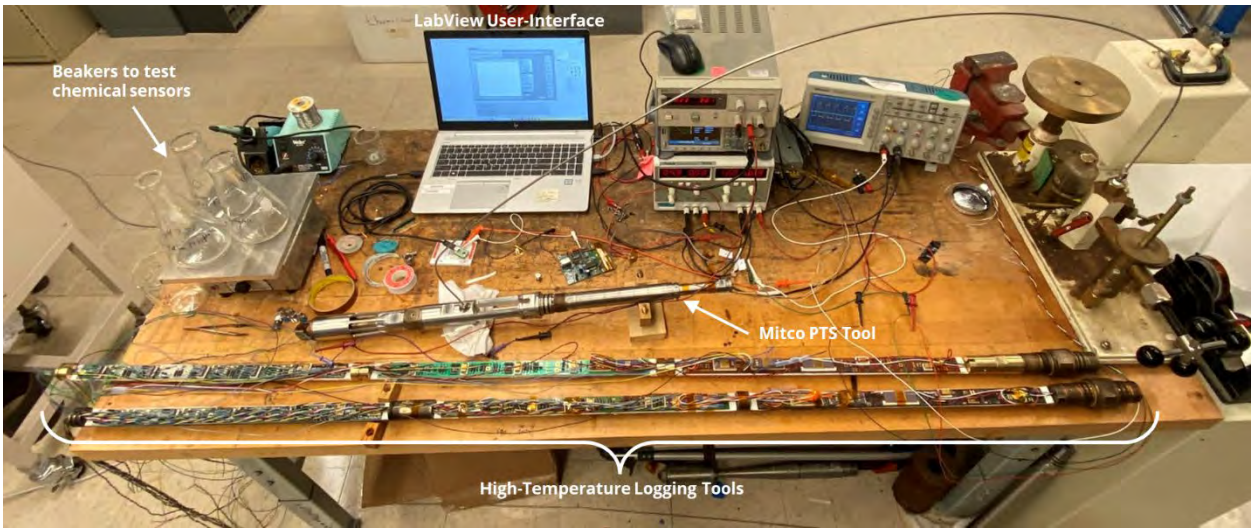

Figure 2-5: Primary High-Temperature Logging Tools being tested to confirm operation in benchtop test.

A LabView user interface has been developed (shown in Figure 2-6) to efficiently handle serial data from the tool, offering real-time data display and recording capabilities on a PC. The interface is designed for compatibility with both the primary and secondary High-Temperature Logging tools. This streamlined field operations for each tool configuration.

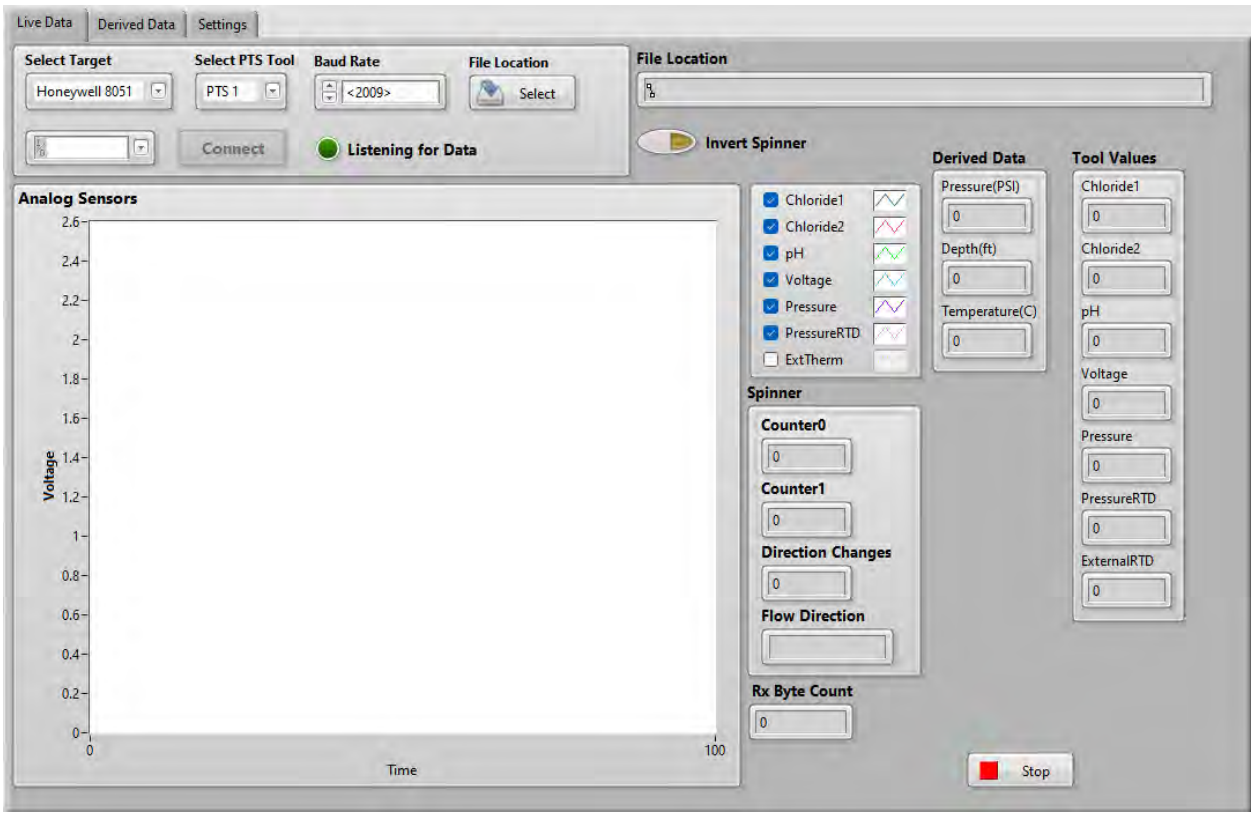

Figure 2-6: LabView User Interface for Field-Scale Chloride Tool

3. Laboratory Experiments

The new iteration of the chloride tool housed two ISE probes, known as ISE probe #2 and ISE probe #3. A calibration was performed to determine an empirical relationship between the voltage readings of the ISE probes and the chloride concentration of the surrounding fluid. The calibration curves for both ISE probes, provided in Equation 3.1 and Equation 3.2, exhibited strong linear relationships ($R^2 = 0.975$ and $R^2 = 0.961$) between their voltage readings and the negative common logarithm of chloride concentration in mol/L.

$$-\log_{10}(\mathrm{M}) = -20.64 * \mathrm{V} + 0.596 \quad (3.1)$$

$$-\log_{10}(\mathrm{M}) = -35.31 * \mathrm{V} + 0.550 \quad (3.2)$$

Using the calibration curves, the voltage readings from both ISE probes could be converted into chloride concentration values. Flow experiments in the artificial well system in the Stanford Geothermal Laboratory were conducted. The first set of experiments involved the chloride tool being held in a static vertical position in the artificial wellbore while a series of two one-minute feed zone flows occurred. These experiments granted insight into the behavior of the chloride tool in response to varying the parameters needed to infer the feed zone inflow rate in geothermal wells.

The first variables tested were the chloride concentration of the feed zone fluid and the vertical location of the chloride tool relative to the feed zone jet. The results of these experiments are shown in Figure 3-1 and Figure 3-2 for ISE probe #2 and ISE probe #3 respectively.

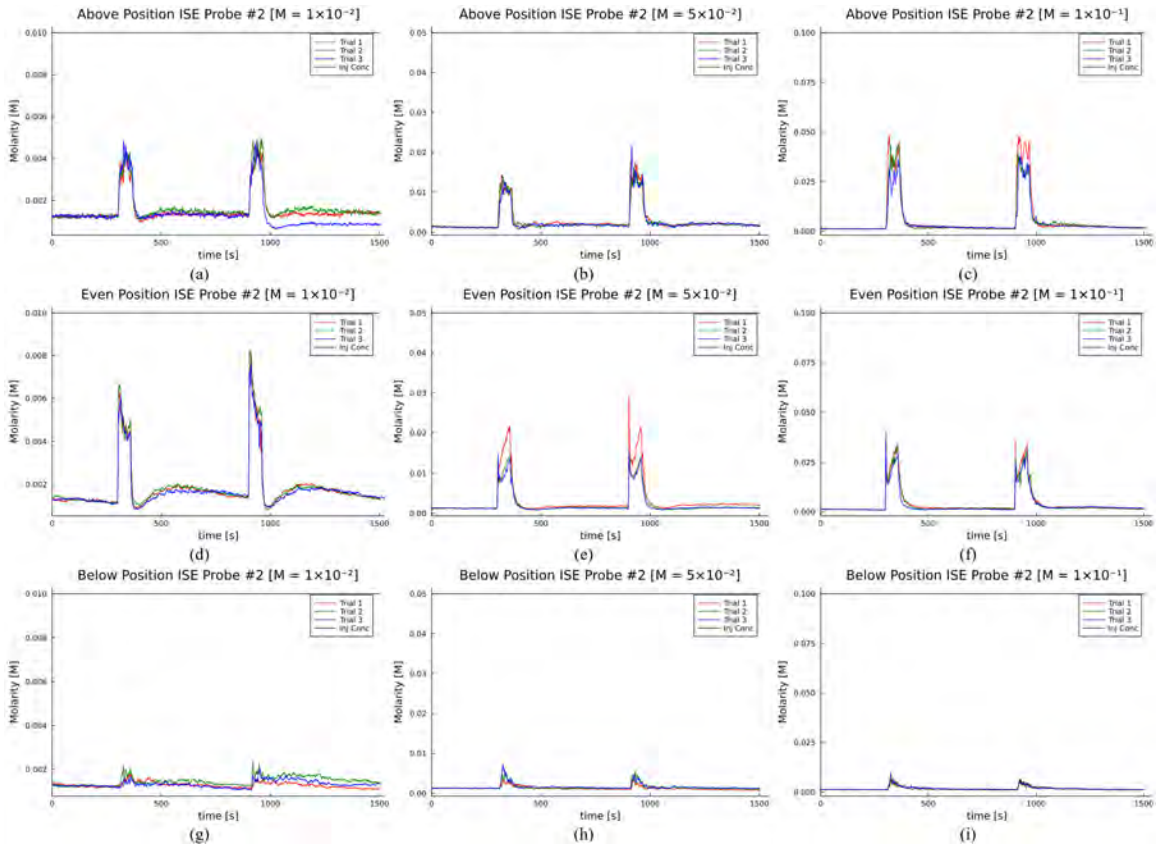

Figure 3-1: Molarity time series for ISE probe #2 in the above, even, and below positions for chloride concentrations of (a, d, and g) 1×10^{-2} mol/L, (b, e, and h) 5×10^{-2} mol/L, and (c, f, and i) 1×10^{-1} mol/L

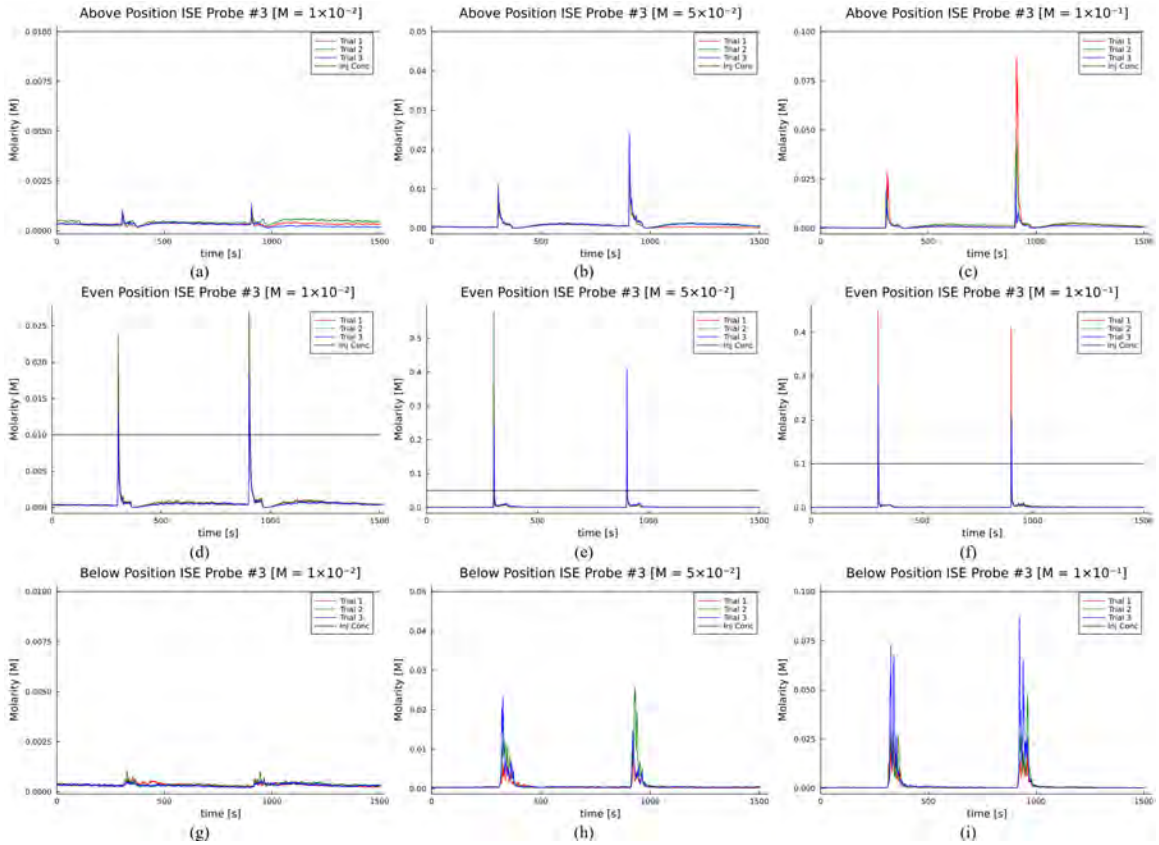

Figure 3-2: Molarity time series for ISE probe #3 in the above, even, and below positions for chloride concentrations of (a, d, and g) 1×10^{-2} mol/L, (b, e, and h) 5×10^{-2} mol/L, and (c, f, and i) 1×10^{-1} mol/L

The most notable result seen in Figure 3-1 and Figure 3-2 was the different behavior of the ISE probes when the chloride concentration of the surrounding fluid changed. Specifically, ISE sensor #2 exhibited smooth and gradual changes to its molarity readings that then plateaued. In contrast, the molarity readings of ISE probe #3 spiked immediately when the chloride concentration of the surrounding fluid changed. Then, the molarity readings of ISE probe #3 decreased, even though no changes to the surrounding fluid occurred. Additionally, these experiments suggested that higher feed zone chloride concentrations produced the most accurate and repeatable responses for both ISE probes.

Additional static experiments with the chloride tool were conducted to determine the effect of varying the feed zone inflow rate and the presence of additional chemical species in the feed zone fluid. The first set of additional experiments found that higher feed zone inflow rates led to higher accuracy when inferring the chloride concentration of the feed zone. The second set of experiments suggested that a significant amount of interference occurred when bromide, and to a lesser extent sulfate, were present in the feed zone fluid. This finding aligns with the literature, which indicates that ion-selective electrodes are imperfectly selective and particularly susceptible to interference from ions such as bromide, iodide, cyanide, silver, and sulfide due to their selectivity coefficients (Baker et al., 1980; Rhodes & Buck, 1980). The interference resulted in the ISE probes massively overestimating the concentration of the individual ions. However, the presence of bromide and

sulfate ions stabilized the readings of the chloride tool when compared to a feed zone fluid containing only bromide, chloride, or sulfate ions. These findings for ISE probe #2 are shown in Figure 3-3.

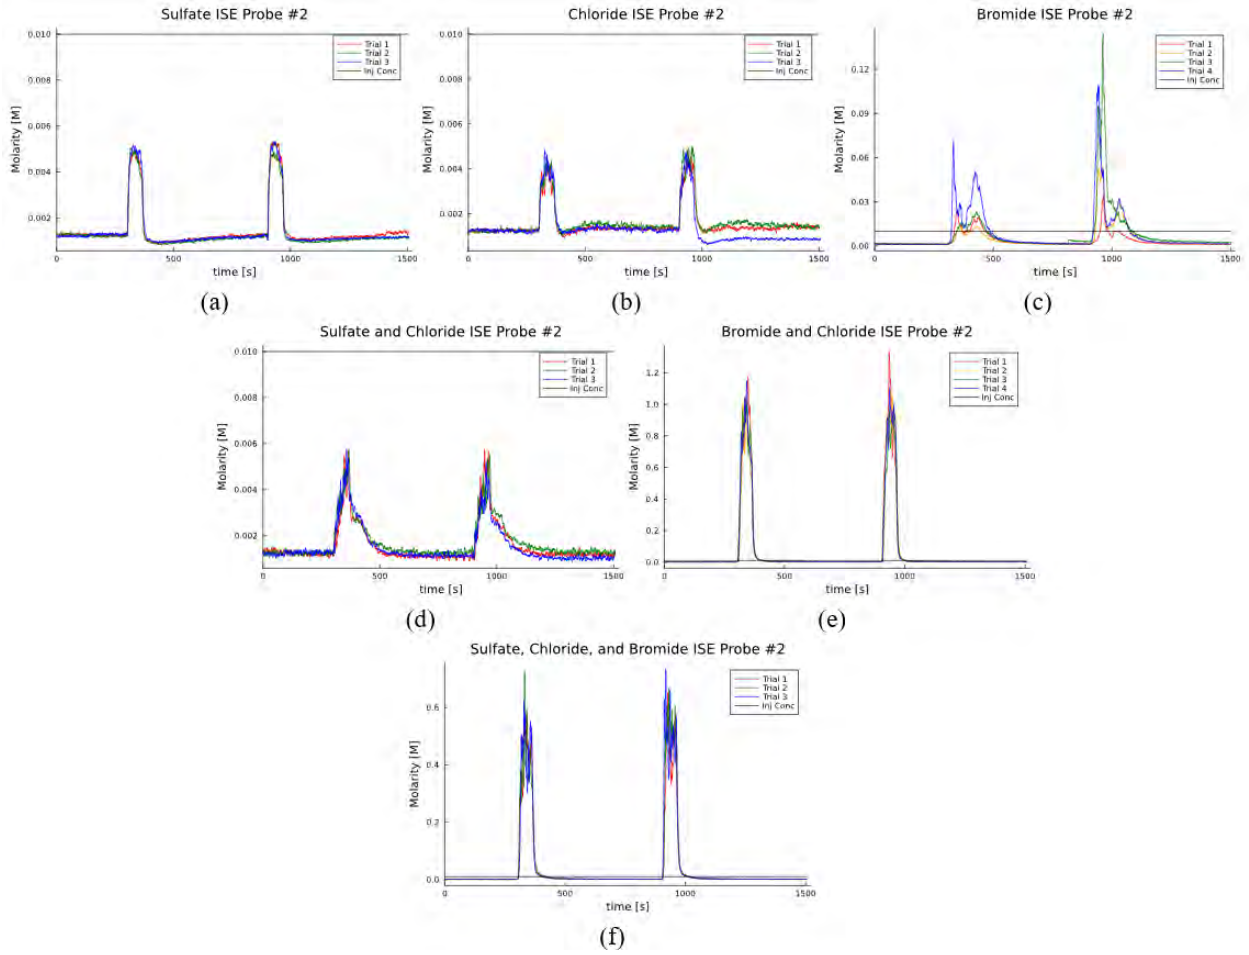

Figure 3-3: Molarity time series for ISE probe #2 for feed zone fluid containing 1×10^{-2} mol/L solutions of (a) sulfate, (b) chloride, (c) bromide, (d) sulfate and chloride, (e) bromide and chloride, and (f) sulfate, chloride, and bromide.

To better imitate field operations, laboratory experiments in which the chloride tool was moved vertically in both directions to measure the chloride concentration across the depth of the artificial wellbore were conducted. These dynamic experiments provided insight into the performance of the chloride tool as it was actuated in the run-in hole (RIH) and pull-out of hole (POOH) directions. The molarity measurements were then used with the analytical solution derived by Sausan et al. (2022) to estimate the mass inflow rate for a single feed zone.

The first series of dynamic experiments tested various chloride concentrations of the feed zone fluid and the direction of motion of the chloride tool. These experiments found that feed zone fluids with higher chloride concentrations resulted in the most accurate feed zone inflow rate inferences. However, these accurate inferences were seen only for ISE probe #3 in the POOH direction. This is likely because the behavior of ISE sensor #3 caused it to best capture the rapid

changes in chloride concentration when the chloride tool moved through the feed zone jet. The results of these experiments are shown in Figure 3-4 and Figure 3-5 for ISE probe #2 and ISE probe #3 respectively. Additionally, Table 3-1 shows the estimates of mass inflow rate $\dot{m}_{in}$ for a single feed zone averaged across the three trials and the percentage error between the actual and inferred inflow rates.

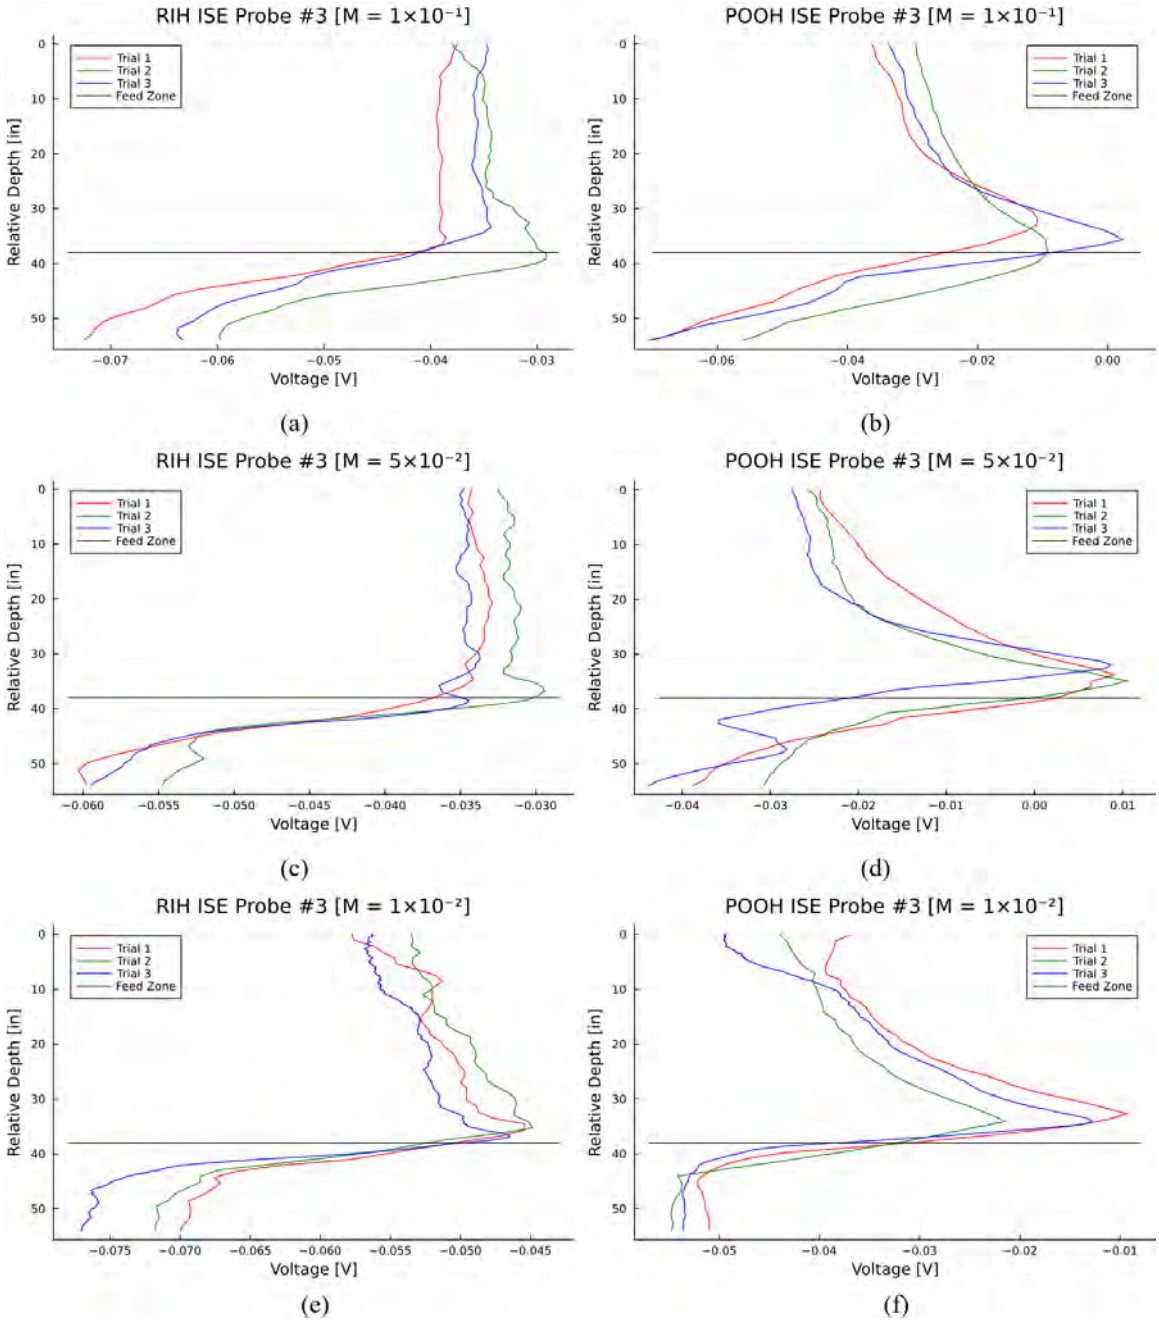

Figure 3-4: Molarity vs. Depth for ISE probe #2 in the RIH and POOH directions for feed zone fluids with chloride concentrations of (a and b) 1×10^{-1} mol/L, (c and d) 5×10^{-2} mol/L, and (e and f) 1×10^{-2} mol/L

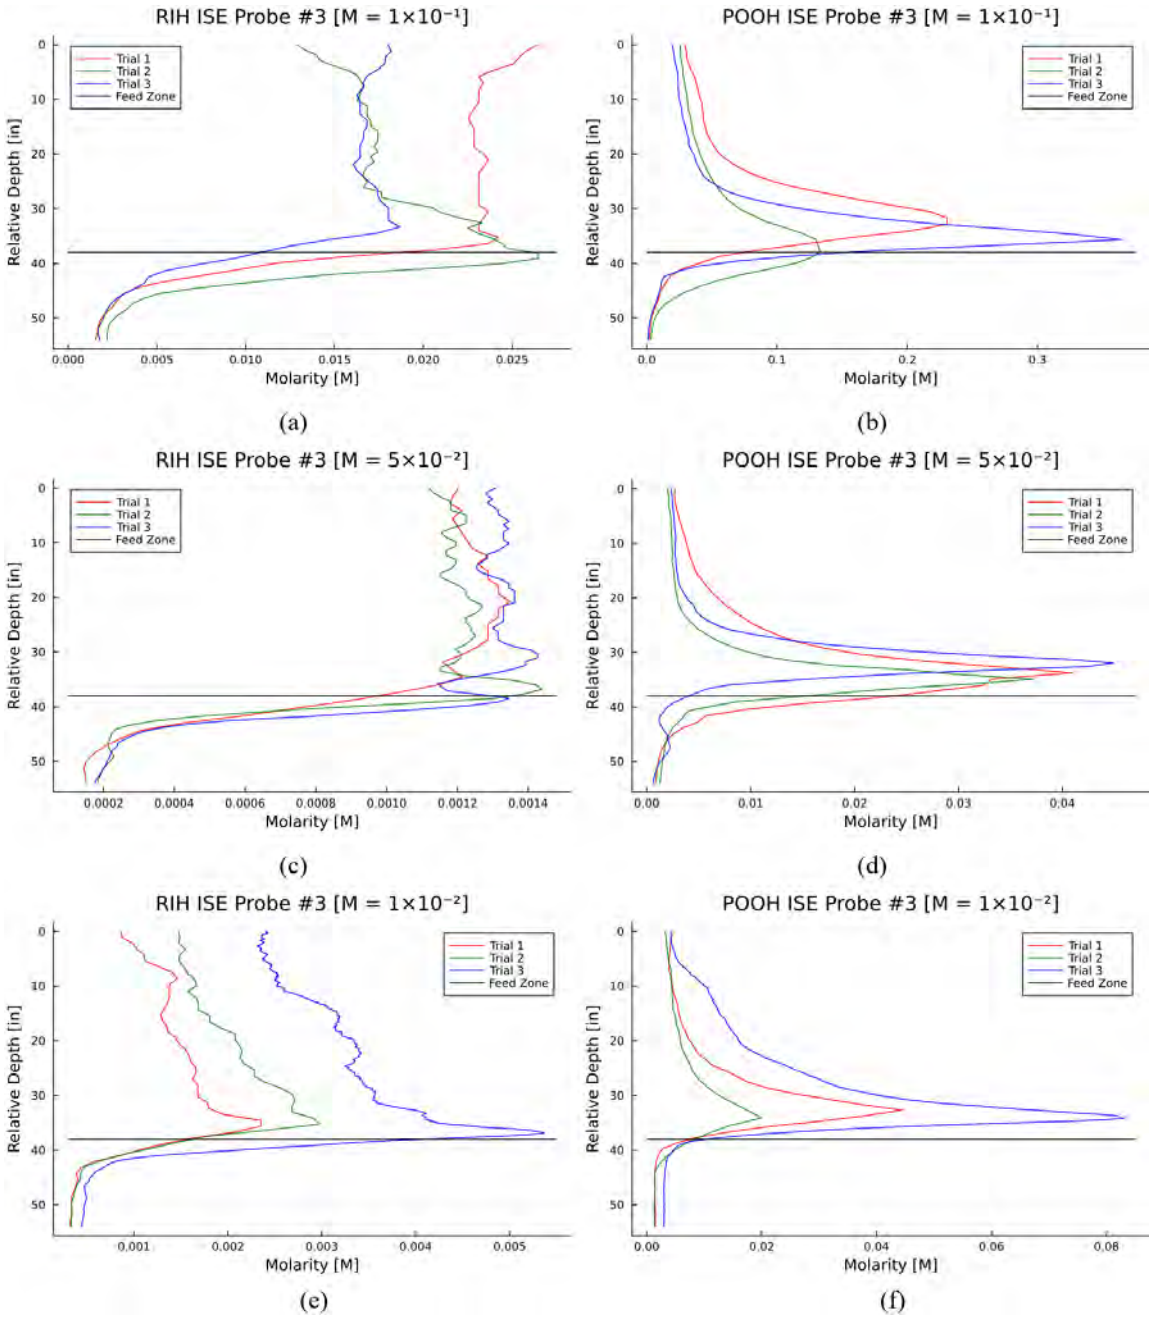

Figure 3-5: Molarity vs. Depth for ISE probe #3 in the RIH and POOH directions for feed zone fluids with chloride concentrations of (a and b) 1×10^{-1} mol/L, (c and d) 5×10^{-2} mol/L, and (e and f) 1×10^{-2} mol/L

Table 3-1: Average inferred feed zone inflow rates and percentage error for the various scenarios at different chloride concentrations of the feed zone fluid

Feed Zone Chloride Concentration	Scenario	ISE Probe	Average Inferred Flow Rate (kg/s)	Percentage Error
1×10^{-1} mol/L	RIH	#2	1.256	993%
1×10^{-1} mol/L	POOH	#2	1.010	778%
1×10^{-1} mol/L	RIH	#3	0.730	535%
1×10^{-1} mol/L	POOH	#3	0.109	-5%
5×10^{-2} mol/L	RIH	#2	1.131	884%
5×10^{-2} mol/L	POOH	#2	0.877	662%
5×10^{-2} mol/L	RIH	#3	0.773	572%
5×10^{-2} mol/L	POOH	#3	0.031	-73%
1×10^{-2} mol/L	RIH	#2	0.866	653%
1×10^{-2} mol/L	POOH	#2	0.886	670%
1×10^{-2} mol/L	RIH	#3	0.393	242%
1×10^{-2} mol/L	POOH	#3	0.078	-33%

Further experiments were conducted to test the following independent variables: the angular position of the chloride tool, the feed zone inflow rate, and the presence of additional ions in the feed zone fluid. These experiments found that the chloride tool underestimated the feed zone inflow rate when the ISE sensors and the feed zone jet were on opposing sides of the well. Additionally, when the feed zone inflow rate was varied, no significant changes to the accuracy of the inferred feed zone inflow rates were seen. Finally, when bromide was present in the feed zone fluid, the magnitudes of the molarity readings were significantly greater than other experiments. However, the relative changes to the measured concentration still provided accurate estimations of the feed zone inflow rate. In contrast, the presence of sulfate ions in the feed zone fluid did not affect the chloride concentration readings of the ISE sensors nor the ability of the chloride tool to infer feed zone inflow rates.

These findings highlight the sensitivity of the chloride tool to multiple parameters that characterize geothermal wells. Overall, these laboratory experiments yielded promising results when measuring a vertical series of chloride concentrations in the artificial geothermal well. As such, the method of inferring feed zone inflow rates in a geothermal well using chloride concentration measurements, albeit on a relative rather than absolute scale, holds promise.

4. Field Testing

The field-deployable chloride tool was deployed in FORGE Wells 58-32, a vertical monitoring well with a total depth of 7,536 ft, and Well 16B(78)-32, a deviated production well drilled to a total depth of 10,947 ft. For 58-32, the weight of the tool was sufficient to lower the tool with gravity; however, in 16B(78)-32, a wireline roller was needed to help convey the tool through the well deviation. Figure 4-1 shows the wells on the Utah FORGE site and Table 4-1 provides an overview of the two FORGE wells and the deployment techniques in each.

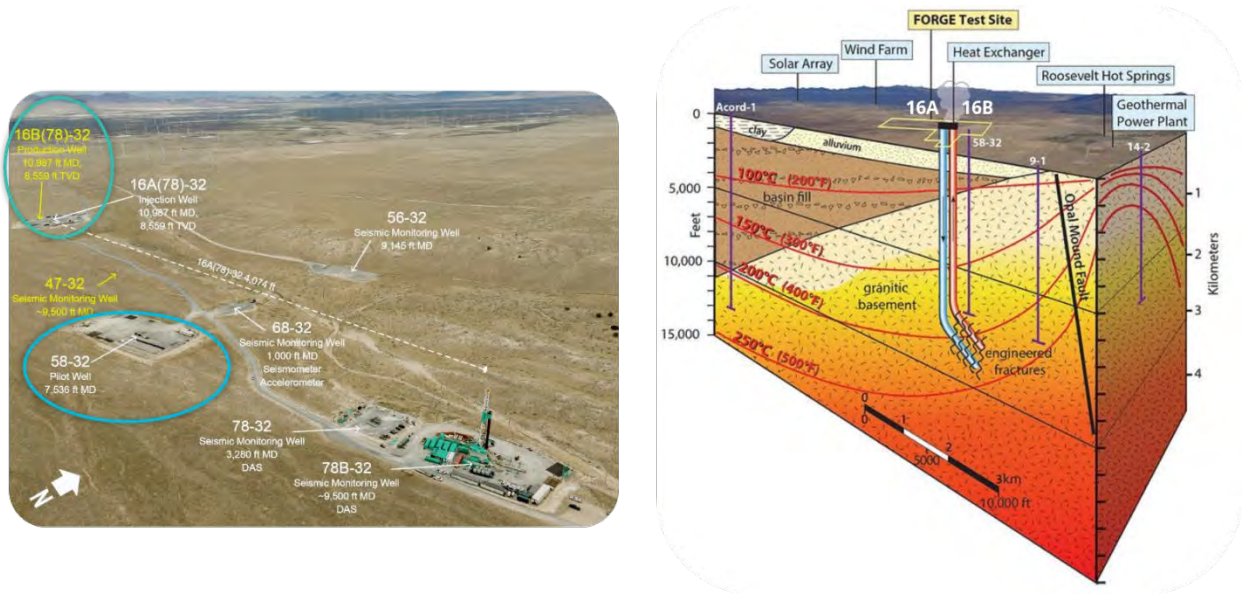

Figure 4.1: Utah FORGE site with planned deployment wells circled (left) and geological and heat model of the Utah FORGE site (right) (source: Utah FORGE)

Table 4-1: Overview of tool deployment scenarios in Utah FORGE wells 58-32 and 16B(78)-32.

FORGE Well	Well Type	Curve Profile	Total Depth	Deployment Technique
58-32	Vertical Pilot Well	N/A	7,536 ft	Tool deployed on Sandia wireline with weight of tool
16B(78)-32	Directional Production Well	5˚/100 ft	10,947 ft	Tool deployed through wireline service company with conveyance rollers to assist with well deviation

4.2 FORGE Well 58-32 Deployment

The first deployment was executed June 12-14, 2024, at Utah FORGE Well 58-32, an open and vertical pilot well. Three tool assemblies were prepared for contingency in the field. The Sandia wireline truck was used to deploy the tool into the well and a tip and body centralizer were used to centralize the tool within the 7” casing. The tool was deployed to five test locations shown in Figure 4-2, above, below, and within the cased and perforated zones to test the capability of the ion-selective electrodes to measure chloride concentration readings around the feed zone and determine if these measurements can be used to calculate the feed zone inflow rate.

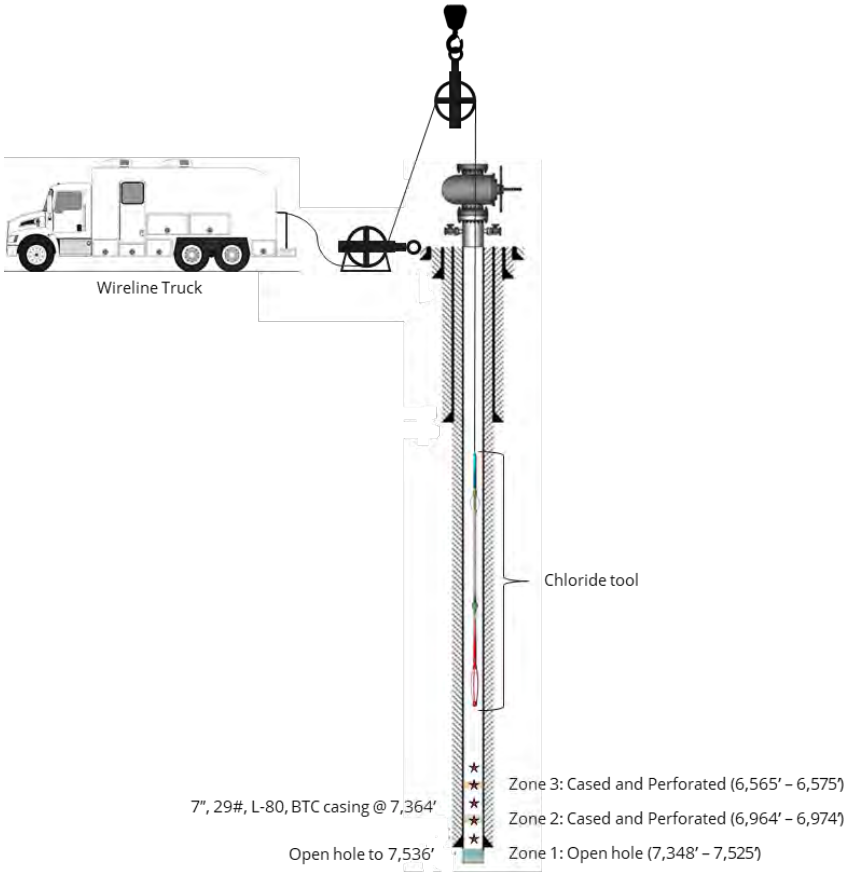

Figure 4-2: Illustration of tool deployment plan for Utah FORGE Well 58-32.

The two primary tools experienced issues during deployment and were pulled out the hole before collecting data. The secondary tool was successfully deployed to 7,168 ft MD with a maximum measured temperature of 190˚C. Measurements were recorded at each test location during the run-in hole (RIH) and pull-out-of-hole (POOH), with noticeably better during the POOH run in comparison to the RIH run. The measurements suggest that there were no internal flows in the well during the logging, which was not unexpected as the well was not producing at the time. Figure 4-3 shows the deployment of the tool into Utah FORGE well 58-32 using the Sandia wireline truck.

Figure 4-3: Deployment at Utah FORGE Well 58-32.

The logging results are shown in Figure 4-4 for the run-in hole (RIH) and Figure 4-5 for the pull-out of the hole (POOH). The first two columns display data from two chemical sensors, while the following two columns show temperature data from the PTS and CPU. The CPU temperature data is considered to be more accurate in magnitude for this particular run, despite the lag in heating up caused by its position inside the electronics component rather than in direct contact with the fluid. The last three columns represent the flow data from the PTS sensor. The perforated zones are marked with yellow regions; the short interval creates the appearance of a line.

A decrease in voltage (i.e., a spike to the left) would correlate with an increase in chloride concentration, indicating inflow presence. If accompanied by a temperature spike coming from geofluid entering the wellbore, the voltage spike will strongly indicate inflow presence. The RIH data shows no strong indication of such a spike around Zone 2 and 3. Meanwhile, spikes in both directions are observed in the chloride voltage columns near Zone 1, which also correlates with a temperature increase. However, the PTS counter did not increase, even with a location pause. Thus, the interval is not interpreted as flowing or experiencing notable internal flow.

The POOH run provides much cleaner data than the RIH run, which was expected as the laboratory experiments have indicated the same behavior. However, chemical sensor voltage data from the shallower part of the POOH, as indicated in Figure 4-5, is erroneous and cannot be used for interpretation. Similar to RIH, spikes are seen near Zone 1 but are not interpreted as flow because

the PTS counter did not change at all. There seems to be a voltage spike near Zone 3, which is also accompanied by a temperature spike. However, the spike was only caused by one data point; again, no corresponding counter or direction change from PTS was present. Thus, it is concluded that the logged interval did not indicate the presence of any inflow. If there were any internal flow happening, it could occur within the open hole section, which was below the maximum depth of our runs as it was considered undesirable to run the tool below the casing shoe.

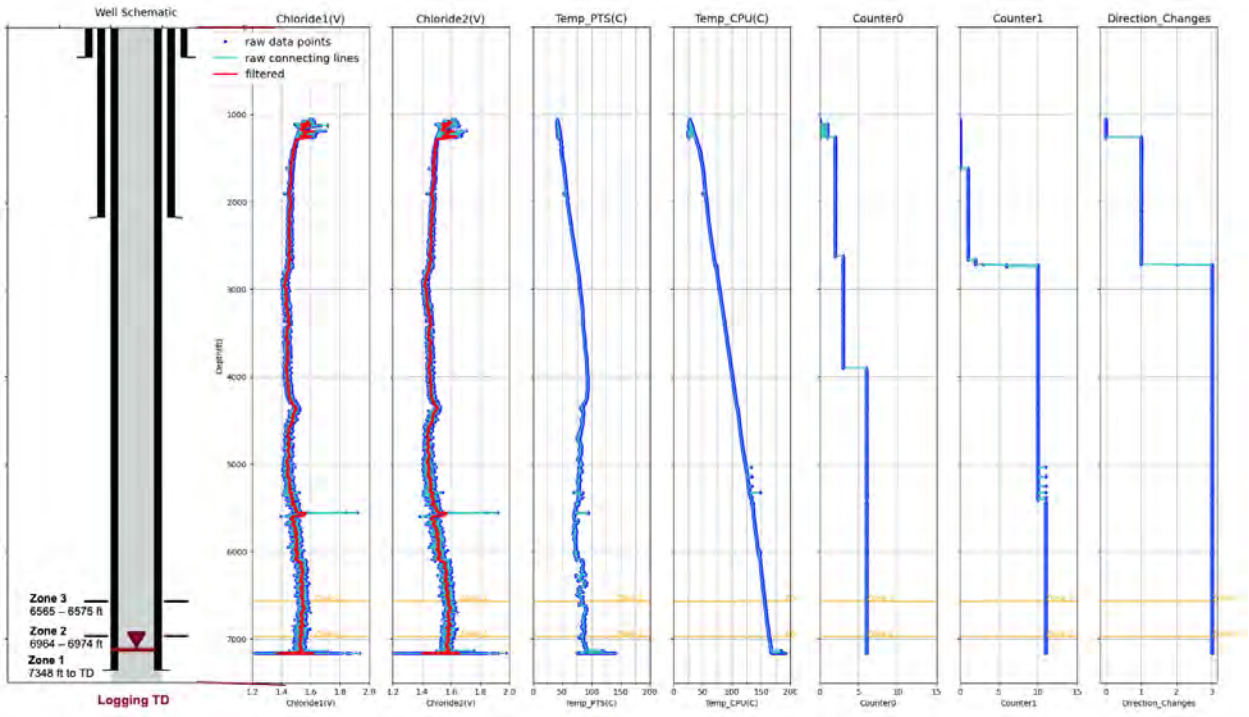

Figure 4-4: logging results during Run in Hole (RIH) at well 58-32.

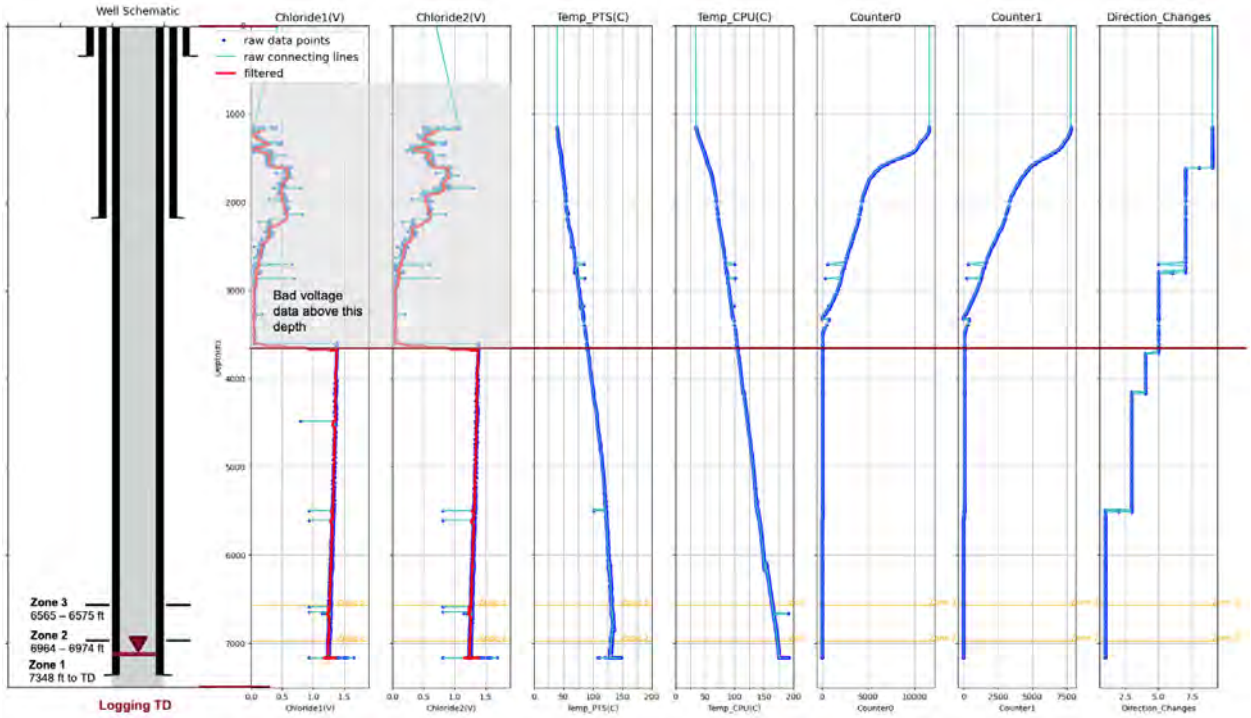

Figure 4-5: logging results during Pull Out of Hole (POOH) at well 58-32.

The voltage signals from the two chemical sensors appear to resemble each other. Thus, the readings from the first sensor were used to evaluate converting the chemical sensor voltage into chloride concentration. Calibration for the field tool used at 58-32 was performed with KCl solution in distilled water and fluid samples from well 16A(78)-32 and 16B(78)-32. The molarity result using the best available calibration curve is shown in Figure 4-6, showing a range of around 0.2 for RIH data and between 0.25 to 0.75 M for POOH data. However, this calibration curve is unreliable due to a discrepancy in the third tool bench calibration after acquisition.

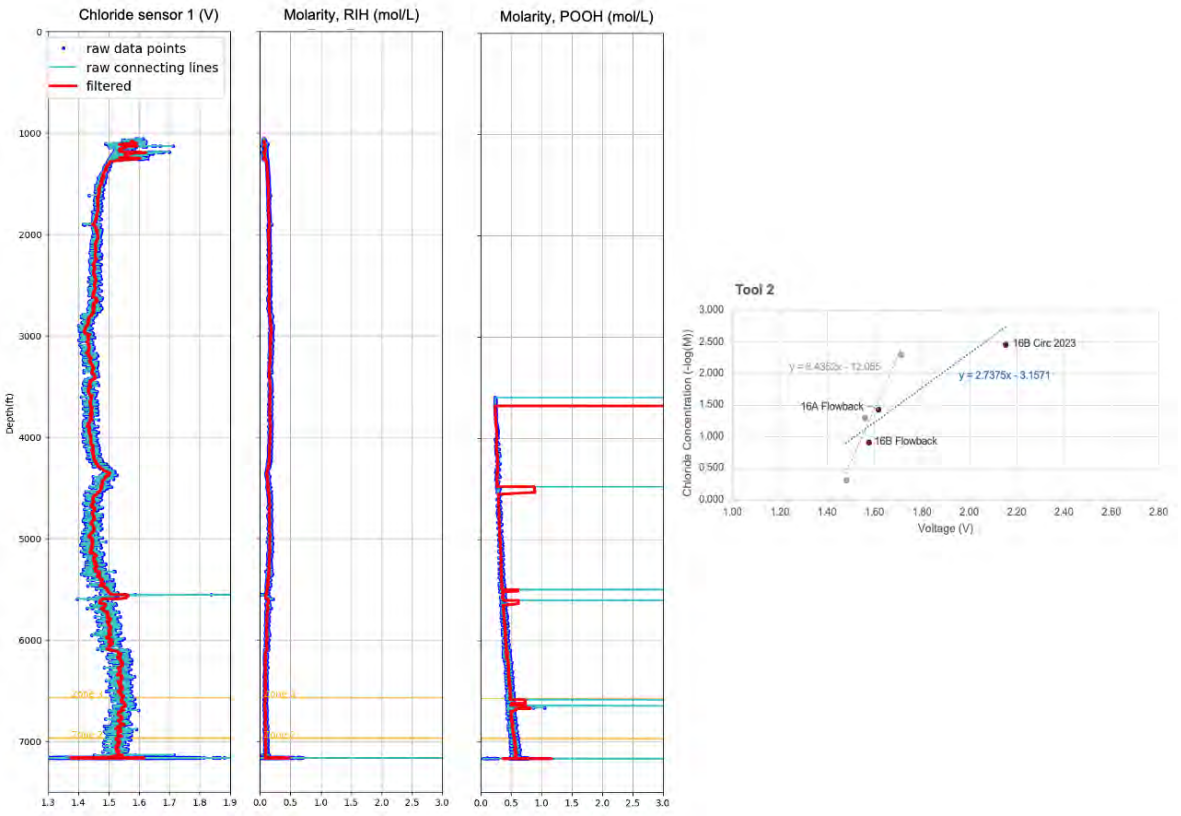

Figure 4-6: converted molarity from the chemical sensor 1 voltage data during RIH and POOH using Tool 2 calibration curve (blue line)

In Table 4-2, the sum of the molarity of relevant chemical species ranges from 0.0046 to 0.12 M. Recent laboratory experiments have shown that in addition to chloride, the ISE is sensitive to bromide (B) and, to a lesser extent, sulfate (SO4), as discussed in Section 3. While chloride is more common in brine water and often determines the molarity, the ISE reacts to bromide and sulfate to varying degrees. The logging results overestimate the chloride concentration compared to available samples, albeit not from well 58-32 itself. Additionally, the RIH data shows a lower concentration than the POOH data, which is closer to the truth. Consequently, improvements will be made to the chemical sensor to ensure more accurate readings for the follow-up test at 16B(78)-32.

Table 4-2; Relevant chemical species of well samples from Utah FORGE Wells 16A(78)-32 and 16B(78)-32

DATE & TIME		WELL	Concentration (mg/l)			Molarity (mol/l)			Sum of molarity (mol/l)
			B	Cl	SO4	B	Cl	SO4

4.3 FORGE Well 16B Deployment

The second deployment was conducted August 19, 2024, at Utah FORGE Well 16B(78)-32 during a 30-day circulation test. Two chemical tool assemblies were prepared for contingency in the field. The tool was deployed using an SLB wireline truck, weight bars, and Petromac rollers to assist in conveying the tool through the flowing and deviated well. This test was conducted to test the feasibility of the geochemistry-based approach to map fractures and quantify feed zone inflow rates in a flowing well. Well 16B has five stages, each with 3-5 guns, this provided the opportunity to map up to 20 fractures. For this deployment, ten test locations were planned, to target measurement at and between perforations. For each test location, the tool was held to allow for a stationary measurement of the chloride sensors and PTS tool. The logging between each test location would provide a blind “fly by” measurement to determine the feasibility of mapping fractures using a running log. Figure 4-7 illustrates the deployment plan, with the measurement locations shown as stars and Table 4-3 summarizes the measured depth of the perforation stages and planned and executed test locations during the RIH and POOH logs.

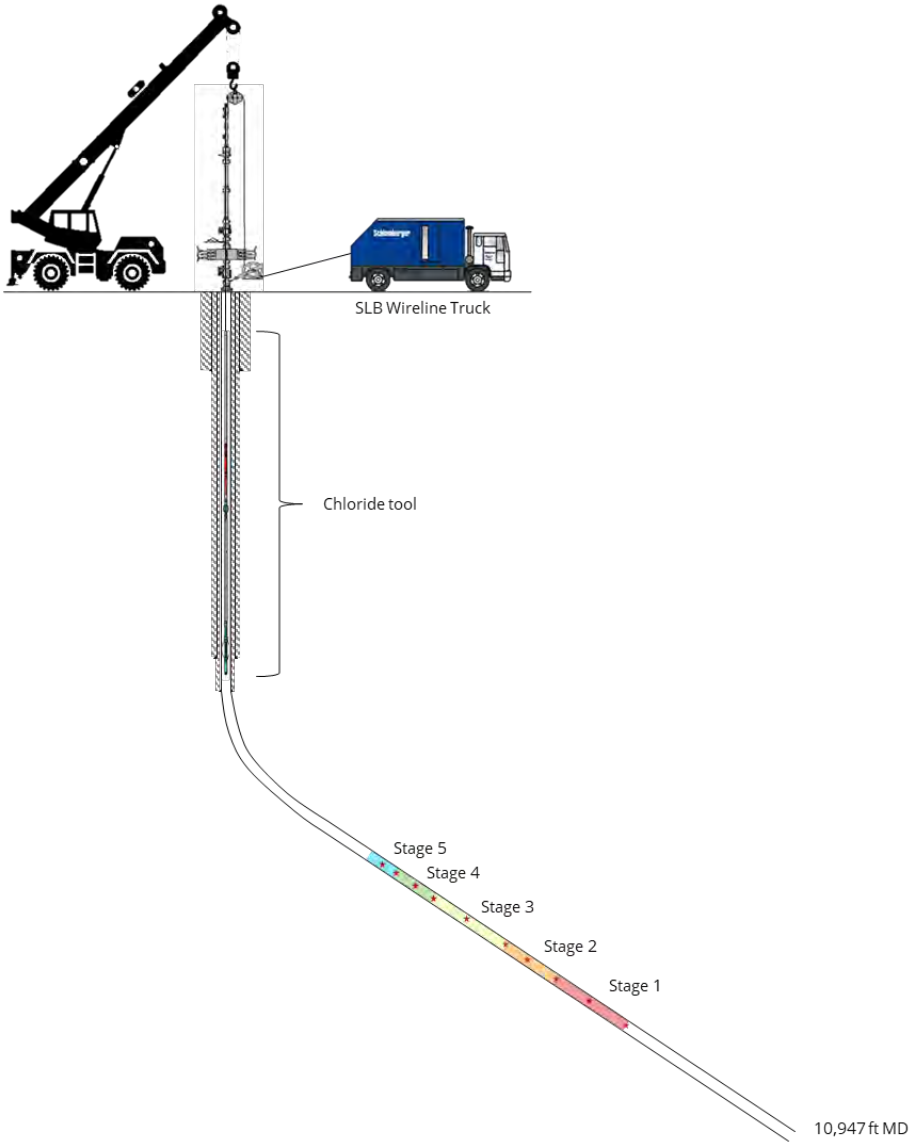

Figure 4-7: Illustration of tool deployment plan for Utah FORGE Well 16B(78)-32. Perforation stages shown in highlighted zones and planned test locations shown as red stars.

Table 4-3: Measured Depth of perforation stages and planned and actual test locations.

	Measured Depth (ft)							
	Gun 1	**Gun 2**	**Gun 3**	**Gun 4**	**Gun 5**	**Planned Test Location**	**Actual RIH Test Location**	**Actual POOH Test Location**
Stage 5	8500 - 8806	8806 - 8855	8855 - 8876	8876- 8920		8865	8865	8865
						8920	8920	8920
Stage 4	8920 - 8978	8978 - 9013	9013 - 9042	9042 - 9155		9030	9030	9030
						9155	9155	9155
Stage 3	9155 - 9306	9306 - 9368	9368 - 9407			9388	9388	9388
						9407	-	-
Stage 2	9407 - 9440	9440 - 9455	9455 - 9469	9469 - 9495	9495 - 9600	9462	-	-
						9600	-	-
Stage 1	9600 - 9720	9720 - 9753	9753 - 9765	9765 - 9800		9759	-	-
						9800	-	-

The tool was successfully deployed to approximately 9,480 ft with a maximum measured temperature on the tool of 210°C. Figure 4-8 shows the fully assembled tool being loaded into the lubricator by the SLB team and Figure 4-9 shows the Utah FORGE Well 16B test site during the logging. The monitor wellhead pressure, flowline temperature, and separator liquid discharge flow during the log were 260-263 psi, 180°C, and 294-330 gpm, respectively. Measurements were recorded through Stage 3, at which point the log began to show potential issues. The wireline operator noted the tool had stopped moving at approximately 9,480 ft. After recovering tension in the line, the tool was brought back up the well for the POOH log to record measurements in Stage 4 and 5. The measurements in the RIH log were of noticeably better quality than the POOH log, potentially indicating damage to the tool. The measurement results indicate a change in chloride concentration in the perforation zones, suggesting the chemical tool is capable of mapping fractures in a flowing well.

Figure 4-8: Full chemical tool assembly attached to weight bars and being loaded into lubricators.

Figure 4-9: Utah FORGE Well 16B test site with lubricator stacks for chemical tool.

5. Conclusion

The latest updates on the chloride tool development have focused on the deployment of the field-scale tool at the Utah FORGE site. Three assembled field-scale tools were constructed and tested in the lab, testing different iterations of the sensor pellet, tool housing, data electronics package, and assembly, and confirming operation of the tool on the wireline. The tool assembly features a Mitco PTS sensor package for secondary measurements, a wire guide component, chemical sensor housing, and HTHP electronics for data transmission through a 7-conductor feedthrough to the wireline. The sensor housing was fabricated using metal additive manufacturing, and was designed to integrate with the logging tool, accommodating Ion-selective Electrode (ISE) sensors, reference sensors, and pH sensors to be exposed to the flow in the well.

Concurrent with the development of the field-scale tool, flow experiments were conducted in the artificial well system at the Stanford Geothermal Lab. These laboratory experiments provided insights into the chemical tool's response to varying parameters, including chloride concentration in the feed zone, the tool's vertical position relative to the feed zone, and the presence of additional chemical species in the feed zone fluid. The findings demonstrated the chemical tool's sensitivity to multiple parameters, suggesting that using chloride concentration measurements to infer feed zone inflow rates in geothermal wells is a promising method.

The tool was successfully deployed at FORGE Well 58-32 an open, vertical well in June 2024, and FORGE Well 16B(78)-32, a pressurized and flowing deviated well in August 2024. Both deployments demonstrated the capability of the tool to withstand Utah FORGE conditions, and the feasibility of a geochemistry-based approach to map fractures in a flowing well (16B), with no false positives in a nonflowing well (58-32).

ACKNOWLEDGMENTS

This work is part of the Utah FORGE project under award number 3-2418 as a collaborative project between Stanford University and Sandia National Laboratory, supported by the U.S. Department of Energy. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525. ABSTRACT

An electrical borehole image log was recorded using freshwater mud in one of an exploration well at Tompaso geothermal field, Minahasa Regency, North Sulawesi Province with well deviation up to 25 degree. The log penetrated volcanic rocks in 2 runs within 12.25inch (1129m length) and 9.875inch (829m length) hole sizes. The objective of this study is to understand the fracture distribution and permeability characteristic of the Tompaso geothermal field by integrating borehole image with mud log, side wall core, petrographic analysis and spinner log to better locate the permeable zone and assessing the potential of this field.

A total of eleven lithotypes were classified. The 12.25-inch section is predominantly composed of volcanic breccia and coarse-grained pyroclastics, with thin lava layers observed at various depths. While lava is more prevalent in the 9.875-inch section, volcanic breccia and pyroclastics remain the dominant lithotypes. There were eleven fracture zones can be divided based on the fracture orientation, density, and lithotype association which later can be correlated with the spinner data to determine the feed zones.

Integration of borehole image data, sidewall cores, and surface geological mapping reveals that high permeability zones within the depth interval of 1023 mMD to 2167 mMD are predominantly controlled by matrix permeability of pyroclastic rocks, lithological contacts, and NE-SW striking fracture zones dipping southeast. This fracture zone likely correlates with the damage zone of the Tompaso fault. In contrast, permeability within the deeper interval of 2167 mMD to 3003 mMD is primarily influenced by E-W striking fractures and faults dipping south, likely associated with the Riendengan Caldera Rim. By targeting specific fracture orientations and lithology, it can enhance the probability of encountering productive zones and maximizing geothermal resource exploitation in the Tompaso field.

1. Introduction

Pertamina Geothermal Energy drilled an exploration well at Tompaso geothermal field, Minahasa Regency, North Sulawesi Province. Borehole image log penetrated volcanic rocks in 2 runs within 12.25in (1129m length) and 9.875in (829m length) hole sizes in the TPS-X well. (Figure 1). The area is part of a complex fault system with various fault patterns, including the NE-SW pattern and the NW-SE pattern that influenced by the NE-SW compressional tectonic regime (modification from Suryanto et al., 2020). There is almost no ENE-striking displacement in the area between instead of the NE-striking lineament such Panasen Fault. Therefore, we believe these volcanoes caldera and crater wall has faked the tectonic lineament which misleads the interpretation of the active left-lateral strike-slip Soputan Fault in the previous literature (Ikhwan et al., 2021). Knowing the fracture characteristic and their relation to the flow zone, therefore it is very important to understand the reservoir behavior with regards to the complexity of the field.

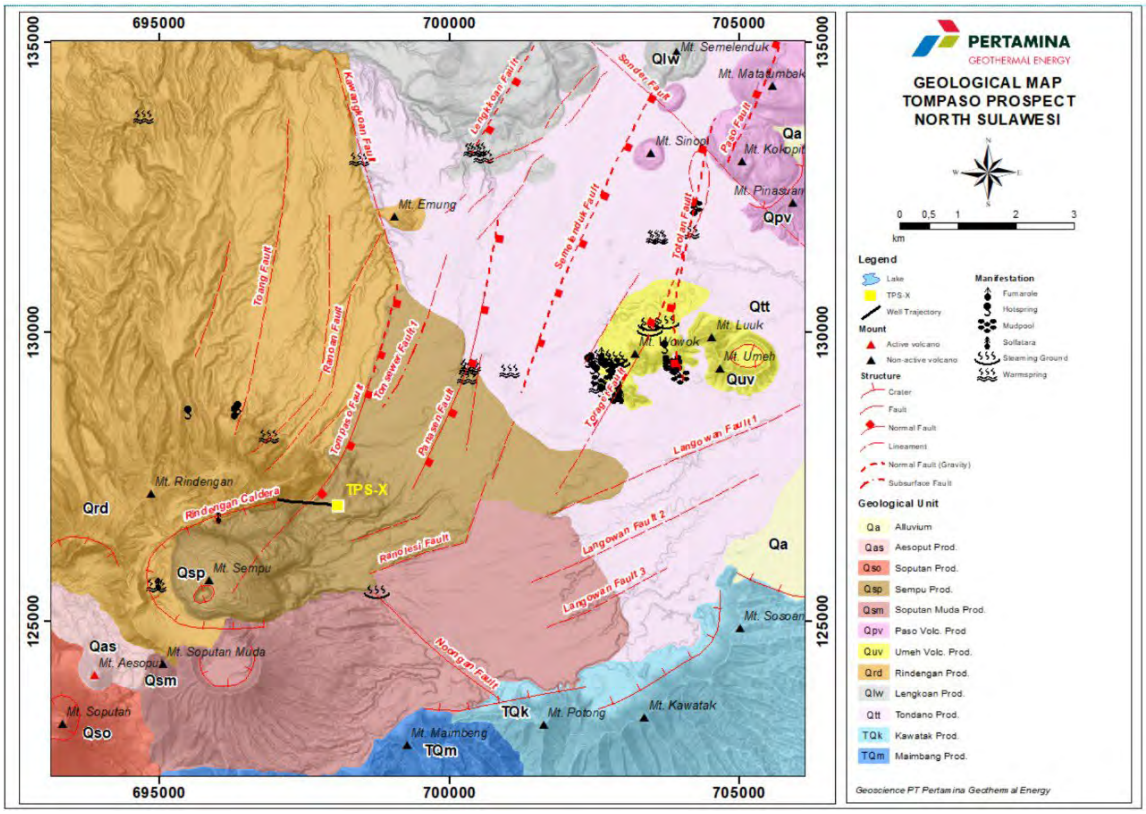

Figure 1: Geological map and geothermal manifestation distribution in Tompaso Field (modification from Suryanto, 2020)

The objectives of the study were to perform borehole image logs analysis including lithotype interpretation, manual dip picking, dips classification, structural analysis, fracture computation, and fracture zonation. Integration with other measurements and their advanced analysis will lead to better locate the permeable zone and assessing the potential of this field.

2. Method

The primary data source for this study was borehole image logs, with gamma-ray and mud logs added to refine lithology characterization. A workflow (Figure 2) was developed, integrating these

datasets to interpret permeable zones. Independent image log interpretation was followed by the use of spinner logs to confirm the presence of flow-contributing fractures. Meanwhile, core data and petrographic analysis confirmed lithotypes identified through image and log analysis, shedding light on the type of permeability sources within the TPS-X well.

The image log was processed to get static and dynamic images, afterward structural features were manually picked by fitting sinusoids to planar or sub-planar features that cut the borehole. Structural features such as fractures and faults were identified as planes that cut across bedding (e.g. fractures and faults). Fractures were further classified as conductive (considered as being open / filled by conductive minerals) and resistive (considered to be healed). While litho-type is defined as distinct combinations of lithology, texture, and structure of a rock (also known as facies). In fracture analysis, lithotype, structural analysis, and fracture computation were used as bases to classify the fracture zonation based on their relation and association. Spinner log, core data, and thin sections are also used to be integrated with the fracture interpretation from the borehole image to identify the location of feed zone.

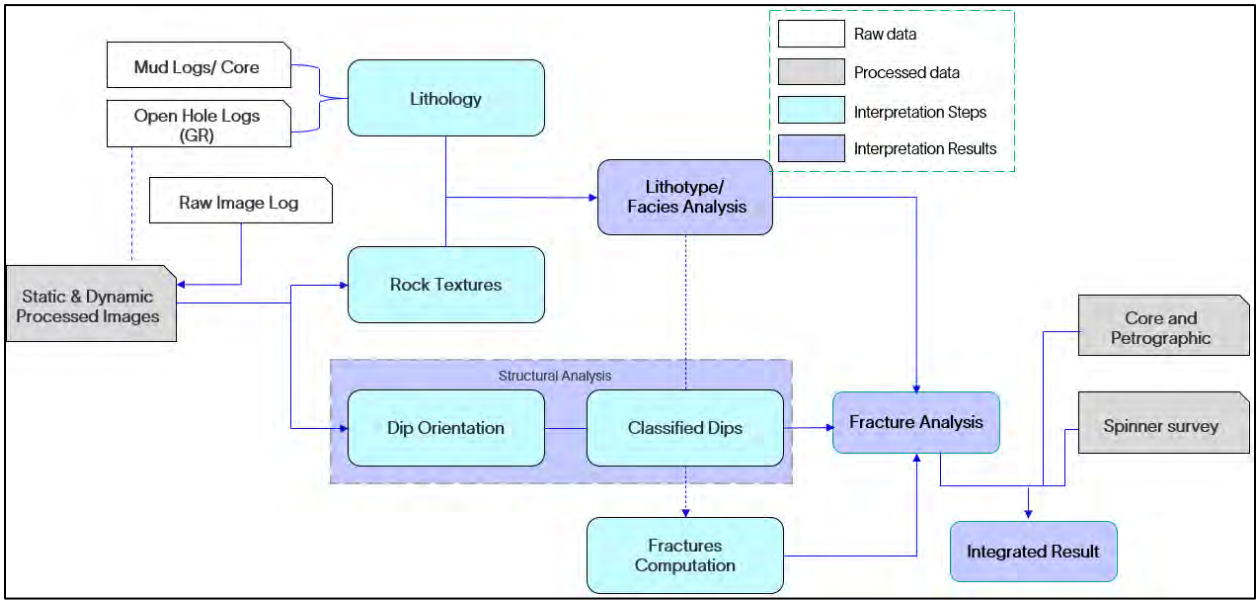

Figure 2: The general workflow of borehole image interpretation in well TPS-X.

3. Borehole Image Interpretation

3.1 Lithotype Interpretation

The lithology was derived and interpreted from the integration of mud logs and conventional log interpretations. Following lithology interpretation, texture and structure were inferred from visual inspection of borehole image appearance (Figure 3).

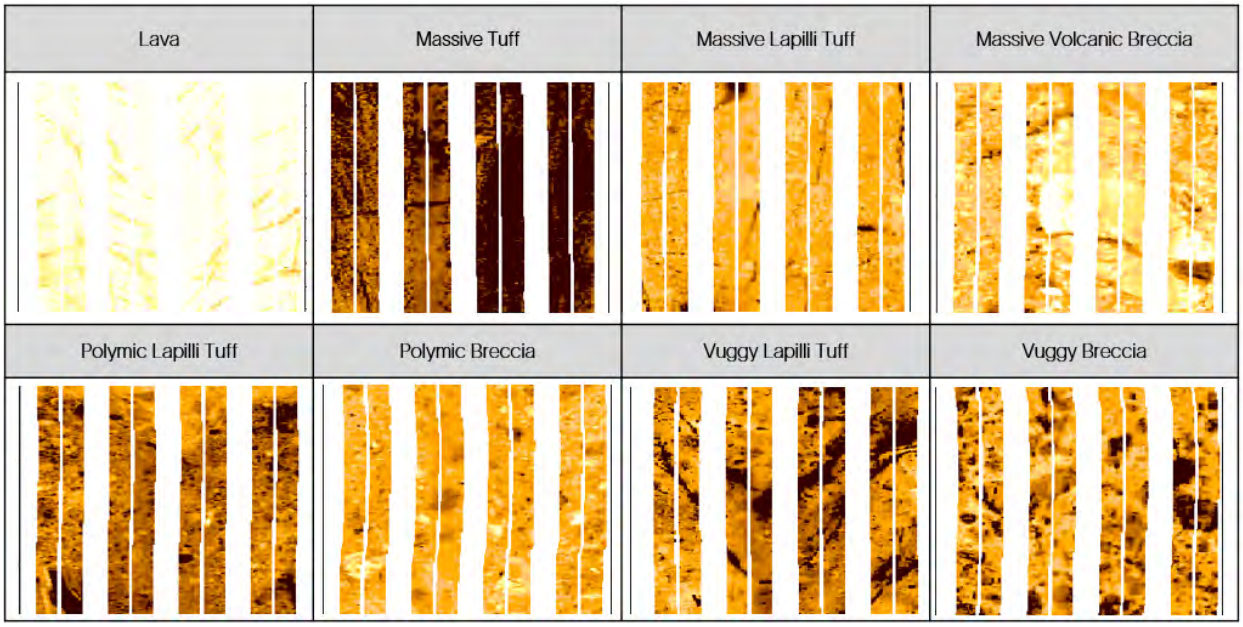

Figure 3: Borehole image textural/ structural features catalog in well TPS-X.

In the TPS-X well, a total of eleven lithotypes were classified (Table 1). In this study, lithotype is defined as distinct combinations of lithology, texture, and structure of a rock (also known as facies).

Symbol	Facies	Descriptions
	Lava	Relatively bright image appearance with massive texture
	Massive Tuff	Relatively dark image appearance with fine apparent texture and structure-less
	Bedded Tuff	Relatively dark image appearance with fine apparent texture and development of beddings
	Massive Lapilli Tuff	Relatively dark image appearance with medium apparent fragment size and structure-less
	Bedded Lapilli Tuff	Relatively dark image appearance with medium apparent texture and development of beddings

Symbol	Facies	Descriptions
	Massive Volcanic Breccia	Relatively dark image appearance with large apparent fragment size and structure-less
	Bedded Volcanic Breccia	Relatively dark image appearance with large apparent texture and development of beddings
	Polymic Lapilli Tuff	Lapilli tuff with mix of medium size resistive and conductive spots interpreted as fragments and relatively high GR
	Polymic Breccia	Breccia with mix of large size edgy resistive and conductive spots interpreted as fragments and relatively high GR
	Vuggy Lapilli Tuff	Breccia with large size resistive and conductive spots interpreted as vugs with relatively low GR
	Vuggy Breccia	Breccia with predominant large size edgy conductive and minor resistive spots interpreted as vugs with relatively low GR

Table 1: Borehole image* textural/ structural features catalog in well TPS-X.

The 12.25-inch section is predominantly composed of volcanic breccia and coarse-grained pyroclastics, with thin lava layers observed at various depths. While lava is more prevalent in the 9.875-inch section, volcanic breccia and pyroclastics remain the dominant lithotypes (Figure 4).

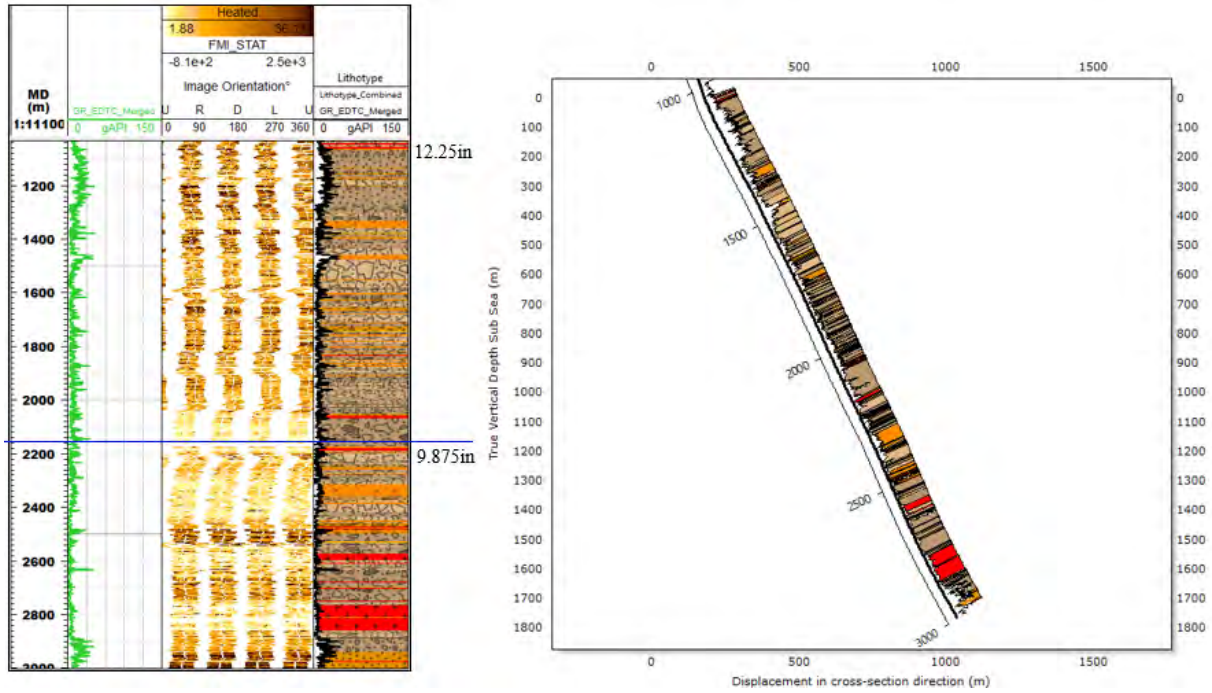

Figure 4: A total of eleven lithotypes were classified in well TPS-X.

3.1 Dip Classification and Structural Interpretation

Planar features intersecting the borehole, such as fractures and faults, were manually identified and analyzed. This process entailed fitting sinusoids to the traces of these features as they intersected the borehole. The dip azimuth is defined by the location of the lowest point on the sinusoid trough, while the dip magnitude is determined by the amplitude of the sinusoid. Fractures were classified as conductive (considered as being open / filled by conductive minerals) and resistive (considered to be healed). Resistive fractures are considered to be healed by resistive minerals such as quartz or calcite (Brata et al., 2014).

Faults are similar in appearance to fractures but show a sense of displacement or associated deformation. Joints are uniform low/moderate/high angle features which are commonly developed in lava lithotype. These joints look similar to fractures, but they are generally occurring in distinct sets.

Structural interpretation involves identifying and characterizing geological features formed by tectonic processes, such as bedding planes, fractures, and faults. This includes determining their orientations to understand the deformational history of the rocks. Additionally, analysis of drilling-induced features can provide insights into the present-day tectonic stress field.

In well TPS-X, the 9.875-inch section has a higher frequency of conductive fractures, possible faults, and joints, which are usually associated with permeable zones. In contrast, the 12.25-inch section has fewer of these features, with bedding planes and resistive fractures being more common (Table 2). Lithological contacts within layered lithotypes can also act as permeable zones. This layering is most evident in the 9.875-inch section, observed as interbeds of volcanic breccia, lapilli tuff, and vuggy breccia.

Section	Number of classification & Orientation	Bedding	Conductive Fractures	Disc. Conductive Fractures	Possible Faults	Resistive Fracture	Joints
12.25 inch	n	47	56	557	2	133	15
	main orientation	NNW	NE-SW	NE-SW	NE-SW & E-W	NNW-SSE	NE-SW
9.875 inch	n	19	146	1560	16	44	275
	main orientation	WNW	N-S	N-S	NNW-SSE	NW-SE	NE-SW

Table 2: Summary table of dip picked over 12.25 in and 9.875 in the well TPS-X.

3.2 Fracture Properties

The electrical image response to fractures is a function of the fracture geometry, the flushed zone resistivity, and the mud resistivity. Quantifying fracture properties can be invaluable in assess the presence of fracture which potentially contributes as permeable zone. Fracture computation was conducted to calculate fracture density, define as number of fractures in window divided by window length (1/m). Conductive fractures, discontinuous conductive fractures, possible faults, and joint and resistive fractures are dip features included in the calculation for the entire logged intervals.

In the 12.25-inch section, a relatively high density of discontinuous conductive fractures is observed in the uppermost and lowermost intervals, predominantly associated with lava lithotypes. Conversely, low to medium fracture densities characterize approximately 80% of this section, primarily within breccia-dominated intervals. The 9.875-inch, display higher overall fracture density compared to the 12.25-inch sections. This elevated fracture density in the 9.875-inch section appears to be correlated with the increased presence of lava lithologies. This suggests that lithological variations play a crucial role in fracture development within the whole study interval. The lava, potentially due to its inherent mechanical properties or emplacement mechanisms, may be more susceptible to fracturing compared to the breccia.

4. Integrated Fracture Interpretation

Integrated Fracture Characterization (IFC) was performed on well TPS-X to assess its fracture development and productivity. This detailed integration provides valuable insights into the well's fracture network, aiding in understanding its production behavior and optimizing future development strategies.

4.1 Integration of Borehole Image and Well Log Data

The logged interval was initially divided into distinct zones based on fracture orientation, density, and lithotype association. This approach identified 11 fracture zones across the 12.25-inch and 9.875-inch hole sections (Figures 5&6). The dips that are considered in defining these zones include conductive fracture (CF), discontinuous conductive fracture (DCF), possible fault (PF), resistive fracture (RF) and join (JT).

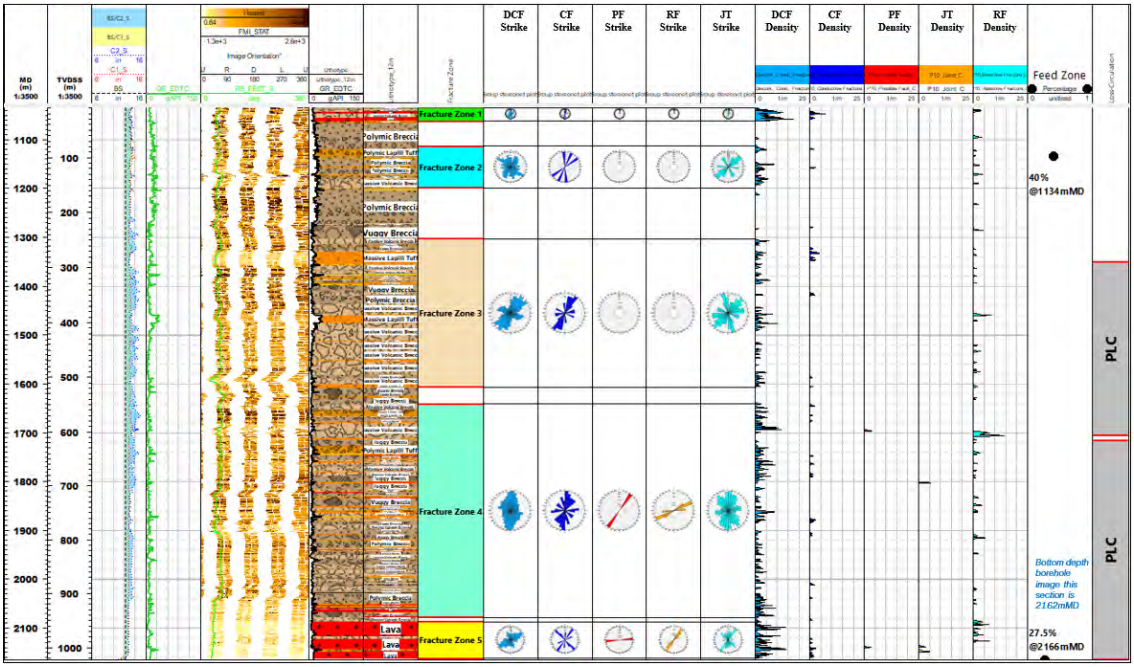

Figure 5: Fracture zone based on fracture orientation, density, and lithotype association in 12.25 inch.

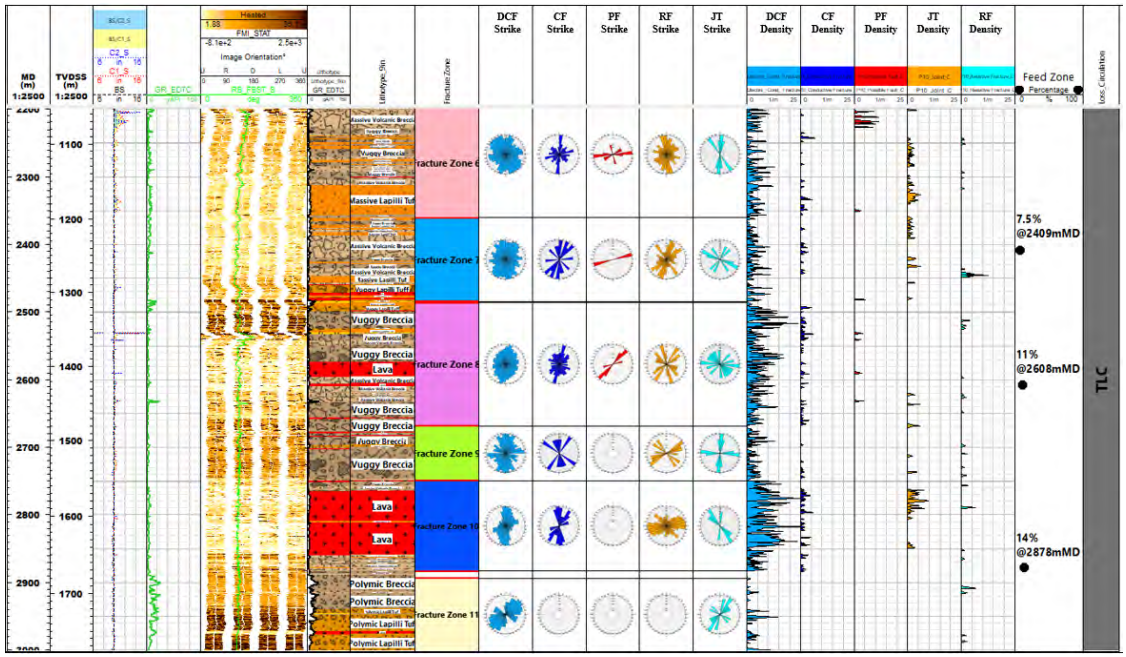

Figure 6: Fracture zone based on fracture orientation, density, and lithotype association in 9.875 inch.

These fracture zones are subsequently integrated with circulation data acquired during drilling and permeability contributions derived from spinner survey data. Notably, in this well, partial losses were observed in the 12.25-inch section, commencing within fracture zone 3 and persisting until fracture zone 5. Subsequently, the well experienced total losses throughout the remainder of the

interval until the end of 9.875-inch section. Table 3 summarizes all fracture zones and their characteristics using all of the previously mentioned criteria.

Section	Fracture Zone	Interval (mMD)	Main Direction					Associate Lithotype	Remarks
			DCF (n)	CF (n)	PF (n)	JT (n)	RF (n)		
12.25 inch	Fracture Zone 1	1035 – 1062	NE-SW (89)	N-S (6)	-	-	NW-SE (5)	Interbedded lava and volcanic breccia capped by polymic breccia.	No loss circulation
	Fracture Zone 2	1113 – 1199	NW-SE (60)	NE-SW (3)	-	-	NW-SE (10)	Volcanic breccia overlain by interbedded polymic breccia and polymic lapilli tuff	No loss circulation
	Fracture Zone 3	1303 – 1607	NE-SW (94)	NNE-SSW (15)	-	-	NNW-SSE & NE-SW (22)	Interbedded of volcanic breccia, lapilli tuff and vuggy breccia with minor lava, tuff and polymic lapilli tuff	Partial loss 2-12.7 BPM
	Fracture Zone 4	1641 – 2078	N-S (222)	NNE-SSW (21)	NE-SW (1)	ENE-WSW (5)	N-S & NW-SE (59)	Interbedded of polymic breccia, vuggy breccia, volcanic breccia, lapilli tuff, vuggy lapilli tuff, polymic lapilli tuff with minor lava.	Partial loss 2-16.5 BPM
	Fracture Zone 5	2087 – 2162	NE-SW (86)	NE-SW & NW-SE (9)	E-W (1)	NE-SW (10)	NE-SW & NW-SE (28)	Interbedded of polymic breccia, vuggy breccia, volcanic breccia, lapilli tuff, vuggy lapilli tuff, polymic lapilli tuff with minor lava.	Partial loss 4-9.4 BPM
9.875 inch	Fracture Zone 6	2173 – 2360	NNW-SSE (265)	N-S (28)	E-W (8)	NNW-SSE (101)	N-S & NW-SE (6)	Interbedded of lapilli tuff, volcanic breccia, vuggy breccia and lava.	Total loss
	Fracture Zone 7	2360 – 2484	NNE-SSW (147)	NNE-SSW (11)	ENE-WSW (1)	NNE-SSW (47)	WNW-ESE (6)	Interbedded of lapilli tuff, vuggy lapilli tuff, volcanic breccia, vuggy breccia and lava.	Total loss
	Fracture Zone 8	2486 – 2668	NNE-SSW (476)	NNE-SSW (58)	NE-SW (7)	NNW-SSE & NNE-SSW (13)	E-W (10)	Interbedded vuggy breccia with volcanic breccia, lapilli tuff, vuggy lapilli tuff and lava	Total loss
	Fracture Zone 9	2668 – 2750	NNE-SSW (109)	NE-SW & NW-SE (8)	-	NE-SW (14)	N-S & E-W (7)	Dominated by vuggy breccia with minor vuggy lapilli tuff and lava	Total loss
	Fracture Zone 10	2750 – 2883	N-S (519)	N-S (40)	-	ENE-WSW (100)	NW-SE (5)	Dominated by lava with interbedded volcanic breccia, vuggy breccia and minor lapilli tuff	Total loss
	Fracture Zone 11	2894 – 3001	NE-SW (44)	-	-	-	NE-SW (10)	Polymic lapilli tuff overlain by polymic breccia with minor lava and volcanic breccia	Total loss

Table 3: Summary of fracture zones based on on fracture orientation, density, and lithotype association.

To better understand the complex relationship between fracture characteristics and permeability contribution, a ranking system was created. This ranking system prioritizes the total average density per square meter of Conductive Fractures (CF) and Possible Faults, excluding Discontinuous Conductive Fractures (DCF) due to their partially closed/healed nature. This ranking is then integrated with pertinent information regarding associated loss circulation events to enhance our understanding of their interrelationships (Table 4).

A key finding from this analysis is that a high total average density of fractures within a zone does not necessarily translate to a proportionally high contribution to permeability. In well TPS-X, the zone with the highest fracture density (rank 1), which is primarily composed of volcanic vuggy breccia with lava, contributes only 11% of permeability. The zone with the highest permeability contribution based on spinner data (fracture zone 2, rank 10) has much less fracture density compare to the highest-ranked zone and is primarily composed of polymic breccia. Notably, fracture zone 2 had no circulation loss during drilling.

Rank	Fracture Zone	Interval (mMD)	DCF 1/m	CF 1/m	PF 1/m	JT 1/m	RF 1/m	Total CC+PF 1/m	Feed Zone (Spinner log)
1	Fracture Zone 8	2486 – 2668	4.96	0.53	0.11	0.08	0.08	**0.64**	11% @2608mMD
2	Fracture Zone 6	2173 – 2360	2.91	0.27	0.32	0.59	0.05	**0.59**	
3	Fracture Zone 10	2750 – 2883	7.77	0.54	0	0.84	0.13	**0.54**	14% @2878mMD
4	Fracture Zone 1	1035 – 1062	6.06	0.48	0	0	0.3	**0.48**	
5	Fracture Zone 5	2087 – 2162	2.63	0.16	0.04	0.14	0.6	**0.2**	27.5% @2166mMD
6	Fracture Zone 7	2360 – 2484	2.26	0.15	0.04	0.43	0.23	**0.19**	7.5% @2409mMD
7	Fracture Zone 9	2668 – 2750	2.32	0.14	0	0.21	0.15	**0.14**	
8	Fracture Zone 3	1303 – 1607	0.55	0.09	0	0	0.14	**0.09**	
9	Fracture Zone 4	1641 – 2078	0.97	0.07	0.01	0.01	0.26	**0.08**	
10	Fracture Zone 2	1113 – 1199	1.14	0.05	0	0	0.19	**0.05**	40% @1134mMD
11	Fracture Zone 11	2894 – 3001	0.93	0	0	0	0.16	**0**	

Table 4: Zone rank summary based on the average density of DCF, CF and PF.

These findings suggest that within this study interval, the dominant contribution to permeability may not be derived from secondary permeability structures like fractures or faults. Instead, primary permeability factors, such as matrix permeability or lithological contacts, may play a more significant role in fluid flow. To confirm lithological interpretations and gain further insights into the permeability characteristics from each lithology and core analysis were conducted. This detailed analysis provides valuable information for assessing the quality and permeability potential of the identified lithologies.

4.2 Integration of Core data and Borehole image

In the well TPS-X, pressure and temperature (P/T) were acquired under static conditions and pressure, temperature, spinner (PTS) were acquired under flowing conditions. Static temperature readings revealed high temperatures, reaching approximately 280°C at 1100 mMD. Spinner data identified several feed zones, with notable contributions at 1134 mMD (40%), 2166 mMD (27.5%), 2409 mMD (7.5%), 2608 mMD (11%), and 2878 mMD (14%) (Figure 7 & 8).

The largest production contribution in well TPS-X originates from 1134 mMD, located within pyroclastic tuff with low fracture density (Figure 8.a). This suggests permeability at this depth is primarily controlled by matrix permeability within the pyroclastic rock or lithological contacts. In contrast, the remaining feed zones at 2166 mMD, 2409 mMD, 2608 mMD, and 2878 mMD are situated within altered andesite and altered andesite breccia, and their permeability is predominantly controlled by fractures and faults striking NE-SW and E-W.

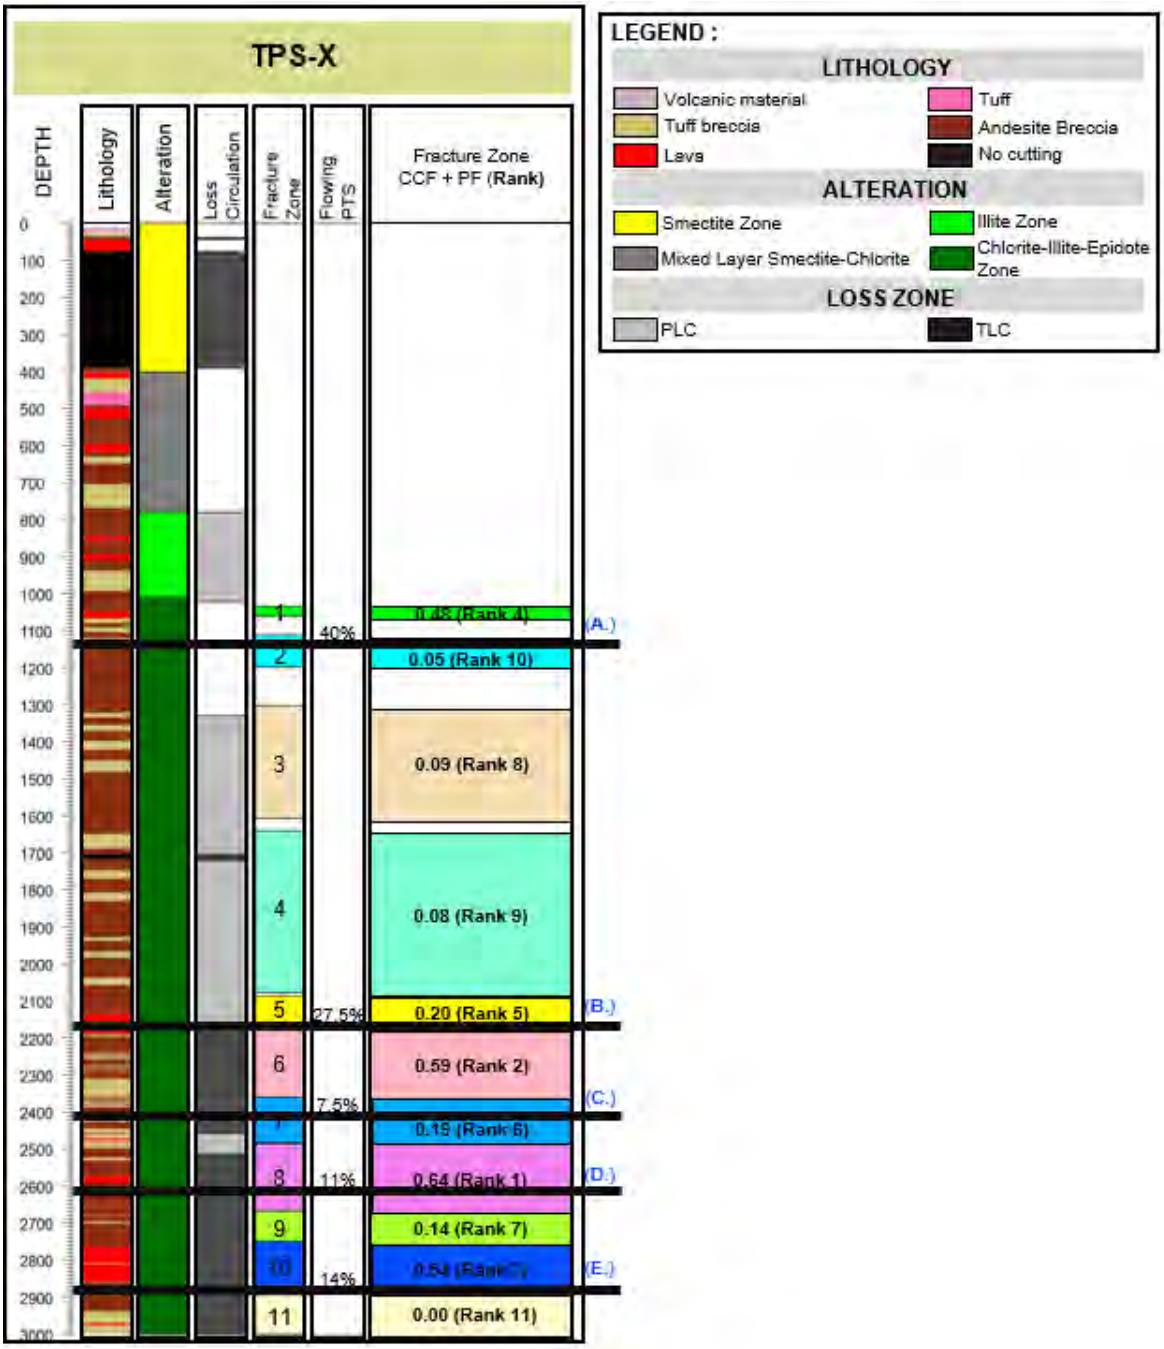

Figure 7: Fracture zone and their association with lithology from core data, alteration zone along with loss zone and feed zone from spinner data.

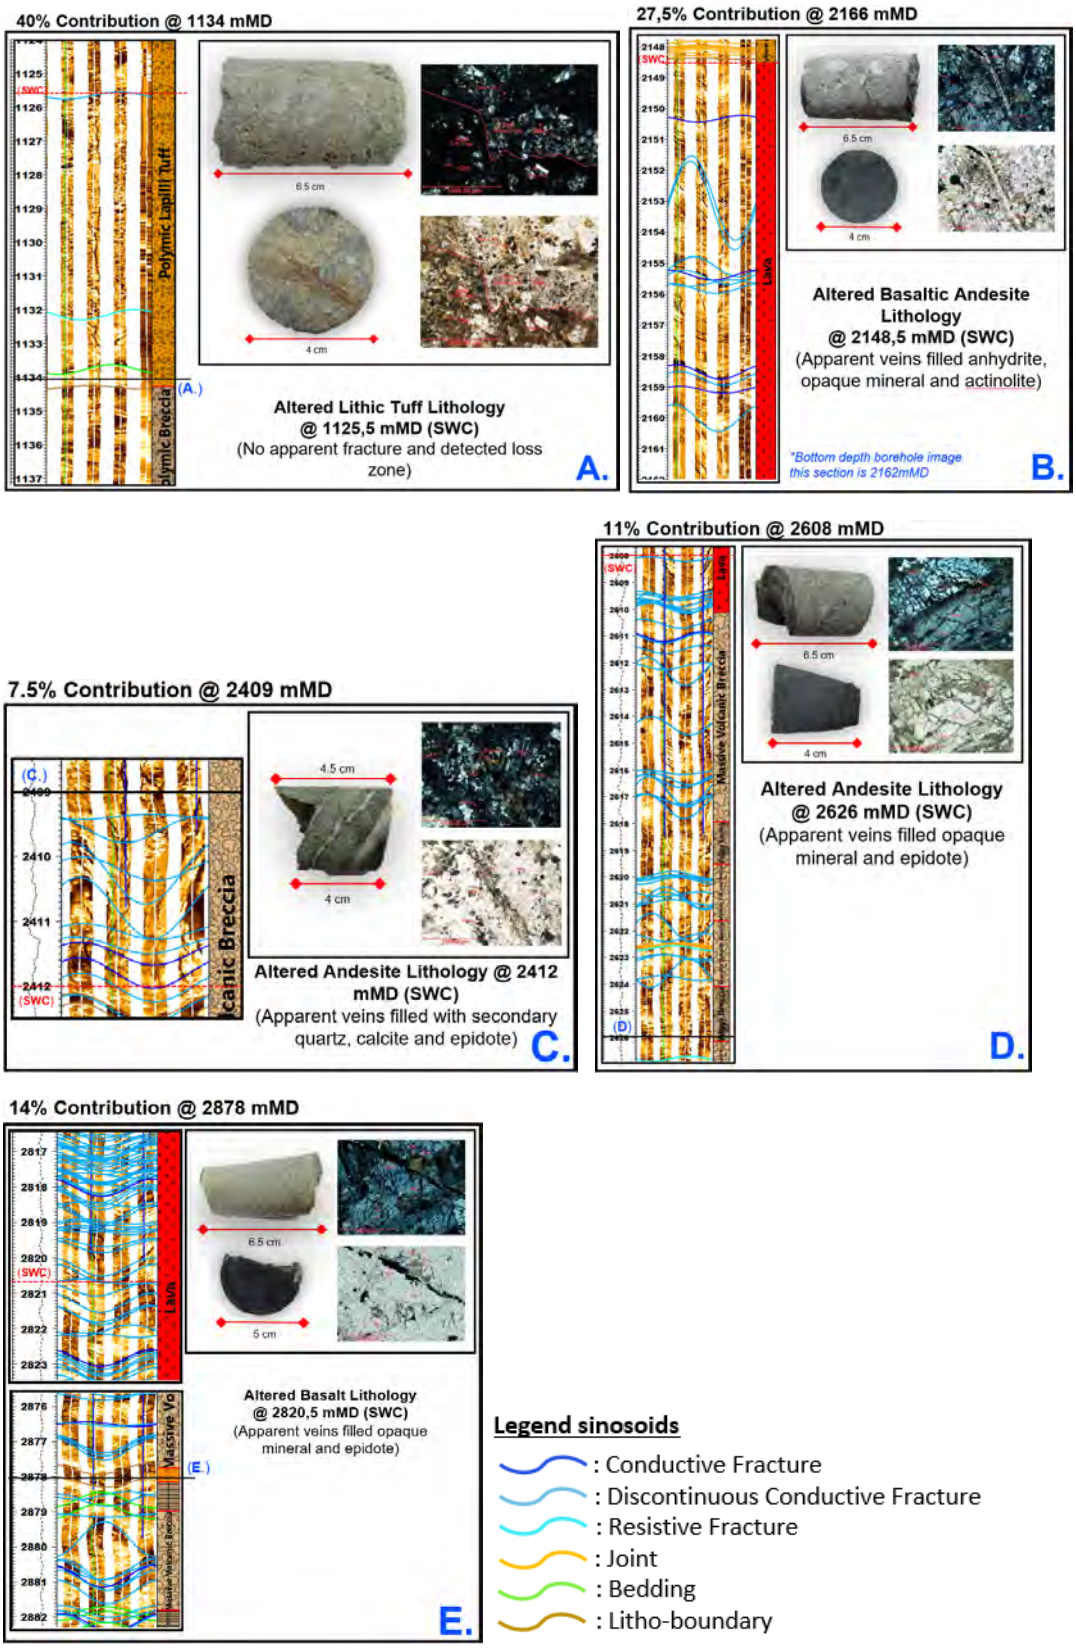

Figure 8: Core data is compared with lithology independently define from borehole image. Feedzone is ploted to see the association. The largest production from 1134 mMD and within pyroclastic tuff (8.A).

Integration of borehole image data, sidewall cores, and surface geological mapping reveals that high permeability zones within the depth interval of 1023 mMD to 2167 mMD are predominantly controlled by matrix permeability of pyroclastic rocks, lithological contacts, and NE-SW striking fracture zones dipping southeast. This fracture zone likely correlates with the damage zone of the Tompaso fault, a primary drilling target in well TPS-X. In contrast, permeability within the deeper interval of 2167 mMD to 3003 mMD is primarily influenced by E-W striking fractures and faults dipping south, likely associated with the Riendengan Caldera Rim. The higher density of conductive fractures and possible faults observed near the Riendengan Caldera Rim (Figure 9) compared to the Tompaso fault region suggests their role as significant permeability pathways.

The drilling of well TPS-X confirms the presence of both the Tompaso fault and Riendengan Caldera Rim. Future drilling efforts can strategically target the NE-SW trending alignment of the Tompaso fault and the E-W trending Riendengan Caldera Rim to optimize geothermal resource exploitation.

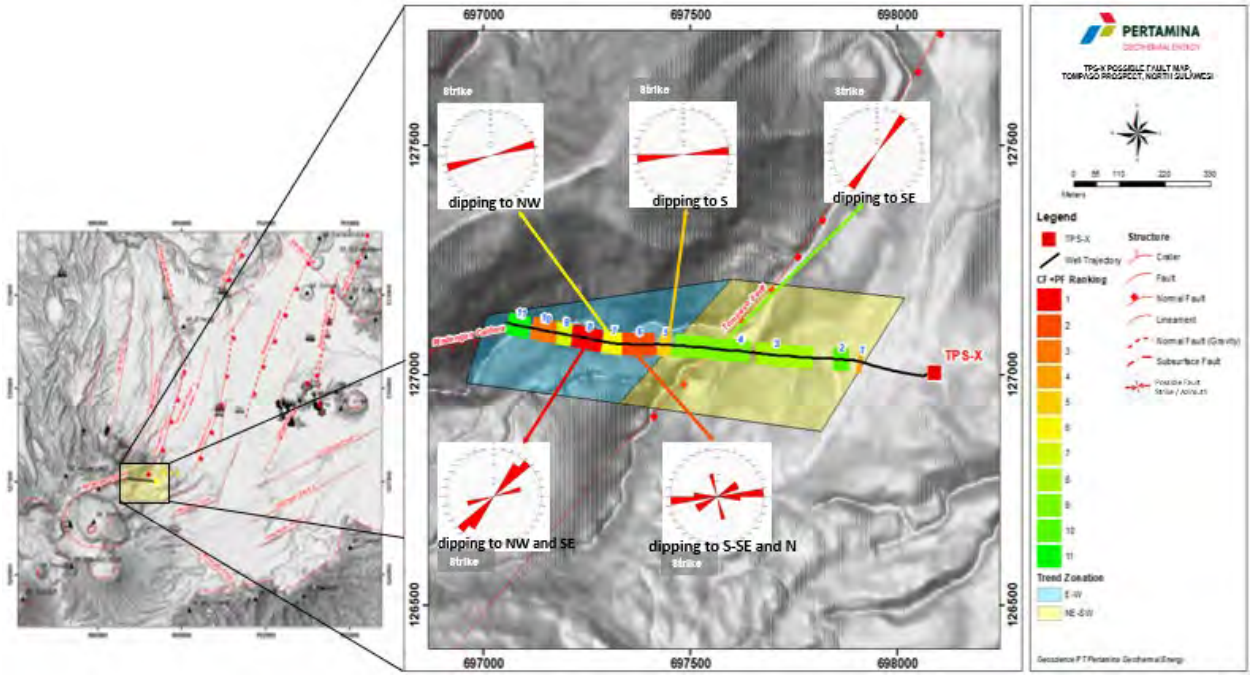

Figure 9: Geological structure map of Tompaso Field, North Sulawesi, Indonesia. The higher density of conductive fractures and possible faults observed near the Riendengan Caldera Rim.

5. Conclusion

The comprehensive analysis of borehole image logs, integrated with geological and wellbore data, has provided valuable insights into the fracture network and permeability characteristics of the Tompaso geothermal field. Eleven distinct fracture zones were identified, with varying orientations, densities, and lithological associations. Contrary to initial expectations, high fracture density did not always correlate with high permeability contribution. Instead, matrix permeability within pyroclastic and lithological contacts played a significant role, particularly in the upper part of 12.25-inch. Notably, the largest production contribution (40%) in well TPS-X originates from

a depth of 1134 mMD, situated within pyroclastic tuff, highlighting the importance of matrix permeability in this specific zone. Deeper intervals (9.875-inch) exhibited permeability dominated by E-W striking fractures and faults with minor direction toward NE-SW, potentially associated with the Riendengan Caldera Rim, respectively.

The findings of this study underscore the importance of integrating multiple data sources in geothermal reservoir characterization. The complex interplay between lithology and fracture properties highlights the need for a nuanced approach to permeability assessment. By targeting specific fracture orientations and lithology, it can enhance the probability of encountering productive zones and maximizing geothermal resource exploitation in the Tompaso field. The identification of the Tompaso fault and Riendengan Caldera Rim as key structural controls on permeability provides valuable guidance for future drilling strategies. Moreover, the presence of pyroclastic tuff in the upper part of the 12.25-inch section, significantly contributes to permeability, further highlighting the importance of understanding lithological controls on reservoir productivity.

Geothermal wells, Drilling, Hydrothermal model, Real-time prediction

ABSTRACT

Drilling cost-efficient, safe, and deep wellbores is key to scaling geothermal energy. However, the elevated costs associated with high non-productive and invisible loss times (NPT/ILT) are taxing on the operators, acting as a severe bottleneck in utilizing geothermal energy. In deep geothermal wells, the leading contributors to NPT/ILT are the failure of downhole tools and/or absence of their measurements.

Continuous downhole parameter measurements are often hindered by mud circulation interruptions or downhole tool failures caused by high operating temperatures. During drilling operations, the mud temperature fluctuates due to its thermal interaction with the surrounding environment, which is typically hotter. This variability is particularly pronounced during activities such as connection and tripping, when mud circulation and downhole measurements are unavailable. Estimating temperature distribution along the wellbore before deploying costly downhole tools is critical to mitigate the risk of failure. Furthermore, developing an effective strategy to cool the mud relies on factors including circulation rate, duration, and inlet mud temperature.

In this study, we introduce an approach that combines physics-based modeling and machine learning techniques to achieve real-time prediction of mud temperature distribution. This method aims to enable precise and continuous estimate of mud temperature along the wellbore, facilitating more efficient well thermal management. An automated calibration system tailored for adjusting parameters within the physics-based hydrothermal model was also developed. This calibration process is designed to enhance the accuracy of the model and further improve the performance of the monitoring system. The calibration system is smartly triggered by Discrete Event Simulation (DES) technique as and when operational conditions change on the rig. The advisory system synergizes with the monitoring system to suggest optimal mud circulation durations and flow rates.

These recommendations are tailored to the inlet mud temperature, thereby ensuring precise control over the targeted temperature profile within the wellbore.

Our approach has been validated using select cases from the Utah FORGE dataset for which wellbore temperature measurements were available. Our real-time monitoring system was able to estimate the mud temperature profile along the wellbore after prolonged stagnation of mud inside the wellbore due to other operations like connection and tripping when bottom hole mud temperature measurements were absent. The automatic calibration technique proved efficient in updating uncertain model parameters to provide improved predictions. Ultimately this approach can drastically improve temperature monitoring and management during the construction of a geothermal well and reduce tool failure.

1. Introduction

Geothermal energy is one of the leading candidates for providing a clean energy infrastructure. However, drilling deep wells to extract necessary heat energy poses a distinctive challenge: the intense temperatures encountered during the exploration of deep underground reservoirs. During the drilling process, drilling mud – an engineered fluid – is circulated through the drill string and up to the surface through the annulus. Drilling mud is essential to maintain pressure inside the wellbore, removal of rock cutting and lubrification, among others. They also act as a conduit for mud pulse telemetry (MPT) for data transmission while drilling from the expensive downhole tools. However, the elevated temperatures encountered in geothermal wellbores lead to increasing wear and tear of downhole tools (Mitchell & Miska, 2011) and thus elevating the risk of tool failure (Kruszewski & Wittig, 2018) leading to lack of critical wellbore information for an efficient drilling operation.

Estimating bottom hole temperature is paramount in geothermal wellbore construction and numerical simulations using finite element models (FEMs) and finite difference methods (FDMs) can be utilized, but their computational burdens often limit their real-time application (Chen & Novotny, 2003). Reduced order models such as analytical models (Hasan & Jang, 2021) and semi-analytical models (Polat, 2022) offer reduced computation effort but compromises on accuracy due to simplifying assumptions that overlook crucial factors like complex wellbore geometries and transient thermal behaviors. Data-driven machine learning (ML) models pose certain drawbacks such as heavy reliance on data quality that are generally lacking and their transferability to new scenarios can be challenging (Kshirsagar & Sanghavi, 2022). An improved approach is necessary to overcome the current approaches requiring static input requirements rendering them impractical for real-time decision-making during a dynamic drilling operation (Gonzalez Angarita, 2020) where the rig states and operational parameters (mud flow rate, drill string rotation, location of bit with respect to hole depth, etc.) change quite frequently. In this study, a Physics-Informed Machine Learning (PIML) model is proposed offering a combination of physics-based FDM model (Hasan, Kabir, & Sarica, 2018) with real-time data suitable for predicting mud temperature distribution along the wellbore.

The strength of using FDM models in simulating heat transfer within wellbores lies in discretizing the wellbore geometry into a grid, allowing for the precise evaluation of heat conduction, convection, and radiation across each individual point (Holmes & Swift, 1970) by considering influencing factors like fluid flow dynamics, formation properties, and frictional heating (Zhang, Xiong, & Guo, 2018). The resulting temperature profiles offer detailed insights into the thermal

landscape within a wellbore (Zhou, 2013). However, FDM models rely heavily on accurate input parameters, including rock and material thermal properties, fluid rheology (Merlo, Maglione, & Piatti, 1995), and wellbore geometry (Hasan, Kabir, & Wang, 2009). In reality, the input parameters come with significant uncertainties due to limited downhole measurements and indirect measurements from historical drilling operations, introducing potential discrepancies between the model predictions and real-world temperature profiles. Although computationally expensive, calibrating these models is necessary, commonly based on iterative trail-and-error approaches, until the simulated temperature profiles match the measured values at certain locations, like mud temperature at the wellbore outlet (Tekin, 2010). In this work, a calibration technique suitable for geothermal wellbore temperature estimation that is computationally efficient for real-time applications is utilized. The hydrothermal model presented in the next section was introduced in Naderi et al., 2024 and repeated here for improved readability.

2. Hydrothermal model

2.1 Governing equations

The borehole is modeled to capture thermal interactions between the wellbore and the surrounding rocks. The model is built on the following key assumptions: (i) the drilling fluid is treated as incompressible, maintaining constant density, specific heat capacity, and thermal conductivity; and (ii) the velocity of the drilling fluid inside the drill string and annulus is considered solely in the axial direction, while the radial velocity is disregarded. Governing equations (1) to (5) describe the heat flow in the fluid inside the drill string, the drill string pipe, the fluid in the annular space, the first layer of casing, and the casing/cement/surrounding formation, respectively and are detailed in the literature (Zhang, Xiong, & Guo, 2018).

$$-\frac{\partial(\rho_1 c_1 v_p T_1)}{\partial z}+\frac{2h_1(T_2-T_1)}{r_1}+\frac{q_p}{\pi r_1^2}=\frac{\partial(\rho_1 c_1 T_1)}{\partial t} \tag{1}$$

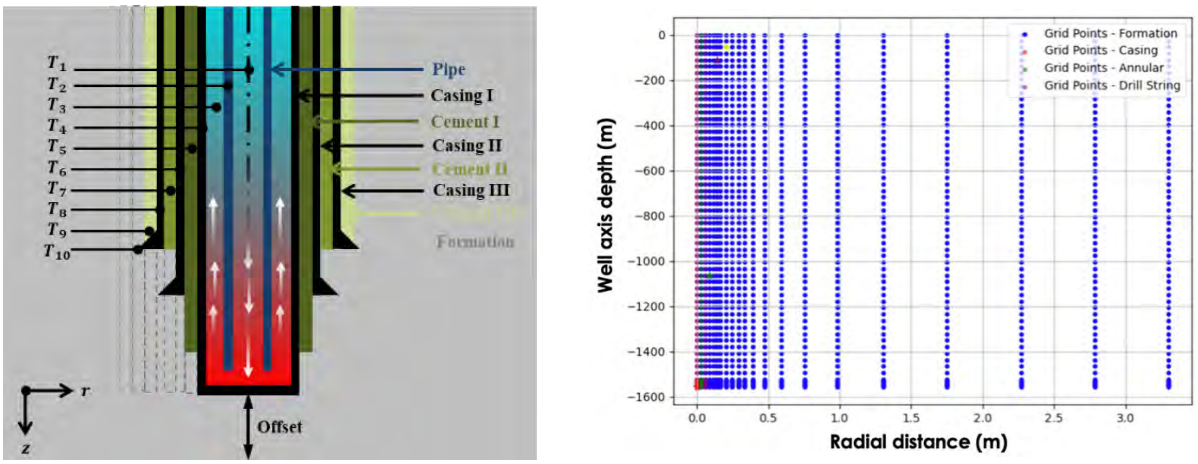
$$\frac{\partial}{\partial z}\left(\frac{\lambda_p \partial T_2}{\partial z}\right)+\frac{2h_2(T_3-T_2)r_2}{r_2^2-r_1^2}-\frac{2h_1(T_2-T_1)r_1}{r_2^2-r_1^2}=\frac{\partial(\rho_2 c_2 T_2)}{\partial t} \tag{2}$$

$$\frac{\partial(\rho_3 v_a c_3 T_3)}{\partial z}+\frac{2h_3(T_4-T_3)r_3}{r_3^2-r_2^2}-\frac{2h_2(T_3-T_2)r_2}{r_3^2-r_2^2}+\frac{q_a}{\pi(r_3^2-r_2^2)}=\frac{\partial(\rho_3 c_3 T_3)}{\partial t} \tag{3}$$

$$\frac{\partial}{\partial z}\left(\lambda_4\frac{\partial T_4}{\partial z}\right)+\frac{2h_3(T_5-T_4)}{r_4^2-r_3^2}-\frac{2h_3(T_4-T_3)r_3}{r_4^2-r_3^2}=\frac{\partial(\rho_4 c_4 T_4)}{\partial t} \tag{4}$$

$$\frac{\partial}{\partial z}\left(\lambda_i\frac{\partial T_i}{\partial z}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(\lambda_{effective}^{i,\,i+1} r\frac{\partial T}{\partial r}\right)=\frac{\partial(\rho_i c_i T_i)}{\partial t} \tag{5}$$

Here, r and z denote radial and axial coordinates, respectively. In Equations (1) to (4), the subscript numbers follow the layer order illustrated in Figure 1a, while the subscript i in Equation (5) denotes the layer number in casing/cement/surrounding formation. While a constant spacing is considered in the axial direction, a gradually increasing mesh is considered in the radial direction, whose schematic is shown in Figure 1b.



(a) (b)

Figure 1: (a) 2D schematic of a coaxial borehole heat exchanger, and (b) schematic of a 2D cross section through 3D model of the discretization of FDM grid. (Adapted from Naderi et al., 2024.)

In the context of the equations, T, h, λ, c and ρ represent temperature, convective heat transfer coefficient, thermal conductivity, specific heat capacity, and density, respectively. The conductivity coefficient between layer i and $i+1$, denoted as $\lambda_{effective}^{i,i+1}$, is calculated using the thermal-electrical analogy (Brown, Cassidy, Egan, & Griffiths, 2021), employing the following formulation:

$$R_{effective} = \frac{1}{\lambda_{effective}}, \quad R_{effective} = R_i + R_{i+1} = \frac{1}{\lambda_i} + \frac{1}{\lambda_{i+1}} \tag{6}$$

This expression signifies that the thermal resistivity of the effective layers can be considered analogous to electrical resistivity in series. The next section details the calculation of q_p and q_a, representing friction-induced heat source in drilling pipe and annular, respectively.

2.2 Source terms

The calculation of the friction-induced heat source involves considerations of fluid dynamics within the drilling pipe and the annulus (Zhang, Xiong, & Guo, 2018). Numerous empirical and analytical models exist for this purpose. Here, the Reynolds number (Re) as a crucial parameter is defined as (Durst & Arnold, 2008):

$$Re = \frac{\rho v D_h}{\mu} \tag{7}$$

where μ is the dynamic viscosity of the mud, and D_h and v are the hydraulic diameter and fluid velocity respectively. It should be noted that for the annular flow, $D_h = 4\,(d_3^2 - d_2^2)/(d_3 + d_2)$, where d_3 represents the diameter of the wellbore, and d_2 is the outer diameter of the drill string. For laminar flow ($Re \leq 2000$), the coefficient of friction resistance (f) is calculated as:

$$f = \frac{16}{Re} \tag{8}$$

In turbulent flow ($Re > 2000$), f is determined using the empirical Darcy friction factor equation:

$$\frac{1}{\sqrt{f}} = 4\log\left(Re\sqrt{f}\right) - 03.95 \quad (9)$$

The frictional resistance pressure drop in the drill string is then computed using:

$$\frac{\Delta P}{\Delta L} = \frac{2f\rho v_p^2}{d_1} \quad (10)$$

where L denotes the flow distance of drilling fluid. Similarly, in the annular region, the pressure drop is determined by:

$$\frac{\Delta P}{\Delta L} = \frac{2f\rho v_a^2}{d_3 - d_2} \quad (11)$$

Finally, the heat source term (q) in Equations **(1)** and **(3)** is quantified by:

$$q = \frac{\Delta P Q}{\Delta L} \quad (12)$$

where Q is the volumetric flow rate of drilling fluid.

2.3 Boundary and initial conditions

The initial temperature in the formation is determined by a linearly increasing geothermal gradient (G). Although a linear, continuous relationship is assumed, adjustments like including stepwise changing G can be made in the assimilation process, as discussed later in the following sections.

The inlet temperature is known and can be measured directly on the ground:

$$T_1(z = 0, t) = T_{in} \quad (13)$$

At the bottom of the well, the annulus drilling fluid temperature is equal to the drilling fluid temperature inside the drill string and the drill string temperature:

$$T_1(z = z_f, t) = T_2(z = z_f, t) = T_3(z = z_f, t) \quad (14)$$

where z_f is the vertical depth at the bottom of the well. There is no heat exchange between the formation and the atmosphere at the surface:

$$\frac{\partial T}{\partial z}\Big|_{z=0} = 0 \quad (15)$$

The formation temperature far away from the wellbore is undisturbed and is equal to the initial formation temperature. This condition is described at r_f, the end of the rock domain in the radial direction:

$$\frac{\partial T}{\partial r}\Big|_{r \to r_f} = 0 \quad (16)$$

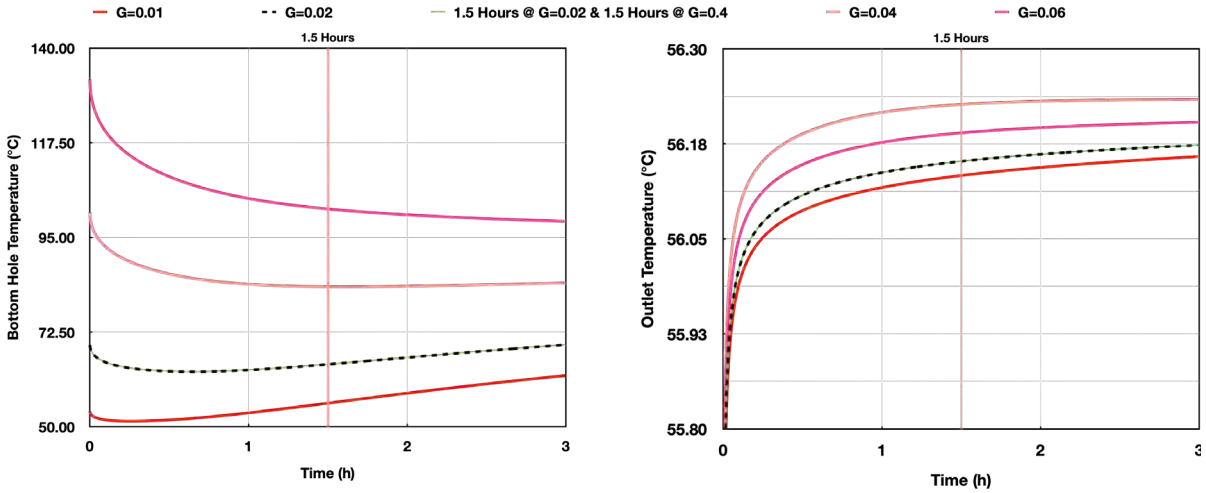
2.4 Numerical solution

An implicit numerical method is implemented for the FDM employed in this work. Details of the implementation are adapted from (Zhang, Xiong, & Guo, 2018). This in contrast with the authors' earlier work (Naderi et al., 2024) where an explicit numerical scheme was implemented. The current approach is preferred for issues related to numerical stability while handling the real time data – streaming from the electronic drilling recorder (EDR) and/or the mud logging units. The FDM employed in this work for solving the governing equations utilizes a first-order forward difference scheme for temporal discretization and a central difference scheme for spatial discretization.

2.5 Sensitivity and observability

The primary objective of this work is to estimate the bottom hole temperature during geothermal drilling operations to better protect the downhole tools from thermal failures. The aforementioned hydrothermal model is dependent on several input parameters with high uncertainties and their perturbations can cause large impact on the estimation of bottom hole temperature. Thus, a preliminary sensitivity analysis is carried out. Since, geothermal gradient is not accurately known a priori to drilling a well, its sensitivity is numerically studied through trail-and-error approach. Two different scenarios are considered in this study: short circulation duration of about 3 hours (see Figure 2) and long circulation duration of about 2 days (see Figure 3). In addition, during the short circulation scenario, the geothermal gradient was changed at half-time, i.e., from 0.02 to 0.4 at 1.5 hours of circulation. The simulation parameters for this analysis are provided in Table 1. In all scenarios, the following observations hold:

1. The wellbore temperature profile is strongly dependent on the initial geothermal gradient. Any nominal variations in the gradient does not affect the bottom hole temperature estimation. Thus, initial model calibration when the required information is available or extracted from the real time data plays a crucial role in utilization of the hydrothermal model for temperature management system.
2. For a given variation in the geothermal gradient, changes in the outlet mud temperature were insignificant and changes in the bottom hole temperature were only slightly better. This leads to our hypothesis that geothermal gradient is not *observable* when only surface temperature is considered as the system measurement and bottom hole temperature is a necessary measurement during the calibration process.



(a) (b)

Figure 2. Evolution of the bottom hole temperature (a) and the mud outlet temperature at the surface (b) during a short circulation scenario of 3 hours, for various geothermal temperature gradients (G). Changing G from 0.02 to 0.4 at 1.5 hours of circulation time shows no variation in the temperature evolution for both the parameters.

Figure 3. Evolution of the bottom hole temperature (a) and the mud outlet temperature at the surface (b) during a long circulation scenario of 2 days, for various geothermal temperature gradients.

3. Model validation using UTAH Forge dataset

3.1 Data handling and calibration technique

As schematically illustrated in Figure 4, this engine comprises two distinct compositions, as already introduced in Naderi et al., 2024.:

1. **Static Data-Based Model:** This model component provides the initial condition to the dynamic model. When necessary, steady state solution can be utilized to transit to the transient simulation of the wellbore thermal dynamics. Since this segment is independent of considering input data in real-time, the choices for simulation time-step and techniques like implicit or explicit approach are open but must be suitably chosen to align with the thermal system's overall dynamics.

2. **Dynamic Data-Based Model:** Starting from the static-data based model simulation results as its initial condition, this model segment integrates live measurements into its simulation. Data assimilation, a critical process fusing observations with model predictions is operational to integrate real-time measurements and dynamics. The time step for this dynamic model aligns directly with the data frequency (here, 1 second) of the thermal-hydro model, ensuring continuous synchronization with real-time conditions.

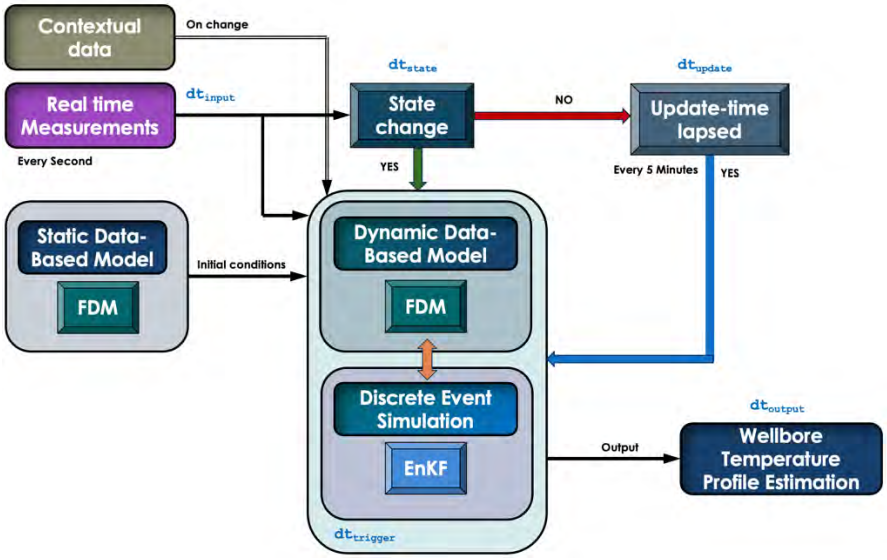

Figure 4: Schematic representation of the integrated framework, illustrating the dynamic assimilation of real-time data into the forward-marching explicit numerical solution. (Adapted from Naderi et al., 2024.)

Discrete Event Simulation (DES) stands as a computational modeling approach designed to analyze and comprehend the intricate dynamics of complex systems. Unlike continuous simulations, where changes unfold continuously over time, DES focuses on events that occur at distinct points in time, capturing the discrete nature of operations and interactions within a system. This is particularly relevant in well construction where rig state change and operational parameter

changes constitute discrete events. For further details on DES in this context, please refer to Naderi et al., 2024.

3.2 Utah FORGE Wellbore sections

This framework was applied to a simulation considering a coaxial well represented by concentric cylinders in 3D with mud flowing through the drill string and rising to the surface through the annular region between drill pipe and casing. The drill string components and casing program for sections using BHA 9 and BHA 18 referencing wellbore 16A(78)-32 are detailed in Table 1. The simulation encompasses a directional well trajectory, incorporating both vertical and horizontal sections.

Table 1: Basic data of drill string and casing program for wellbore 16A(78)-32.

Parameter	Inner diameter (mm)	Outer Diameter (mm)	Depth (m)
Drill Pipe	110	127	Variable
First Casing	220	240	1062.5
Second Casing	320	340	116.4
Third Casing	480	510	39.3

In configuring the model for evaluation and calibration using the Utah FORGE dataset, the static segment of the framework was defined from the surface down to the section corresponding to BHA 9 and 18 separately – the regions chosen for assimilation performance assessment. The raw data were trimmed and processed to enhance data quality and provide distinct case of continuous drilling operation for simplicity in model validation. Later, all operations in the respective BHA sections were considered. The time windows considered for sections BHA 9 and BHA 18 are clearly marked in Figure 5(a) and 6(a), respectively. As noted in the earlier sections, correct estimation of the initial conditions, i.e., the static model is important in simulating the temperature evolution through the dynamic model. This is reflected in the simulation results for BHA 9 and BHA 18. It can be noted from Figure 5(a) that by manipulating the initial estimate of geothermal gradient allowing for least error between the simulated and measured temperature profiles at the simulation start, the temperature dynamics follows the measurements. However, this is not the case when the input parameters are erratic as can be seen from Figure 5(b); although the initial conditions were manipulated in order to track the temperature dynamics at the later stage, there exists significant differences in the predicted and measured temperature in some regions. The initial state calibration was carried out through trial-and-error approach in this study but can be extended to an automatic calibration technique with ease. Similar observations can be noted for simulations in section BHA 18 as reflected in the Figure 6.

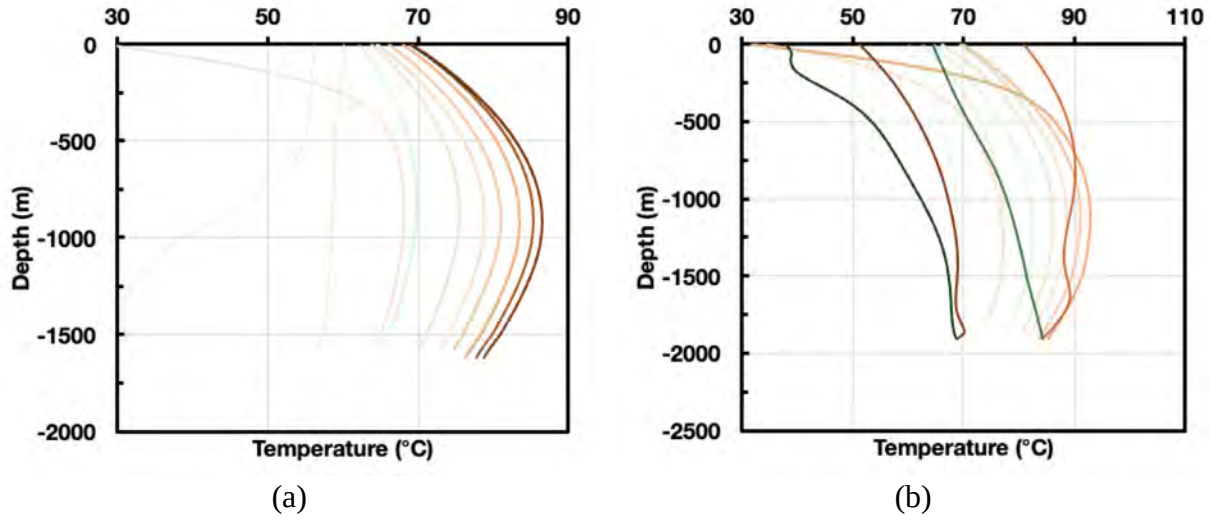
4. Wellbore thermal management system

A hydrothermal simulator is an important tool for drilling geothermal wells offers important insights into the temperature distribution along the wellbore. It can be noted in the considered cases that the maximum temperature encountered in the wellbore are not always necessarily at the bottom. This is shown in the Figure 7 for two sections: nearly vertical BHA 9 and deviated BHA

18. The considered system generates the temperature profile along the wellbore depth at set time intervals, say every 5 minutes and provides information on the maximum temperature and the depth at which it is experienced. Given the computationally efficient model considered in this study, circulation rate and timing can be iterated over a certain interval to manage the wellbore temperature distribution accordingly. This information is crucial in cases like tripping in with downhole tools wherein they experience temperatures higher than their operational limit before they reach the bit is on-bottom. Thermal management becomes important to extend the operational lifetime of such tools and in avoiding significant NPT/ ILT due to downhole tool failures.



(a) (b)

Figure 7. Time evolution (light to dark) of the temperature profile for the full dataset along the measured depth of the well for sections BHA 9 and BHA 18 of Utah FORGE well. Green line represents the temperature profile of mud inside drill string and brown the mud in annulus.

5. Conclusions

In this work, a computationally efficient hydrothermal model was developed to estimate the temperature distribution along the wellbore. The model has been updated from the authors' previous work to ensure numerical stability while handling real time data from the mud logging unit. The sensitivity analysis shows that the initial estimate of the geothermal gradient is important to follow the temperature dynamics of the system and that the gradient is not observable from the surface temperature as a measurement alone. Thus, bottom hole temperature measurements are necessary to calibrate the model through ML methods to accommodate the model uncertainties. The DES triggers the model to simulate temperature profile on system changes and the maximum temperature region is identified to inform on the mud circulation rate and time to allow for the downhole tool operations.

To build an automated thermal management system, further analysis of the controllability and the observability of the hydrothermal system is necessary. This shall pave way to designing an efficient controller for real time recommendation of the circulation rate and the circulation time for an optimized wellbore temperature profile.

Long-term High Temperature High Pressure Cable for Geothermal Logging Tools

Andrew Wright

Sandia National Laboratories

Keywords

Geothermal, Long-term, High Temperature, High Pressure, Cable, Logging Tools, 300°C

ABSTRACT

Downhole logging tools are commonly used to characterize multi-thousand-foot geothermal wells. The elevated temperatures, pressures, and harsh chemical environments present significant challenges for the long-term operation of these tools, especially when real-time data transmission to the surface is required via data cable lines. Teflon-based single or multi-conductor cables with grease-filled cable heads are typically used for downhole tools. However, over extended periods of operation, the grease used to seal the conductors can slowly dissolve into the well fluid, creating electrical shorts and disabling data transmission. Additionally, when temperatures exceed 260 °C, Teflon can soften, potentially allowing parallel conductors to make contact and cause shorts. Between 2009 and 2015, Draka Cableteq USA, now part of the Prysmian Group, developed a multi-conductor/fiber cable and a four-conductor cable capable of operating above 300 °C. While a full study was conducted on the conductor/fiber cable, the evaluation of the four-conductor cable remained incomplete. With the increasing need for long-term high-temperature (HT) operation of logging tools, Sandia National Laboratories is now completing the evaluation of the four-conductor cable. The four-conductor cable has two major novel aspects. Firstly, its glass braid insulation can operate above 300 °C, eliminating the potential for shorts. Secondly, the insulated conductors are encased in metal tubing along the full length of the cable, creating a high-pressure seal between the cable and the tool. This metal tubing eliminates the need for a grease seal, a major limiting factor in the operation time of common cable lines. Sandia National Laboratories will conduct multiple tests to characterize the cable at temperatures above 300 °C and pressures up to 5,000 psi. This cable would enable tools to operate continuously at elevated temperatures, pressures, and in harsh fluids for extended periods, potentially lasting months.

1. Introduction

Evaluating a geothermal well is essential for assessing well integrity, reservoir formation, and overall characterization. Various subsurface instrumentation tools are used to collect different data

sets depending on the type of well, temperature and pressure profile, and well conditions. Most commonly, instrumentation tools with local energy storage and memory store all the data locally, referred to as memory tools. These memory tools are lowered into multi-thousand-foot wells, continuously storing data until they are either brought back to the surface, the energy storage is depleted, or the memory is full. Memory tools are an economical approach for short-term (<24 hours), low data rate, non-real-time measurements (i.e. temperature, pressure, and fluid chemistry).

For applications requiring long-term (>24 hours), high-speed data rates, or real-time measurements, instrumentation with a data line is necessary, as illustrated in Fig. 1. Most current instrumentation tools use single or multi-conductor cables with Polytetrafluoroethylene (PTFE) insulation surrounded by a metal wire rope due to their cost-effectiveness and rated temperature range (up to 260 °C for short-term operation). These cables transition to the instrumentation tool through a 'cable head.' Since the cables use wire rope, the cable head is filled with high-temperature grease to prevent fluid from contacting the exposed conductors. However, over hours of operation in the well's harsh environment, the grease erodes away, eventually causing electrical shorts and disabling the tool's functionality. Additionally, when the cable reaches temperatures above 260 °C, the PTFE insulation begins to soften, potentially causing shorts between parallel conductors.

With the growing need for long-term measurements, especially for enhanced geothermal system (EGS), it is becoming essential to develop data cables that can sustain temperatures from 250 °C to 320 °C, while being exposed to pressures reaching 5,000 psi and the harsh fluids of the well for durations ranging from one day to several months.

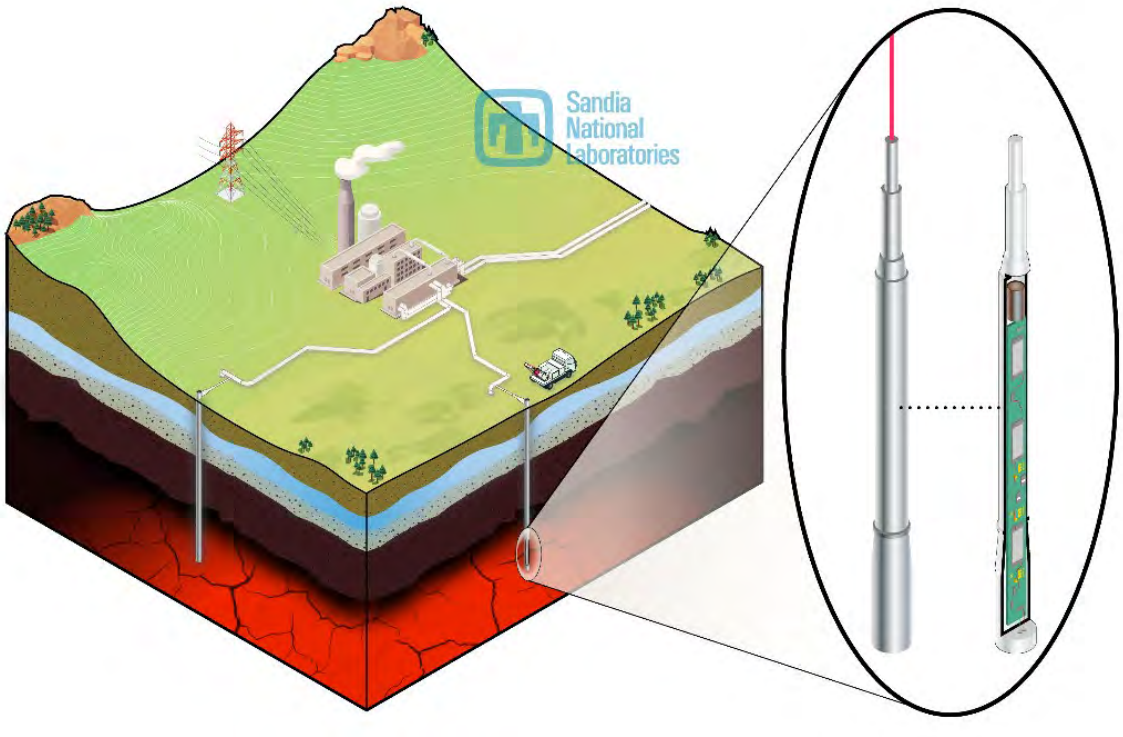

Figure 1: Illustration of the instrumentation tool lowered into a multi-thousand foot well with communications between the tool and wireline truck.

One such solution for a long-term, reliable data cable has been developed by the Prysmian Group. Under an American Recovery and Reinvestment Act (ARRA) grant in 2009, Draka Cableteq USA, now part of the Prysmian Group, was awarded funding to develop a high-temperature cable for EGS applications. Prysmian developed two types of cables: one with conductors and optical fiber surrounded by high-temperature epoxy as the dielectric[1], and a second cable with four conductors but with glass braid insulation. This paper focuses on the second cable, which consists solely of conductors.

The cable comprises four 18 AWG 2% nickel conductors with mica tape and glass braid insulation. Surrounding the conductors and dielectric is an Incoloy-825 tubing with a 0.25” outer diameter and a 0.028” wall thickness. The braid surrounding the tubing is made of 0.040” Incoloy-825 to support the weight of the instrumentation tool. Swagelok fittings are used at the end of the tubing to create a high-pressure seal with the instrumentation tool. Sandia has access to 5,000 – 8,500 feet of this cable. Prysmian's goal for this cable is to achieve continuous operation at 374 °C. An image of the four-conductor cable is shown in Fig. 2. Sandia has been evaluating the four-conductor cable at elevated temperatures and pressures to confirm its functionality.

Figure 2: Spool with 5,000 to 8,500 feet of cable from Prysmian. Consists of four 18 AWG 2% nickel conductors with mica tape and glass braid insulation. Surrounding the conductors and dielectric is an Incoloy-825, 0.25” outer-diameter, 0.028” wall thickness tubing. Braid surrounding the tubing is made with 0.040” Incoloy-825 to support the weight of the instrumentation tool. Swagelok is used at the end of the tubing to create a high-pressure seal with the instrumentation tool.

2. Cable Evaluation

The first experiment for the cable involves evaluating its performance at temperatures reaching 300 °C. Initially, it is expected that the binder within the glass braid will degrade, potentially affecting the electrical isolation between conductors at elevated temperatures. However, this issue can be mitigated by baking the binder at the elevated temperature for an extended period. To monitor for the effect of the glass braid's resistance over time at elevated temperatures, the four conductors were connected to an ohm meter data acquisition (DAQ) system capable of measuring up to 90 MΩ.

Figure 3: Ten feet of Prysmian cable to go under evaluation in an oven set to 300 °C.

The four conductors were referenced to the metal tubing of the cable. A ten-foot section of the cable was cut from the spool and placed in the oven, connected to the DAQ system. The cable was baked at 300 °C for approximately 17 hours. As shown in the data in Figure 4, the resistance between the conductors and the tubing initially dropped rapidly from an unmeasurable level down to about 5-6 MΩ. After 1-2 hours, the resistance began to increase and continued to rise over the next 15 hours.

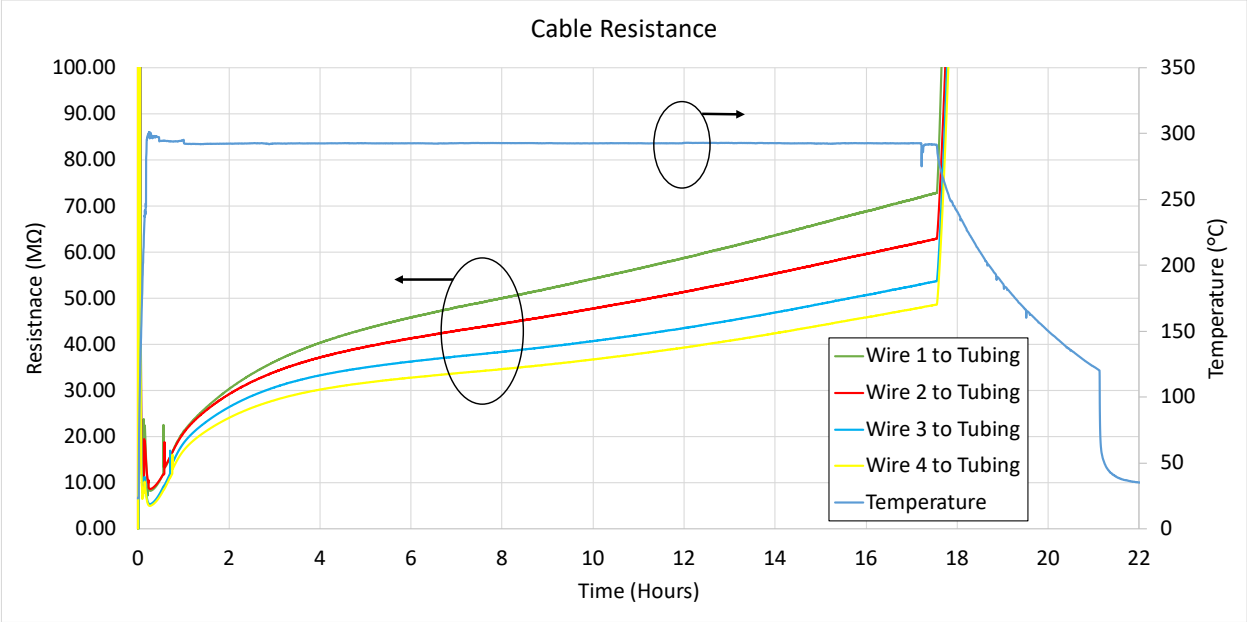

Figure 4: Recorded cable resistance of each of the four conductors in reference to the Incoloy-825 tubing while in the oven at a temperature of 300 °C.

At room temperature, the resistance between the conductors and the metal tubing across the >5,000 ft length of the cable is 50-70 kΩ, while the resistance between conductors is 100-120 kΩ. The resistance of the conductor from one end to the other is approximately 73 ohms. Without baking out the binder, the cable would not function properly at elevated temperatures. However, after the

baking process, the cable performs as expected at both room temperature and 300 °C. From the results, it would take close to 24 hours to bake out the binder.

Next, the cable was evaluated in a 300 °C, 5000 psi autoclave. The cable was fed through the lid port and sealed with a 0.25” Conax fitting with a Lava seal rated to handle the elevated conditions. Inside the autoclave, a Swagelok cap was used to seal the tip of the cable tubing, while the wires on the other end were exposed to the environment. This test aimed to determine if the Swagelok seal would fail under these conditions. Figure 5 shows the cable seal to the autoclave lid along with the Swagelok cap end. The autoclave was filled with tap water that contains a pH of 9. The cable exhibited no observable leaks with the autoclave set to 300 °C and 5000 psi for 27 hours. Future testing with real geothermal fluid is necessary to accurately mimic the corrosive behavior of the well. Though these initial tests indicate that the cable is suitable for the harsh temperatures and pressures of a geothermal wells.

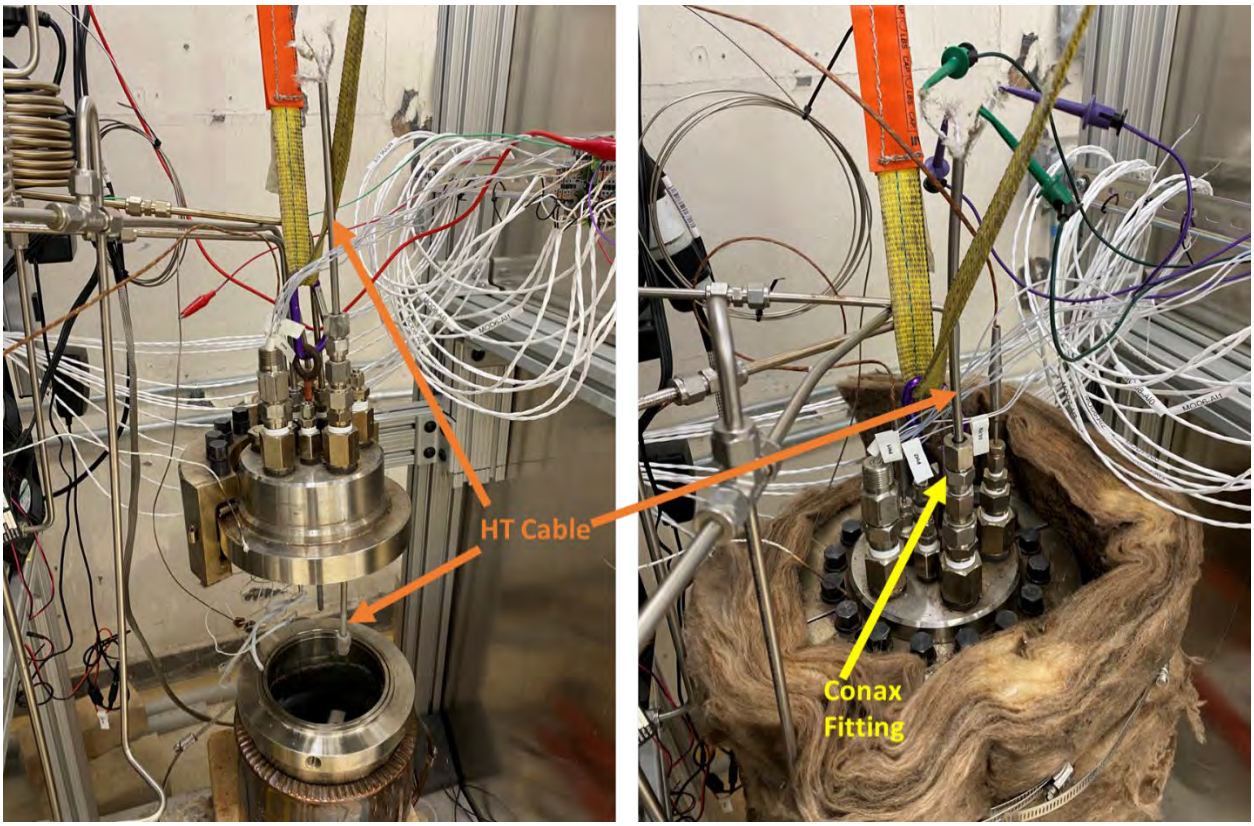

Figure 5: Prysmian cable under evaluation in the autoclave under conditions of 300 °C and 5,000 psi.

The final test Sandia will conduct involves baking the entire >5,000 ft length of Prysmian cable at 300 °C. The cable will be unspooled from the reel and placed within a steel container, allowing it to expand at high temperatures and mitigating potential damage. This setup will enable us to evaluate changes in resistance and measure the spectral response (RF frequencies that can propagate through the cable) at elevated temperatures. Spectral response measurements will be taken before, during, and after the baking process to assess the cable's communication performance. This experiment will be conducted soon at Sandia, with the results to be presented in a final report.

3. Conclusion

In conclusion, Prysmian Group has developed a cable specifically designed for geothermal applications. Engineered to function at 300 °C and 5,000 psi, this cable is ideal for both short-term exposure to temperatures above 260 °C and long-term applications. Its ability to seal directly to the cable without the need for high-temperature grease significantly reduces the risk of leakage over extended periods. This study found that the cable can sustain temperatures reaching 300 °C with high parallel cable resistance once the binder has been baked out. Additionally, the cable was tested at 300 °C and 5,000 psi, showing no signs of leaks after 27 hours of continuous operation. This technology is critical for effectively evaluating enhanced geothermal systems where logging tools must operate continuously at elevated temperatures. It will enable the industry to measure formations, assess well integrity, and monitor changes in fluid flow.

300 Degree Celsius Electronic Component Packaging for Geothermal Tools

Andrew Wright, Manuel Montano, Joshua Larson, Deborah Hagen, and Steven Larson

Sandia National Laboratories

Keywords

Geothermal, High Temperature, Packaging, Ceramic, Gold-Tin, Wire bonding

ABSTRACT

Downhole logging tools embedded with various sensors are commonly deployed into multi-thousand-foot geothermal wells to gain a deeper understanding of the well's characteristics. One of the significant challenges in evaluating geothermal wells is that formation temperatures can exceed 200 °C and commonly reach up to 320 °C. A common technique for logging tools involves using low-temperature electronic components, which can operate at high speeds and provide high resolution, housed inside a specialized enclosure known as a vacuum flask. These flasks are designed to mitigate heat transfer to the components, allowing the tool to operate at elevated temperatures for several hours. However, when a logging tool is required to operate at 250 °C for long-term periods, the vacuum flask is not a viable solution. With the increasing need for fracture formation detection and well integrity characterization in enhanced geothermal systems (EGS), tools must operate in harsh environments for durations ranging from 24 hours to 6 months. Using a geothermal downhole tool for these extended periods at temperatures above 200 °C necessitates that all components are rated for such high temperatures. Sandia National Laboratories is developing methods to improve the reliability of embedded electronic systems to operate at temperatures reaching 300 °C. By utilizing off-the-shelf high-temperature (HT) integrated circuits (ICs), the ICs will be either gold-tin bonded or wire bonded (depending on the device format) onto a ceramic printed circuit board (PCB). Unlike other PCB materials, ceramic PCBs do not degrade at 300 °C. In addition to these bonding methods, Sandia will explore various epoxies with similar thermal coefficients of expansion to conformally coat the ICs, further enhancing reliability under vibration and mechanical shock. Employing these techniques will enable long-term operation of geothermal subsurface instrumentation at temperatures reaching 300 °C.

1. Introduction

Evaluating geothermal wells using electronic systems presents a unique set of challenges primarily due to the extreme environmental conditions encountered deep underground. One of the foremost

issues is the high temperature, often ranging between 200–300 °C, which can severely impact the performance and reliability of electronic components. Most commercially available electronics are not designed to operate at such elevated temperatures, leading to potential failures or degraded performance. This necessitates the development and use of specialized high-temperature electronics that can withstand these harsh conditions. Additionally, the high-pressure environment, coupled with the presence of corrosive fluids, further complicates the design and deployment of electronic systems, requiring robust packaging and protective measures to ensure long-term functionality.

Another significant challenge is the transmission of data from subsurface sensors to the surface. The low analog signals generated by state-of-the-art subsurface sensors degrade significantly as they travel through the 5,000–10,000+ feet of cable required to reach the surface. This degradation can cause the signals to fall below the noise floor, making them difficult to distinguish and analyze. To address this, real-time data acquisition systems must convert these low analog signals into digitized signals using embedded electronic systems (EES) positioned near the sensors. These EES units, which include microcontrollers and other components for local signal processing, must also be qualified for high-temperature operation. However, the limited availability of commercially viable components that can reliably function above 200 °C poses a significant hurdle. Overcoming these challenges requires innovative solutions in high-temperature electronics, advanced packaging techniques, and robust data transmission methods to ensure accurate and reliable evaluation of geothermal wells.

Sandia National Laboratories are evaluating methods to package EES that would be capable of operating at temperatures up to 300 °C. Recently, Sandia completed a study using RelChip's RC10001 microcontroller in a surface-mount device (SMD) configuration, which is the only modern microcontroller on the market that can function at 300 °C. Several challenges were identified when using standard packaging techniques for 300 °C operation. This evaluation focuses on four high-temperature packaging techniques; ceramic printed circuit boards (PCB), gold-tin soldering, wire bonding, and conformal coatings; to address the issues observed with SMD packaging. If successful, these techniques will enable the EES to operate reliably for long-term characterization of deeper and hotter wells at temperatures up to 300 °C.

2. Surface Mount Device Packaging Challenges

Integrated circuits (ICs) can be constructed using various packaging techniques, including thru-hole devices, surface-mount devices (SMDs), and dies. Thru-hole devices are designed with leads that pass-through holes on a printed circuit board (PCB) and are soldered on the opposite side, providing strong mechanical bonds and reliable connections, making them suitable for high-stress environments. Surface-mount devices (SMDs), on the other hand, are mounted directly onto the surface of the PCB, offering a smaller footprint and enabling higher component density, which reduces the overall size and cost of electronic systems. This makes SMDs particularly advantageous for compact and cost-sensitive applications. Dies, which are diced wafers containing the circuit before being placed in a thru-hole or SMD package, represent the most basic form of ICs. They are often used in custom or high-performance applications where direct bonding to a substrate is required, allowing for optimized thermal and electrical performance. Each packaging technique has its own set of advantages and is chosen based on the specific requirements of the application, such as mechanical strength, space constraints, and thermal management.

To achieve the goal of operating electronic systems at 300 °C while minimizing the cost of the tool, we aim to use SMD and die components. However, we have identified three significant challenges for SMD ICs at temperatures reaching 300 °C:

Challenge 1: Typical PCBs, such as Roger materials (e.g., RO3003, RO4003) and polyimides (e.g., Arlon85N), have decomposition temperatures around 260 °C. Consequently, these PCBs have a limited operating time at 300 °C. The material begins to decompose, leading to both dielectric-to-metal and dielectric-to-dielectric delamination (Fig. 1), which strains the electrical connection between the PCB and the SMD IC.

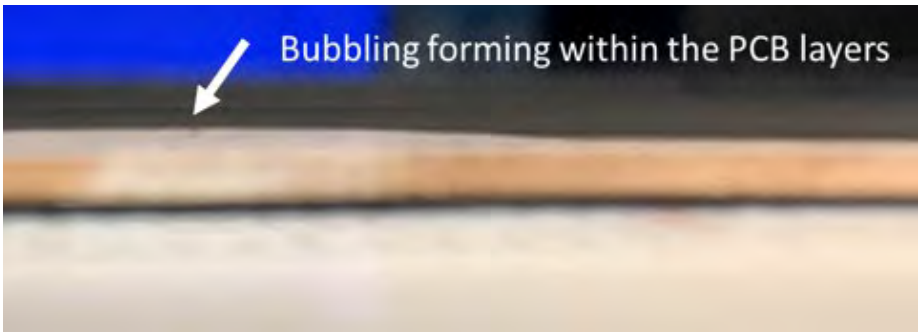

Figure 1: Rogers4003 PCB cross-section, showing a bubble forming between the multilayer board after baking at 300 °C.

Challenge 2: High-temperature (HT) solder, such as 93.5Pb/5Sn/1.5Ag, which has a melting point of 301 °C, interacts with the gold plating on the pins of off-the-shelf SMD ICs at elevated temperatures. Gold tends to diffuse into the solder, degrading the solder joint and weakening the electrical and mechanical connection between the SMD and the PCB. Gold plating is necessary on HT SMDs because gold does not oxidize under high-temperature conditions. Degradation of the solder is evident in Fig. 2.

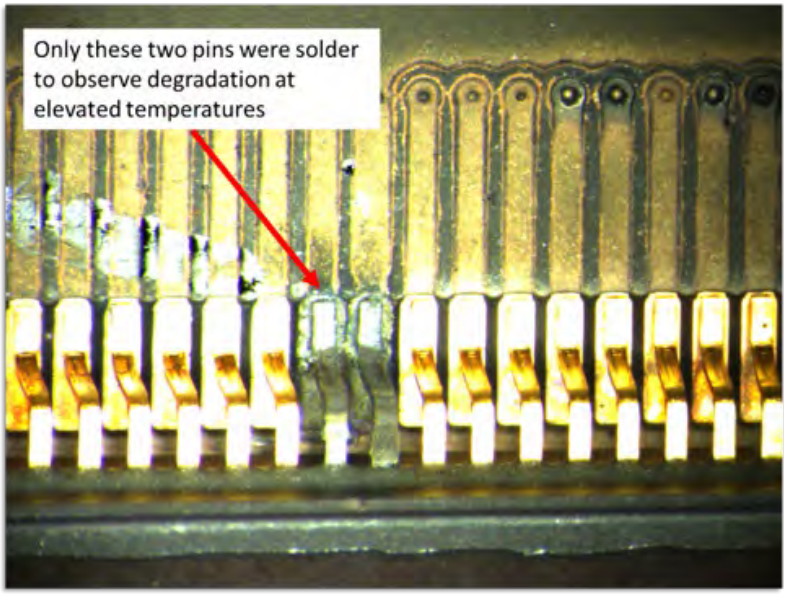

Figure 2: Two pins of the IC had been soldered with observation of the gold wicked into the HT solder .

Challenge 3: Every material has a temperature-dependent coefficient of thermal expansion (CTE). When the CTE of the IC materials differs from that of the PCB materials, the PCB may expand more quickly than the IC, leading to strain between the IC and the PCB.

The combination of these challenges can cause the SMD to debond from the PCB, thereby diminishing or completely halting the functionality of the embedded electronic system (EES). Geothermal tools must operate reliably under harsh well conditions for extended periods, often hours at a time. Additionally, these tools require minimal maintenance to keep the costs of each geothermal evaluation low. To address these issues, we are exploring alternative materials and packaging techniques for SMD and die ICs.

3. Surface Mount Device Packaging Techniques

To enhance the reliability of off-the-shelf ICs packaged onto PCBs for operation at 300 °C, our team is investigating following key factors: the PCB material, the electrical connection between the IC and PCB, and the conformal coating over the IC and electrical connections to protect them from the harsh high-temperature environment and strengthen the mechanical bond. Specifically, Sandia is exploring the use of ceramic for the PCB, gold-tin (Au/Sn) solder, wire bonding, and high-temperature epoxy for the conformal coating.

3.1 Ceramic Printed Circuit Boards

Ceramics can operate effectively at temperatures well above 300 °C and are commonly used in power electronic applications, where ICs generate excessive heat. Given its widespread use in power electronics, ceramic is readily available for industrial manufacturing. In this study, Sandia has been evaluating alumina (Al_2O_3) ceramic (Fig. 3) for packaging the ICs.

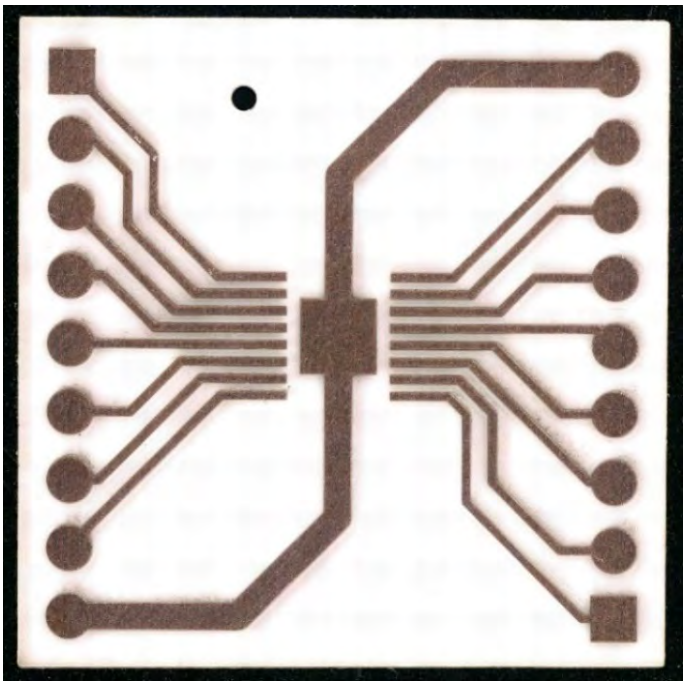

Figure 3: PCB circuit etched onto Al_2O_3 with a thickness of 0.020". The copper is attached via a titanium seed layer to improve adhesion of the copper to the ceramic.

We selected the electroless-nickel electroless-palladium immersion-gold (ENEPIG) plating pattern, commonly used for wire bonding die ICs, with the following targeted thicknesses: Ti/Cu/Nickel (Ni)/Palladium (Pd)/Gold (Au) at 150/750/250/250/250 nm, respectively. Thin Au coatings have been employed for many years in sputtering and electroplating to control corrosion and oxidation of underlying films. However, this simple mitigation strategy can be compromised by the diffusion of both species: Au moving into the base coating and the base coating migrating through the Au. This diffusion depends on the physical and chemical properties of the metals and the temperature. A common material system that exhibits this issue is a Cu coating capped with Au, where a thicker Cu layer is protected from oxidation by Au. While this approach works in the short term at room temperature, over a few months, the Cu will slowly migrate to the surface and form copper oxides. If the coating is exposed to elevated temperatures, this transformation can occur in minutes rather than months. These oxides reduce conductivity and eliminate wettability for soldering. With sufficient diffusion, the entire coating can oxidize.

The common solution to this issue is the addition of a barrier material between the Cu and Au. Many materials have proven effective as diffusion barriers, including Ni, Ti, Pt, Pd, W, and others. For this study, the industry standard ENEPIG stack was initially chosen and adapted for sputter deposition. The ENEPIG stack uses a bulk Cu layer followed by Ni as the main diffusion barrier. Two capping layers are then applied: Pd, which further acts as a diffusion barrier and reduces the total amount of Au needed, and Au as the final capping layer. A titanium adhesion layer was added to improve the adhesion of the stack to an oxide substrate.

The standard ENEPIG stack was evaluated at 300 °C, and after a couple of weeks, the Au surface oxidized, indicating the diffusion of Cu. By a fortunate accident, another ceramic sample with the metal stack was missing the Cu due to a fabrication error. It was discovered to be missing the Cu because the gold plating did not oxidize after baking at 300 °C for a full month. This serendipitous finding revealed that the lifetime operation of the metal stack is significantly improved simply by removing the Cu. To compensate for the lack of Cu, the Ni layer will be made thicker to enhance electric current flow.

For our lab experiments, a circuit was etched onto the board using laser machining. The laser needed to etch through a metal stack thickness ranging from 900 to 1650 nm. We utilized an LPKF Protolaser R4 picosecond laser with a wavelength of 515 nm for this purpose. This compact tool is primarily intended for rapid PCB prototyping (typically on FR4 substrates) and short production runs, but it is versatile enough to process a wide variety of designs and materials. We found that the tool effectively minimizes the heat-affected zone due to its short-duration pulses and produces highly accurate, well-defined parts, as shown in Fig. 3. The material was placed on the tool stage (vacuum chuck) and aligned with the digital circuit design. A sequence of routines was used to process the circuit board, including isolation, hatching, and cutting.

First, the traces were defined and isolated using an isolation routine with the following laser parameters:

- Laser Power: 3.65 watts
- Laser Frequency: 150 kHz
- Routing speed: 600 mm/s
- Number of laser repetition paths: 20

The isolation routine, typically used on laminated substrates to facilitate subsequent processing, may be omitted in the future. We found it might be unnecessary for good trace definition on the non-laminated substrate and could remove an excessive amount of material.

Next, the hatching routine removed the areas of thin film remaining between the traces. For non-laminated substrates, total ablation is necessary. This step used the following laser parameters:

- Laser Power: 7.3 watts
- Laser Frequency: 300 kHz
- Routing speed: 1900 mm/s
- Number of laser repetition paths: 2

Finally, the cutting routine defined the board outline and the vias. Each of these features required slightly different parameters due to their size. Small features like the vias experience a much higher level of laser interaction compared to the larger board outline, thus requiring fewer repetitions to fully remove the part.

Via:

- Laser Power: 8 watts
- Laser Frequency: 200 kHz
- Routing speed: 300 mm/s
- Number of laser repetition paths: 750

Board Outline:

- Laser Power: 8 watts
- Laser Frequency: 200 kHz
- Routing speed: 300 mm/s
- Number of laser repetition paths: 500
- Analyses of ENEPIG degradation

With the finalized PCB featuring a lack of copper ENEPIG stack up and a laser-machined circuit pattern, minimal degradation was observed after 700 hours at 300 °C. The traces remained strongly bonded to the ceramic substrate, with only slight discoloration of the gold (Au).

3.2 Gold-Tin Solder

Having demonstrated a non-degrading PCB at elevated temperatures, we proceeded to evaluate the electrical bonding of the IC using gold-tin (Au/Sn) solder. We employed Mitsubishi Materials USA gold-tin (Au78/Sn22) solder with specific particle sizes (5-16 µm), flux type (AS1), viscosity (90 Pa-s), and solidus/liquidus states (278 °C / 301 °C, respectively) to bond the SMD to the PCB. A four-stage Sikama oven, running a temperature profile as shown in Fig. 4, was used to properly process the gold-tin solder while minimizing the time the IC was exposed to elevated temperatures.

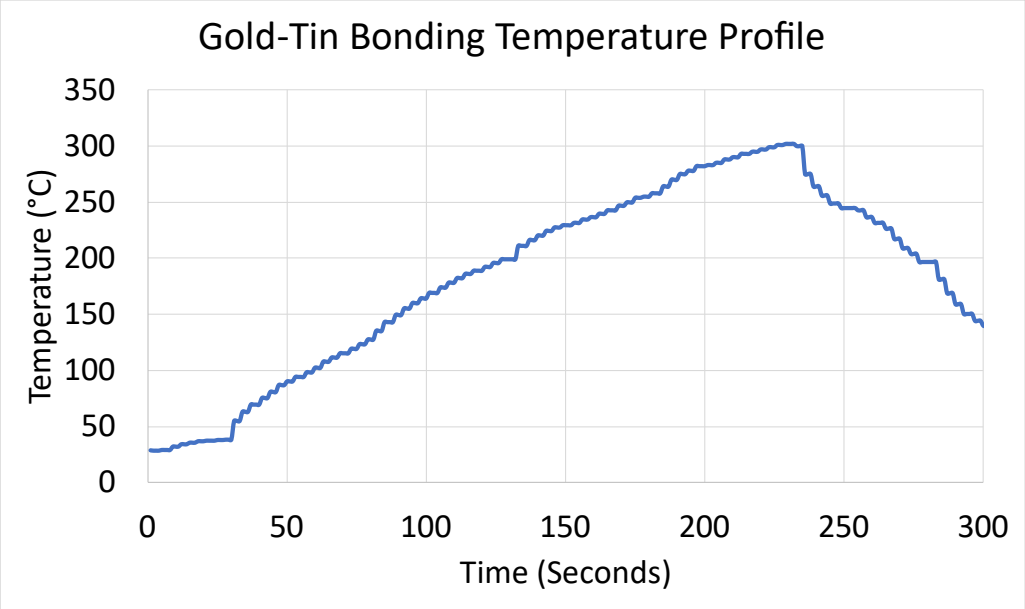

Figure 4: Four-stage Sikama oven temperature profile for the Au78/Sn22 solder. In this profile, the temperature max was 300 °C, but sometimes the temperature may reach up to 320 °C.

A Cissoid CHT-RIGEL voltage regulator was bonded to the ceramic PCB using gold-tin solder (Fig. 5). The sample was subjected to a constant temperature of 300 °C for 170 hours. The regulator remained functional up to 270 °C, after which the thermal protection deactivated the device at 300 °C. While no delamination of the SMD IC from the PCB was observed, the Au traces blackened, as shown in Fig. 5, due to the presence of Cu in the ENEPIG stack. This sample was tested before discovering that the absence of Cu in the metal stack significantly improves performance. Despite the oxidation of the Au, a strong bond was maintained between the IC and the traces. The images also show that the gold-tin solder mitigated the oxidation of the traces near the pins. Moving forward, we plan to test the packaged PCB under vibration at 300 °C to determine whether the gold-tin is entering a liquidus state and/or whether fusion of the deposited metal layer causes degradation of the solder joint.

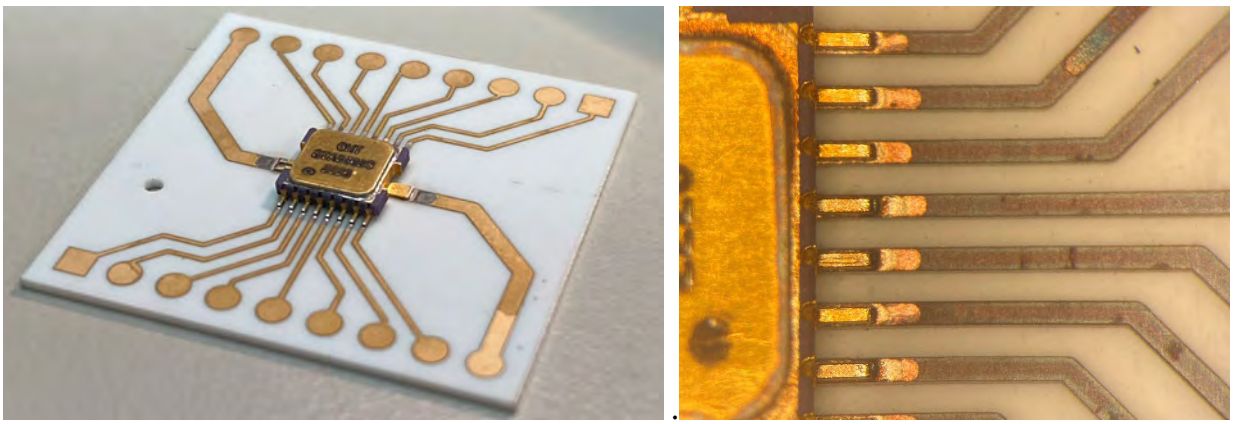

Figure 5: (Left) Al_2O_3 with ENEPIG plated circuit with a gold-tin bonded CHT-RIGEL IC. This ENEPIG stack up contained Cu. The lack of Cu improve, was discovered after this evaluation. (Right) A strong bond remained on the Au/Sn even the oxidation observed on the gold traces.

3.3 Chip-on-Board Wire Bonding

As an alternative to Au/Sn bonding, an unpackaged IC in die format can be directly attached to the ceramic PCB using conductive curable paste and wire bonding. This approach offers the advantage of wire bonds acting as strain relief for the electrical connection in the event of a CTE mismatch between the IC and the PCB. However, there are some disadvantages: only a limited number of industrially produced HT ICs are available in die format, and the die is significantly more fragile than an SMD IC, making it more susceptible to damage during packaging.

The die attach material must meet both processing and operational constraints. Key requirements include a strong bond between the die and the alumina substrate, survivability at temperatures up to 300 °C, electrical conductivity, and resistance to corrosion. Additionally, die attach materials must have very low unbound ionics, typically less than 25 ppm for each ion. Ions such as sulfur, sodium, and lithium are known to promote corrosion.

Typical die attach epoxies are unsuitable for environments at 300 °C because the polymers degrade at such high temperatures. Eutectic solders are often used to attach dies to ceramics, especially for ceramic packages. However, the processing temperatures for solders such as Sn/Pb eutectic solders and no-lead tin-based solders like SAC305 are below the operating temperature of 300 °C. Brazing materials, on the other hand, have processing temperatures that are too high for silicon dies.

For this application, sintered silver die attach was selected. Sintered silver die attach materials contain very small silver fillers mixed into polymers and solvents, which can be dispensed as a paste. The high surface area to volume ratio of the silver particles allows them to sinter, or fuse together, during curing at approximately 200 °C. The fused silver forms a metallurgical bond with the back of the silicon die and the gold on the alumina substrate. During curing, the solvents evaporate, leaving very little polymer behind. The strength of the bond between the die and the substrate is achieved through the metallurgical joining facilitated by the silver.

Abelstik ICP 9000 (hybrid sinter silver) was selected to electrically attach a Cissoid CHT-RIGEL voltage regulator in die format to the PCB. A thermogravimetric analysis (TGA) was conducted on the sintered silver to measure mass loss at elevated temperatures. The results from the TGA are shown in Fig. 6.

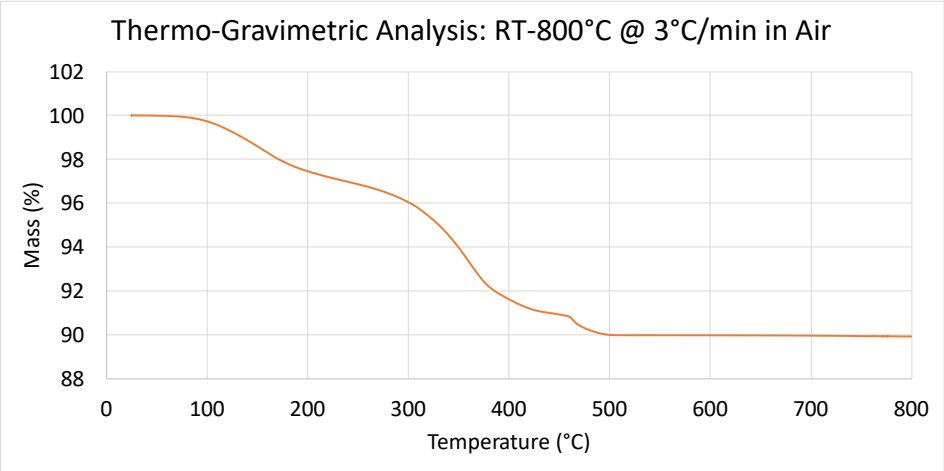

Figure 6: Thermo-gravimetric analysis of the Abelstick ICP 9000 hybrid sintered silver.

After attaching the IC die to the PCB, 0.001" wire was ball-bonded between the die and PCB to establish the electrical connection. The packaged device is shown in Fig. 7. The device was then evaluated in an oven at 300 °C. In die format, we were able to deactivate the thermal protection and observed voltage regulation at 300 °C, but only for a short period before the device failed. After failure, the input voltage matched the output voltage at 250 °C and dropped to 0.4 V at 300 °C. Despite this, since a voltage was still observable, the test continued. The device was baked at 300 °C for 300 hours, during which the wire bonds remained strong and the voltage remained consistent. As shown in the right image of Fig. 7, the gold discolored after the extended baking process, but the wire bond remained intact. In this ENEPIG stack up, there was no Cu.

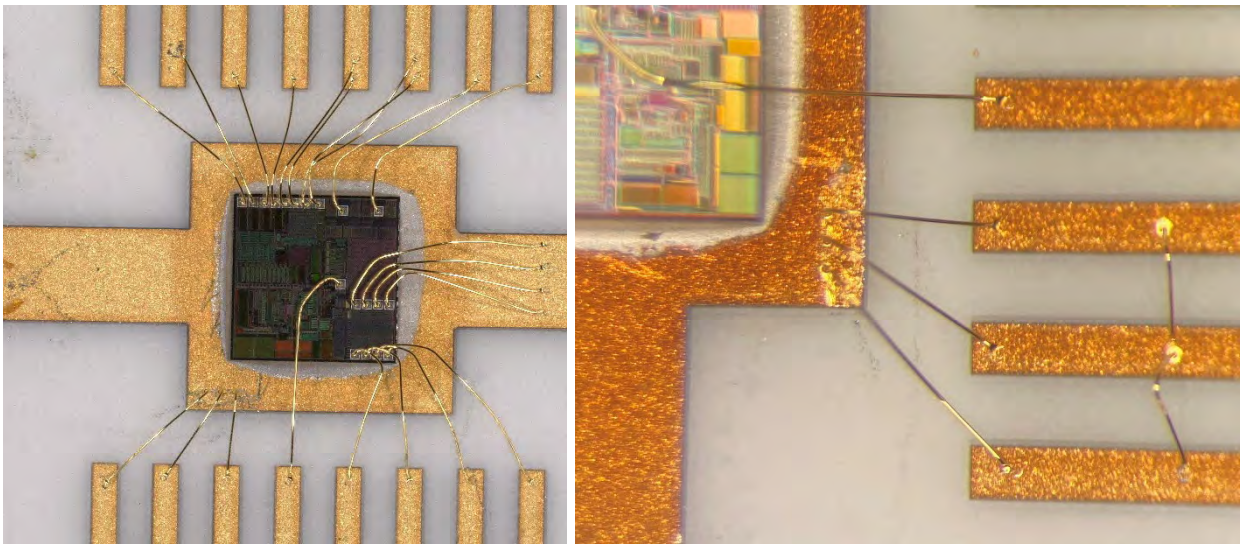

Figure 7: CHT-RIGEL in a die format epoxied to the gold pad on the ceramic PCB (Left) before baking and (Right) after baking at 300 °C for 300 hours.

3.4 Conformal Coating

We hypothesized that applying a conformal coating over the electrical connections could strengthen the mechanical bond between the IC and PCB. To test this hypothesis, we evaluated several off-the-shelf high-temperature (HT) epoxies from multiple companies. We established three criteria for a desirable epoxy: (1) low viscosity to allow for the application of a thin layer over the structures, (2) suitability for HT operation, and (3) a coefficient of thermal expansion (CTE) like that of the ceramic PCB (6–9 ppm/˚C). Ultimately, we selected Micro Measurements' 800 °C line of ceramic epoxies: WC-16 (CTE 7.2 ppm/°C), HG-1 (10.8 ppm/°C), and NCC-3 (12.6 ppm/°C). Due to its close CTE match, we expected WC-16 to be the most promising candidate.

The epoxy was applied to the wire-bonded device reviewed in section 3.3, with an image of the epoxied device shown in Fig. 8. The device was re-evaluated at 300 °C for another 300 hours. Further analysis is required for this approach, as the output voltage dropped and high current was observed on the input. The connection could not be visually inspected due to the opaque color of the ceramic epoxy. It is predicted that the high current draw is due to further degradation of the IC, as the ceramic epoxy remained dielectric and did not produce conductivity. Additional experiments were conducted on the WC-16 epoxy applied to wire bonds between two traces on

the PCB. After 500 hours at 300 °C, an electrical connection was still observed through the wire bonds, indicating the wire bond survived.

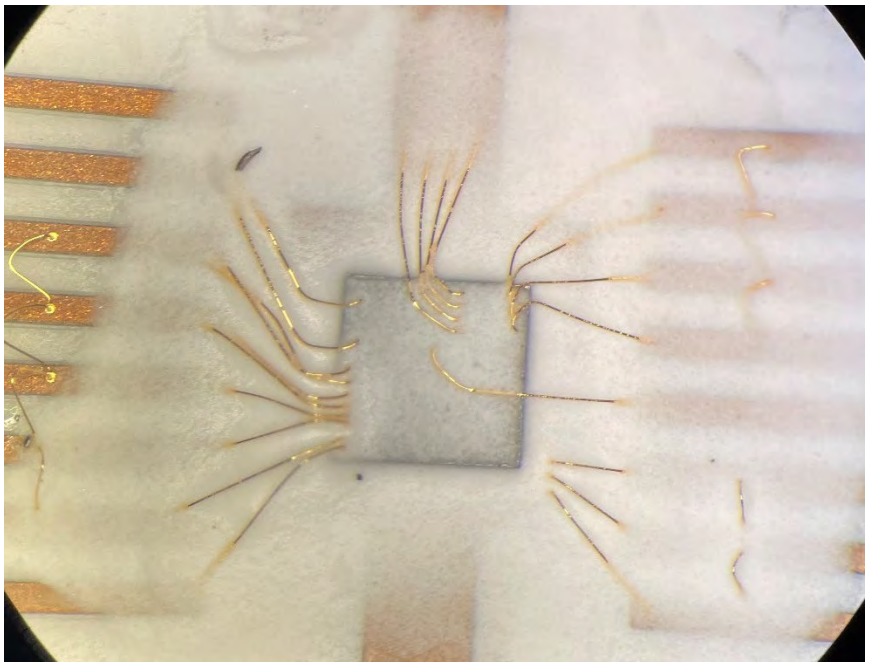

Figure 8: Wire bonded CHT-RIGEL on a ceramic PCB that has been conformal coated with WC-16 ceramic epoxy.

4. Conclusion

Sandia's preliminary experiments indicate that ceramic PCBs with altered ENEPIG stack up, gold-tin soldering, wire bonding, and high-temperature conformal coatings all hold significant potential for enhancing the performance and reliability of embedded electronic systems exposed to temperatures of 300 °C and above for extended periods. However, further testing is necessary to evaluate yield and confirm performance under vibration conditions. One major concern is the possibility of gold-tin solder reaching a liquidus state at 300 °C, although the conformal coating may provide mechanical support to mitigate this issue. These techniques represent a promising advancement in the development of HT electronics, particularly for long-duration geothermal hardware applications.

In the second year of this effort, Sandia will use these techniques to develop and evaluate a data link capable of operating at 300 °C. Initial evaluations have identified some essential components that can survive at 300 °C for a short period before failure. Proposed future research will require the focus on the development of silicon carbide (SiC) ICs that are rated to operate continuously at 300 °C and greater, further advancing the field of high-temperature electronics.

Drilling

Extending Drilling Tool Life in Geothermal Wells with Recent Advances in Low Thermal Conductivity Coatings

Michael Adams and Reza Fard

Tuboscope NOV

Keywords

Geothermal drilling, Enhanced geothermal systems, thermal conductivity, insulated coating

ABSTRACT

Drilling into geothermal reservoirs challenges the reliability and long-term operability of drilling tools in the bottomhole assembly (BHA). The sensitive electronics in many downhole tools often fail at high temperatures, which drives up drilling costs by adding downtime to pull the string and replace failed components in the BHA.

This paper presents a novel solution: an internal insulating drill pipe coating that helps keep drilling fluids and the BHA below a certain temperature threshold to extend tool life downhole. The solution builds on coating advances originally developed to protect tubulars in aggressive oil and gas environments from corrosion, wear, and deposit buildup while improving hydraulic efficiencies to reduce pumping horsepower.

It also includes components that reduce heat transfer rates through the drill string and keep the fluid cooler. The new coating has a thermal conductivity of $k = 0.1808\ W/mK$, nearly 250 times lower than the conductivity of steel pipe, which vastly increases the thermal insulation of the pipe.

In the field, the insulated coating helped keep mud temperatures below 115°C (239°F), well under the standard 150°C (302°F) threshold for most geothermal operations.

The insulated, coated drill pipe is being successfully deployed at several geothermal and oil gas projects globally, with operators placing new orders.

1. Introduction

Of the many renewable energy sources currently driving the energy transition, geothermal offers a vast, sustainable, and essentially inexhaustible energy source that could produce clean, reliable, baseload-level power at scale. It is also the only renewable energy source that naturally produces heat. Because large-scale heating and cooling applications contribute an estimated 40% of all

carbon emissions worldwide (Lund & Toth, 2021), geothermal is also viewed as a viable option for resolving a significant share of human-produced carbon emissions.

However, despite its potential as a reliable, carbon-free energy source, conventional geothermal power production capacity worldwide currently stands at roughly 16 gigawatts, equivalent to just 0.5% of electricity generation capacity from renewable sources (International Renewable Energy Agency, 2023).

Global interest in geothermal energy is growing thanks to its promise of abundant, reliable, and carbon-free heat and baseload power. Other factors spurring greater interest in geothermal energy include technological advancements, societal demand for sustainable energy, and bipartisan governmental support for renewable energy projects that promise long-term job growth. Rystad Energy predicts that by 2030, the anticipated global installed capacity for geothermal power generation will reach nearly 32 gigawatts (Rystad Energy, 2023), roughly double what it is today.

To deliver this anticipated capacity, project developers have realized that conventional geothermal systems are not the answer. Traditional geothermal systems tap into naturally occurring hot water sources in relatively shallow and lower-temperature reservoirs, many of which are found in only certain locations around the world.

Enhanced geothermal systems (EGS) are being developed at a faster pace due to the higher energy production and location flexibility they provide compared to conventional geothermal. Rather than relying on natural underground water sources, most EGS projects in development are closed-loop systems comprising multiple wells—at least one injector and one or more production wells (Figure 1). These projects pump water from the surface into the injection well, deep into dry rock formations at temperatures of 200^{o}C (392^{o}F) or higher. The injected water becomes superheated as it migrates through the hot rock before traveling back to the surface through a production well. As a result, EGS creates a continual loop of water injection and superheated water production, without an underground water source, to expand geothermal’s reach to many more places around the globe.

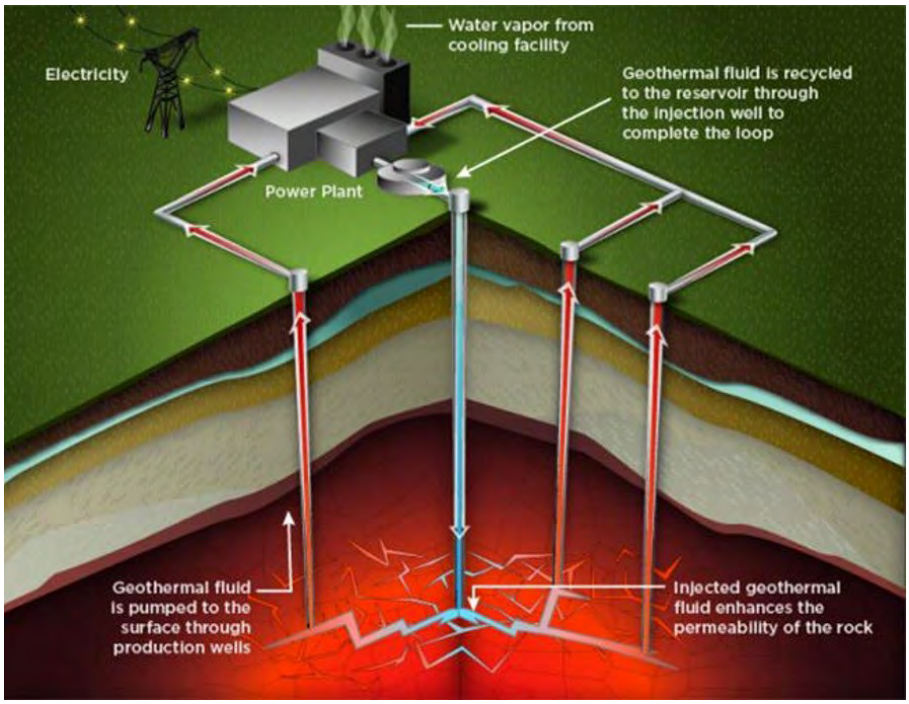

Figure 1: General layout of an enhanced geothermal system, with one injector well and three producing wells. Source: US Department of Energy (2013)

Constructing a closed-loop EGS requires drilling injection and production wells deep into hot-rock reservoirs (typically two miles [3.2 km] or greater beneath the surface). It also requires drilling multiple lateral sections that connect the injectors and producers to help achieve sufficient heat transfer surface area to collect geothermal heat in quantities required to make the project economically viable.

Creating the multilateral sections requires directional and measurement-while-drilling (MWD) tools in the bottomhole assembly (BHA). These tools help steer the drill bit during drilling so that the bit stays in the geothermal zone of interest and effectively intersects the wellbore.

Such tools were developed initially and used successfully in oil and gas drilling operations. However, the higher reservoir temperatures in EGS drilling exceed the maximum operating temperature limit of many typical BHAs and the sensitive electronics in MWD sensors, which are currently rated to 150°C-175°C (302°F-347°F). The drill string and the BHA tools are exposed to these high reservoir temperatures for extended periods while drilling long multilaterals. This essentially guarantees a high risk of tool failures and results in a “drilling blind” scenario in which the drilling team continues building out the multilateral without the necessary downhole data to make informed directional drilling decisions.

One option to improve drilling performance in EGS reservoirs is to redesign the BHA components and MWD tools to operate reliably at higher temperatures. While such developments are being investigated, they require significant time, effort, and investment to re-engineer key components and will delay the widespread adoption of geothermal production at scale.

A faster and more economical option calls for developing solutions that keep existing tools cooler while drilling. This paper examines one such solution: insulated pipe coatings that lower the

thermal conductivity of drill pipe to reduce heat exchange between drilling fluids inside the pipe and in the annular space between the reservoir and pipe. By keeping drilling fluids cooler, such a solution would reduce bottomhole temperatures at the BHA and help protect sensitive electronics to make directional drilling possible. This paper includes work presented by the authors previously (Adams & Fard, 2023), but with additional discussions on the thermal conductivity, corrosion, and chemical resistance testing performed to confirm a coating candidate's performance in the aggressive, high-temperature environments of EGS reservoirs.

2. Thermal Conductivity Control Holds the Key to Temperature Control

The thermal conductivity of a material is a measure of its ability to conduct heat (Figure 2). Thermal conductivity is typically calculated from the defining equation for Fourier's Law for heat conduction (Bird, Stewart, and Lightfoot, 2006):

$$q = -k * \frac{T2-T1}{L} \qquad (1)$$

Where q is the heat flux (W/m^2), k is the thermal conductivity (W/mK), T2 and T1 are the two temperatures on either side of the conducting material (in K), and L is the separation distance (in m).

For geothermal drilling applications, the lower the thermal conductivity, the better. Low thermal conductivity translates to lower heat transfer rates through the drill string, keeping the drilling fluid cooler to minimize the temperature impact on BHA tools and retaining more high-energy heat in the pipe on its way to the surface.

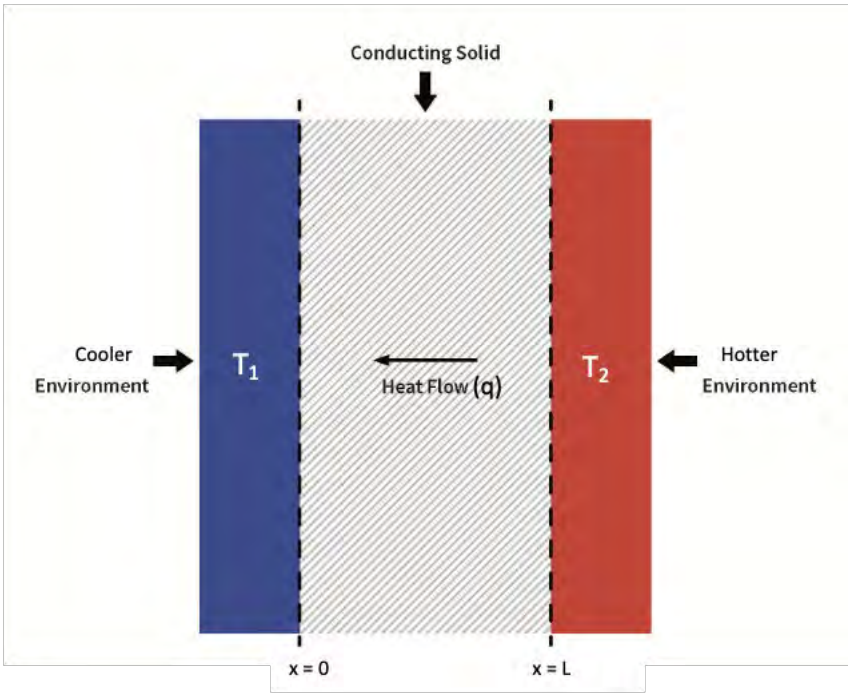

Figure 2: The thermal conductivity of a solid material (of a given thickness L) can be easily defined in terms of the heat flow (q) across a temperature difference (T_2-T_1).

Discussions with geothermal operators guided the target thermal conductivity value of the drill string to protect sensitive BHA electronics. While many tools are rated to 150°C or above, operators want to keep drilling fluids below 120°C (248°F) to provide extra precaution against damage to the BHA components. To stay below this temperature threshold, a drill string with a thermal conductivity of 0.5 W/mK or lower was required.

Carbon steel is the most commonly used drill string material in most drilling applications due to its relatively low cost (compared to other alloys) and proven history of performance over decades. However, the thermal conductivity of unprotected carbon steel is 45 W/mK, two orders of magnitude higher than the required thermal conductivity value (Table 1).

Table 1: Thermal conductivity values of various materials

Material	Thermal Conductivity (W/mK)
Diamond	1,000
Copper	401
Aluminum	237
Carbon steel	45
Water	0.5918
Polyurethane foam	0.03

Rather than begin a lengthy research project to find an entirely different starting material for drill pipe that provided the desired thermal conductivity, the focus shifted to developing an insulating coating material for carbon steel with a thermal conductivity of 0.5 W/mK or less.

Internal plastic coatings have been applied to tubular goods and drill pipes for more than 70 years to provide long-term corrosion control, improve hydraulic efficiency by reducing surface roughness and friction, and prevent deposit buildup on the pipe surface (Lauer, 2007). However, until recently, the insulating properties of such coatings were not an essential requirement or consideration.

Tuboscope embarked on a project to develop a low-conductivity coating for geothermal drilling applications, using its own proven drill pipe coatings for oil and gas applications as a starting point. The development plan was as follows:

- Establish the thermal conductivity and properties of current oil and gas drill pipe coatings
- Adjust the coating formulation to decrease thermal conductivity to 0.5 W/mK or lower, as needed
- Verify that the new coating maintains the required chemical and corrosion performance required in drilling applications

3. Testing Methodology

3.1. Thermal Conductivity Testing of Drill Pipe Coatings

The ASTM E1530-19 test method (ASTM, 2019) was used to measure the thermal conductivity of various coating materials. This test is the primary measurement method for solids such as metals, polymers, composites, and paste less than 25 mm thick and under controlled conditions.

This steady-state measurement of thermal resistance represents the full sample thickness and mature heat transfer properties of test materials. Thermal conductivity is calculated from the thermal resistance measurements and is considered the most accurate method of testing the true thermal conductivity of heterogeneous materials.

3.2. Measuring Physical Properties and Chemical/Corrosion Resistance of Coating Candidates

Researchers conducted additional tests to ensure that the formulation modifications to produce a low-conductivity coating did not alter or negatively impact the coating's ability to improve hydraulic efficiencies and mitigate corrosion in the drill pipe.

Chemical and corrosion performance testing was performed in autoclave and immersion tests. The autoclave tests were designed to measure the integrity of coating materials under elevated temperature and pressure in both sweet (CO_2) and sour (H_2S) environments. Varying degrees of sour testing can be achieved up to 15% H_2S by volume.

Immersion tests on coatings subject the material to extended exposure to various corrosive solutions. These tests can be carried out at elevated temperatures in clear reaction vessels to study the degradation of the material.

A range of physical property tests were conducted to evaluate the coating's ability to withstand high flow rates of drilling fluids in the presence of solid particulates that may enter the drill pipe as contaminants from the drilling process. These tests include Taber abrasion tests that measure coating loss (in mils [thousandths of an inch] or microns), impact resistance (both direct and reverse), and flexibility (both ring crush and mandrel bend testing). The surface roughness of the applied coating was also measured to ensure that the new coating maintained the desired level of hydraulic efficiency and steady flow of drilling fluids through the pipe.

4. Laboratory Testing Identifies Suitable Coating Candidate

Per the ASTM E1530-19 test method, the current coating class had an average thermal conductivity of 0.8360 W/mK, much lower than carbon steel alone (45 W/mK) but still higher than the operator's target value. Through iterative formulation adjustments, researchers arrived at a coating formulation with an average conductivity of just 0.1808 W/mK, well below the conventional coating value and the operator's target (Figure 3).

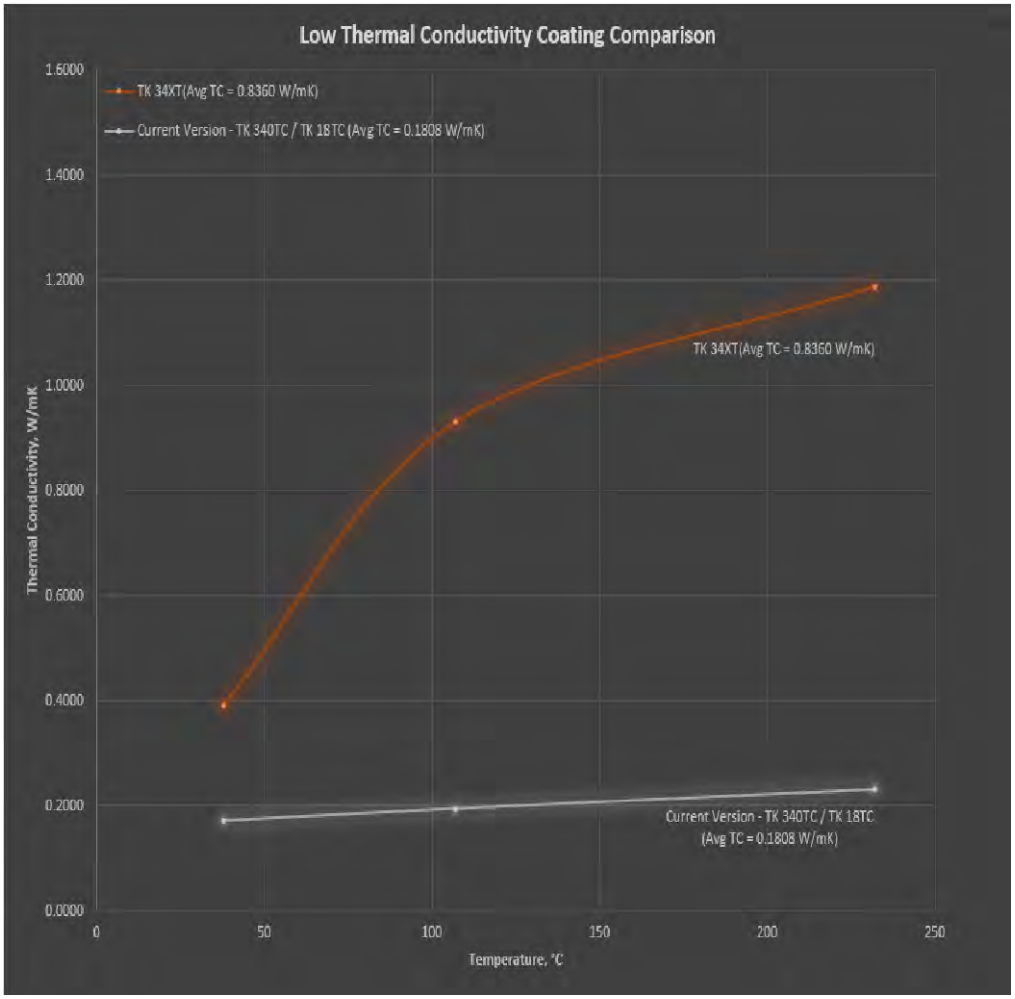

Figure 3: Compared to the conventional coating (red curve), the insulated coating (white curve) delivered far lower thermal conductivities across a wide temperature range.

Additional testing of the new formulation's physical properties showed the same level of reliable downhole performance as the previous generation of coatings (Table 2). The insulated coating demonstrated superior impact, chemical, and abrasion resistance as well as excellent corrosion mitigation properties—all of which helped verify the coating's robustness in harsh geothermal drilling environments.

The coating applies evenly and smoothly to minimize surface roughness and increase hydraulic efficiencies. A smooth coating surface will help prevent the buildup of scale and other solid deposits while promoting the laminar flow of drilling fluids in the pipe. This optimizes mud pumping efficiencies at the surface and provides additional cooling benefits to the BHA downhole.

Table 2: Summary of thermal conductivity and physical properties, comparing the incumbent conventional coating with the optimized, low-conductivity coating

	Conventional coating	Low-conductivity coating
Type	Liquid epoxy phenolic	Powder modified Novolac
Applied thickness	5-9 mils (127-229 microns)	20-30 mils (508-762 microns)
Abrasion resistance (Taber Thickness Loss, mils/1000 Cycles)	0.6	0.32
Surface Roughness (Rz µm)	11.97	2.43
Thermal Conductivity (w/mK)	0.8360	0.1808
Ring crush, mils of deflection	50	108
Reverse impact (in*lb)	51	185
Direct impact (in*lb)	80	88

5. Proving Its Potential in The Field

A geothermal operator evaluated the new insulating coating on drill pipe as part of an EGS development project in New Mexico, USA. The operation called for drilling a single well, with a sidetrack, more than 5 km (3.1 mi) deep in granite with rock temperatures of ~250°C (482°F). Local geothermal gradients in the region can exceed 50 °C (122°F) per km. The operator selected the single well and sidetrack design to replicate one half (either the injector or a producer) of a commercial closed-loop EGS project.

The new insulating coating was applied to the inside of a 5.5-in. base pipe at a thickness of 20-30 mils. In addition to temperature measurements from MWD tools, the operator placed temperature sensors along various parts of the drill string to record annular fluid temperatures and validate a transient thermodynamic drilling model.

The well was drilled a total of 18,000 ft (5.5 km) into the reservoir at temperatures up to 250°C. With the coated drill pipe in the hole, the mud temperature never exceeded 95°C (203°F), well below the operator's target temperature of 120 °C to prevent BHA damage. After drilling, an examination of the coated drill pipe showed that the insulated coating withstood the high torque and tensile loads and maintained high integrity to enable drilling at depths of 5.5 km or greater.

Based on these test results, the operator purchased an additional string of insulated, coated drill pipe for a commercial geothermal project planned in Europe.

Other geothermal applications for the insulated drill pipe await as operators secure funding and regulatory approvals. In the meantime, the coated pipe is catching the attention of oil and gas operators who face similar drilling challenges in high-temperature reservoirs of 150°C or higher.

6. Conclusions

- Thermal conductivity is key to optimizing geothermal drilling. Drill strings with low thermal conductivity keep drilling fluid and tools cooler for longer.

- Low conductivity coatings initially developed for oil & gas can be easily modified/refined for drilling long multilaterals in deeper, hotter geothermal reservoirs.
- Thorough testing and refinement of coatings delivered a low TC coating (<0.5 W/mK target) that maintained superior corrosion, chemical, and hydraulic performance.
- Field testing confirmed that the new coating kept mud below the 120°C threshold to protect BHA tools while drilling an 18,000-ft geothermal well.
- Encouraged by early successes, operators are placing more insulated drill pipe orders to continue field trials.

Acknowledgments

The authors thank our oil, gas, and geothermal customers who continue evaluating low thermal conductivity, insulated drill pipe in their extreme temperature drilling operations. Thanks to NOV for their support and efforts in advancing alternate energy developments like geothermal. Moreover, thanks to NOV's scientists, laboratory technicians, and manufacturing centers for consistently designing and delivering low TC coatings that meet the demands of deeper, hotter reservoirs.

Well Control Considerations for a Global Geothermal Industry: A Historical Review and an Assessment of Current and Future Requirements

Andrew Barry and Mohamed Amer, Wild Well Control, and Julmar Shaun S. Toralde and Robby L. Darby, Weatherford

Keywords

Well control, blowout, geothermal

ABSTRACT

Geothermal well blowouts pose a significant financial and reputational risk to companies exploring for or developing geothermal energy resources. The potential catastrophic impact of a major geothermal blowout can tarnish in the arena of public opinion the recent gains of the geothermal renaissance that the nascent and fast-growing global geothermal industry is experiencing.

Given the increasing geological and geographical distribution of geothermal projects, the introduction of new well architectures and advanced drilling technologies and the drive towards hotter supercritical geothermal reservoirs to achieve greater global energy contribution and scale, a comprehensive assessment of the well control and blowout contingency considerations unique to the geothermal industry is needed.

With this in mind, a thorough historical review of available well-control-related information, publication and events will be conducted. This will provide a solid foundation for the determination of the current and future well control risks and blowout contingency requirements of the geothermal industry. The paper also intends to cover the issues involved with the direct application of conventional oil and gas well control techniques and methods in the geothermal industry and to raise relevant concerns about what the geothermal industry is doing and identify possible pitfalls in the direction that the industry is headed.

1. Introduction

Geothermal formations are comprised of reservoirs of hot water that naturally occur or are man-made at varying temperatures and depths below the earth's surface. As defined by Naturally occurring geothermal formations (with heat, water, permeability) that have historically been developed for heating and electricity generation purposes are usually classified as of the hydrothermal type (US Department of Energy, Office of Energy Efficiency and Renewable Energy, 2024), but other types such as geopressured-geothermal systems, which contain water with somewhat elevated temperatures and with pressures well above hydrostatic for their depth, as

well as magmatic systems, with temperature ranging from 600°C to 1400°C also exist. Man-made geothermal systems usually target Hot Dry Rock (HDR) geothermal resources, with ideal temperatures from 200°C to 350°C, and are usually referred to as enhanced geothermal systems (EGS) or advanced geothermal systems (AGS) or advanced closed loop (ACL), depending on the technologies being used to develop the resource. Rock types are typically granite, granodiorite, quartzite, greywacke, basalt, or volcanic tuffs but geothermal reservoirs in sedimentary rock types are also possible.

Because geothermal formations are usually under pressured (pore pressure less than fluid pressure in a full wellbore), influx into the wellbore is rare. Geothermal well control considerations, as described by Wild Well Control (2024), are primarily due to these two causes for loss of control:

- An unexpectedly hot formation is encountered at a shallow depth where the annulus pressure is insufficient to keep the drilling fluid or the formation fluid from flashing to steam.
- Lost circulation causes the fluid level and the pressure in the wellbore to suddenly fall far enough for the same thing to happen.

If complete control is not lost, simply pumping cold water into the wellbore can usually kill the well.

Like in oil and gas drilling settings, the apparatus that controls a geothermal kick and potential outflow at the wellhead is called the blowout preventer (BOP) or blowout prevention equipment (BOPE). According to the Handbook of Best Practices for Geothermal Drilling published by Sandia National Laboratories, the geothermal BOP stack comprises five types of device to shut off the wellbore and prevent fluid flow out of it: rotating control devices (RCD) or rotating heads, annular preventers, pipe rams, blind rams, and shear rams. The basic function of each is to shut off the wellbore, but they operate in slightly different ways. Below the BOP stack, there is a drilling spool with two valved lines (called the choke and kill lines) connected to the drilling spool so that fluids can be either released from or pumped into the wellbore as part of the well-control process. (Finger & Blankenship, 2010) (Weatherford, 2024)

Compared to the sedimentary formations of most oil/gas reservoirs, hydrothermal geothermal formations are, by definition:

- Hot (production intervals from 160°C to above 300°C)
- Often hard (240+ MPa compressive strength), abrasive (quartz content above 50%)
- Highly fractured (fracture apertures of centimeters)
- Under pressured
- Often contain corrosive fluids
- Some formation fluids have very high solids content [total dissolved solids (TDS) in some brines it can be above 250,000 ppm]

Purba et al. highlight that the fundamental differences between petroleum and geothermal environment systems lie in reservoir and fluid temperatures, rock permeability and pressure and the heterogeneity of the rock-forming systems. (Purba, et al., 2022).

Purba et al. also emphasizes that the generalization of well control methods and blowout preventer (BOP) designs between petroleum and geothermal can be dangerous because generally well control methods and equipment in the petroleum industry are designed to anticipate pressure. It adds that geothermal is likely to face a well control situation that is influenced by temperature, and that the availability of a continuous supply of cold water, the ability and reliability of the pump on the rig, and an adequate BOP temperature rating are the main factors that must be considered.

Finger and Blankenship (2010) highlight that though pressures in geothermal drilling are almost always lower than those encountered in oil and gas drilling, the key to control is having adequate casing setting depths, which will permit shutting the well if a kick is detected in the early stages. They warn that unexpected steam flow in a permeable formation that is not completely sealed by casing is particularly dangerous; because steam can begin to flow up the outside of the previous casing string ("underground blowout") and eventually destroy the casing's integrity and often causes loss of the drill rig.

The geothermal well control incidents in the following section highlight these hazards and emphasizes the fact that geothermal well blowouts pose a significant financial and reputational risk to companies exploring for or developing geothermal energy resources. Though most of the well control case studies featured in this paper are from historical geothermal development projects involving hydrothermal resources, the risks involved and lessons learned will have a high degree of applicability to the new technologies being tested or piloted involving enhanced and advanced geothermal systems (EGS / AGS / ACL) that are receiving a lot of recent attention from the global energy community.

Adaptations that might be required from a well control standpoint to accommodate these new geothermal technologies and methods that have the potential to bring geothermal anywhere and everywhere are presented in the section following the case studies.

2. Geothermal Well Control Incidents and Statistics

With the rapidly evolving and expanding geothermal energy industry future in mind, a historical review of publicly available well-control-related information, publication and events was conducted as part this paper. It is intended to provide a solid foundation for the determination of the current and future well control risks and blowout contingency requirements of the geothermal industry.

So in terms of risk, how does geothermal energy systems compare to other energy sources and which what is the level of risk involved with well blowouts? A paper published on "Comparative accident risk assessment with focus on deep geothermal energy systems in the Organization for Economic Co-operation and Development (OECD) countries" provides some insights on the matter. The paper concludes that the drilling and stimulation phases of deep geothermal energy development are considered the riskier due to the potential of blowouts or release of drilling muds and stimulation fluids during these operations. Within the drilling phase, blowout accident risk is significantly higher than the transportation, storage and use of caustic soda. In both the stimulation phase and drilling phase of geothermal operation blowouts are among the highest risks. This is related to the fact that if a blowout happens the effect can be catastrophic not only for the deep geothermal project itself, but for the workers in the area. It is interesting to note that blowouts in the drilling phase are higher with respect to the stimulation phase. This could be possibly due to

the fact that during a stimulation phase the bore should have been stabilized in terms of pressures, while during the drilling phase, kicks from different gasses, i.e. natural gas, hydrogen sulfide, could still happen in an unpredictable way, leading to an increased risk. (Spada, Sutra, & Burgherr, 2021)

It is interesting to note that the study also developed and compared deep geothermal cases (best and worst) against fossil, hydrogen and selected renewable technologies, in terms of expected accident risk. The lowest fatality rate, i.e., expected risk, was found for the deep geothermal energy best case. The deep geothermal energy worst case is similar to wind offshore and performs better than the fossil, hydrogen, hydropower and biogas energy chains. In contrast, in terms of extreme accident risk, maximum consequences, i.e., extreme risk, for both deep geothermal energy scenarios were similarly low as for other renewables, implying that they are substantially less prone to high-consequence events than fossil, hydrogen, and hydropower energy chains.

Going further into the details of geothermal well blowout incidents and risks, the table below lists down by country and by approximate year the instances of the same available in published literature and in the worldwide web, using the search terms “blowout” or “well control” in the publication title or in the Internet or AI Chatbot search query. Snippets of the incidents found (in chronological order) are provided in the paper but the complete list of sources (including links to available geothermal blowout videos) are also provided in the References section.

Legend: Complete Country Names: HUN – Hungary; IND – India; IDN – Indonesia; JPN – Japan; NZL – New Zealand; PHP – Philippines; TRK – Turkey; USA – United States of America.

2.1 New Zealand – 1958 and 1960

This article published in the Geothermics journal describes three blowouts that have occurred in Wairakei: at bore WK26 which blew out early in 1960, at bore WK204 later the same year, and bore WK201, which happened in 1958. The paper mentions that the location of two of these is still marked by large craters (WK201, 204), while the situation at the third (WK26) was recovered and there is now little evidence of the events that took place. None of the blowouts resulted in loss of life, but all provided learning experiences and had a substantial influence on subsequent geothermal drilling practices at Wairakei and elsewhere in New Zealand. (Bolton, Hunt, King, & Thompson, 2009)

A Ministry of Works video on WK204, the 'Rogue Bore' of the Wairakei Geothermal Field has been uploaded by user DamageIncNZ and is available on YouTube, the link to which is provided in the References. (DamageIncNZ, 2015)

2.2 USA - California - 1976

The effects of the blowout of Union Oil Company geothermal well "G.D.C." 65-28 are described, photographed, and diagrammed in this paper. Attempts to control the well are also described. This well, like over 50 percent of the wells drilled at The Geysers, was sited on a Quaternary landslide, according to the authors, and an attempt was made to determine whether or not the well blew out as a result of renewed movements on the old slide. (Bacon, 1976)

2.3 USA – California - 1983

This paper describes the drilling of a relief well Thermal 15 in the Thermal Shallow Reservoir in the Geysers, which was drilled in November, 1983, to a total depth of 700 feet. A steam entry encountered at 490 feet was found to communicate with the high permeability upflow zone of the Thermal Shallow Reservoir. A low-flowrate, higher-pressure steam entry at 600 feet was not detected while drilling but was indicated during a subsequent spinner survey. The pressure, flowrate, and enthalpy of the five wells completed in the upflow zone, including the Thermal 4 blowout, were monitored and recorded over a four month period before, during and after Thermal 15 was drilled. It was found that the Thermal 4 blowout communicates with the upper flow zone of the Thermal Shallow Reservoir, the Thermal 4 flowrate is controlled by the shallow reservoir pressure, and the high permeability of the upflow zone allows such strong interference effects that three of the four commercial production wells will maximize production from this reservoir. (Mogen & Maney, 1985)

2.4 USA - Utah - 1983

This GRC Transactions paper describes the capping of a geothermal blowout near Cove Fort, Utah. The blowout occurred on October 24, 1983, and was considered uncontrollable after four days of attempts by the drilling crew to cool and cement the well. Well control specialists arrived on October 29th, 1983 to establish procedures for containment of the blowout. Upon arrival to the rig site, it was estimated that the flow rate through the 20" conductor casing was 800 ft/sec, with an estimated minimum of 100 ppm hydrogen sulfide. Attempts had been made to measure the temperature of the 97% steam and H2S mixture, with the result being the destruction of a 400 F temperature probe. Steam temperature was estimated to be between 400°F and 600°F. The initial step, in order to control the well, was the removal of the drilling rig, followed by putting in place

surface casing support for the installation of blowout prevention equipment. Wellbore stability was then established followed by the cementing and plugging of the well. (Gray & Gass, 1984)

2.5 USA - Nevada - 1989

This publication focuses on Ormat's 14-6 well that blew out near Fallon, Nevada, on January 1989. The well was drilled using the same drilling program followed on other field wells. However, an unexpected fault caused severe lost circulation, and eventually, the well blew out. The nature of the problems required a combination of surface and subsurface well control techniques. Time was important because the well was flowing 5,000 gpm of 350°F geothermally heated water. (Adams & Thomson, 1989)

2.6 USA - Hawaii - 1991

In June 1991, a high-pressure high-temperature geothermal well, KS-8, being drilled by the Puna Geothermal Venture located in Hawaii kicked and unloaded at 3,476 ft (1,059 m). This well was estimated to have a possible bottomhole temperature of 650°F (343°C) and a reservoir pressure approaching 2,300 psi (15,858 kPa). (Rickard, et al., 1995)

After the well blew out, Hawaii state officials ordered a halt to all drilling. The incident routed 75 people from their homes on the island of Hawaii. The state Department of Health and the county ordered the company to stop drilling while the incident was investigated. (Essoyan, 1991)

Immediate attempts to kill the well were unsuccessful, and the long process of well control was started. Several attempts to kill the well over the next 2 weeks were unsuccessful. The volume of water required to cool the well necessitated drilling a water well. Specialists in the area of well control began transporting snubbing equipment and personnel to Hawaii and their snubbing operation was critical in the final kill operation. (Rickard, et al., 1995)

2.7 Philippines - 2003

This paper describes a blowout that occurred on PNOC-EDC Well 5R-12D, which was drilled as a reinjection well in pad 5R4 of the Malitbog sector to augment the injection capacity of the 231 MW Malitbog Visayan Geothermal Power Corporation (VGPC) power plant. The well was spudded on July 19, 2003 and its 610 mm surface casing was set at 110m. Drilling of the 533 mm hole proceeded normally until partial and subsequently total circulation loss (TLC) was encountered, and blind drilling using water was performed until 450 m. After pullout of the string to 106 m, the well kicked. The annular preventer was closed while the excess pressure was bled off through the bleed line. Water was then pumped through the string at 37 li/s but apparently this was insufficient to quench the well. After a few minutes, steam was noticed coming up in the cellar area. Additional water was pumped in the annulus through the connected cementing lines at 26 li/s. The steam discharge intensified, forming a mushroom-like cloud that rose some 50 m above the well, and thereafter, spewing mud, soil and rocks. A crater structure soon developed around the concrete cellar area that made the whole rig fall on its side after 8 hours of continuous and uncontrolled discharge. (Herras, Caranto, & Palma, 2004)

Another paper on a related topic documents how PNOC-EDC drilled Well 5R-13D, the first geothermal relief well in the Philippines. Well 5R-13D is probably the only relief well in the geothermal industry drilled using a single shot directional survey system. This well was designed

to relieve the pressure of the uncompleted Well 5R-12D that blew out and toppled down the drilling rig on top of it after encountering a shallow pressurized two-phase zone at 450m estimated at about 4 MPa. Early completion of Well 5R-13D was very important to control the environmental, social and economic impact brought about by the continuous discharge. In spite of the various drilling constraints like the proximity of the drilling pad against the main geologic fault prompting a revised welltrack, the non-utilization of MWD tools and time constraints, Well 5R-13D successfully intersected and quenched Well 5R-12D. As an added bonus, the completion test results suggest that this well can even be utilized as a production well. To fully seal off the formerly discharging Well 5R-12D at surface, a series of cement plugs were set through its cut-off casing. (Jumawan, Mendita, Aguilar, Belista, & Retuya, 2005)

2.8 Hungary - 2010

This paper describes the existence of a high temperature and highly over-pressured geothermal reservoir that was proven during a steam blowout in Fabiansebestyen, South-eastern Hungary. The pressure balance of the drilling mud broke down during an incorrect drilling operation. An intensive inflow took place from a fractured dolomite reservoir at 3880m depth. The pressure of the reservoir was 73.1 MPa, its temperature was 199.6°C. The abrupt pressure increase pushed the drill collar to the blowout preventer, seriously damaging the safety valve. The blowout displaced the mud from the borehole and in a very short time it developed into a steam blowout. The blowout held constant for 46 days until staff succeeded in sealing the well. The mathematical model of the blowout is also presented in the paper. (Toth, 2010)

2.9 Japan - 2010

The Onikobe single-flash steam turbine geothermal power plant in Japan has been supplying electricity to the grid for 36 years. Numerous natural geothermal manifestations were present in the field prior to development. New fumaroles accompanied by hot liquid discharges spontaneously appeared near Well 128 on 8 September 2010. The new features were monitored carefully – the manifestations intensified abruptly on 8 October, and engulfed Well 128 the same day. The fumaroles continued to grow until a large scale steam explosion occurred on 17 October 2010. A crater-lake formed and the Well 128 wellhead became submerged in hot water. After the steam explosion, steam and water continued flowing from the crater-lake. Fluid sampling was performed using a radio-controlled helicopter, and results of the chemical analysis of the fluid showed that the fluid in the crater was identical to production well 128 fluid. This suggests that Well 128 was damaged by the steam explosion incident, and that the residual flow from the crater-lake afterwards could be due to a casing failure in Well 128. This paper describes the sequence of crater-lake events and relief well drilling which finally succeeded in killing and plugging Well 128. (Takizawa, et al., 2013)

2.10 Turkey - 2010

Alasehir is the most important geothermal site in western part of Turkey. Many geothermal wells have been drilled in Alasehir Plain to produce the geothermal fluid from the deep reservoir in the last 10 years. A blowout accident happened during a geothermal well drilling operation in Alasehir Plain, and significant amount of geothermal fluid surfaced out along the fault zone in three locations. When drilling string entered the reservoir rock about 1000 m, blowout occurred. As the well head preventer system was closed because of the blowout, high-pressure fluid surfaced out

along the fault zone cutting the Neogene formation. In order to understand the geothermal fluid effects on groundwater chemistry, physical and chemical compositions of local cold groundwater were monitored from May 2012 to September 2014 in the study area. The geothermal fluid was found to be of Na–HCO3 water type, and especially, arsenic and boron concentrations reached levels as high as 3 and 127 mg/L, respectively. The concentrations of arsenic and boron in the geothermal fluid and groundwater exceeded the maximum allowable limits given in the national and international standards for drinking water quality. (Rabet, Simsek, Baba, & Murathan, 2016) Another related study by Timur intended to determine contaminated area in Alesehir by using magnetic susceptibility measurements for the surface and VLF-R method for underground layers. (Timur, 2013)

2.11 USA - Nevada - 2010

This news article mentioned that a legislative audit in Nevada mentioned that there was a 2010 incident where geothermal fluids and steam temporarily flowed uncontrollably on the surface. No one was hurt during the incident. The audit also provided information on oil and geothermal production in Nevada. In 2012, 2.4 million megawatt hours of electricity were provided by Nevada geothermal wells, mostly found in Churchill and Washoe counties, enough to power 219,000 homes. (Vogel, 2014)

2.12 USA - California - 2014

This news article reported that an Ormat geothermal well north of Brawley blew out in May 2014. It was described as a blown well head at the Ormat geothermal plant north of Brawley and it was still shooting into the air uncontrolled when the article was published by the local news outlet. It did not appear that anyone was injured. (Imperial Valley Press, 2014)

2.13 Indonesia - 2016

This technical paper documents capping job activities in three geothermal wells that were done successfully in Indonesia, at a PT. Pertamina Geothermal Energy (PGE) location in Cluster-A Hululais Field. A landslide in Bukit Beriti 2 km away from the location of Hululais-A had damaged three production wells that broke all of the wellheads. In order to prevent more severe effects, immediate and effective well control action was taken. Before the capping job was conducted, clearing work was done, and an appropriate well control method was then selected based on the actual condition of each well, before the capping job was successfully carried out using the BOP method. (Toni, et al., 2017)

2.14 Indonesia - 2018-2019

Wayang Windu geothermal field in Indonesia completed a drilling campaign in 2020 in order to maintain full generation of unit 1 and unit 2 at 277 MW. Four new makeup wells were drilled from two different pads, MBA pad and MBD pad, with two wells drilled in each pad. Two of the four wells drilled had well control events that occurred in different wells and pads. The sequence of well control events were recorded and documented clearly from initial condition until well is safely secured, through combination of down hole pressure and temperature sensors installed in Measure While Drilling (MWD) tool as well as surface pressure, temperature and flow sensors installed in surface line. Some of takeaways from well control events are as follows: (1) In total losses condition, well control events can be grouped into two conditions, steam flow from above and

below the head liquid column; (2) Steam flow from above the head liquid column may occur due to the hydrostatic column drops below steam feed zone that allows saturation condition to occur and fluids flashing into steam; (3) Steam flow from below the head liquid column may occur due to the wellbore hydrostatic pressure drops significantly that leads to an underbalanced condition relative to the formation pressure. This allows hot fluid circulation from deeper depth and flashing at surface; (4) Continuous water supply is safeguard for well control risk and water supply shall be tested prior to spud in and maintain back up water storage full all the time. (Souvanir, Putra, & Darmawan, 2021)

2.15 Indonesia - 2020

This news article from ThinkGeoEnergy mentions that PT Medco Energi has shared details on a recent well steam kick out at its Blawan Ijen geothermal project in East Java, Indonesia. The incident occured on April 24, 2020 and has since been contained and the well is under control again. PT Medco Cahaya Geothermal (MCG) is a joint venture company between of PT Medco Power Indonesia and PT Ormat Geothermal Power informed that there has been a steam kick during the drilling of IJN 6-1 well at IJEN PLTP project located in Blawan Ijen, East Java. This steam kick occurred during the time of drilling at IJN 6-1 entering a shallow depth high temperature steam reservoir at 630 m.The BOP functioned properly during the incident, however due to the increase of the pressure and temperature of the well, steam flowed to the surface. AS of publication, MCG is still working to manage the steam kick and stabilizing the well by pumping heavy drilling mud and it is expected the situation will be stabilized soon. The incident has been reported and coordinated with the related government body, local authorities and socialized with local communities. (Richter, 2020)

2.16 India 2022

This news article by the DownToEarth website mentions that the Oil and Natural Gas Corporation Energy Centre (OECT) and the Iceland Geosurvey (ISOR), which have signed a memorandum of understanding (MoU) for developing a geothermal plant in Puga, Ladakh, have termed a recent accident at the site as a ‘freak incident’ and that they have also said the geothermal fluid that leaked from the ground and flowed into the Puga nullah, a tributary of the Indus, was benign. (Patil, 2022)

The article also mentions that Ravi, the director-general of OECT, told media in Leh August 31, 2022 that the team at the site had encountered a shallow reservoir at a high temperature of 120-130 degrees Celsius while drilling between August 4 and 9. The team immediately stopped the drilling at a depth of 39 metres depth. Further drilling required cooling the shallow reservoir. Due to heavy rain on August 16, the power supply from the grid needed for cooling failed. There was a delay of 20 minutes in restoring the power supply and this is when a blowout occurred. The ONGC has now closed the borehole and is all set to conduct further exploratory drilling at a different location on the same 5 hectares of land in the Puga hot spring area that has been granted wildlife clearance by the state board for wildlife. (Patil, 2022)

A video of a ground report by ThePrint's Simrin Sirur & Praveen Jain tracks the Ladakh renewable energy project's challenges & prospects. The link to the video is provided in References. (ThePrint, 2022)

2.17 Japan 2023

This news article from Kyodo News mentions that four people have so far complained of illness in a town near Hokkaido's Niseko mountain resort after steam erupted during drilling for a geothermal energy development project, Mitsui Oil Exploration Co. said. Hydrogen sulfide at the site in Rankoshi and a high level of arsenic in water collected in a nearby area were detected. Mitsui Oil began drilling on June 25 to survey the potential resource, and the steam erupted four days later. According to the company and the town, the arsenic level detected from the nearby water was 1,590 times higher than the standard for drinking water and 318 times higher than that for water for agricultural use. Mitsui Oil has been disposing of water accumulated at the site of the steam eruption by dumping it in an area approximately 500 meters away from a pond known for being a tourist site, according to a company official. At a press conference in Rankoshi, Mitsui Oil President Hidenori Harada stated that the Hokkaido government has instructed the company to cease dumping water outside the site. However, it is expected to take approximately two weeks to construct a pipeline that will redirect the accumulated water to a well about 1 kilometer away. (Kyodo News, 2023) (Kombrink, 2023)

3. Well Control Considerations for Future Geothermal Development

Given the increasing geological and geographical distribution of geothermal projects, the introduction of new well architectures and advanced drilling technologies and the drive towards hotter supercritical geothermal reservoirs to achieve greater global energy contribution and scale, an assessment of the well control and blowout contingency considerations unique to the geothermal industry is needed.

3.1 Hydrothermal

3.1.1 BOPE for Mining Drilling Equipment Used Geothermal Drilling Operations

All drilling operations inside the geothermal environment, including mining drilling, have the same risk on the well control side. Well control equipment is normally not required in mineral/mining drilling exploration, but for some mineral coring operation that intersect a geothermal area, high temperature of water/steam and/or gases could be encountered during the drilling operation. Irwansyah et al (2021) stipulates that in order to safely conduct drilling, we need to consider the use of well control equipment for mineral/mining drilling operations in geothermal areas. For the application of the geothermal well control to mining drilling operations, the mining well schematic should be modified. There are two additional sections that have to be drilled with 9-1/2” and 6-1/2” IADC bits. Those additional sections will support the installation of a 7-1/16” diverter, thus ensuring the safety of the mining drilling operation. Then the mining drilling can be continued for the rest of the section by installing IPI (inflatable packer). (Irwansyah, Gilang, Augustino, Adityatama, & Wiharlan, 2021)

3.1.2 Kick Detection and Temperature Management

The Sandia Handbook of Best Practices for Geothermal Drilling mentions that better methods for inflow and returns metering are available, and if well control is expected to be an issue, these methods should be investigated. Other indicators of impending flow from the well are the influx of gas, rapid rise in the temperature of returning fluids and encountering rapid drilling, particularly if associated with a loss of returns. It adds that as in many contexts, prevention of a problem is

more efficient than a cure and a number of methods are available to estimate the wellbore temperature profile and warn that a problem may be near: comparison of drilling fluid inflow and outflow temperatures; maximum-reading thermometers either run just above the bit or lowered through the drill pipe on a wireline; or onboard logging tools that can transmit temperature data in real time, as it is always important to know as much as possible about the downhole environment. (Finger & Blankenship, 2010) Technologies for early kick detection and inflow and returns flow and temperature measurement have already been partly deployed in geothermal settings through managed pressure drilling (MPD) methods. (Weatherford, 2024)

3.2 Enhanced and Advanced Geothermal Systems

3.2.1 BOPE for Big-Bore Wells

Deeper and hotter plays and requirements for bigger wellbores to be able to increase the commercial viability of geothermal development projects. Well architectures associated with new geothermal technologies are increasingly requiring larger BOP equipment to be able to deliver the volumes of steam required while drilling fewer wells for their projects. However, BOP systems available in inventory that are mostly geared towards oil and gas applications do not usually go as large as those that are required by the geothermal big-bore designs (17-1/2" or larger), thereby possibly putting a constraint on implementing future EGS / AGS / ACL projects because of the very limited number of larger BOP systems available, unless more of these BOP systems will be manufactured by BOP systems providers.

3.3 Oil and Gas Well Conversion to Geothermal

3.3.1 Well Control Considerations for Both Geothermal / Oil & Gas

Finger and Blankenship (2010) mention that there are geothermal fields (such as Cooper Basin, in South Australia) in which hydrocarbon resources are also found and that this, of course, means that well control procedures and equipment must be capable of handing the somewhat different characteristics of both drilling environments. With the advent of "geothermal everywhere", and initiatives to be able to convert legacy oil and gas assets into geothermal systems, especially in existing petroleum basins, it is important that both the geothermal and oil and gas aspects of well control be properly taken into consideration when planning operations in these hybrid environments.

3.4 Supercritical Geothermal Systems

3.4.1 BOPE Elastomer Seals Good For 260°C

The Sandia Handbook of Best Practices for Geothermal Drilling states that though there will usually be detailed local regulatory requirements for the BOPE the critical factors are to make sure that the BOP pressure rating is adequate and that all the elastomer seals in the equipment are qualified for high temperature. It mentions that most BOPE are dressed with the normal temperature rubbers, which have a working temperature limit of 121°C, because of the high cost and limited availability of high temperature BOP rubbers. It adds that even dressing the BOP's with high temperature rubbers may not provide adequate safety, as they have a working temperature limit of 177°C and as pressures increase when circulating out a high temperature kick, even these higher temperatures can be exceeded. For this reason, a cooling line should be

connected below the pipe rams to pump cool water down through the inside of the BOP and out the choke line during a kill operation, if the temperature might exceed the working temperature of the BOPE. (Finger & Blankenship, 2010)

The high temperature capability of elastomeric sealing elements used in ram type blowout preventers was being addressed by a research project described in a paper by Parker (1995) that require that they must be capable of operating in steam and brine up to 500°F (260°C). Typical well drilling equipment used for oil and gas drilling is designed to operate up to 250°F and under special conditions up to 350°F. The paper reports on the final phase of a joint development project in which high temperature elastomers were tested in ram type BOPs under geothermal conditions. Tests were conducted at ENECs Secolo #1 geothermal well near Larderello, Italy in the period from November 1990 to April 1991. The final phase testing demonstrated improved high temperature elastomer compounds and specially designed ram packer plates would permit operation at 425°F and 1800 psi for significantly longer periods of time than the test goal of 54 hours. (Parker, 1995)

4. Conclusion

The incident case studies and considerations for future development highlight that geothermal well control can be a complex topic, but it is clearly critical to a successful geothermal drilling operation so a holistic approach to well control should be adopted. As such, well-control engineering and procedures and risk management should be part of well planning, so that the proper casing design is developed during the planning stage. Careful planning, modeling and execution of geothermal projects should also comprise a robust well control contingency plan. Sound engineering, multi-disciplinary engineering design, and analysis will ensure a successful outcome. It is essential that proper well control preparations be established and crews will be familiar with them when drilling begins so that rig crews be trained to react quickly and appropriately to an unexpected event that might jeopardize the well.

Given the rapidly increasing volume of geothermal wells being drilled globally of the natural and man-made reservoir type as well as the intention of geothermal operating companies to drill larger, deeper and hotter wells to improve the commercial viability of geothermal energy, it is important that the industry be made aware of the potential catastrophic impact of a major geothermal blowout and mitigate against or prepare for it. Failure to do so might squander the immense gains of the global renaissance that the resurgent and expanding geothermal industry is experiencing.

Revolutionising Geothermal Well Design and Operations with High-Temperature Metal Expandable Packer Technology: A Novel Approach in Drilling and Workover

Joven John Cayao[1] and Alger Danielle Ballon[2]

Welltec A/S[1] and Geological Society of the Philippines[2]

Keywords

Metal Expandable Packer (MEP), relining, tieback, low-pH wells

ABSTRACT

The unique differences between geothermal and oil and gas wells require a tailored approach to well design, aimed at extending the lifespan of geothermal wells and addressing the critical challenges of operating mature geothermal fields. Oftentimes, geothermal wells have to intersect faults and other complex lithologies to maximize production. As a result, partial to massive losses lead to uncertainties in cementing operations and cement quality.

In some cases, channeling, development of micro-annulus, and cement degradation result in compromised well integrity and declining production. To address these integrity issues that shorten the effective life-of-well, a workover must be executed in a cost-effective way while ensuring that wells remain safe, efficient, and profitable to operate.

Welltec and a geothermal operator in the Philippines have worked together to address these challenges in four geothermal production wells in need of workover due to collapsed and parted casing within the 13-3/8” casing. A conventional workover by which wells are relined using a bridge plug was deemed unsuitable as drilling out the plug and chasing the debris to bottom could cause further damage to the liners subjected to low pH fluids. Furthermore, the risk of trapped fluid could lead to another casing failure. Thus, the solution requires a certain degree of cementing and control to achieve casing integrity.

This paper presents a solution design featuring high-temperature Metal Expandable Packer (MEP) technology and second stage cementing collar/s, and its application in case studies involving a geothermal production field in Leyte, Philippines. The study focuses on how MEP technology enables the reinstatement of well integrity without the need for a drill-out run.

By applying the learnings from previous deployments, the improved MEP facilitates long-string tieback and relining to ~1,300 meters, which was previously deemed unfeasible due to collapse issues, limiting deployment to depths of ~700 meters.

Designs for upcoming new corrosion-resistant-alloy (CRA) wells have been reviewed and evaluated to overcome very acidic environments.

These wells require immediate relining of production casings as part of the improvements from previously drilled CRA wells in the same sector and would utilize the MEP to avoid damaging the CRA casings during drill out of plugs.

This new design and strategy to include MEP technology in workover and drilling situations can be adapted to mitigate integrity issues resulting in premature failure, and extend the effective life of geothermal wells. This innovative drilling technology designed specifically for geothermal wells provides a pathway to greater repeatability, safety, and control to effectively harness geothermal resources.

1. Introduction

Channeling, development of micro-annulus, and cement degradation result in compromised well integrity and declining production (Jimenez, 2022). Challenges in maintaining the integrity of the wells in one of the major fields of a geothermal operator in the Philippines were related to having poor casing cementing jobs (i.e. channeling and the development of micro-annulus) and the extreme temperature cycles (i.e. cement degradation and casing collapse/break due to cyclic loading). These challenges, coupled with the low pH reservoir fluids, made the conventional relining method through the use of a bridge plug unsuitable as drilling out the bridge plug and chasing the debris to the bottom through the perforated/slotted production liners could cause further damage to the liners that were embrittled by the low pH reservoir fluids.

The objective of this paper is to illustrate the method in conducting long relining operations on wells with compromised well integrity due to shallow collapsed casing and casing breaks within the 13-⅜" production casing interval, with deep production casing setting depths (i.e. 1,400 meters and deeper) using Metal Expandable Packer (MEP) and port collar.

The long relining concept, utilizing the MEP and port collar, was developed to address the challenge of relining deep production casings. This approach reduces the installation costs of corrosion-resistant alloy liners by allowing them to be set conventionally with three liner joints overlapping the production casing shoe, rather than using the current design that requires a long composite casing string with the top-of-liner at a depth of 700 to 800 meters. However, this solution also brought forth challenges, mainly pertaining to having a good reline cementing job. The high temperature delta from the MEP setting depth, the high pumping pressure of cement volumes that pose risks to the casing integrity in terms of the burst and collapse rating, as well as the capacity of the MEP needs to be addressed to make this concept viable for operation.

2. Methods, Design and Technology

2.1 Well Design

Relining with cementing is usually undertaken to address casing problems in the 9-5⁄8" production casing in instances of regular-sized holes and 13-⅜" casing in instances of big holes. The conventional practice is to run a bridge plug and set it just above the top-of-liner to isolate the production casing during the relining/tieback casing-cementing operation. Since the traditional bridge plug is not retrievable, this would entail drilling out the plug and chasing the debris to the bottom of the perforated liners.

The minimum reline setting depth is determined by the expected reservoir pressure. However, the current workover design on low pH wells is venturing on long relines to ensure that the whole production casing will be repaired.

2.2 Design Approach

Driven by the increasing associated costs of drilling a new well and the risk of compromising the integrity of the well while conducting a workover, the geothermal industry has always tried to optimize the design and strategy in repairing geothermal wells. Due to the extreme conditions, such as high temperature cycling whereby a well can be cooled down to ~40 °C and heated up to ~350 °C during production, a proper cement job is deemed critical to ensure that there will be no trapped fluid that could result in annular pressure build up and casing collapse. An innovative MEP technology has been designed and engineered specifically for geothermal well construction and workover applications.

This MEP provides enhanced integrity via a metal expansion sleeve mounted onto the liner / casing, set hydraulically to create an annular seal within minutes. The technology, with its design, also allows rotation during deployment, making it easier to reach the target depth without the risk of prematurely setting the packer.

Being utilized in oil and gas for more than a decade, the MEP can function not only as an independent barrier, but also in conjunction with cement as a supplementary annular barrier proven by successful deployments in the past with the same operator utilizing a high-temperature MEP.

However, this has been limited to shallow relining whereby setting depths were not more than ~780mMD. This improved approach to geothermal relining will pave the way to a workover program that will make long relining feasible. These optimizations can be achieved by introducing a thermally robust MEP technology with the ability to withstand high temperature and highly corrosive fluids while providing a V0 qualified seal.

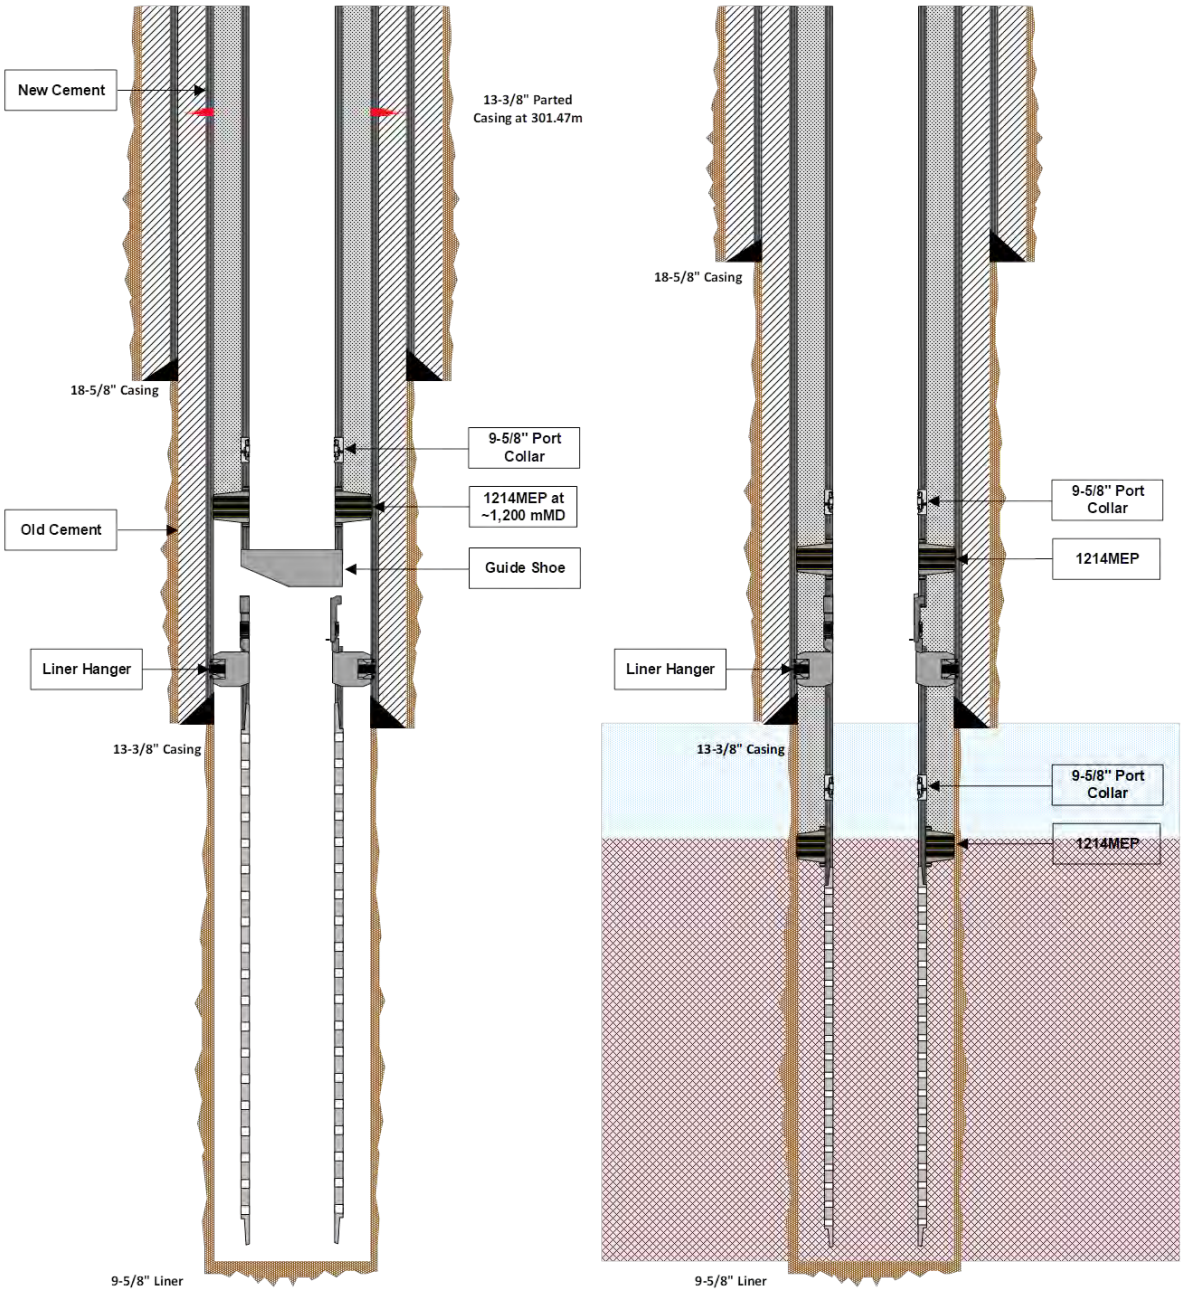

Figure 1 (Left): Well configuration using the MEP and port collar for Workover Operations.
Figure 2 (Right): Well configuration using the MEP and port collar for Drilling Operations.

All these improvements in eliminating the dedicated drill-out run during well relining can be achieved by introducing thermally robust MEP technology with the ability to withstand temperatures in excess of 300°C – this technology provides a reliable, high-integrity zonal isolation element to function as a fixed part of the well construction. A two-stage cement port collar also needs to be utilized and positioned above the MEP for cementing operations.

Simulations during the design phase showed that there is a risk of trapped fluid between the cement port collar and the MEP. Despite the MEP being rated at 6,000 psi differential pressure, the trapped fluid poses a risk to the reline casing between the two tools. To mitigate this risk, rupture disks, which serve as a pressure relief device, are incorporated in the design, and installed between the MEP and the cement port collar. This allows greater control of the well ensuring better efficiency throughout its life.

A valve block system is incorporated in the design of the MEP enabling higher differential pressure rating. In addition to this, and to complement the two burst disks installed, a rupture disk was also incorporated in the valve block system to relieve any fluid that may be trapped between the base

pipe and the MEP expansion sleeve.

With the ability of the MEP to hold the aforementioned differential pressure and the design optimization implemented, a long relining with depths ranging from ~1,000mTVD to ~2,200mTVD are deemed feasible.

2.3 Initial Operations Planning

As the design is flexible enough to address issues in both new and old wells, careful and detailed planning must be done to address the issues of each.

For wells where casing integrity is almost absolute, like newly drilled ones, tieback or casing relining can immediately proceed without conducting any diagnostics. However, in instances where wells are challenged with abrasive or extremely acidic fluids such as in low pH wells, it is recommended to perform caliper logging to ensure that the MEP will be set in a competent casing.

An MEP can be set in an open or cased hole with and have the ability to conform with the shape of the hole it is being set in. However, in the event that the casing is extremely compromised leaving channeling behind, a caliper log coupled with pressure-temperature spinner survey to detect leaks and diagnose the well will help in ensuring the objective is met.

Furthermore, in cases where a cold zone is identified and cannot be cased off by the previous casing, the same MEP configuration can also be set in an open hole and seal off the cold zone preventing the production of the well to be compromised.

3. Conclusion

For decades, the geothermal drilling industry has relied on drillable plug in addressing the relining requirements of the wells. Until recently, the strategic options of drilling and well engineers were limited to drillable solutions that often resulted in further damage and reduced life-of-well.

As this paper demonstrates, the novel MEP features an innovative and flexible design enabling it to be used in drilling and workover applications for both open and cased hole while addressing the risks associated with cementing. The MEP, which serves as a pressure-tight base to prevent cement contamination, and the cement port collar for stage cementing, brought about a solution design that completely eliminates the dedicated drill out run after a cement job, thereby reinstating well integrity while delivering rig time savings and the ability to accelerate the production.

The rupture disks combined with the unique valve block system facilitate long relining requirements without the need to use multiple packers and cement port collars allowing flexibility during the initial well construction, providing an efficient and economical solution.

Despite the thermal cycles adding extra strain and the challenging well conditions, the varied range of seals and valve block configurations that can be utilized make the MEP one of the primary options in relining and tieback applications, especially for low pH geothermal wells. The robust nature of MEP technology and its anchoring capability at high temperature makes it ideal for geothermal applications.

With the understanding of the criticality to maintain the integrity and prolong the life of geothermal wells, this new design and strategy in the workover and drilling of new wells can be adapted to mitigate well integrity issues otherwise resulting in premature failure and shorter effective life-of-well. Furthermore, this innovative drilling technology designed specifically for geothermal wells provides a pathway to greater repeatability, safety, and control to allow the operators to effectively harness geothermal resources.

The actual deployment of this solution is scheduled for H2 of 2024.

Breaking the 200°C Barrier – Development of an Integrated High Temperature Directional Drilling System

John Clegg, Peter Harvey, Steve Krase and Matthew White

Hephae Energy Technology Corp

Keywords

EGS, AGS, unconventional, high temperature, electronics, cooling, MWD, RSS.

ABSTRACT

So-called “unconventional” geothermal wells, also known as “EGS” (Enhanced Geothermal System) and “AGS” (Advanced Geothermal System) wells, are increasingly being funded and are starting to be drilled in large numbers. For understandable reasons, initial projects have been drilled at temperatures similar to those found in hotter oil and gas wells – initial EGS and AGS projects have been drilled at temperatures below 175°C in order to take advantage of existing oil and gas drilling technologies that have been developed to operate under those conditions.

However, because unconventional geothermal wells are drilled for heat, not hydrocarbons, an arbitrary temperature limit based on what was an appropriate specification for a different industry makes no sense. This is particularly true because, as will be demonstrated in the paper, there is a strong correlation between temperature of the reservoir and economic performance of an asset.

Further, although we cannot yet be certain which of the many proposed designs for EGS and/or AGS will ultimately prevail, almost without exception the pilots being drilled and the projects being proposed rely for their performance on accurately drilled horizontal wells, often pairs or multiples of wells drilled closely together, sometimes at a given offset and sometimes even intersecting. This requires a high degree of accuracy and control when drilling and therefore strongly suggests that the technologies used for drilling horizontal and extended reach wells has a place in geothermal drilling – if only it could be made to work reliably at higher temperatures. Ideally the temperatures limits of those technologies could be increased to beyond 200°C and ultimately as high as 300°C.

Unfortunately, although the oil and gas industry has made great strides over the years in getting the operating temperature of downhole electronics from below 100°C to 175°C, and, even on rare

occasions, to 200°C, the approaches taken in oil and gas tools do not lend themselves to getting to the even higher temperatures that unconventional geothermal will need.

This paper describes a unique, blank sheet of paper, approach to the design and packaging of electronics and sensors, to create a brand-new tool that combines the functions of Measurement While Drilling (MWD) and Rotary Steerable Systems (RSS) and which will be able to break that 200°C barrier.

It describes the design decisions made and modelling done to ensure enhanced thermal performance without sacrificing any of the resistance to shock and vibration that oil and gas tools have acquired over the years – shock and vibration being significant in the hard, high friction basement formations that EGS and AGS will most likely inhabit.

It will show the results of thermal testing and lessons learned along the way and demonstrate the viability of a fully working integrated MWD/RSS system capable of operating in the previously "forbidden" region above 200°C.

1. Introduction

As noted above, EGS and AGS pilot wells have tended to be drilled at temperatures below 200°C, and it would appear to be more than just coincidence that this is the technical limit of the directional drilling and measurement tools that have been developed over the years for the oil and gas industry. Some of the unconventional geothermal pioneers have publicly stated their desire to drill deeper and at much higher temperatures, for example Eavor (Lowdon & Hodder, 2024).

Research using the US Department of Energy Geothermal Electricity Technology Evaluation Model (GETEM) reveals the significant leverage of temperature over the economics of geothermal wells, as seen in Figure 1 below.

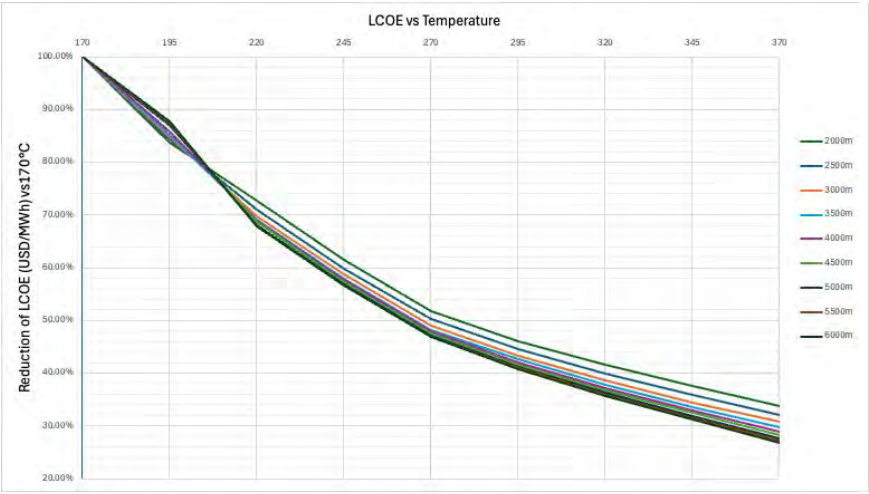

Figure 1: LCOE as a function of reservoir temperature.

Figure 1 results from modelling multiple scenarios and then normalizing for the levelized cost of electricity (LCOE) produced. What is clear is that the normalized curves follow a very consistent pattern. They show a substantial decline in LCOE as a result of temperature for the EGS systems

that we modelled using GETEM. Although the results are not shown here, increasing temperature has a similar impact on AGS system economics.

Compared with 170°C, increasing the reservoir temperature to 210°C will reduce the LCOE by approximately 25%. Increasing the reservoir temperature further to 300°C reduces LCOE by 65-75%. This reveals very powerful economic value that could be realised by drilling deeper and hotter wells.

2. The growth, and then stall, of drilling temperature capability

If we step back to the last century, when MWD tools were first introduced, the temperature ratings were driven by the rating of commercially available electronic components. In 1978, the first commercial MWD system was introduced with a temperature rating of 85°C. By 1996 a commercial MWD had been released with a temperature rating of 175°C, and others followed by 2001. So, in less than 20 years, the industry gained 90°C of capability and the ability to drill the majority of oil and gas reservoirs.

In a Journal of Petroleum Technology article written by Robin Beckwith in 2013, Baker Hughes' Robert Estes stated that 200°C is the new target: "high temperatures in the oil field seem to go in jumps of 25°C and these jumps may take 10 years". However it's been more than 10 years since that article was written and we haven't seen a 25°C jump yet.

Effectively, progress seems to have stalled since the turn of the century.

Even the apparent temperature capability of the tools that the oil and gas industry has got used to using are not necessarily all that they seem. Research based on operations in a high temperature field in North America shows that while MWD failures show a correlation with temperature, they tend to occur a long way below the 175°C temperature rating of the tools.

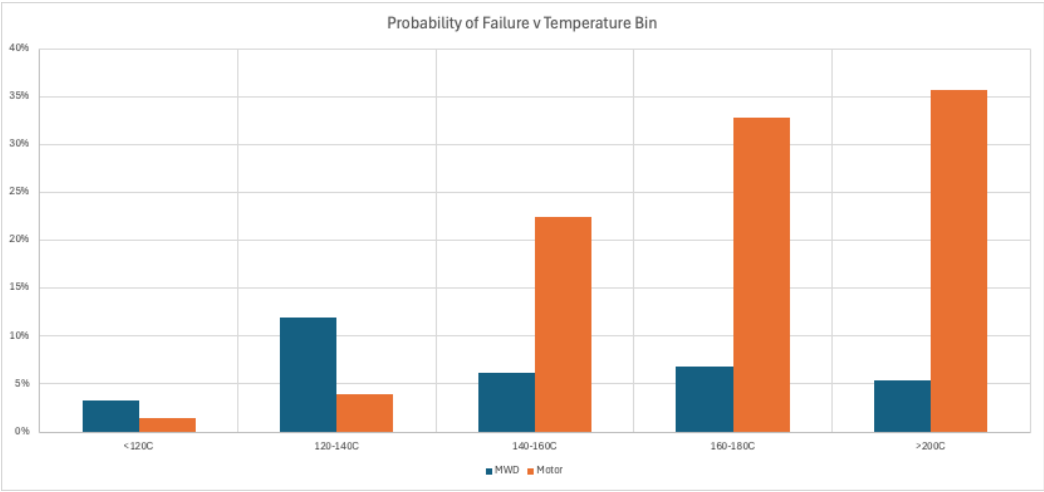

Figure 2: Probability of run terminating failure as a functional temperature.

It can be seen from figure 2 that MWD failures pick up between 120°C and 140°C. They appear to fall away above 140°C, but the reason for this is because the motors used to drill these wells, having significant elastomeric content, tend to fail in this range. These motor failures then mask MWD failures because the data plotted is based on the reason for pulling out of hole. Therefore, a

rapid motor failure could hide an incipient MWD failure. This strongly suggests that the electronics used in existing MWD and RSS tools for oil and gas drilling is going to be difficult to apply to the higher temperatures required for unconventional geothermal.

3. What about mitigating technologies?

Of course, there is a difference between the circulating temperature to which drilling tools are normally exposed and the reservoir temperature. This is because drilling mud coming from the surface tends to be cooler and picks up a limited amount of heat on its way downhole. In theory, this means that drilling equipment can be protected from the worst temperature excesses of the downhole environment.

Innovations including coated drill pipe, insulated drill pipe, and mud chillers on the surface, can enhance this effect further. Chillers can reduce the temperature of the fluid being introduced to the well and the insulated pipe can keep it colder for longer. However, there is a growing recognition that these complementary technologies are not a complete solution to high temperature drilling. A recent report produced for the Clean Air Task Force suggested that a hybrid solution incorporating mud chilling, insulated or possibly just coated pipe, and high temperature electronics would be the best way forward. This is partly because this combination will allow drilling tools rated up to 300°C to work in much deeper, super-hot reservoirs. It is also in no small part because, at risk of stating the obvious, because cooling fluids that are colder than the reservoir temperature will only keep tools cool while the mud is flowing.

Figure 3 shows mathematical modelling of the heating and cooling of an MWD tool in a high temperature well during and after a connection. The exact values have been redacted for confidentiality reasons, but the pattern is clear. During the six minutes it takes to make a connection, a tool will gain significant heat and its temperature will rise. It is possible to protect a tool against temperature rise during a connection, but any mitigation that is put in place will likely involve insulation, and the same insulation then traps the heat gained inside the tool after the connection is completed. Once circulation recommences, the rate of temperature loss is much lower than the rate at which the tool gained temperature, and it can take perhaps twenty minutes for the tool to recover to the circulating temperature. This makes it very difficult for cool mud and drill pipe installation to protect tools in deeper, hotter wells.

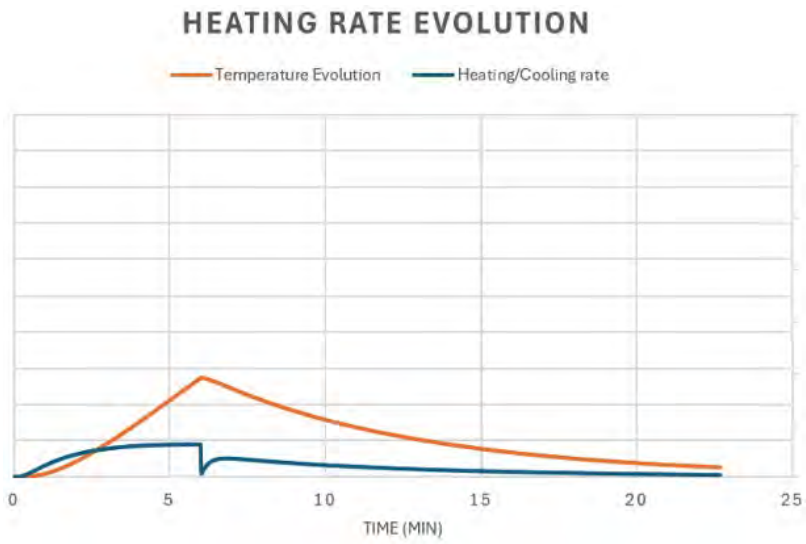

Figure 3: Temperature evolution during a connection.

A second problem is encountered when running into a hot well to get the drill bit and the bottom hole assembly (BHA) to the bottom of the hole. There is no circulation while running in hole and so any tool in the drilling assembly will be exposed to mud which has likely been heated to reservoir temperature. It is possible to mitigate this using a technique known as staging (see for example Javay *et a*l, 2020), whereby a tool is run into the hole until it approaches its temperature limit, and then fluid is temporarily circulated in order to decrease the bottom hole temperature and to cool the tool down. This process then repeats until the tool gets to bottom. It is not unusual for this to add as much as a day to operations when running into deep, hot wells. Increasing the survival temperature for the electronics and sensors on board the drilling tool would significantly reduce the amount of staging required.

Insulation of downhole tools combined with cooling has also been tried, but generally for entire systems.

One case history is DESCRAMBLE, or “DEep Super CRitical AMBients of continentaL Europe”. (Vedum et al, 2017) This project was funded by the European Union and managed by SINTEF in Oslo, Norway. It built a logging tool specified to 450°C using components rated between 200°C and 300°C in addition to a dewar type heat shield. But it was only rated for eight hours operation. It was tested in a 250°C geothermal well in Lardarello, Italy and yielded some useful insight into the behaviour of the electronic components we will need at high temperature.

Another is a logging while drilling (LWD) tool created for the IDDP-2 well in Iceland. In 2018, Stefánsson *et al* described a 300°C system which included a relatively standard, 175°C capable MWD that was put into a flask and kept cool using phase change materials. The requirement here was for 50 hours operation. There is no published record of the tool being used downhole, but the reference describes successful laboratory test results.

Both examples just shown illustrate the use of insulation and cooling systems to protect electronics. As we push for higher and higher operating temperatures, it is likely that some type of cooling will be necessary. However, it might not be necessary to cool the entire tool, as was attempted here, and the paper will return to this.

4. High temperature electronics technologies

As far as the oil and gas drilling industry is concerned, the approach to high temperature electronics has traditionally been one of screening and selection (Beckwith, 2013), whereby components that might not be rated to the operating temperature of the tool are screened to see which, and how many, of any design will survive at higher temperature. The evidence would seem to suggest that this approach cannot get us reliably beyond 200°C .

A few oil and gas manufacturers have managed to get drilling tools close to this temperature, for example Weatherford's 200°C rated logging while drilling (LWD) tool.

To get to this temperature, designers have used application specific integrated circuits (ASICs) or multi-chip modules (MCMs). These technologies can certainly help, for example MCMs offer high density for improved electrical performance with a reduced amount of substrate material. The significantly reduced size and aspect ratio of these components can also make them very effective in high shock and vibration environments.

Unfortunately this design approach can be expensive with very high non-recurring engineering (NRE) charges. This can make it hard to use them for projects where there is likely to be a low volume, for example, high temperature MWD and RSS tools.

A better approach in the short term is likely to use discrete components either selected for the temperature resistance or protected from the temperature, as this is a much more economical way of building small quantities of tools.

Materials science and pressure from other industries (notably aerospace and deep space) are driving demand for higher temperature components. Most notably, see NASA's Venus Rover program and its specification of 480°C! In the future we might expect to see fully depleted Silicon on Oxide (FD-SOI) substrates become available. This technology will lower parasitic capacitance and will significantly reduce leakage currents, and is expected to be good to 300°C with only small changes to existing manufacturing processes. It has a high Technology Readiness Level (TRL) but has historically been difficult to get in small quantities. As the industry grows, it might be possible to interest manufacturers, but this is not a solution for the next few years.

Group III to V semiconductors (based on alloys containing elements from group III and V in the periodic table) will potentially work to 500°C but these are years away from being ready for prime time.

5. A new approach to downhole, high temperature electronics

This paper will now describe a different approach to high temperature electronics.

The approach is based on three key requirements:

- Protect the assembly from the external borehole temperature
- Protect components from themselves and efficiently and quickly remove the heat that the components generate internally
- Take the rejected heat from the components to a place where it will do no harm.

Dewar, or Thermos, flasks can be used to provide protection from the external environment but can be problematic in that they prevent the internal heat from escaping. So, they must be used with care. Heat needs to be removed as well as repelled. Components do not just have to be protected from the environment – they also must be protected from themselves and the heat they generate.

A lot of thought must go into how to get heat away from the components quickly and into places where the heat will do no harm. For lower temperatures, this can be as simple as conducting it into the drilling mud flowing past the tool. For higher temperatures, other strategies may be required including cooling technologies. A board design and mounting scheme is needed that can work in either case.

Figure 4 shows a new generation, high temperature circuit board. Unlike the boards used in almost all RSS, MWD and LWD tools, it is not a long, thin rectangular shape designed to run the length of an electronics chassis or insert.

Instead, it is relatively small, and circular, and surrounded by a thermally conductive ring which serves to take the heat away rapidly as part of a “thermal superhighway”. This affords significant advantages. It means that no individual component is far from the “superhighway”. It allows for optimisation of the axial and radial location of components in the assembly. The shape of the boards promotes radial transport of heat as the effective thermal resistance reduces as the heat flows from the centre of the board.

This arrangement also means that boards can be combined in a modular architecture for thermal management (see below). And the resonant frequency of the resulting board is very high, much higher than conventional RSS/MWD/LWD boards, which will be of use in the high shock and vibration environments expected in deep geothermal wells.

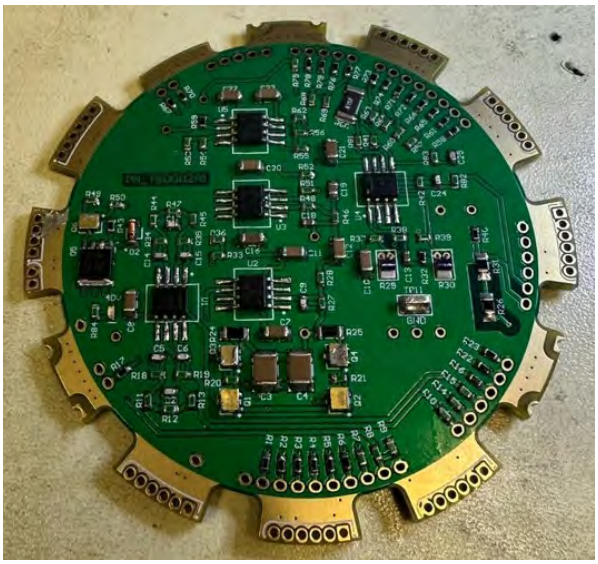

Figure 4: High temperature printed circuit board.

Individual circular boards are stacked together, a bit like potato chips in a tube, to create subassemblies of a handful of boards. The subassemblies are connected by steel rings which form the “superhighway”. Figure 5 shows how this is achieved.

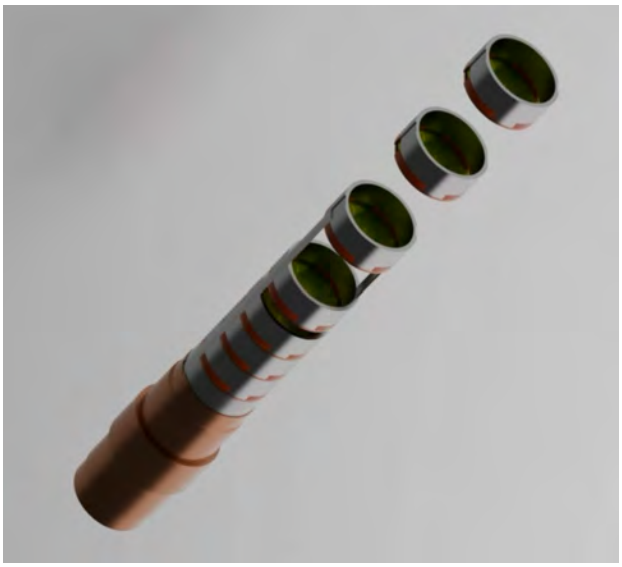

Figure 5: Stack of circular boards surrounded by "thermal superhighway".

And Figure 6 shows a close-up of an individual board with its corresponding ring element.

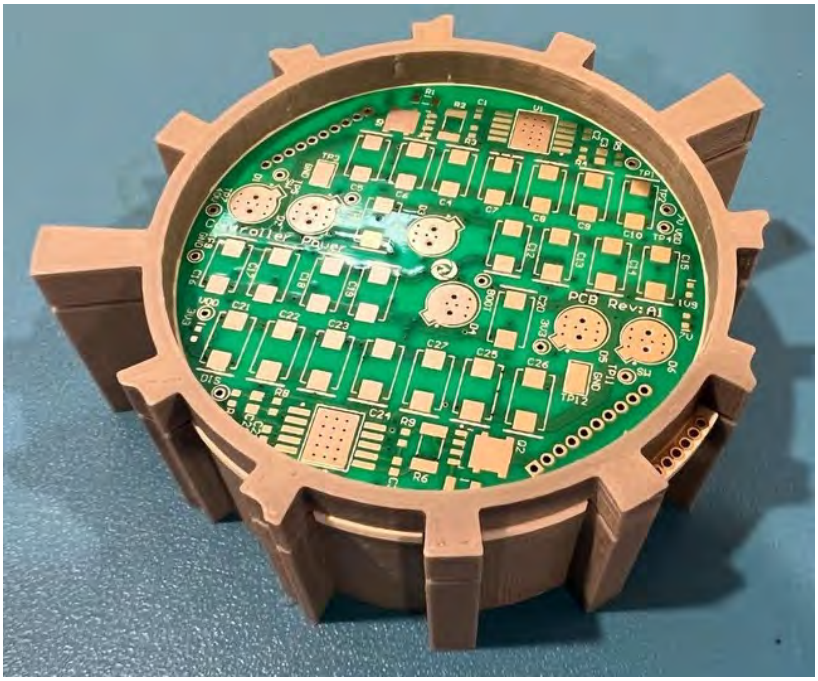

Figure 6: Individual circular board with "superhighway" ring element.

The combination of board design, materials selection and ring element design has been optimised through thermal modelling. The combination has been shown to manage the temperature of components at the centre of the board very effectively, keeping them within 2°C or less of the surrounding environment. It is worth remembering here that components have to be protected from themselves and the heat they generate. For this reason, the best that can be achieved is to get them to the same temperature as whatever medium is being used to cool them.

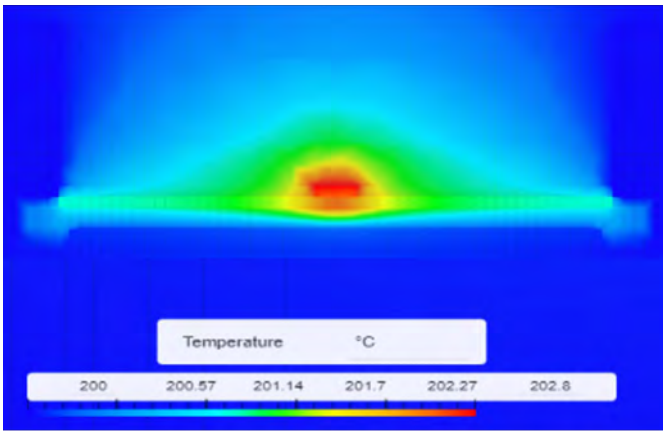

Figure 7: Thermal modelling of circuit board.

For a 210°C MWD tool, drilling mud cooling will be sufficient. Most electronic components to be used are already manufacturer rated to 210°C and the rest have successfully been repackaged in ceramic to work at higher temperatures. Test results are described in the next section.

For higher temperatures, some form of cooling will be needed. This could be by using phase change, or heat sinks, for example, but in every case the heat must be effectively transported from the board to the cooling device. The board stack described above has been designed to do this – heat generated on any board can very effectively be rejected to cooling.

Thermoelectric devices may also play a part. Thermoelectric coolers are based on a phenomenon known as the Peltier-Seebeck effect. Using this effect, heat can be removed when current is driven through a thermocouple junction. Miniature thermoelectric coolers can be placed in intimate contact with electronic devices to selectively move heat away. Currently, the reliability of commercially available devices falls off significantly at temperatures between 200°C and 220°C. Fortunately, materials developed for the space program have allowed thermoelectric devices to operate at temperatures as high as 500°C in deep space probes, which means that they could be available to us in the future.

In order for systems to remain cost effective, cooling must be used selectively. Previous projects described above have attempted to cool the whole assembly to the minimum capability of any individual component. This can work for short periods of time, however this approach can be very expensive and power hungry. An alternative approach is to build a series of small chambers and cool each to an appropriate temperature for the weakest component therein. This will avoid cooling a lot of components that do not need it and is much more efficient than maintaining the whole tool at a low temperature. The modular design described above was created with modular cooling and small chambers in mind.

6. Initial test results

Initial testing has focused on proving “the physics” for a 210°C MWD tool – that is, heat testing components and boards temperatures between 220°C and 230°C for extended periods to make sure that there are no fundamental issues there will prevent components from working – such as leakage or capacitance issues. This testing has proved successful, with components, prototype boards and downhole ready boards heat soaked at these high temperatures for over 500 hours.

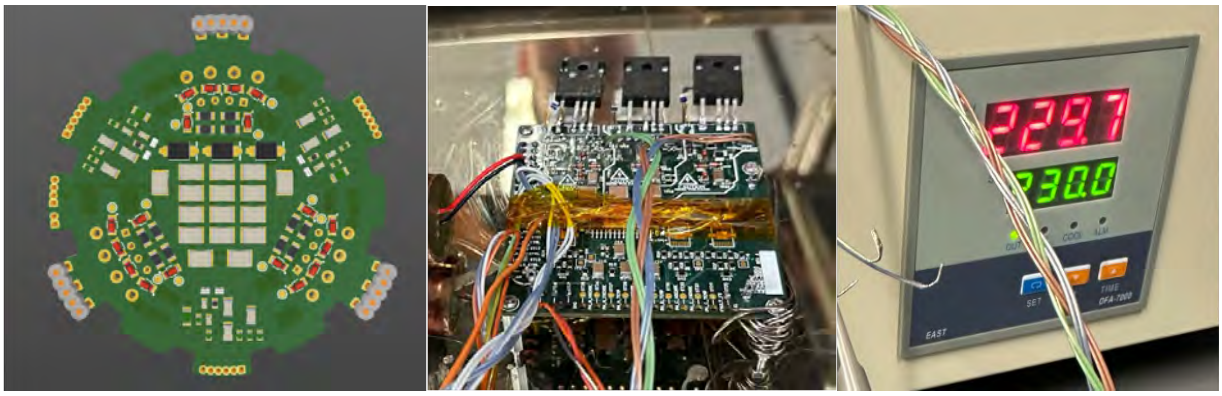

Figure 8: Three phase inverter PCB: downhole design; prototype and temperature measurement.

At the time of writing, this testing will be followed by highly accelerated life testing (HALT) of subassemblies and modules, combining temperature with shock and vibration. It will be no surprise if some issues arise during these tests, but the key point is that solving these problems is simply engineering. It doesn't require new laws of physics. Getting to reliable high temperature electronics is now simply an engineering task.

7. Conclusions

Although AGS and EGS wells have initially been drilled at wells below 200°C, developers are looking to drill much deeper and hotter, driven by substantial reductions in LCOE and improvements in economics that come with increasing temperature.

To drill the well profiles needed, the geothermal industry will need MWD and RSS tools with the ability to operate at these higher temperatures.

The temperature capability of MWD tools used in oil and gas wells grew rapidly from 85°C to 175°C at the end of the last century, but has struggled to grow since then.

Mitigating technologies like insulated drill pipe can help, but only when drilling mud is circulating. When mud circulation stops, MWD tools will heat up rapidly.

To protect electronics at high temperature, three issues need to be addressed:

- Protect the assembly from the external temperature
- Protect components from themselves by efficiently and quickly removing the internally generated heat
- Take the rejected heat to a place where it will do no harm.

A new generation of circular PCBs arranged in a stack with carefully designed thermal conductivity can address all three of these issues.

Cooling may be required for operation at high temperatures, but it is not necessary to cool the entire tool – only those components that need it.

Testing has demonstrated the ability to operate at temperatures up to and above 210°C without cooling.

Lost Circulation, Geothermal Wells, Fractures, Vugs, Viscosity, Sandstone

ABSTRACT

This paper demonstrates the effectiveness of thermally activated materials (TAMs) in managing severe to total fluid losses during geothermal (GT) well construction. The objective is to address lost circulation challenges in scenarios where conventional methods, such as the use of lost circulation pills and cement squeezes, fail to provide a satisfactory solution.

During GT drilling, severe lost circulation events frequently occur when the drilling fluid infiltrates fractured or vugular formations. The lost fluid experiences a temperature increase in the fractures and vugs due to the exposure to higher in-situ formation temperature with invasion depth. This temperature rise can be strategically utilized to seal the fractures or vugs. If TAMs are inherently present in the lost fluid, they can alter the viscosity, increasing it and making the fluid harder to displace, thereby preventing further fluid losses. This study examines the inclusion of TAMs in fluid formulations for use in targeted cement squeeze jobs.

Several types of TAMs have been identified and evaluated in different fluid formulations. To validate the effectiveness of TAMs, fracture plugging tests were conducted. Fluid formulations with TAMs were circulated through the sample, and their plugging behavior was observed and quantified. The resulting samples were then visualized using CT scans. These tests demonstrated that TAMs effectively sealed the fractures, providing robust evidence of their ability to mitigate fluid losses and the efficacy of the thermal activation mechanism. TAMs are novel materials that can be engineered to mitigate severe losses in GT wells, where lost circulation is one of the crucial challenges.

1. Introduction

High-temperature geothermal (GT) wells are being constructed more frequently due to their ability to provide reliable and sustainable energy. However, lost circulation remains one of the key factors contributing to non-productive time (NPT) in the GT well construction (Blankenship et al., 2005). When lost circulation events occur, GT drilling companies must address them before resuming drilling, which significantly increases well construction costs. These events represent up to 10 to 20% of well construction costs and sometimes even exceed 20% for exploration wells (Finger and Blankenship, 2010). The selection of remediation techniques in managing fluid losses is mostly based on trial and error (Alsaba et al., 2014) and this approach may not be ideal for GT wells due to the currently small number of wells being drilled, making it essential to get it right the first time. For example, a study conducted on fifteen GT wells in Japan revealed no clear trend between the success or failure rates of lost circulation materials with respect to depth and temperature (Hyodo et al., 2000). This lack of a definitive pattern leaves significant room for assumptions and highlights the need for a more systematic approach to address lost circulation.

In GT wells, cement squeeze jobs are commonly employed to address severe fluid losses in the formation. However, these jobs have a high failure rate, reaching up to 80% (Cole et al., 2017). Multiple squeeze jobs are typically needed to seal fractures effectively, yet the overall probability of success remains below 50% (Magzoub et al., 2020). This emphasizes the need for a more reliable method with a higher likelihood of success. Traditional lost circulation materials, including fibrous (e.g., mica, cellulose), granular (e.g., nut shells), and flake (e.g., cellophane) types, are commonly used to manage lost circulation (Alsaba et al., 2014). Although effective in some situations, their performance in GT wells is inconsistent due to the presence of high-temperature conditions. These materials eventually lose their structural integrity, failing to properly seal fractures or vugs (Magzoub et al., 2020).

Several researchers have investigated epoxy and polyester-based resins to determine their effectiveness in establishing a durable seal that is capable of withstanding thermal stresses. However, these resins lose their sealing capability once they encounter 200°F (Saleh et al., 2020; Loeppke et al., 1990), making them unsuitable for higher temperatures. Thus, developing a tailored solution for lost circulation control is essential for the economic GT well construction, especially to tackle severe losses.

This paper will demonstrate how thermally activated materials (TAMs) are suitable for managing severe lost circulation events in GT wells. The fluid formulations are designed to take advantage of the temperature difference between the wellbore and the fractures or vugs. By leveraging this temperature variation, we aim to show how TAMs can effectively seal fractures or vugs and control fluid losses.

2. Materials and Experimental Methods

2.1 Cementitious Materials

Two types of cementitious materials were utilized in this study to develop fluid formulations: Ordinary Portland Cement (OPC) and Class F Fly Ash (FA). The oxide compositions of these materials, expressed as mass percentages, are shown in **Table 1**. The OPC and FA were obtained from Texas Lehigh Cement Company and SEFA Group, respectively.

Table 1: Chemical composition of cementitious materials used in this study.

Material	Content (%)								
	Al_2O_3	SiO_2	Fe_2O_3	CaO	MgO	SO_3	Na_2O	K_2O	Loss on ignition
OPC	5.30	20.80	6.33	61.70	1.30	2.60	0.57	0.50	0.90
FA	27.40	54.10	9.62	1.70	1.00	0.20	2.35	2.51	1.12

2.2 TAMs

Four distinct types of TAMs were identified and used in this study, as shown in **Table 2**. These belong to the categories of polymers, salts, and non-polar materials. For the OPC-based fluid formulations, which were prepared with a water-to-solid ratio of 0.385, TAMs were incorporated. For the FA-based fluid formulations, different alkaline activators were added to create geopolymers or alkali-activated materials, with a water-to-solid ratio of 0.35.

Table 2: TAMs and their properties.

Material	Family	Color and State	Specific Gravity
TAM 1	Polymer	Opaque brown liquid	1.012
TAM 2		Clear liquid	1.005
TAM 3	Non-polar material	Brown liquid	1.019
TAM 4	Salt	White powder	1.200

2.3 Rheology and Mechanical Properties

The rheological profiles of fluid formulations are critical in assessing the effectiveness of TAMs. For temperatures below 200°F, a rotational viscometer was employed to obtain these profiles. At temperatures exceeding 200°F, a High-Pressure High-Temperature (HPHT) Consistometer was used to evaluate the fluid consistency profile, which is related to the fluid's rheology. Compressive

and tensile strength tests were conducted to evaluate the mechanical behavior of TAMs once they enter fractures or vugs.

2.3.1 Rheology and Consistency

Rheological profiles as a function of temperature were obtained using a Couette coaxial cylinder rotational oilfield viscometer, following the guidelines of API RP 10B-2 (2010). The fluid was subjected to a constant shear rate of 150 rpm and the temperature was gradually increased from surface temperature (73°F) to 200°F.

Fluid consistency tests were performed using an HPHT Consistometer, where the temperature was gradually increased from 73°F to 350°F over 90 minutes. The pressure was initially set at 1000 psi and progressively increased to 3000 psi during this period. The fluid was subjected to a constant shear rate of 150 rpm throughout the test. When the fluid achieves a Bearden consistency (Bc) value of 70, it is considered non-displaceable, indicating its ability to mitigate further fluid losses.

2.3.2 Compressive and Tensile Strength

Three cylindrical samples (4 inches in length and 2 inches in diameter) of the fluid formulations were cured for one day at the temperature expected in the fractures. Compressive strength was estimated using Equation 1, following ASTM C39/C39M (2021), with a ramp rate set at 48 psi/sec. Tensile strength was calculated using Equation 2, with a ramp rate set at 12 psi/sec, following ASTM C496/C496M (2017).

$$Compressive\ strength(psi) = \frac{F}{A} \quad \text{..... (1)}$$

$$Tensile\ strength\ (psi) = \frac{2F}{\pi LD} \quad \text{..... (2)}$$

F represents the load at failure (lbf), A is the cross-sectional area (in^2), L is the length of the sample (in), and D is the diameter of the sample (in).

2.3.3 Fracture Plugging Tests and CT Scans

The fracture plugging tests were conducted using the setup illustrated in **Figure 1**. A cylindrical sandstone sample with a fracture size of 0.25 inches / 0.63 cm was used, and it was equipped with a heating jacket to provide the necessary heat. After incorporating the TAMs into the fluid formulations (at temperature T1), the fluids were circulated through the fracture in the pre-heated sandstone sample, which was heated to match the temperature (T2) that the fluid would encounter in a GT well fracture. A collector was placed beneath the sandstone sample to gather any passing fluid. If a significant amount of fluid was collected, the formulation was considered ineffective for plugging the fractures. On the other hand, if only a minimal amount of fluid was collected, the formulation was considered highly effective at sealing the fractures. The sandstone samples were then examined using CT scans to visualize the plugging behavior of the formulations.

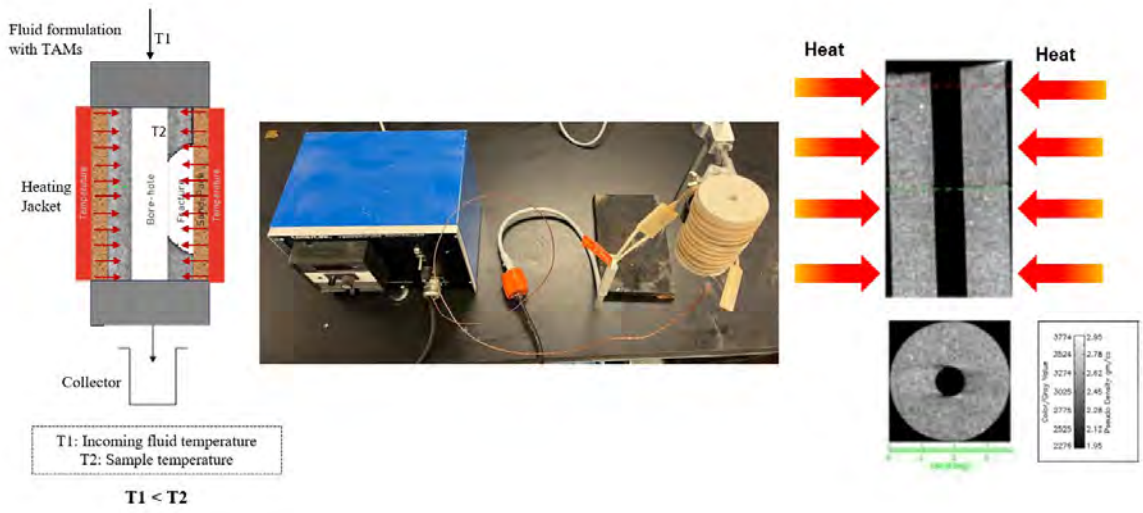

Figure 1: Fracture Plugging Test Setup. All sandstone samples were heated to the target temperature and allowed to equilibrate for 30 minutes before initiating fluid circulation.

3. Experimental Results and Discussion

During circulation, drilling mud or cement formulations encounter the bottom hole circulating temperature (BHCT) in the wellbore. However, once entering fractures or vugs, the formulations quickly experience the bottom hole static temperature (BHST), which is higher than the BHCT due to the natural GT gradient. This temperature contrast is exploited in this study which can help seal the fractures or vugs in GT wells. Denduluri et al. (2024) demonstrated this effect using a thermo-hydraulic simulation in a Utah Forge GT well, where the BHST of 315°F contrasts sharply with a BHCT as low as 200°F. The core idea is that when TAMs are incorporated into the fluid formulations, the mixture remains in a liquid state in the near wellbore region. However, upon entering the fractures or vugs, it undergoes a phase change, becoming highly viscous or solid, effectively sealing the fractures. These temperature conditions are crucial for understanding and designing TAMs for different GT wells.

Low and Medium-Temperature Plugging Solution

TAMs 1, 2, 3, and 4 were incorporated into the OPC fluid formulations and tested for viscosity as a function of temperature, as shown in **Figures 2 and 3**. The results were compared to the viscosity of the OPC fluid formulation (without TAMs), the standard choice for cement squeeze operations in GT wells. The viscosities of formulations with TAMs 1, 2, 3, and 4 displayed a sharp increase at various temperatures known as trigger temperatures. For example, 5% TAM 1 demonstrated an increase in viscosity at 184°F. In contrast, the viscosity of the OPC formulation remained steady without significant changes, highlighting why many cement squeeze jobs fail. The viscosity increases caused by TAMs upon entering fractures can be highly effective in mitigating fluid

losses. By adjusting the concentration of TAMs in the fluid formulations, the trigger temperatures can be effectively modified, which is beneficial for developing solutions tailored to a variety of GT wells. These formulations are particularly suitable for shallow GT wells where the temperatures encountered are not extremely high.

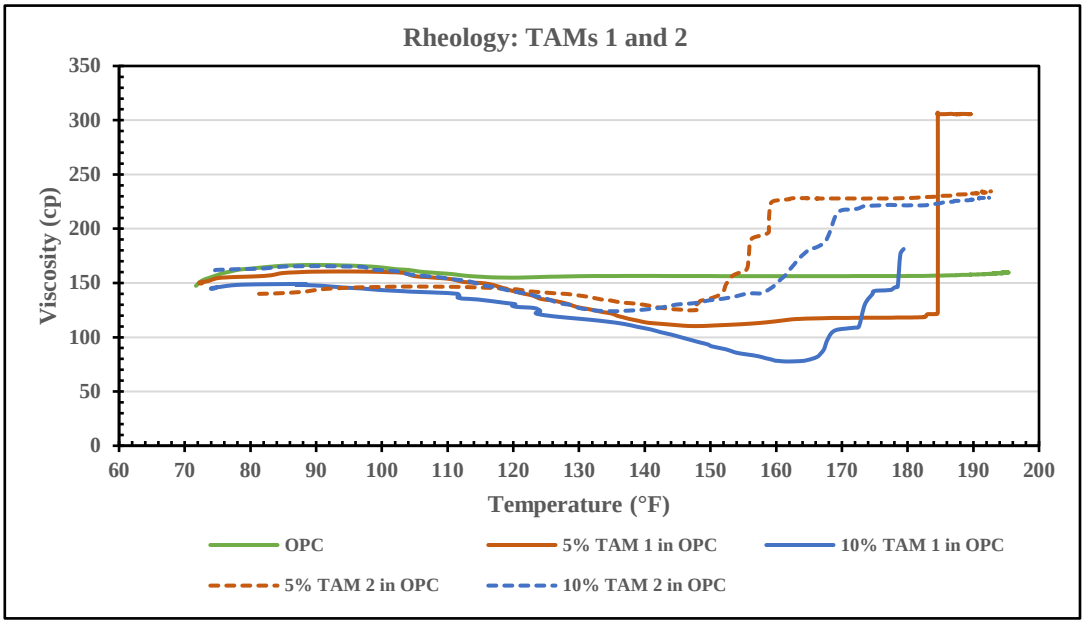

Figure 2: Rheology profiles of fluid formulations with TAMs 1 and 2. When viscosity increases and flatlines after reaching the trigger temperature, the formulation is no longer pumpable.

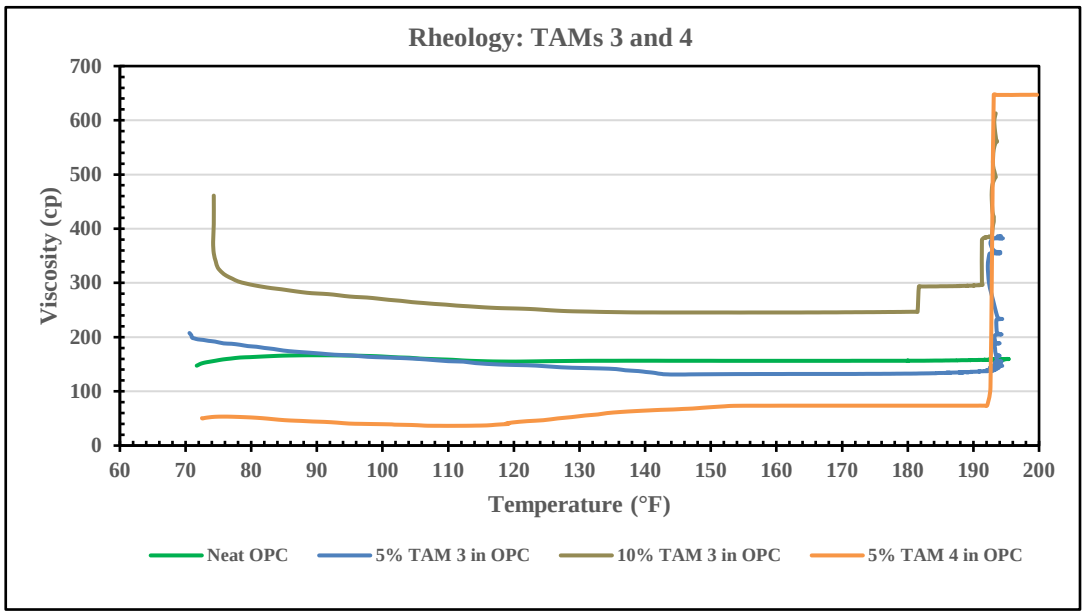

Figure 3: Rheology profiles of fluid formulations with TAMs 3 and 4. When viscosity increases and flatlines after reaching the trigger temperature, the formulation is no longer pumpable.

High-Temperature Plugging Solution

A high-temperature plugging solution for GT wells can be found in the geopolymer family. Unlike OPC, which is susceptible to acid gases such as CO_2 and H_2S commonly encountered in high-temperature GT wells, geopolymers provide high resistance to these gases (Khalifeh et al., 2018). Thus, geopolymers can be explored for lost circulation control purposes in GT wells. Geopolymers have been researched for their application as a high-temperature cementing material, displaying excellent thermal stability and superior casing-cement bond strength (Denduluri et al., 2023; Ogienagbon et al., 2023). In this study, FA was used as a cementitious material (aluminosilicate source), and different alkaline activators were utilized to create the geopolymer formulations. HPHT consistometer was used to evaluate the consistency of the formulation as a function of temperature, as shown in **Figure 4**. Two high-temperature plugging systems were developed, displaying trigger temperatures of 262°F and 362°F, respectively. These fluid formulations become effectively non-pumpable or non-displaceable at temperatures exceeding 262°F and 362°F, making them highly suitable for deep GT wells.

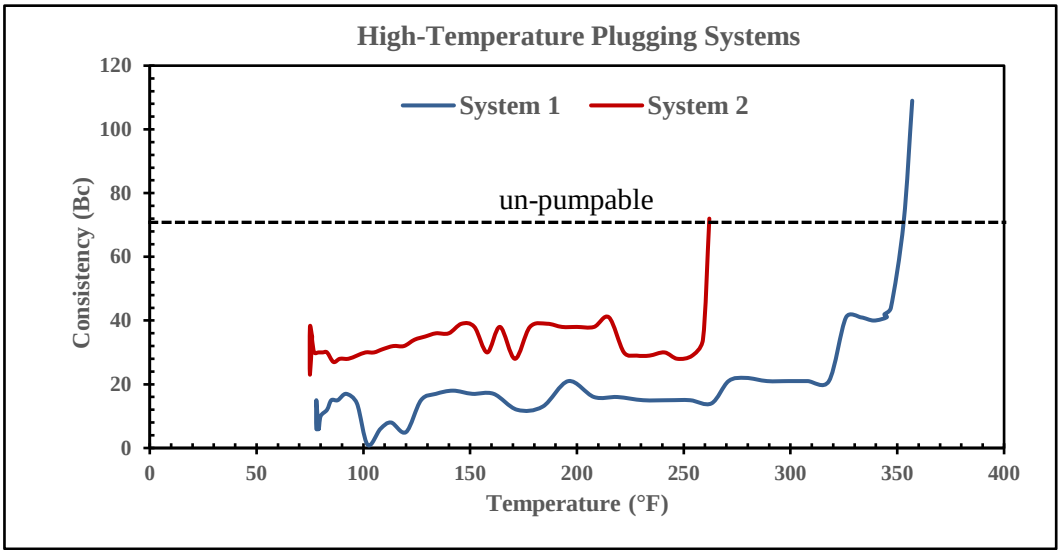

Figure 4: High-temperature plugging systems for lost circulation control in GT wells. The formulation is considered no longer pumpable once the consistency reaches a value of 70 Bc.

Mechanical Properties

The compressive and tensile strength values of fluid formulations with TAMs 1, 2, 3, and 4 are presented in **Figure 5**. These formulations were cured at 180°F for one day to estimate their strength. This information provides insight into the appropriate timing for resuming GT drilling operations to avoid further fluid losses after a cement squeeze job. The lost fluid needs substantial compressive and tensile strength to maintain mechanical integrity within the fractures or vugs. The values in Figure 5 demonstrate that the mechanical integrity of the fluid formulations developed in this study will be well-preserved, which ultimately helps in controlling fluid losses. On the other

hand, traditional materials, such as cellulosic/fibrous materials used for controlling lost circulation exhibit poor mechanical performance (Lin et al., 2024).

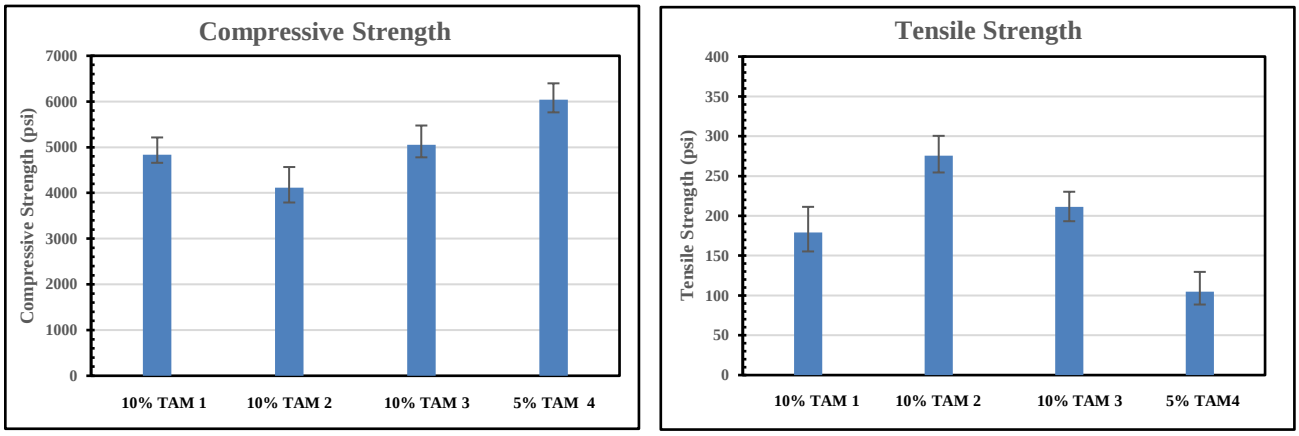

Figure 5: Mechanical properties of the fluid formulations with TAMs.

Fracture Plugging Test and CT Scans

The sandstone sample was pre-heated to the trigger temperatures indicated in Figures 2 and 3, after which the fluid formulations with TAMs were circulated through the borehole. When the OPC fluid formulation (conventional formulation used in GT wells) was circulated, 80% of the fluid was collected in the bottom collector. In contrast, for the OPC fluid formulations with TAMs 1, 2, 3, and 4, no fluid was collected at the bottom. This indicates that the fluid completely plugged the borehole in the sandstone sample, demonstrating the thermal activation mechanism of TAMs 1, 2, 3, and 4. Following these tests, CT scans of the sandstone samples revealed that the borehole was predominantly plugged, with invasion depths illustrated in **Figure 6**. TAMs can be utilized for cement squeeze jobs to effectively seal fractures or vugs in different formations within GT wells.

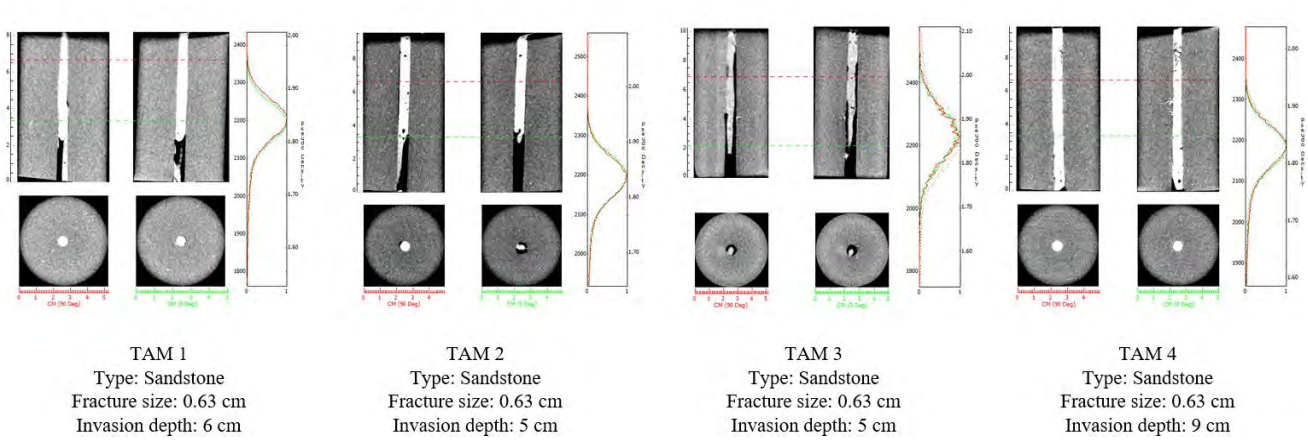

Figure 6: CT scans of sandstone samples circulated with fluid formulations containing TAMs 1, 2, 3, and 4 show that the borehole is effectively plugged, arresting further fluid losses.

4. Conclusions

This paper showcases the feasibility of using TAMs to address lost circulation challenges in GT wells. By leveraging the temperature contrast between the wellbore and fractures or vugs, fluid formulations with TAMs are designed to undergo a phase change, becoming highly viscous or solid, effectively sealing the fractures or vugs. This approach heavily relies on precise temperature modeling, which is essential for developing tailored solutions for different wells. Fluid formulations can be customized for different geological formations and GT gradients or depths. The compressive and tensile strengths of TAMs demonstrate their ability to maintain structural integrity within fractures or vugs. Fracture plugging tests and post-test CT scans also confirmed the effectiveness of TAMs in sealing fractures. Implementing TAMs in fluid formulations offers a promising solution for reducing well construction costs and NPT associated with lost circulation in GT wells.

Acknowledgments

We are very thankful to the members of the Rig Automation and Performance Improvement in Drilling (RAPID) research consortium for their guidance and financial support. We also extend our thanks to Akshay Thombare and Munir Aldin for their support.

ABSTRACT

Exploration drilling is key to answering critical resource questions. Projects can appear uneconomic before a resource is understood if sunk exploration costs are too high, thus low-cost exploration is key to growth. The importance of reducing early exposure is becoming more relevant as the data set from extensive drilling campaigns in the 1970's and 1980's has been consumed. Available levers to reduce exploration cost typically require a compromise in scope.

The utilization of small diameter drilling, primarily using mining technology has been attempted in the past by multiple operators where this technique has traditionally failed to significantly reduce cost while delivering adequate scope. A recent drilling campaign has demonstrated an 85% campaign cost reduction utilizing wireline coring on a mining rig, resulting in significant reduction in total exploration spend. This campaign has reached a technical limit with high reliability and low non-productive time (NPT) forcing the team to investigate more novel ways of working to drive further gains. Sufficient subsurface information has been obtained to de-risk prospects while reducing environmental impact. Key methods to achieve these savings are discussed and are comprised of the following elements. Firstly, a robust performance improvement process that started with focusing on building reliable repeatable operations, followed by a plan/monitor/review/feedback loop to continuously learn. Secondly, a project-based way of working was utilized to empower team members, push decision making to the appropriate level and set the project up for scaling by ensuring a common group was working each prospect. Thirdly, project scope was reduced to the lowest practical level. Lastly, the overall operating

model leveraged expert knowledge with a focus on learning together and building vendor relationships. This paper summarizes the success of the campaign with a learning curve showing dramatic well on well reductions that are comparable to learning curves published from the Oil and Gas (O&G) industry. Additionally, the impact of moving from field to field is highlighted showing that most of the learnings were transferable.

1. Introduction

Ormat Technologies Inc (Ormat) operates the largest number of geothermal resources generating electricity globally, with operations across six countries. They have seen steady growth over the last 25 years with a large portion through exploration and development. More than 40 prospects have been explored most of which are centered in the Great Basin located in the United States within Nevada and California. With continued demand for new geothermal electricity, they have focused their efforts towards increasing exploration activity to meet this demand and to fill new power purchase agreements (Ormat 2024). A core drilling campaign was recently undertaken showing large performance gains with a high level of technical information provided.

Reducing exploration costs is the key to opening additional resource for two reasons. Firstly, lower exploration costs reduce project sunk costs, resulting in better returns on successful projects and reducing expenses writing-off unsuccessful projects. Secondly, reduced exploration costs allow higher risk prospects to be drilled, proving more prospects and while drilling to test the upside of a project.

Classically, slim hole drilling has been used to de-risk resources using small conventional drilling equipment and hole sizes down to six inches. Ever increasing competition from Oil and Gas has made it difficult to acquire and contract rigs in a cost-effective manner. Figure 1 shows the operator's Exploration and Development Workflow. Risks, time, and costs are considered when it comes to the Exploration Drilling stage, whereby projects move through slim hole drilling to full size drilling. However, if the cost differential between slim hole and full size is too small, projects are incentivized to move directly to full size drilling, where a successful well may be commercially utilized for either production or injection. For this reason, reducing slim hole drilling cost can simplify decision making and reduce early exposure by introducing data early on a project's viability.

Due to costs associated with classic slim hole drilling rigs, a mineral exploration rig was sourced for a slim hole campaign with bottom hole sizes near 4 inches. Because of the limited footprint mineral exploration rigs also enable the ability to drill wells prior to an Exploration Environmental Assessment (EA) being completed, making use of Categorical-Exclusion provisions, resulting in a reduced project development timeframe by allowing full-size drilling upon receipt of an approved EA.

Between July 2022 and June 2024, the campaign has drilled 18 wells with significant learnings throughout. The small hole diameter has presented challenges requiring in-depth review of operations to drive reliability. Once proven reliable the team focused on improving performance with an overall 85% reduction in well cost from the first to last well.

Detailed analysis of drilling performance has yielded several key insights that can be used when planning future campaigns.

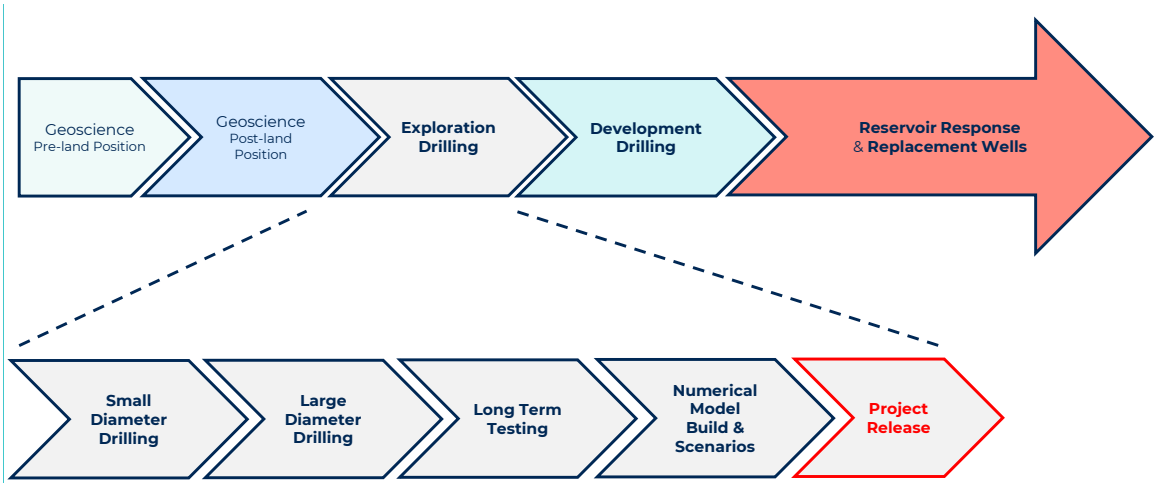

Figure 1: Operator Exploration and Development Workflow

The following definitions apply in this paper. Campaign refers to the entire coring campaign over 18 wells. Prospects refers to individual prospects or operating areas and wells refers to each well drilled. Operations refers to the process of constructing a well from initial pad construction to drilling to TD and cementing all casing strings.

2. Competitive Market for Slim-hole Rigs

Slim-hole drilling generally provides a significant capital reduction due to the smaller footprint, less manpower, and reduced infrastructure required. The merits of slim-hole drilling and the frequency of past campaigns are evident and summarized by Mackenzie et al (2017). Typical slim-hole campaigns have utilized hole diameters greater than 6 inches and utilize smaller conventional drilling equipment. With hole sizes greater than 6 inches slim-hole drilling has proven effective and provides data on-par with full size drilling at a reduced cost, however these well sizes typically aren't suitable for commercial production or injection use.

Recently the number of smaller conventional rigs has reduced, especially in the Western United States. The driving forces behind this reduction in the market have been large shifts in the Oil and Gas industry, predominantly in California where most geothermal drilling equipment is sourced. Additionally, the United States has a large rig fleet operating in the unconventional Oil and Gas industry, this draws suitable rigs away from the Geothermal industry where long-term contracts may be available. This creates an environment where the geothermal industry can't effectively compete for rigs.

Core drilling has been intermittently used within the operator over the last 25 years, with the last major campaign taking place a decade ago. Due to this and based off historical experience the operator sourced a rig from the mineral exploration industry. An LF230 built by Boart Longyear is being utilized to continuously wireline core wells. This approach helps isolate the campaign from the market influence coming from Oil and Gas.

3. Core Drilling Overview

Slim hole drilling is generally defined as wells ending with a hole size near six inches. This is the lower limit for most drilling equipment utilized in the geothermal and O&G industries. Smaller than 6 inches requires less common drill strings, smaller motors and presents unique challenges for most equipment. In the mineral extraction industry small diameter drilling has been done with wireline core rigs for decades. This process involves drilling with thin-walled core rods hoisted and driven by a rig. The bottom hole assembly (BHA) consists of a hollow drill bit and a stationary core tube. As the rock is drilled core moves into the core tube and is retrieved by a wireline overshot every 10'. The core retrieved can be evaluated to determine what formations are present.

This process has several unique advantages compared to conventional slim hole drilling. Less formation is removed by the drill bit reducing the power required reducing overall rig size. Pad sizes, water consumption and manpower requirements are dramatically reduced when compared to a typical drilling rig, reducing environmental impact as well as simplifying permitting in certain jurisdictions. Thin-walled flush joint core rods can be sized to nest inside one another. Common sizes are PQ, HQ and NQ with diameters of 2.75", 3.50" and 4.625" respectively as shown in Figure 2. By similarly sizing all components smaller sizes fit into larger sizes allowing holes to continue if a string gets stuck without the need to pull the stuck string from the well.

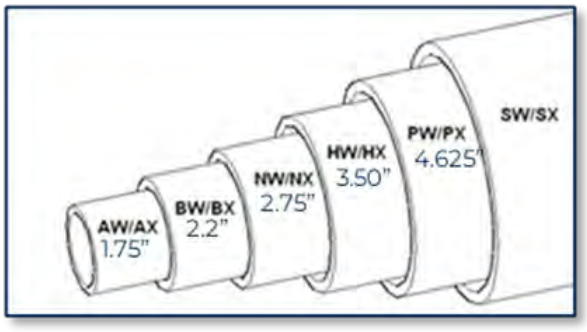

Figure 2: Common Core Rod Sizes

The advantages of core drilling aren't without drawbacks limiting the scope where this technology can be utilized. Typical coring open hole and rod sizes limit the effectiveness of cementation. A typical PQ hole is drilled with a 4.9" bit with 4.5" casing installed. Small annular clearances dramatically decrease the casing standoff, reducing the likelihood that a adequate cement job can be accomplished. Reduced power available from the drilling rigs and reduced strength of the thin wall core rods limits the depth that can be drilled and increases the risk of parting a tool string in tough hole conditions. Typical mineral exploration rigs are not equipped with blow out prevention equipment as this technology is not a default requirement.

An additional advantage of a core rig set up and associated lower-foot print, is the ability to permit core wells as Categorical Exclusions. Under the Geothermal Steam Act of 1970, a categorical exclusion may be used for activities that pose no significant risk to the quality of human environment. When approved, drilling core wells as temperature gradient wells above the reservoir still maintains high value and can mitigate preparing an environmental assessment prior to resource mapping. Figure 3 shows the small footprint of the LF230 rig utilized in this campaign.

Figure 3: Boart Longyear LF230 Core Rig

4. Core Well Utility

Core wells differ from traditional slim-hole wells largely because the final hole diameters are reduced from ~6 inches to <4 inches. This introduces many challenges for data acquisition and has an impact on the available well objectives that can be achieved.

Prior to starting the campaign, the operator sought to characterize the core itself, temperature log the entire well, image log the final hole section and where possible obtain permeability data where permits allow. If all these pieces of data could be obtained core wells could be used to fully supplement early exploration drilling.

During the campaign, cores were logged and many image logs were obtained. Additionally, substantial temperature data has been used to detail trends within the prospects. Permeability data has proven challenging for multiple reasons related to the small hole size. Well objectives were modified to rely on qualitative permeability data vs quantitative. This result wasn't a surprise due to the high frictions present in small holes, resulting in minimal change to the overall campaign plan.

5. Core Campaign Overview

The core drilling campaign has been ongoing across Nevada since the third quarter of 2022. The rig is currently drilling the 19th well over a total of 5 prospects as of June 2024.

When pre-planning the campaign historical well designs were used as the starting point. The current standard core well design is shown in Figure 4 and includes:

- 7” conductor set in 9-7/8” hole, this section is drilled with a 6-1/4” rotary bit and opened to 9-7/8” to reduce the total power requirements
- 4-1/2” surface casing set in 6-1/4” hole, this section is drilled with a PQ core bit to 4.9” and opened to 6-1/4” to allow space for an adequate cement job.
- HQ hole drilled at 3.83” to well total depth (TD), if required this section can be extended by stepping down to NQ hole drilled at 2.9”, 3.5” casing or HQ rods are used to keep the hole open when extending.
- The well is completed with slotted 2-1/16” liner. The installation of a liner allows for future function of the well for temperature gradient or monitoring purposes without risk of hole collapse.

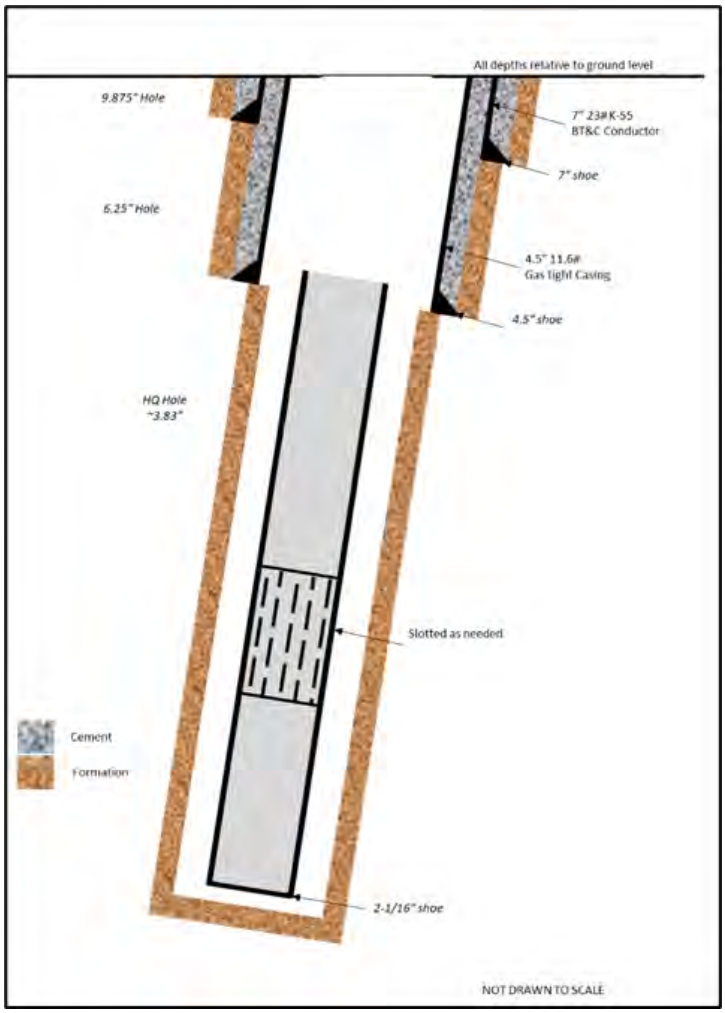

Figure 4: Typical core Well Design

6. Core Campaign Performance Journey

The operator has seen a continuous core drilling campaign as an avenue to continue portfolio growth and to find new hydrothermal systems projects to develop. Due to the length of the campaign the performance improvement has been a unique journey and consists of challenges and learnings not seen in many other Geothermal campaigns. The core campaign success can be attributed to a focus on reliability, project-based workflow, reducing project scope and working closely with vendors.

6.1 Reliability Before Performance

The first two wells in the campaign were constructed at nearly two times the proposed budget. An after-action review was put together that highlighted many inconsistencies in operational procedures, damaged equipment and a lack of supervision. To ensure the poor performance wasn't duplicated the campaign was paused and a project wide workshop was performed to identify issues and solutions. This process was done over the course of two days.

Members of the rig team, onsite supervision, engineering and any other staff involved were invited. The workshop was loosely based off the standard hazard identification (HAZID) process where the drilling process was broken into more than 50 steps. Each step was reviewed in detail before risks and mitigations were identified. If mitigations had not been implemented an owner was assigned to ensure implementation. At the close of the workshop 73 actions were identified with 10 having a high ranking for immediate implementation. These 10 actions could result in loss of a well if the risk associated with it was realized.

70% of the action items were resolved on the subsequent two wells yielding a reduction in well construction time by approximately 50%. To ensure ongoing mitigation of issues a new format for the drilling program was built which included specific activities with responsible parties. These items are checked off during each operation to mitigate complacency. The new drilling program was rolled out with the assistance of the drill site managers and contractor supervisors to ensure onsite buy in, alleviating any concerns of excess micromanagement.

Additionally, a detailed project risk register was developed. The risk register was broken into sections where risks that were common to every operation were part of the standard drilling program and risks unique to each location were covered as needed.

To ensure the activities in the drilling program and risks in the risk register were addressed the drilling program was used as the basis of the drill the well on paper (DWOP) exercise with no additional preparation of materials. This ensured that onsite personnel, engineering staff and subsurface staff were familiar with the program and the risks embedded within it. This also confirmed buy in from all levels of the project team before the start of operations.

6.2 Removing Excess Oversight: Project Based Workflow

Core drilling was used as the basis for updating the working team structure within the operators organization, whereby a matrix organization was developed. In this new organization a project manager (PM) became responsible for delivery of all aspects of well construction with each discipline reporting via a dotted line to the PM. The project team was empowered to make decisions and mature the project inline with project or well objectives. This reduced the ability of

a specific function to drive decisions. For example, a well wasn't drilled to the maximum depth to prove it was feasible, instead wells were drilled to minimum TD to satisfy data collection requirements. Another example would be choosing a suboptimal directional plan that still delivers 90% of the technical data but allows the project to utilize core drilling.

The project-based workflow forced the project team to identify clear well objectives. These objectives were used to design wells with the minimum technical scope. Operations were performed with the objectives in mind and excess was removed from the system as it was clear what was required to meet the objectives.

6.3 Avoiding Excess Complexity by Limiting Scope

During the after-action review, it became evident that the project had experienced scope creep from its initial inception. Complex bottom hole targets with multiple intercepts were included on the second well. The after-action review found that core drilling in un-stabilized hole either due to washouts or open cavities will likely damage the drilling rods. This is due to the high fatigue experienced at coring revolutions per minute (RPM's) in over gauge hole. In mineral extraction, targets like this are avoided. Geothermal has a unique requirement that wells target open fractures and often times drill through clay rich zones above these fractures. To ensure future wells had the best chance of reaching the required depth, complex targets were removed in favor of drilling two wells in environments with multiple targets. This ensured that the worst well issues were encountered at a point where total depth could be called early, and most data had been obtained. The eventual low cost per well facilitated this shift to simple targets with increasing well count.

Additionally, it was confirmed that core wells supply high quality temperature and image log data and typically can only provide qualitative permeability data. This is due to the high friction when flowing into or out of the small diameters in core wells. Limited infrastructure and shallow casing shoes further exacerbate this issue. Based off this learning project workflows and objectives were updated whereby core wells were only used to provide qualitative permeability data. In many cases due to the permits utilized for drilling of the core wells, injection testing was not employed due to being permitted under categorical exclusion provisions. It was possible to conduct injection testing if wells are permitted as a Geothermal Drilling Permit (GDP) which can only occur once an environmental assessment is in place.

As the campaign progressed significant learnings were realized. The project team has ensured that project scope has not increased and that stakeholders were aware of what core wells could and couldn't do. This has ensured that the expectations from prospect to prospect remain constant and that all wells can be drilled following a common methodology. This is key for ensuring learnings can be captured and passed from well to well.

6.4 Creating a Team: Vendor Partnerships

The after-action review highlighted multiple technical and procedural gaps between conventional mineral extraction drilling and geothermal drilling. Due to this a focus was placed on integrating vendor and operator knowledge to ensure a high level of integration. The rig supplier was relied upon as the expert in operating coring equipment and the operator understood the unique subsurface risks in conventional geothermal reservoirs. It was confirmed that resolving many of the issues found in the after-action review wouldn't be possible without a continuous operational

campaign. For this reason, the campaign was not stopped in favor of starting again after procedures were updated.

The rig provider in a close partnership with the operator developed several new ways of working including heightened pipe inspection criteria, batch cement mixing, consistent rig layouts, minimal civil engineering criteria, and staffing models to support the high workload. This was especially critical as the campaign accelerated and the project team had little time to rework prospect to prospect.

Other major service providers for drilling fluids and civils work were integrated into the project team as well. This ensured that objectives were clear and that providers gave input early in the project maturation.

The mud provider worked closely with the operator to formulate a mud program that could apply to most core drilling situations. This program evolved over the first 5 wells in the campaign with a full-time mud engineer on site. As the process became repeatable the mud engineer was removed in favor of having the rig manage drilling fluids.

The after-action review showed gaps in supervision, as a result the level of staffing during operations was tailored to support the unique scope of work. The operator deployed 24-hour supervision and the rig provider added an additional supervisor to cover 24 hour operations. This ensured sufficient staffing onsite to confirm the quality of each step in the process.

7. Learning Curve Analysis

Throughout the campaign a learning curve was experienced. As of June 2024, 18 wells have been drilled across Nevada in six separate prospects. Throughout the campaign performance has been tracked on multiple metrics including dollars/ft, days/100’ and dollars for the first 1000’. All metrics show the same general trend with some differences later in the campaign.

7.1 Evaluating the Learning Curve

Below is a summary of all wells drilled to date. 3 of the wells were drilled in two operations showing 21 operations total. Well names have been replaced with a prospect and well identifier whereby the first digit identifies the prospect, and the second digit identifies the well within that prospect. The third digit denotes wells that were deepened through a separate event.

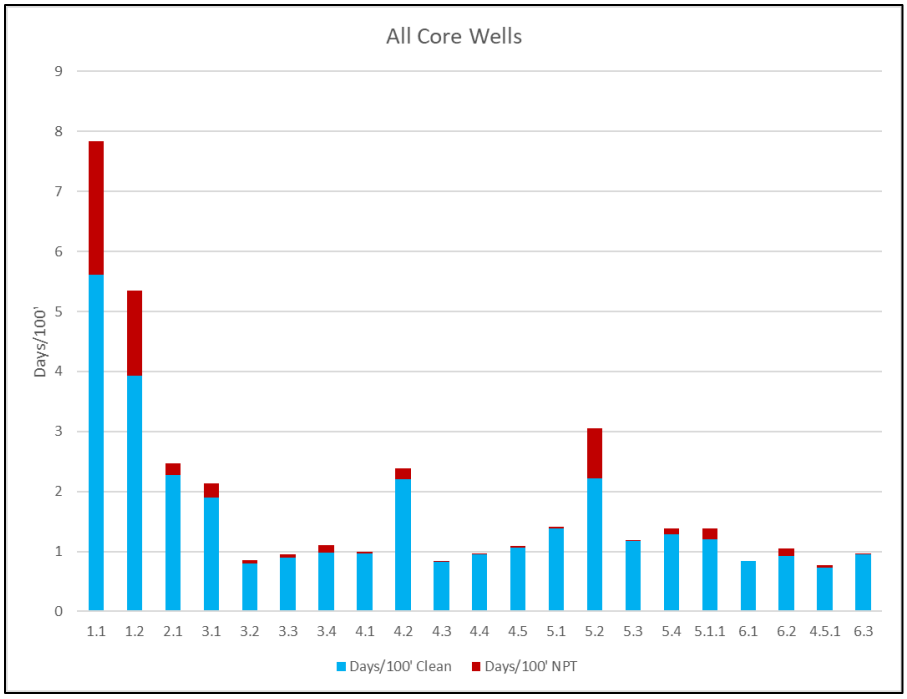

Figure 5: Whole Campaign Performance days/100'

Figure 5 shows that significant learnings over the campaign were realized. It also highlights that the full well set is too diverse to compare as the trends vary later in the campaign due to non-drilling impacts, masking performance changes.

Plotting the data from Figure 5 for the first 1000' in each well gives the most representative data set to highlight learnings as all wells would have shared the same operational steps up to this point including drilling and setting conductor, drilling and setting surface casing, installing and testing Blowout prevention equipment (BOPE) and drilling HQ hole.

This breakdown is required as 3 wells were deepened in separate well entries. They don't carry the higher capital and time expenditure to cement surface and conductor strings. It also normalizes the unique challenges encountered in wells drilling deeper than 3000' where hard rock and the diversity in permitting limitations impacts the well construction durations. Examples include temperature limitations, directional limitations, or TD restrictions. This data set also doesn't account for differences in planned vs NPT activities as NPT activities were part of the process to construct those wells. Figure 6 shows the performance of all wells drilled to 1000'.

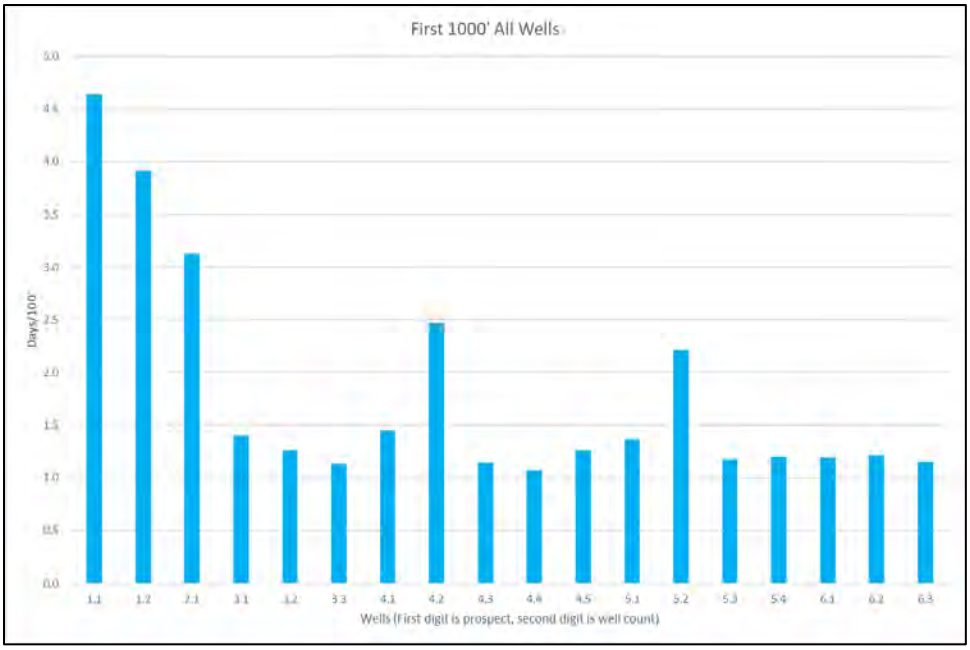

Figure 6: All wells to 1000' days/100'

Wells in prospect 5 had significantly deeper surface casing than all other campaigns, due to this, durations for that section were normalized by truncating the drilling duration to match the average of all other wells. The deeper surface casing is considered a technical step change making the wells distinctly different as equipment and procedural changes took place to accomplish those wells. Figure 7 shows the results of truncating wells in prospect 5.

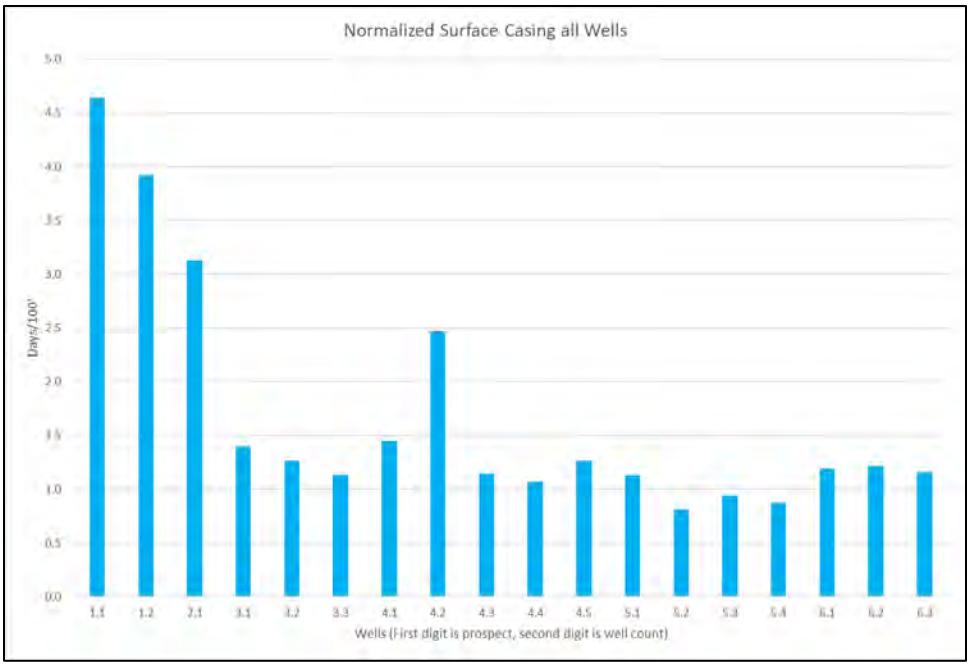

Figure 7: All wells with normalized for surface casing to 1000', plotted in days/100'

Figure 7 contains the scope of work where >70% of campaign expenditure has occurred. Reducing durations and cost on this scope of work will yield the biggest campaign impacts at this time.

7.2 Learning Curve Insights

7.2.1 Reliability First: After Action Review Process

An in-depth after-action review and integrated workshop yielded results on the third and fourth wells that were immediately evident as shown in Figure 5. The biggest cumulative impact from the workshop was a reduction in NPT from ~40% to ~9% by the third well. Reducing NPT and increasing reliability of operations allowed the team to move from immediate problem solving to performance engineering. Both macro and micro drilling key performance indicators ("KPI's") could be tracked more easily because the data wasn't masked by high NPT. From this data the team could analyze all operations in a well and focus on improvements on an operation-by-operation basis. A continuous feedback loop was created and utilized to further drive performance and capture learnings. This feedback loop is shown in Figure 8.

Figure 8: Continuous performance feedback loop

7.2.2 Days vs Depth Curves: A way to quickly share information

KPI's evolved over the campaign from macro to micro. Macro KPI's include; gross drilling time, section rate of penetration (ROP), gross move duration. Micro KPI's include; a detailed time for each section of a well (13 sections total), BOPE rig up and testing time, wellhead installation time, on bottom ROP, circulating time and wait on cement time. As more data was collected the KPI's were used for planning cost and time estimates on future wells, where subsurface expectations were broken into 3 well types and projected to the proposed well depths. Days vs Depth ("DvD") curves of all wells were used to compare estimates and communicate to stakeholders real time

performance. Figure 9 gives an example of the estimating process mid campaign. The green DvD curve is the estimate produced by analyzing the other wells in the data set, the overall drilling duration is prolonged due to applied contingency. This can be seen in the rightward shift of the estimate and reduced slope when compared to the other wells.

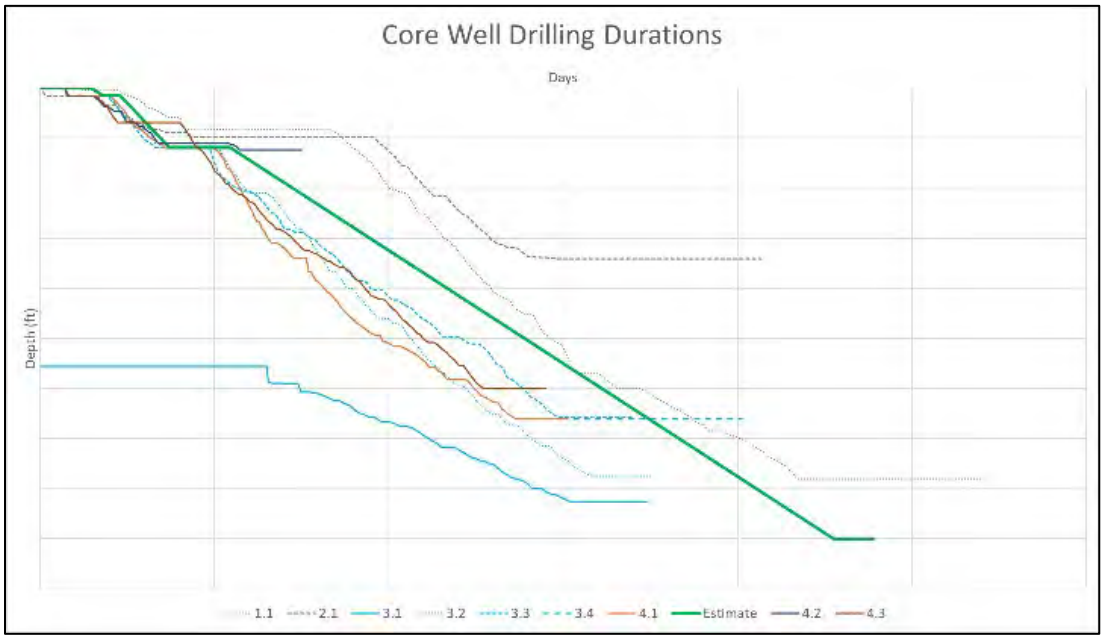

Figure 9: Days vs depth estimating example

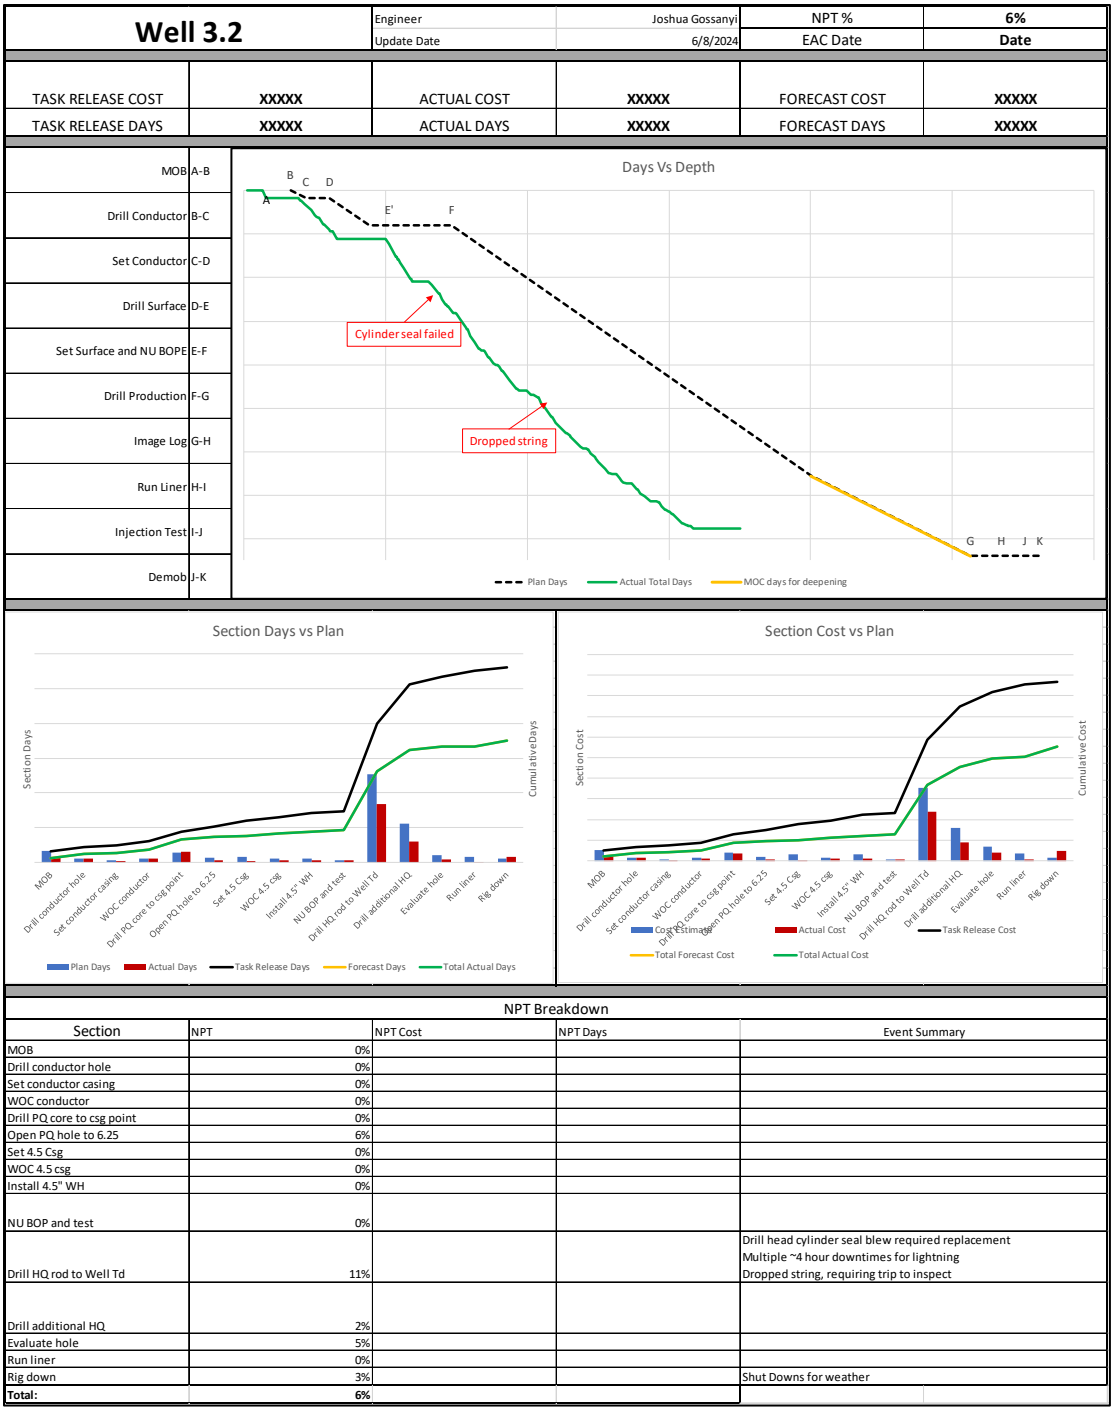
A dashboard was developed to track real time well performance real time and uses the DvD curve as the basis for showing where a current well is vs plan. Figure 10 shows a sample of an early dashboard that was adopted.



NPT Breakdown

Section	NPT	NPT Cost	NPT Days	Event Summary
MOB	0%			
Drill conductor hole	0%			
Set conductor casing	0%			
WOC conductor	0%			
Drill PQ core to csg point	0%			
Open PQ hole to 6.25	6%			
Set 4.5 Csg	0%			
WOC 4.5 csg	0%			
Install 4.5" WH	0%			
NU BOP and test	0%			
Drill HQ rod to Well Td	11%			Drill head cylinder seal blew required replacement Multiple ~4 hour downtimes for lightning Dropped string, requiring trip to inspect
Drill additional HQ	2%			
Evaluate hole	5%			
Run liner	0%			
Rig down	3%			Shut Downs for weather
Total:	**6%**			

Figure 10: Well performance dashboard

The dashboard in Figure 10 was manually updated and tracked through excel. As the campaign matured and interest within the company grew to monitor performance an automated dashboard was built to update from the operators well data system via a Microsoft Power BI application. The new dashboard uses a similar layout and gives users an immediate progress update.

7.2.3 Practice Makes Perfect: Continuous Campaign Advantage

A continuous campaign has allowed the team to implement the performance loop effectively. This would not be possible in a non-continuous campaign typically seen in conventional geothermal with a small well count split into several drilling events.

The campaign has reached a technical limit, the point at which existing tools and procedures are fully optimized. Further improvements are only possible by implementing new ways of working, new technologies, new procedures, or other new novel approaches. Continuing to utilize the existing ways of working and technology is unlikely to produce significant performance improvements. To move the technical limit the team has worked up multiple bespoke tools that will reduce well construction time. To ensure these items are implemented a performance waterfall was built and used to get stakeholder buy in when investing in new approaches. Items are broken up into three categories:

1. Changes in procedures such as a reduction in required wait on cement time by utilizing different blends.
2. New technology deployment such as a unique wellhead installation technique.
3. Procurement updates such as reducing the support or oversight of a particular vendor.

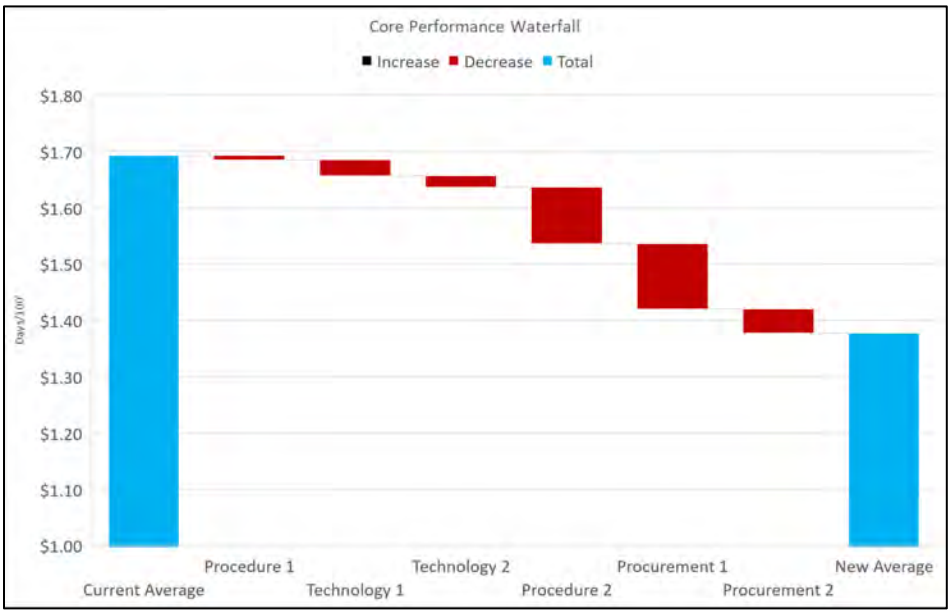


Figure 11: Performance Improvement Staircase

Figure 11 shows the relative impact on days/100' when converted from the total dollar amount of initiatives that are being matured. At the time of writing ~30% of the improvements identified in this waterfall have been implemented or will be implemented on the next well with all planned for implementation by the end of 2024.

Safety performance was improved and maintained because of continuous operations. The operator and the major service providers focused on ensuring crews involved in the campaign were consistent. This allowed many safe working procedures to be specialized for the unique operations. No lost time incidents occurred during the campaign and first aid cases reduced as

safe work practices were updated. The stability of crews has also provided a strong training base for new employees joining the team where short service employee percentages are low.

7.2.4 Large Campaign Decisions Matter: Assess Impacts When Planning

Larger campaign strategy has an impact on performance. Wells in campaign 5 occurred during the winter months in a remote high elevation location. The risk that was realized during this campaign was inadequately characterized before starting and resulted in many wells coming in over budget. The mischaracterization was largely due to confidence gained during previous campaigns with low NPT and quick learnings. This is evident in Figure 6. The highest contribution in that campaign to NPT was poor road conditions limiting the ability to move water. That contribution was most strongly seen in the deep drilling sections where a high loss rate required large volumes of water, which was trucked in. In comparison campaigns 3 and 4 occurred in good weather and were co-located in the same general area. This allowed learnings to be more directly carried from one campaign to the other. Early campaign planning now incorporates these learnings and will seek to reduce winter exposure as well as co-locate prospects as much as possible.

7.2.5 Moving to New Locations Can be Hard: New Prospects Require Focus

Figure 6 shows the campaign sees an uptick in drilling duration every time the rig moves to a new prospect. Each time the rig is broken down for a long move it requires time to get it back up and running effectively. This is commonly known as shake-down time and is a result of ensuring equipment has been re-assembled correctly. Additionally, each prospect introduces new subsurface challenges. When drilling in a new area the crew may intentionally slow down to limit the likelihood of issues occurring. Changes from prospect to prospect also occurred due to differences in basement depth, alluvium depth, rock composition and remoteness.

The coring campaign has been effective at reducing the impact of moving from prospect to prospect. Limiting project scope and adhering to the same procedures at each prospect has reduced the NPT encountered when moving to an acceptable level. Due to this, prospects can be broken into smaller well counts allowing the subsurface teams to glean as much information from early wells before making decisions on future wells.

8. Conclusion

Core drilling has proven a valuable process in the operators exploration toolbox. Overall drilling costs in the campaign have been reduced by 85% between the first well and the most recent well. The process has become repeatable with accurate estimates being used to release well budgets. The low costs have increased flexibility within new prospects to allow ever more challenging resources to be explored.

The team has worked very hard to first reduce NPT and make operations repeatable. This allowed a focus on KPI’s to drive further performance. To ensure continued improvements going forward an improvement staircase was developed and is being implemented.

The 85% reduction in well cost has come at very little loss in well utility whereby wells are still regularly logged and qualitative permeable data is obtained.

A learning curve in Figure 5 was realized and confirms the lessons in this paper as well as validates the ways of working used within the core project team.

The large reduction in cost has allowed the program to function independently of full-size drilling giving flexibility and accountability to the project team to either move exploration prospects to full size drilling or release the projects that aren't viable.

Acknowledgement

I appreciate the support of all authors and members of the team early-on, specifically Rob Selwood, Chris Gates, Daniel Lawrie and CJ Triola. Thank you goes to all vendors who have worked so hard to support this core hole drilling campaign. Thanks to Ormat for allowing publishing of this paper.

ABSTRACT

High Temperature Reservoir Thermal Energy Storage (HT-RTES) is a promising solution for large-scale energy storage that can stabilize the electric grid, increase its flexibility, and provide energy on demand. Despite its advantages, the HT-RTES wells require a higher standard for cement integrity due to higher temperatures and thermo-mechanical stresses during injection and production. In this study, we provided a thorough mechanical investigation on the hydrophobic fly ash cenospheres (FCS) incorporated calcium aluminate cement, which exhibits a lower thermal conductivity compared to conventional oil and gas well cement to prevent heat losses. The cement was treated with superhydrophobic polymethylhydrosiloxane (PMHS). The compression tests were conducted under in situ high pressure high temperatures, with pressure reaching up to 10 MPa and temperature up to 180 °C. The findings revealed that the PMHS-treated specimens, after undergoing simulated thermo-mechanical stresses, showed an increase in cement compressive strength from 4.6-30 MPa to 6.1-33 MPa, an improvement in elastic modulus from 0.34-1.37 GPa to 1.1-3.3 GPa, and an enhancement in Poisson's ratio from 0.07-0.15 to 0.1-0.33. Therefore, lightweight calcium-aluminate cement formulations with PMHS treated FCS could preserve its mechanical performance after subjecting to thermal shock. We further incorporated the measured properties into a fully coupled thermoporoelastic model for wellbore integrity analysis. Results show that the novel PMHS treated FCS could resist large range of pressure and temperature perturbations during heat injection and production. Overall, this novel formulation could be a promising solution to the durability of the HT-RTES wells.

1. Introduction

In a thermal storage site, hot fluid is injected into a subsurface reservoir, where the formation rock absorbs and retains the heat energy from the injected fluid. When the heat energy is needed, those hot liquid will be produced to the surface. The cyclic injection and production occur daily, seasonally, or even longer durations based on specific applications. To achieve the long-term

effective thermal storage, safe wellbores are essential, and cement integrity is one of the primary concerns for the wellbore durability. A proper cement system needs to have the following characteristics: (1) good resistance to thermal shock and thermal cycling over large temperature ranges; (2) low thermal conductivity to minimize the thermal loss during the repeating injection and production across the wellbore; (3) low modulus to withstand severe pressure and temperature perturbations caused by injection and production; and (4) low density to avoid fracturing the weak, unconsolidated, or naturally fractured rock formations.

Ordinary Portland cement (OPC) is known for its poor performance in thermal shock resistance. Temperatures between 200-300 ℃ could cause micro-cracking propagation (Boquera et al., 2021). The dihydroxylation of portlandite happens in OPC at temperatures ≥ 500 ℃, leading to free lime formation that converts to highly expansive hydration products (Sugama et al., 2018). In contrast, Calcium aluminate cement (CAC) is capable to withstand thermal shock at temperatures over 500-600 ℃ (Sugama et al., 2018; Boquera et al., 2021). The usage of fly ash and silica flour improved cement performance at elevated temperatures.

The thermal conductivity of OPC depends on the water saturation content, density and porosity. It varies between 0.3 and 1.3 $Wm^{-1}K^{-1}$ (Wolterbeek et al., 2023). According to Fourier's law of heat conduction, the heat loss due to conduction is linearly related to material thermal conductivity. Zhou et al. (2023) developed a chemical-induced nitrogen-filled foam cement with low thermal conductivity of 0.3 $Wm^{-1}K^{-1}$ that achieved a 11.77 °C higher temperature at the wellhead compared to adjacent wells using fly-ash low density cement.

The elastic modulus of OPC can go up to over 40 GPa, and the oilwell cement has an elastic modulus between 1 and 10 GPa (Nelson, 2006). The geothermal cement has been found with similar elastic modulus as oil well cement (Philippacopoulos and Berndt, 2001; Pyatina, 2018). Higher elastic modulus up to 15 GPa has been reported under specific testing conditions and formulations (Pang et al., 2021; Meng et al., 2023). Well integrity modeling analysis have shown that elastic modulus is more important than compressive strength in maintaining well safety (Lavrov and Torsæter, 2016; Meng et al., 2021).

Cement density ranges from 1400 kg/m^3 to 2400 kg/m^3 depending on specific applications. Density can be adjusted by using heavyweight additives (Barite, Hematite, Ilmenite) or lightweight additives (gas, bentonite, microspheres). For the geothermal well, the formation might be naturally fractured, and a lightweight cement is beneficial to avoid fracturing the formation.

To achieve the preferred properties of geothermal cement, one type of PMHS treated FCS incorporated calcium aluminate cement has been created (Simerjeet, 2012; Sugama et al., 2018; Sugama and Pyatina, 2021). Its mechanical properties under uniaxial compression conditions, thermal conductivity, water-repellent property, phase identification, and microstructures have been quantified (Sugama and Pyatina, 2021). However, the mechanical properties under triaxial conditions have not been evaluated. In this paper, we have conducted triaxial compression tests under high temperature high pressure conditions, with pressures up to 10 MPa and temperatures up to 180 °C. Our results have demonstrated the good performance of PMHS-treated cement in thermal resistance under simulated wellbore conditions.

2. Methods

2.1 Experiments

The materials used to prepare the PMHS-treated alkali-activated calcium aluminate cement with Class F fly ash have been described in detail by Sugama and Pyatina (2018) and their description will not be repeated here. The preparation procedures, however, are as follows.

1) Pouring cement slurry into the test mold, followed by 24 hours curing at room temperature;
2) Removing the mold and curing the samples at 99±1% relative humidity for 24 hours at 85 ˚C;
3) Autoclaving the samples for 24 hours at 250 ˚C.

For each formulation, we evaluated their mechanical performance before and after undergoing thermal shock. The thermal shock is performed by three-cycle of 200 °C heating for 24h, followed by old water quenching for 30 minutes. The detailed experimental matrix is shown in Table 1.

Table 1 Experimental matrix

Specimens	Thermal Shock	Testing Conditions
1	No	Uniaxial compression test
2		Uniaxial compression test
3		Uniaxial compression test
4		10 MPa confining pressure
5		180 °C, no confining pressure
6		180 °C, 10 MPa confining pressure
7	Yes	Uniaxial compression test
8		Uniaxial compression test
9		Uniaxial compression test
10		10 MPa confining pressure
11		180 °C, no confining pressure
12		180 °C, 10 MPa confining pressure

We utilized our high-temperature and high-pressure triaxial compression equipment (Figure 1) to measure the mechanical properties of cement. The equipment can withstand temperatures up to 200 °C and provides a confining pressure range from 0 to 70 MPa. The load capacity of the equipment is 1000 kN. Axial and radial deformations were monitored using high temperature linear variable differential transformer rated up to 200 °C. Throughout the compression tests, we maintained the strain rate at approximately 10^{-6} /s. For high temperature high pressure experiments, a customized rubber is required to tolerate the harsh environment and avoid fluid communication between the sample and the silicone confining oil.

This facility shown in Figure 1 is capable to control and monitor pore pressure as well. However, the pore pressure was not applied in our experiments because cement typically has low permeability, and it takes a long time for pore pressure to stabilize. Thies PMHS treated cement has a low permeability of 0.1-0.15 micro-Darcy (Bauer et al., 2020). During the high temperature test without confining pressure, we left the pore pressure line open to the atmosphere to allow free water evaporation. This was necessary to prevent thermal induced pore pressure from building up and potentially breaking the rubber in the absence of confining pressure. As to the high temperature high pressure tests, it is recommended to increase the confining pressure to at least 2 MPa before raising the temperature. The water boiling point at 2 MPa is over 212.5 °C, which avoids

significant thermal induced pore pressure. If the sample is brittle, the confining pressure can go directly to the designed value. Since the cement samples seem to be ductile, it is better to elevate the pressure to 10 MPa after temperature reached 180 °C. During the heating stage, a continuously constant confining pressure control was maintained with self-designed software.

Figure 1: Triaxial compression equipment with sample setup

2.2 Modeling

The measured parameters have been implemented into one thermoporoelastic analytical model. The model development and details have been described in our previous publications (Meng et al., 2021, 2023; Zhang et al., 2022). The model demonstrates how the cement performs under pressure and temperature perturbations during fluid injection and production.

3. Results

3.1 Mechanical properties of cement before thermal shock

Three uniaxial compression tests have been conducted, and their mechanical properties are close to each other with small variance (Figures 2 to 4). The compressive strengths are 4.7 MPa, 4.6 MPa, and 5.1 MPa, respectively. The elastic modulus is (1.15 ± 0.05) GPa, (1 ± 0.03) GPa, and (1.2 ± 0.1) GPa. Poisson's ratios were recorded at 0.14 ± 0.1 for the first two tests, and 0.10 ± 0.1 for the third test. The stress strain curves in Figures 2 to 4 indicate plastic deformation near the peak strength values. For instance, in Figure 3, axial strain increases from 0.4% to 0.6% as axial stress approaches the maximum value of 4.6 MPa, and continues to increase to 1.2% as axial stress drops to 2 MPa. This demonstrates the strong ductility of the cement, which is not typical for brittle Class G cement. In our previous experiments, the axial deformation for Class G cement with silica flour is around 0.4% at the maximum axial stress point and the stress dropped quickly after that (Meng et al., 2023). Additional evidence of ductility was observed in the triaxial compression test under 10 MPa confining pressure, where axial strain exceeded 10% as the axial stress continued to rise (Figure 5).

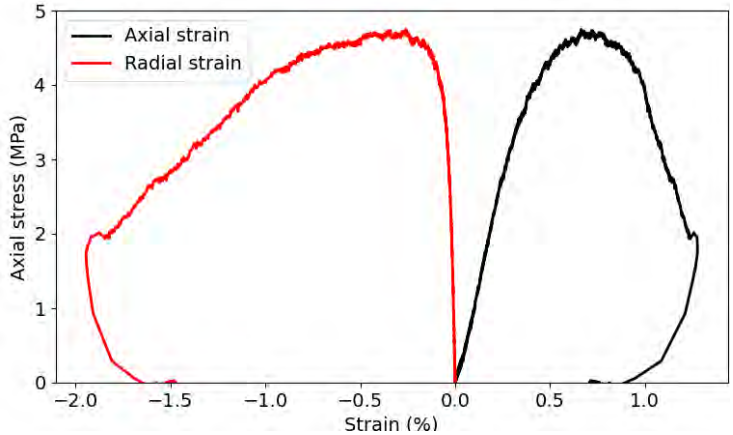

Figure 2: Stress - strain curve of the first uniaxial compression testing before thermal shock

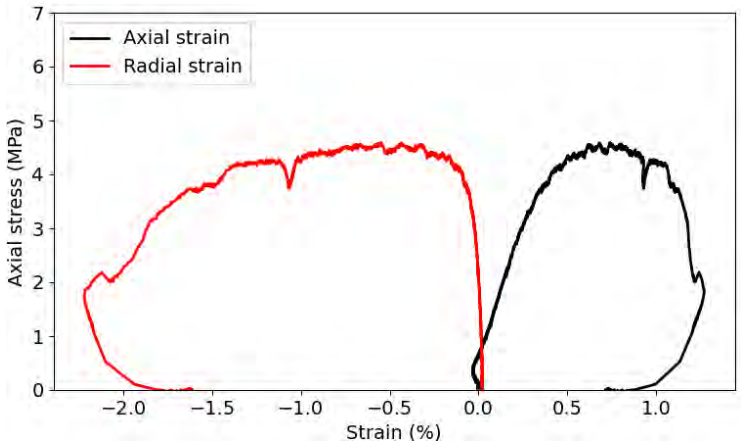

Figure 3: Stress-strain curve of the second uniaxial compression testing before thermal shock

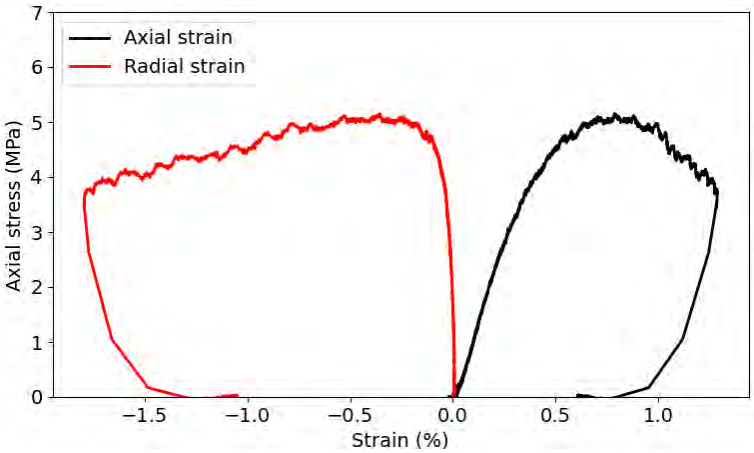

Figure 4: Stress-strain curve of third uniaxial compression testing before thermal shock

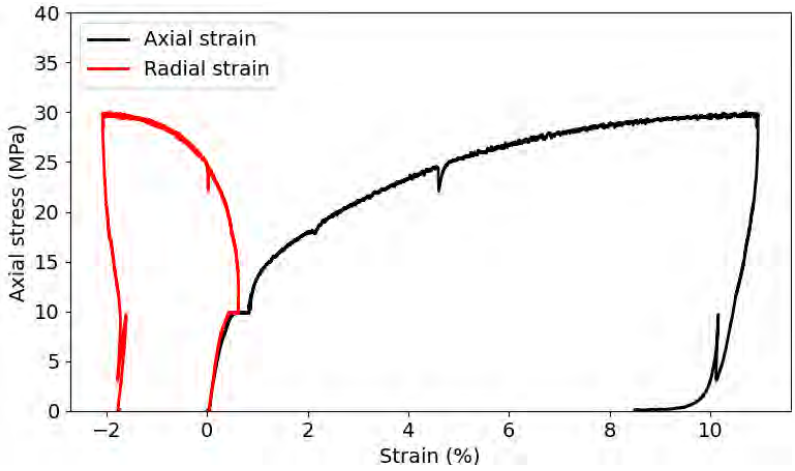

Figure 5: Stress-strain curve under 10 MPa confining pressure before thermal shock

In the following 10 MPa, 180 °C triaxial test, the stress-strain curve shows more complex behavior compared to the test conducted under high confining pressure alone (compare Figure 6 with Figure 5). Figure 7 shows the process of the progressively increasing pressure, temperature, and compression stress. Initially, the confining stress was raised to 10 MPa, during which the axial strain increased from 0 to 2%, and radial strain from 0 to 0.7%. With the confining pressure held constant at 10 MPa, the temperature was then raised to 180 °C. During this stage, the axial strain further increased to 6%, while the radial strain sensor failed. After temperature reached to 180 °C, the axial strain was still increasing under a slower rate. To save time and avoid axial strain sensor out of range, the specimen started to be compressed. This strong ductile performance creates challenges to our measurement.

There are two ways to improve the future testing performance. Firstly, as mentioned in the Experiments section, initially setting the confining pressure to a lower value of 2 MPa before elevating the temperature might help mitigate deformation during the temperature elevation, though it would not prevent the deformation after 10 MPa is applied. Secondly, curing the specimen under 10 MPa and 180 °C during the specimen preparation stage might prove beneficial. The cement sample was prepared under ambient pressure conditions, which is expected to be less consolidated than high pressure curing. If the curing conditions were maintained the same to the testing conditions, the specimen might show less plastic deformation.

For uniaxial compression test under 180 °C, the specimen shows stronger deformation compared to uniaxial compression tests under room temperature. Axial strain is 1.4% when reaching the peak value for the 180 °C, while the ambient tests showed only ~0.6% axial deformation at the peak stress point.

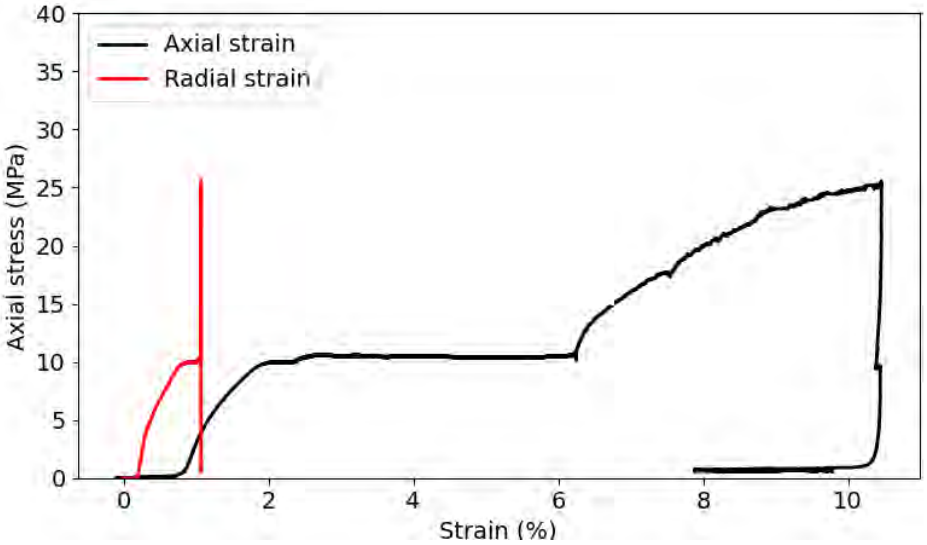

Figure 6: Stress-strain curve under 10 MPa confining pressure and 180 °C before thermal shock

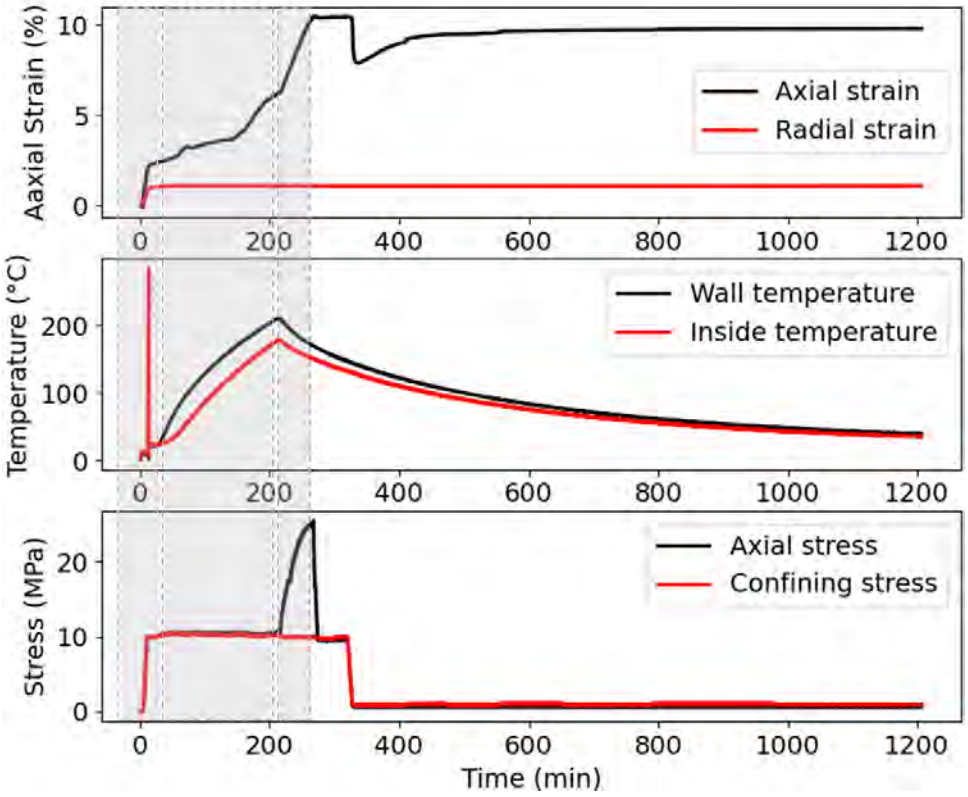

Figure 7: Triaxial compression testing under 10 MPa confining pressure and 180 °C. The first grey area shows that this cement has strong deformation during confining pressure application. The second grey area shows that the deformation continues during the heating stage. The third grey area shows the compression stage.

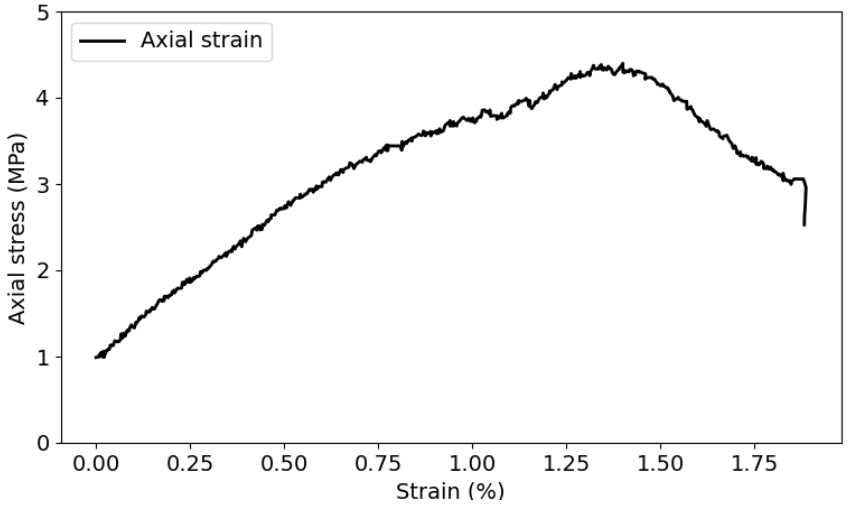

Figure 8: Stress-strain curve under 180 °C before thermal shock

3.1 Mechanical properties of cement after thermal shock

The same types of experiments were conducted on the specimens after undergoing thermal shock. The detailed stress-strain curves are shown from Figures 9 to 14, and the mechanical properties are summarized in Table 2. After experiencing thermal shock, the compressive strength of the specimens increased to 7.6 MPa, 6.14 MPa, and 6.7 MPa, representing a 42% increase compared to the samples without thermal shock. The elastic modulus also increased to (1.75 ± 0.15) GPa, (1.15 ± 0.05) GPa, and (1.6 ± 0.1) GPa, demonstrating an increase of 34%.

In the 10 MPa confining pressure compression test, the compressive strength increased slightly from 30 MPa to 32 MPa, while modulus increased from (1.7 ± 0.2) GPa to (2.5 ± 0.4) GPa. Comparing the shapes of the stress-strain curves in Figures 5 and 12, the specimen subjected to thermal shock reached near peak strength at just 4% axial strain, whereas the stress for the non-thermal shock specimen continued to climb until reaching 10% axial strain. This behavior indicates that the thermal shock reduces the ductility of the cement.

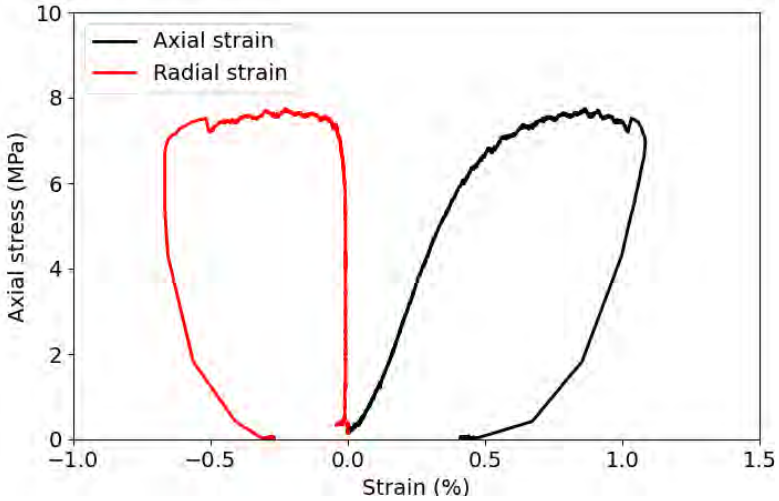

Figure 9: Stress-strain curve of the first uniaxial compression testing before thermal shock

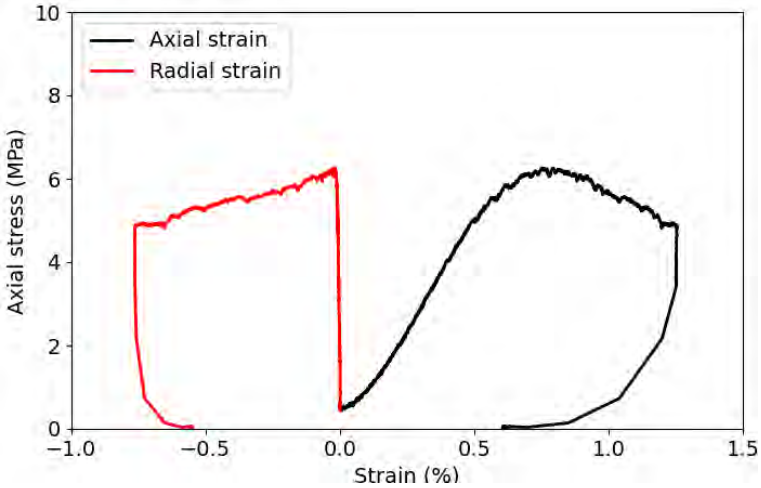

Figure 10: Stress-strain curve of the second uniaxial compression test after thermal shock

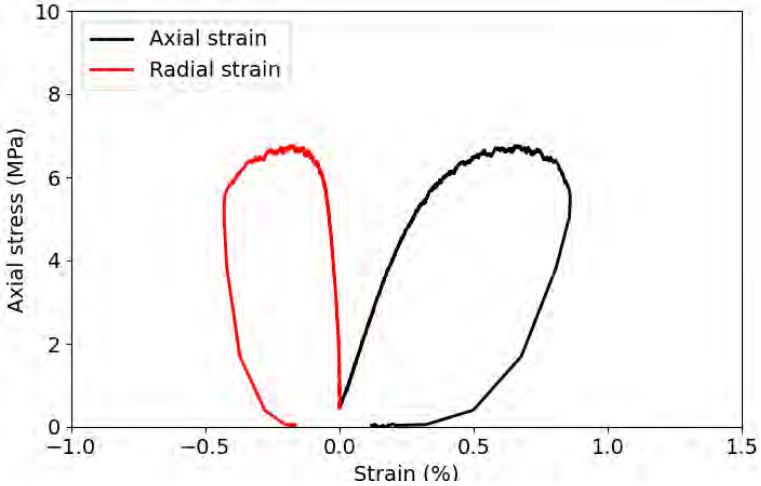

Figure 11: Stress-strain curve of the third uniaxial compression test after thermal shock

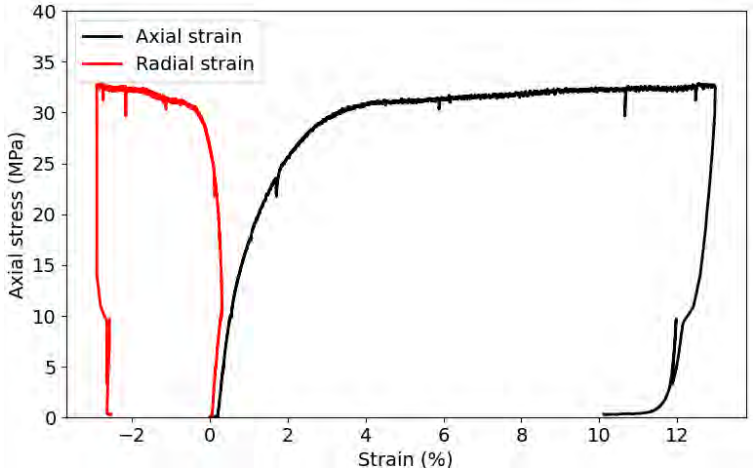

Figure 12: Stress-strain curve under 10 MPa confining pressure after thermal shock

Similar behavior was observed in the compression tests conducted under 180 °C and 10 MPa confining pressure, as shown in Figures 6 and 13. After undergoing thermal shock, the compressive strength increased from 25 MPa to 32.3 MPa, and the elastic modulus increased from (1.33 ± 0.05) GPa to (3.15 ± 0.15) GPa. At near maximum axial stress, the axial strain recorded was only 3% for the specimen that had undergone thermal shock, in contrast to the continuing increase in stress beyond 10% axial strain observed in the specimen without thermal shock.

The results of uniaxial compression tests under 180 °C further confirmed this pattern of increased compressive strength coupled with reduced ductility, as shown by comparisons between Figure 14 and Figure 8.

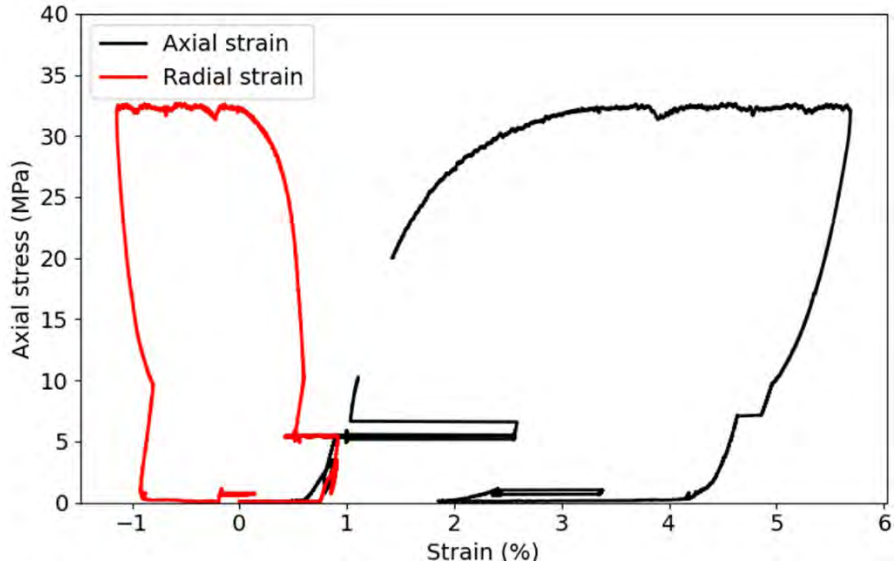

Figure 13: Stress-strain curve under 10 MPa confining pressure and 180 °C before thermal shock. Axial strain data was lost in the middle of the test, resulting in the disconnection of the black curve.

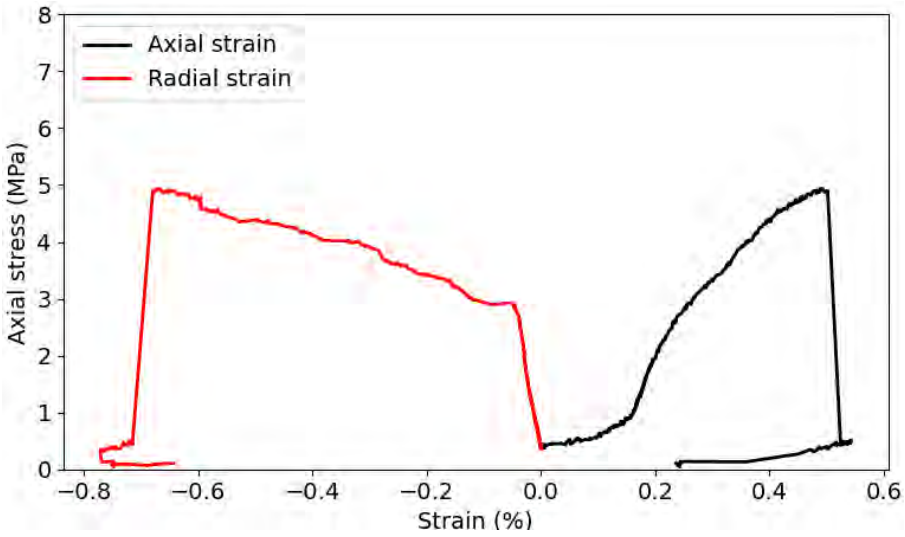

Figure 14: Stress-strain curve under 180 °C after thermal shock

Table 2 Mechanical properties of the PMHS treated cement before and after undergoing thermal shock.

PMHS treated Cement	Before Thermal Shock			After thermal shock		
	Strength (MPa)	Modulus (GPa)	Poisson's ratio	Strength (MPa)	Modulus (GPa)	Poisson's ratio
UCS 1	4.7	1.15 ± 0.05	0.14 ± 0.01	7.6	1.75 ± 0.15	--
UCS 2	4.6	1 ± 0.03	0.14 ± 0.01	6.14	1.15 ± 0.05	--
UCS 3	5.1	1.2 ± 0.1	0.1 ± 0.01	6.7	1.6 ± 0.1	--
UCS average	4.8	1.12 ± 0.06	0.08 ± 0.01	6.8	1.5 ± 0.1	0.04 ± 0.01
10 MPa	30	1.7 ± 0.2	0.09± 0.02	32	2.5 ± 0.4	0.13 ± 0.02
180 C	4.34	0.35 ± 0.01	--	4.9	1.9 ± 0.3	0.3 ± 0.02
10 MPa 180 C	25	1.33 ± 0.05	--	32.3	3.15 ± 0.15	0.17 ± 0.02

The above experimental results show the promising performance of this PMHS treated FCS incorporated calcium aluminate cement after undergoing thermal shock. The fundamental mechanisms have been explained by Sugama and Pyatina (2008), which were summarized here:

(1) Cenospheres + sodium metasilicate → silanol and sluminol groups on the surface

(2) Silanol and sluminol groups + PMHS → siloxane oxygen-linked M-FCS

(3) At high temperatures of 175 °C or 250 °C → depolymerization at the FCS surface

(4) Siloxane → low crosslinked silicon-like polymer after repolymerization

(5) The repolymerization-induced product protects FCS from pozzolanic reactions

3.2 Modeling results

Using the data obtained from our triaxial compression tests, we applied a thermoporoelasitc model to determine the safe operating envelope for this cement. Figure 15 shows that this cement has a wide range of safe applications. No failures were observed in the normal range of pressure and temperature perturbations. The temperature drawing down by 50 °C is an aggressive change that typically challenges regular brittle cement. The main reason for this wide envelope is due to low modulus of this cement.

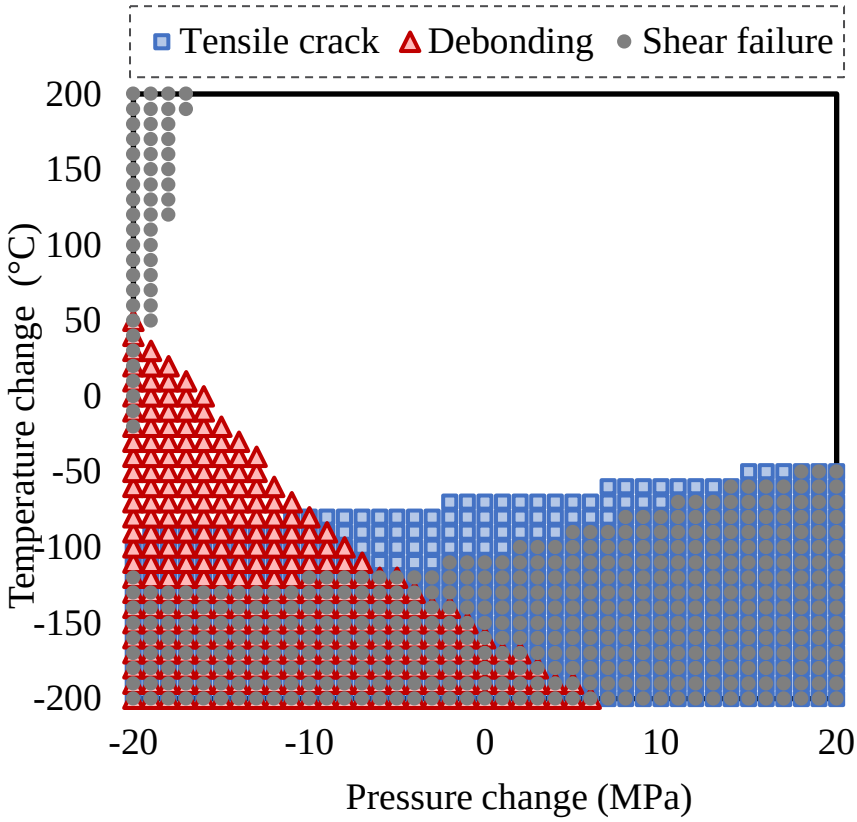

Figure 15: Safe operating envelope for the PMHS treated cement

4. Conclusions

Our study focused on PMHS-treated alkali-activated calcium aluminate cement with Class F fly ash, subjecting it to thermal cycling and measuring their mechanical properties through triaxial compression tests under high pressure and high temperatures. The key insights are summarized as follows:

1. This novel cement formulation demonstrates robust performance in resisting thermal shock. Instead of mechanical degradation, both the strength and modulus of the cement increased after exposure to thermal shock.

2. PMHS induced the dehydrogenation, depolymerization, and repolymerization processes, resulting in the formation of polymers that protects the FCS from pozzolanic reactions. This explains the cement's capability to maintain its mechanical performance under thermal shock.

3. The low modulus of this cement contributes to a broad safe operating envelope, as shown by modeling analysis. This highlights the cement's capability to effectively handle variations in pressure and temperature, offering significant advantages for its use in harsh environments.

ABSTRACT

Deep drilling through hard rock is a significant economic obstacle to the widespread adoption of enhanced geothermal systems (EGS). Decreasing drilling costs with polycrystalline diamond bits is a high priority for the geothermal industry. Therefore, it is important to characterize the mechanical behavior of rock in high-pressure, high-temperature environments and develop predictive rock cutting simulations for further optimization of drilling.

In this paper, we utilize laboratory compression tests up to 200° C to characterize rock cores from the Utah FORGE site. Two rocks were studied: A granodiorite from well 16A(78)-32 at a depth of approximately 5900 ft MD, and a gneiss from well 78B-32 at a depth of approximately 8500 ft MD. Triaxial compression tests were performed on these samples at several confining pressures up to 6,000 psi, and at temperatures up to 200° C.

After laboratory testing, a discrete element model was developed using the PFC3D software package. The model was tuned to match rock properties at room temperature and at elevated temperature through a series of triaxial compressive simulations. Then, single cutter scraping experiments were modeled. Cutting forces from the model were compared to cutting forces from single cutter rock scraping experiments, showing that the model can be used to predict and further optimize cutting performance.

1. Introduction

When drilling hard rock for enhanced geothermal systems (EGS), mechanical properties of the rock are critical to understanding drilling mechanics and reservoir stimulation. While rock recovered from the Utah FORGE site has been studied extensively at room temperature (e.g. LeBaron et al, 2023; FORGE, 2022), rock mechanical properties at high temperatures have not been studied. With reservoir rock at Utah FORGE reaching temperatures of 230° C, it is important to understand whether the rock behaves differently in situ than at room temperature.

With increasing interest in EGS, many scholars have studied the effects of temperature on igneous rocks associated with EGS. Ma et al (2020) and Yin et al (2021) both studied triaxial compression in granite at temperatures up to 400° C and confining pressure up to 60 MPa. Ma et al (2020) found that peak strength increased until the rock reached a critical temperature of 200°-300° C, and then decreased. Yin et al (2021) found that Young's modulus increases slightly up to a threshold temperature of 300°-350° C, and then decreases. Zhao et al (2017) performed triaxial tests on granite at temperatures up to 600° C and pressures up to 25 MPa. They found that Young's modulus decreased with increasing temperature, and that at 400° C and 25 MPa confinement the rock did not fail but exhibited ideal plastic flow, a different phenomenon than that observed at room temperature. Zhou et al (2024) tested a gneiss granite at 25° and 200° C, finding that strength decreased at 200° C while there was no trend in elastic modulus.

In this paper, we evaluate two rock types from the Utah FORGE site using triaxial compression tests at temperatures up to 200° C and confining pressure up to 41 MPa. We then perform a rock cutting simulation with a discrete element model calibrated to the granodiorite samples and discuss the effects of rock temperature on drilling mechanics.

2. Experimental Procedure

Tests were performed using a high-temperature load frame. The test matrix is shown in Table 1. From each rock type, 6 axially aligned plugs were made and subjected to triaxial testing: 3 at room temperature (nominally 25° C), and 3 at 93° C.

For high temperature samples, a nominal confining pressure (around 2 MPa) was applied. Then, the sample was heated and held at temperature overnight. Next, confining pressure was increased to its target value, the rock was held at this target pressure for an hour, and then axial load was applied to fail the sample.

Specimens measuring 25.4mm in diameter and 50.8mm in length were plugged from the original cores. Sample images of granodiorite and gneiss specimens are shown in Figure 1.

Table 1: Triaxial Test Matrix

Rock Type	Temperature	Confining Pressure (MPa)
Granodiorite Well 16A(78)-32 Approx. 5,800ft MD	25° C	10.3, 20.7, 41.4
	93° C	10.3, 20.7, 41.4
Gneiss Well 78B-32 Approx. 5,800ft MD	25° C	10.3, 20.7, 41.4
	93° C	10.3, 20.7, 41.4

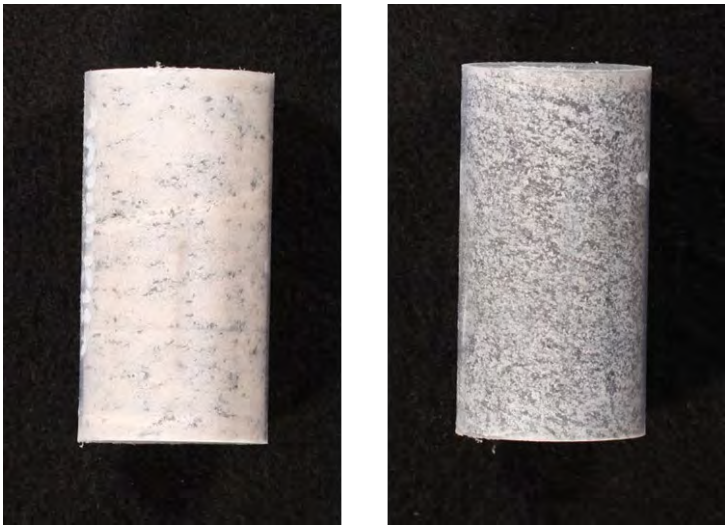

Figure 1: Granodiorite (left) and gneiss (right) plugs before testing

3. Experimental Results

3.1 Peak Strength

Peak axial stress results are shown in Figure 2. For both rock types, there was no consistent increase or decrease in strength with temperature. For the gneiss, there was almost no difference between the low temperature and high temperature tests. For the granodiorite, there was more variability but no clear trend with temperature.

3.2 Static Young's Modulus

Static Young's modulus was higher in the granodiorite than in the gneiss, with unconfined values around 55 GPa and 30 GPa, respectively. While the granodiorite showed on average no change in Young's modulus with increasing temperature, the gneiss showed slightly higher modulus at high temperature (Figure 3). However, the sample size is not adequate to draw any significant conclusions.

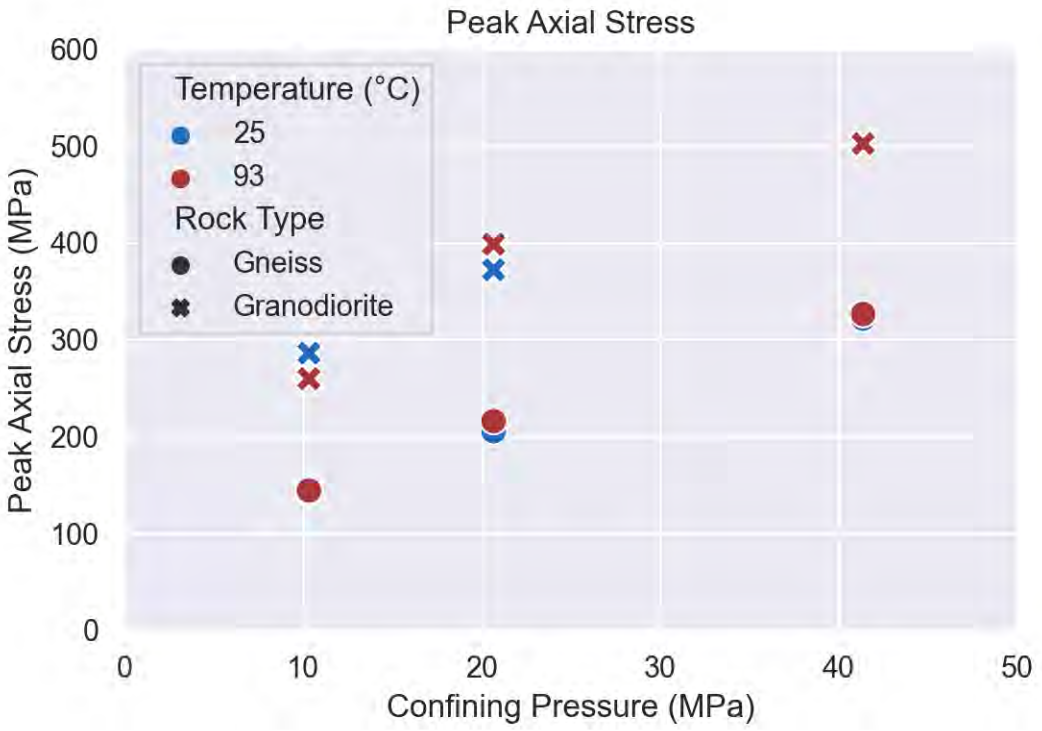

Figure 2: Peak Axial Stress for both rock types at both temperatures

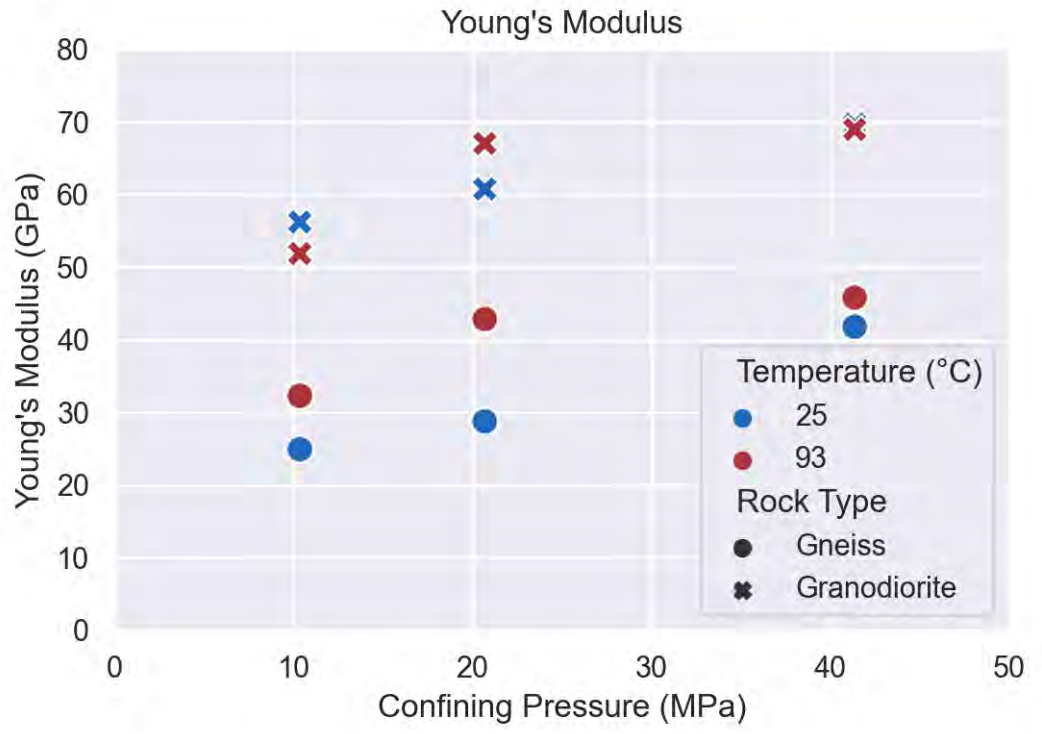

Figure 3: Static Young's modulus as measured during triaxial tests

3.3 Yield Stress

Stress at yield was determined using the Point of Positive Dilation (PPD) method; i.e. the stress at which volumetric strain changed from decreasing to increasing was taken as the yield stress of the material. As expected, yield stress consistently increased with increasing confining pressure (Figure 4). However, there was no correlation between temperature and yield stress.

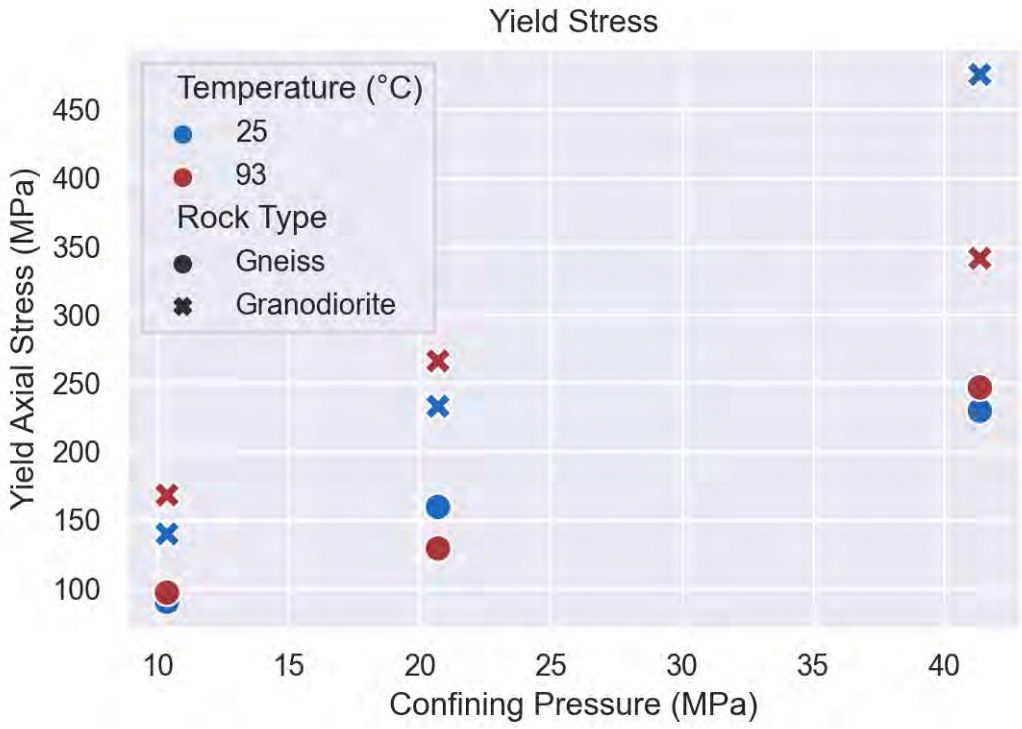

Figure 4: Yield Stress

3.4 Tests at 200° C

An additional set of paired tests was performed at room temperature and 200° C under 0.7 MPa (100 psi) of confining pressure. These pseudo-UCS tests are part of a planned series of tests at 200° C, and more results will be given in a future publication. In the data presented here, one sample of each rock type was tested at room temperature and one sample of each rock type was tested at 200° C. Axial strength for the granodiorite drops from 261 MPa at room temperature to 217 MPa at 200° C, a 17% decrease (Figure 5). Given the inherent variability of rock and the small sample size, we cannot make any broad conclusions about the strength of the granodiorite at high temperature. The gneiss showed a 4% increase in strength at 200° C, which we interpret as negligible given the inherent variability in rock.

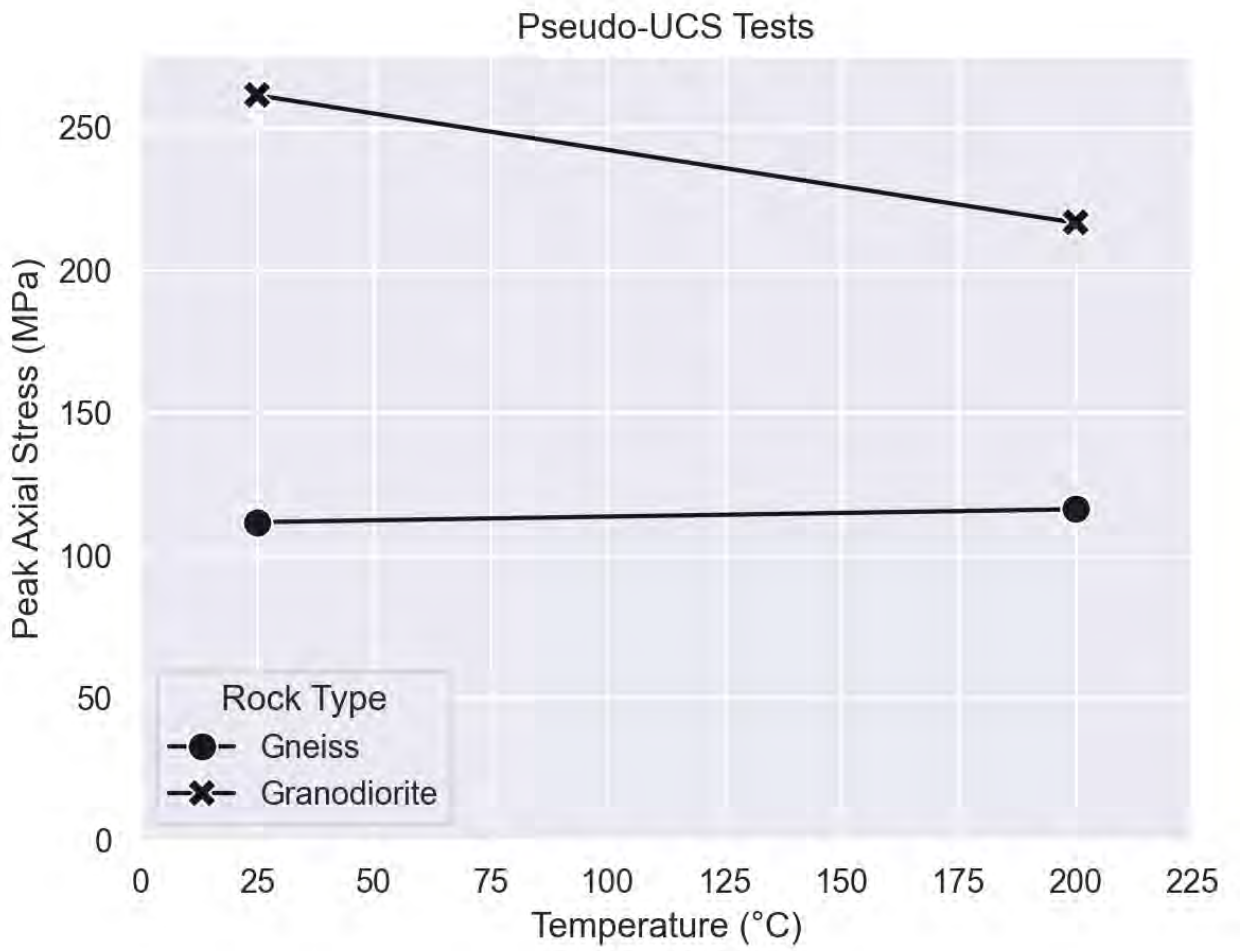

Figure 5: Axial Strength under 0.7 MPa confining pressure

4. Rock Cutting Simulation

4.1 Description of Method

Discrete Element Modeling (DEM) is a non-continuum explicit modeling technique that has been widely applied to rock cutting (e.g. Ledgerwood, 2013; Kalogeropoulos and Michalakopoulos, 2023). In DEM, rock is represented as a densely packed network of particles, typically spheres. These particles are connected by bonds that can transmit forces and moments until their strength is exceeded. We used the commercial package Particle Flow Code 3D (PFC3D) to simulate rock cutting in the granodiorite. The simulations represented rock as a random packing of rigid balls connected by deformable bonds. Then, a rigid body representing a polycrystalline diamond cutter was moved through the rock at a constant velocity and fixed depth of cut.

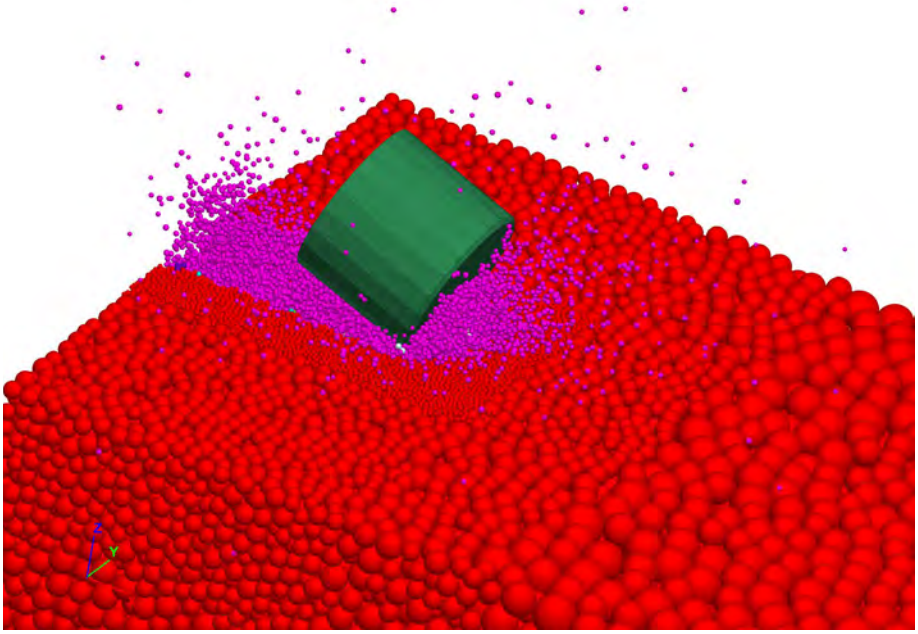

Figure 6: Screenshot of rock cutting in PFC3D at 0.060" depth of cut and 20° backrake.

In PFC3D, ball-ball interactions are governed by the parallel bond model. When intact, a parallel bond can transmit force and moment between balls. If the bond is broken by being loaded to failure, it can only transmit compressive forces and frictional shear force (Figure 7). The bond is given a tensile strength value and a shear strength envelope. If either is exceeded, the bond is considered failed and transformed into the unbonded state. The failure envelope for the parallel bond is illustrated in Figure 8. For more details on the parallel bond model, see Itasca (2021).

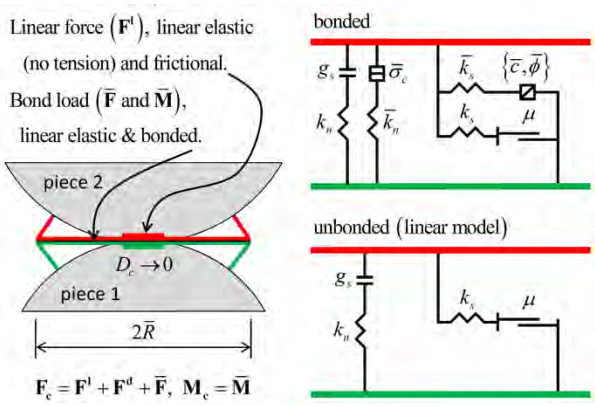

Figure 7: Schematic of the linear parallel bond model. From Itasca (2021)

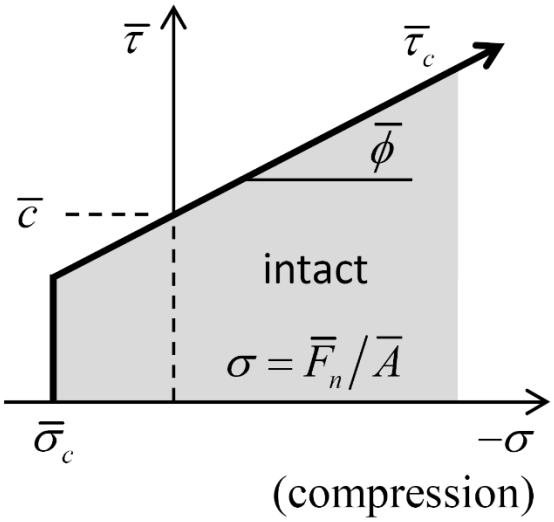

Figure 8: Failure envelope for a single linear parallel bond. From Itasca (2021).

The synthetic rock was assembled as a graded distribution of randomly packed balls. The balls that underwent cutting were the smallest, while balls furthest from the cutting zone were the largest (Figure 6). The graded arrangement permits high-fidelity simulation in the cutting zone and a realistic far-field elastic response while minimizing computational cost. Numerical damping was used to create a quasi-static rock cutting model. Damping force is applied to ball *i* as:

$$F_i + F_i^d = M_i A_i \tag{1}$$

Where F_i is the sum of physical forces applied to the ball, F_i^d is the non-physical damping force, and M_i and A_i are the mass and acceleration of the ball. The non-physical damping force is

$$F_i^d = -\alpha\, |F_i| sign(V_i) \tag{2}$$

Note that the negative sign in Eq. (2) ensures that the magnitude of velocity is always decreasing. In this study, $\alpha = 0.7$ to implement a quasi-static condition.

4.2 Model Parameters

A synthetic rock material was calibrated to match the triaxial compressive strength of the granodiorite from this study. Models were set up to generate cylindrical rock samples 12.5mm in diameter by 25mm long. For the uniaxial compressive test, the rock material was compressed axially between displacement-controlled rigid walls. For triaxial compressive tests, an outer wall simulating an elastic membrane was applied to the rock sample and pressure was applied until the desired confining pressure was reached. Then, the displacement-controlled rigid walls were applied to produce axial stress. Figure 9 shows a sample after failure from a confined compression test. Displacement in the vertical (z) direction shows a shear band running from top right to bottom left of the specimen, mimicking the actual failure mode of rock compressed axially under high confining pressure.

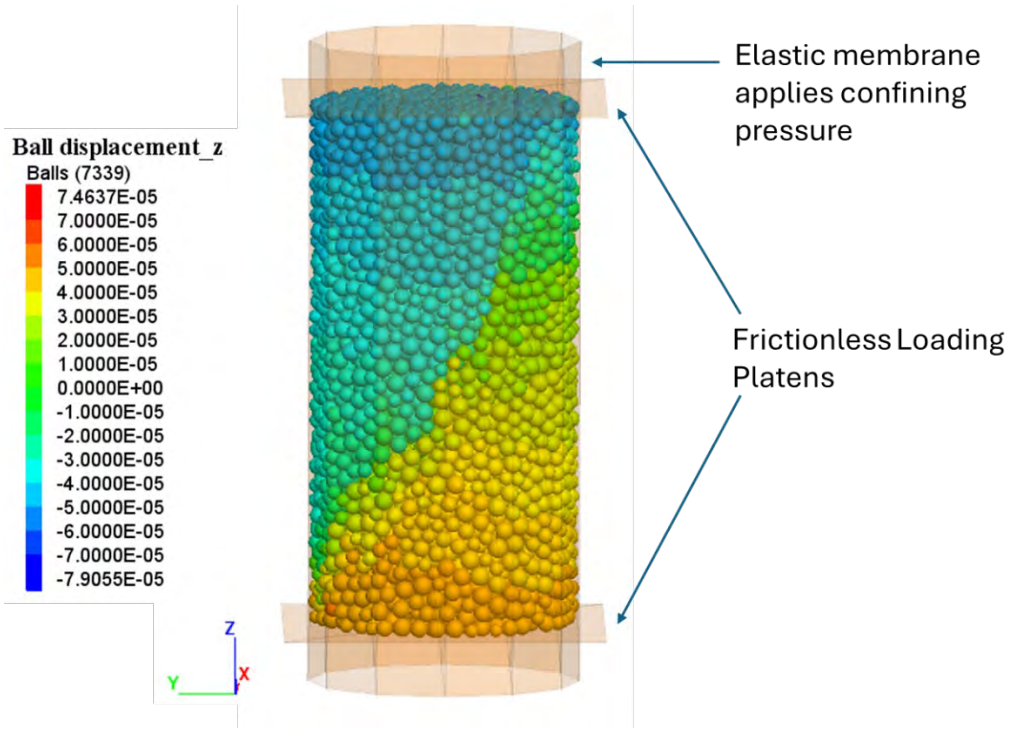

Figure 9: Ball displacement after failure in a triaxial compression test. A shear band runs from bottom left to top right.

Bond and ball micro-parameters are given in Table 2. While most properties were assigned as constants, ball diameter and bond strength were assigned randomly for each ball and bond. The value was chosen by randomly sampling a distribution. For ball diameter, a uniform distribution between 0.4 and 0.6 mm was used. For bond tensile strength and cohesion, a Gaussian distribution was used based on the mean and standard deviation given in Table 2

Table 2: Micro-parameters for granodiorite

Parameter	**Value**
Bulk Density	2600 kg/m^3
Ball Minimum Diameter	0.4 mm
Ball Maximum Diameter	0.6 mm
Bond Elastic Modulus	29 GPa
Bond shear modulus $\overline{k_s}$	9.1 GPa
Ball-Ball Friction Coefficient μ	0.5
Parallel Bond Installation Gap	7E-5 m
Parallel Bond Tensile Strength $\bar{\sigma_c}$	120 MPa mean, 24 MPa Standard Deviation
Parallel Bond Cohesion $\bar{c}$	120 MPa mean, 24 MPa Standard Deviation
Parallel Bond Friction Angle $\bar{\phi}$	60°

These model parameters reproduced the peak strength of the rock under triaxial compression well (Figure 10), especially at higher confining pressure. Note that unlike real rock, the parallel bond model does not recreate the increased elastic modulus observed at high confining pressure. The discrete element model also fails to replicate the residual strength and post-peak softening seen in

the laboratory tests. Instead, stress drops quickly after reaching peak strength, with none of the models showing notable softening. Nonetheless, the parallel bond model can predict the forces associated with rock cutting.

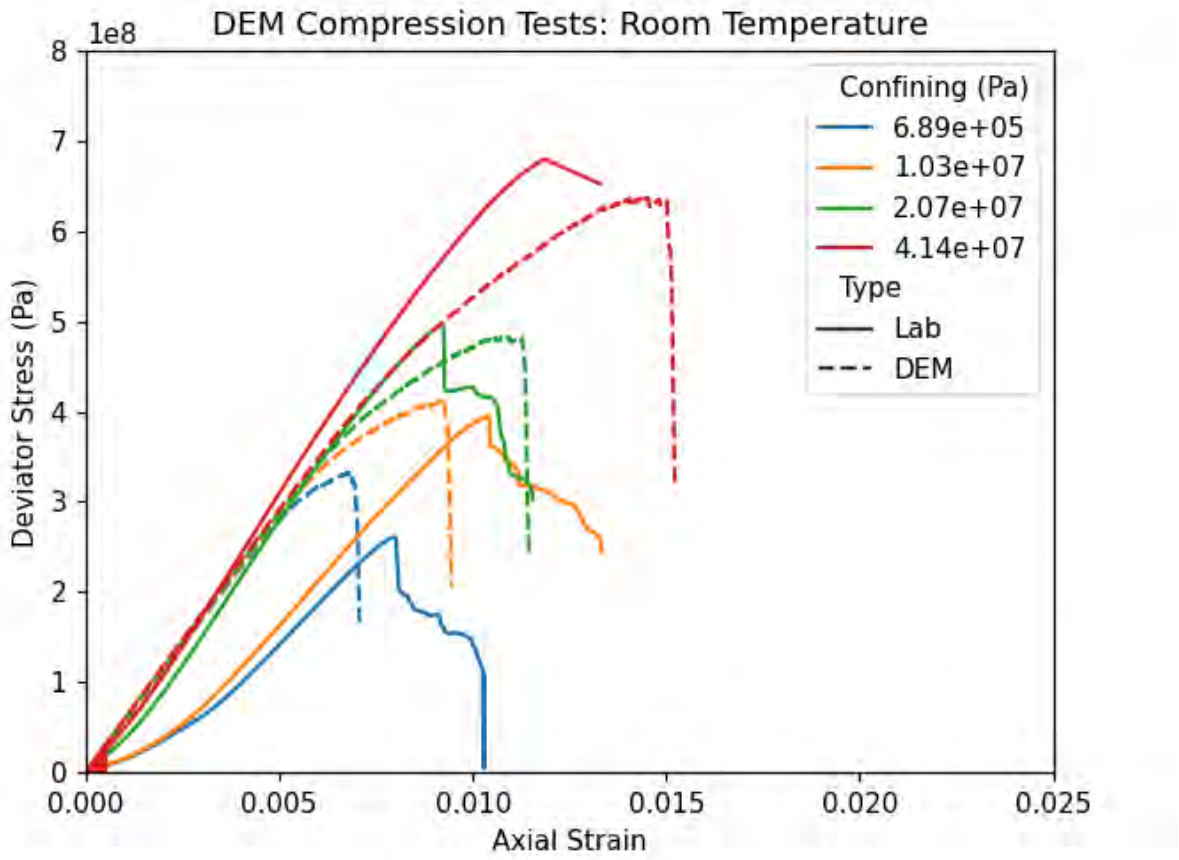

Figure 10: Stress-strain response of DEM and laboratory experiments for unconfined and confined compression.

4.3 Rock Cutting Model

After the model was calibrated via unconfined compression and triaxial compression, a graded rockmass was generated using the micro-parameters from the calibration. The discrete element model was evaluated at 0.5, 1.0mm and 1.5mm depth of cut. Cutting force results were compared to laboratory results reported by LeBaron et al (2023) for the granodiorite at these same DOC.

At all depths of cut, the model showed a good match with mean cutting force and the standard deviation of cutting force (Figure 11). While many rock cutting modelers report a correlation between peak forces (e.g. Qianqian et al, 2015) or mean force (e.g. LeBaron et al, 2023), the model presented here shows a good reproduction of the mean force and peak force.

Peak forces are the highest forces experienced by the cutter and are the forces associated with rock chipping. In these models, peak forces, taken here to be the 95th percentile of forces recorded during cutting, matched well at all three depths of cut (Figure 12).

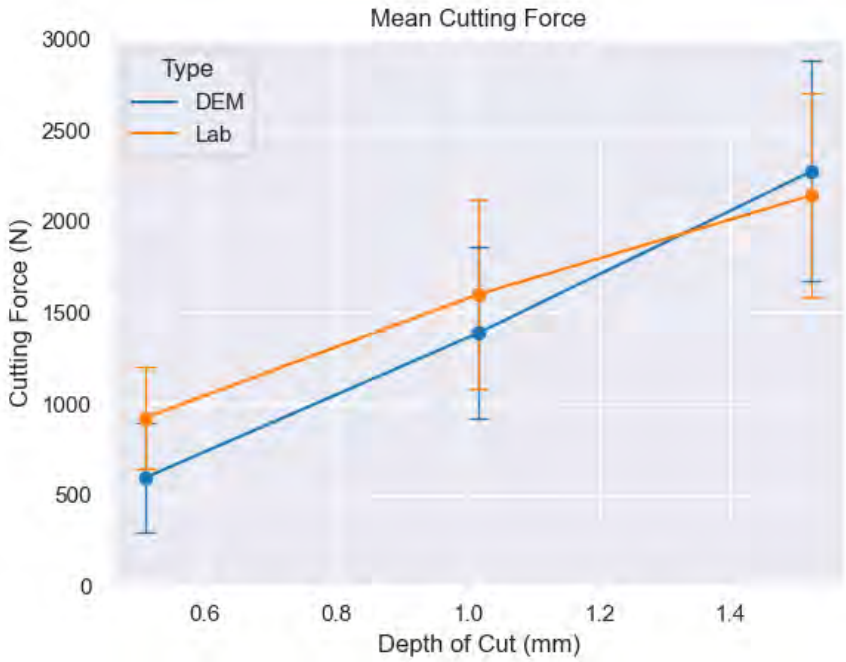

Figure 11: Mean Cutting force at various depth of cut. Error bars represent one standard deviation.

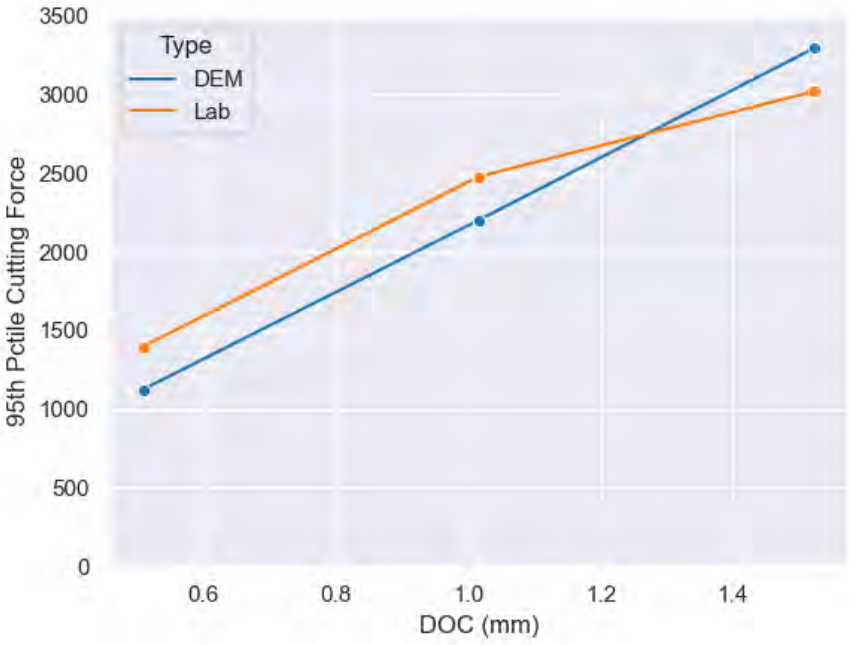

Figure 12: 95th percentile cutting force for all three DOC.

5. Conclusions

With drilling as one of the key challenges in EGS, it is critical to understand the in-situ mechanical behavior of dry hard rock to optimize cutter and drill bit design and operating parameters. The

granodiorite and gneiss presented here are two of the major rock types encountered during drilling at the Utah FORGE site. The high temperature tests shown here do not support the conclusion that rock mechanical properties are inherently different at 93° C than they are at room temperature. However, the preliminary tests shown at 200° C may show an effect of decreasing strength and increasing Young's modulus at high temperature. Further results will help to clarify the trend.

Discrete element models implemented in PFC3D, are a promising tool to predict rock cutting efficiency. The parallel bond model, one of the simpler bonded particle models available in PFC3D, appears adequate to predict rock cutting forces as validated by laboratory tests at multiple depths of cut. The rock cutting forces discussed here show a good match of not only mean force, but the overall distribution of forces experienced by the cutter during rock cutting. By knowing the full range of force fluctuation that the cutter undergoes, it may be possible to use this tool to predict cutter fatigue life or even vibrations at the rock-cutter interface.

Geothermal well drilling; HTHP formation; lost circulation material; CFD-DEM; fracture sealing.

ABSTRACT

Lost circulation is one of the major problems encountered in drilling geothermal and HTHP (high temperature and high pressure) formations. A part of these problems can be attributed to the high temperature and presence of hard and fractured rocks. Consequences and treatment of these lost circulation events can be extremely costly. Underbalanced drilling and LCMs (lost circulation materials) are the two most common methods to address the lost circulation problem. However, some LCMs have proved to be unsuccessful due to the unpredictable nature of fractures, complicated dynamics of LCM, as well as the change of mechanical properties of LCMs under high-temperature conditions. Long-distance circulations in high-temperature environments usually lead to the decline of size, strength, and friction coefficient of LCMs in parallel to the reduction of drilling fluid viscosity, and eventually failure in sealing fractures. In this paper, we developed a coupled CFD-DEM by combining computational fluid dynamics with discrete element methods to simulate the fracture sealing process by LCMs. The viscosity of drilling fluid, particle size, Young's Modulus, Poisson's ratio, and friction coefficient of LCMs were determined to represent possible variations under geothermal conditions. A series of sensitivity studies were conducted to further understand the fracture sealing efficiency of LCMs at elevated temperatures. The results show that a reduction in particle size, friction coefficient, and Young's modulus lowers bridging's probability, and slows down bridging initiation, but deepens the sealing depth, and tighter but the result is an unstable sealing zone. We noticed that the bridging mechanism changes from single-particle bridging to dual-particle bridging as particle size reduces. Also, the reduction of drilling fluid viscosity makes the sealing zone form faster and shallower.

1. Introduction

Geothermal energy is an important renewable energy resource especially for off-grid locations. It has received increasing attention in recent decades because it is an almost renewable, clean, low-carbon, safe, and ubiquitous resource. Therefore, geothermal energy can be an alternative to traditional fossil energy and a supplement for the growing energy consumption worldwide. The

geothermal well has been the most effective technique to get geothermal energy from underground to the surface. Drilling the well is the primary element in the cost of geothermal energy application, however, due to high temperatures (160~300+ °C), hard formation rocks (240+ MPa compressive strength), highly fractured (fracture apertures in the order of centimeters) and under-pressured situations, lost circulation has been one of the major in increasing the costs for drilling and completion in geothermal wells. Lost circulation treatments may represent possibly 15% of the total well cost (Finger and Blankenship, 2010). Lost circulation may also lead to troublesome, unsafe and costly consequences, such as drilling fluid loss, significant down times, stuck pipe, wellbore instability, well kick, incomplete primary cement job and in severe case well abandonment. The treatment for these issues can be very challenging and costly (Pierce and Livesay, 1994).

Lost circulation materials (LCMs), cementing, blind drilling and underbalanced drilling are the most common methods to address the lost circulation problem during geothermal drilling and completion. LCMs are routinely added to the drilling fluid to prevent lost circulation and primarily used when lost circulation is encountered. Unfortunately, most of the LCMs developed and used in oil and gas drilling have proved to be little or no use due to the unpredictive nature of the fractures (with the width in the order of centimeters), the complicated motion of LCM particles, as well as the change of mechanical properties of LCMs at elevated temperatures (Loeppke et al. 1990; Visser et al. 2018). However, using LCMs is still the first choice of drillers to treat lost circulation problems because it takes up very little time and minimum equipment and is reasonably inexpensive if successful. Using LCMs is also a better choice for temporary sealing of production zones rather than permanent sealing by cement (Finger and Blankenship, 2010). It is noteworthy that LCMs can be added to the cement slurry to cure severe lost circulation events induced by large fractures.

Three typical LCMs are used in geothermal drilling: fibrous, flaky and granular. Fibrous and flaky LCMs bridge the fracture to change the fracture into a porous structure and catch the following LCMs. Granular LCMs form a porous bridge, which gradually reduces the permeability of the sealing zone (Nugroho et al., 2017). Loss of circulation due to induced or natural fractures is best remedied by Mica flakes which have proven to function adequately, whereas conventional LCM materials used in drilling muds should be avoided (Visser et al., 2018). Unfortunately, although the application of LCMs is not satisfactory, the underlying mechanisms for the failure of LCMs to seal fracture are still unclear. This paper develops a CFD-DEM model to simulate the fracture sealing process by LCMs. The viscosity of drilling fluid, particle size, Young’s Modulus, Poisson's ratio, and friction coefficient of LCMs were determined to represent a possible variation range under the geothermal temperature range. A series of sensitivity analyses were conducted to further understand the sealing efficiency of LCMs in fractures for temperatures rising up to 300 °C. Through this, we are trying to understand the mechanisms behind the failure of conventional LCMs in sealing fractures in geothermal environments.

2. Effect of elevated temperature on basic properties of LCMs and drilling fluid

Temperature heavily influences the viscosity of the drilling fluid. Regardless of the base fluid, AV (apparent viscosity) of the drilling fluid generally decreases with an increase in temperature. However, PV (plastic viscosity) of drilling fluid is found to decrease initially, and then slightly increases with an increase in temperature (Wang et al. 2012; Garcõâ et al. 2001; Amani and Al-

jubouri 2012; Sheng-ying et al. 2008). Table 1 gives the viscosity variation of different drilling fluids at elevated temperatures. We can see that the viscosity of the drilling fluid can decrease from nearly 300 mPa·s to 1 mPa·s as temperature raises over 200 ℃. The lowest viscosity of drilling fluid is 0.25 mPa·s at high temperatures (Garcõâ et al., 2001).

Table 1 Viscosity variation of drilling fluid at elevated temperatures.

Drilling Fluid	Density (g/cm^3)	T (℃)	AV (mPa·s)	PV (mPa·s)	Reference
Fresh water-based	2.2	50~220	320~63	312~51	Wang et al. (2012)

Mentor26 mineral oil-based	1.32	23.9~204.4	(80~217)~(12~29)	(58~167)~(7~18)	

When LCMs are pumped and circulated from the ground to the thief zone, they will experience a series of environmental changes as well as physical and chemical reactions such as increases in temperature and pressure, or drilling fluid immersion, high-speed shearing, collision between particles and flow boundaries and collision between particles. Then the abrasion of LCMs can be promoted by thermal, mechanical, and chemical interactions occurring during the transport process. Experimental studies have shown that walnut shell, graphite, marble granules, calcium carbonate, and other common LCMs experienced a significant reduction of particle size under a specific shear rate in the drilling fluid at high temperatures for a one-half to a complete day (Scott et al. 2012; Yang 2015; Valsecchi 2014; Grant 2016). Kang et al. (2019) showed through experiments that size degradation of granular calcium carbonate by abrasion is slightly sensitive to the fluid temperature (80~160 °C). Their later work shows that walnut shell and millimeter-scale granular calcium carbonate experience both quality and size loss after heating to 180 °C in the oil-based drilling fluid (Kang et al. 2019). Decreasing fluid viscosity can result in a higher size degradation rate (Kumar et al., 2013). Therefore, size degradation of LCMs may aggravate at elevated temperatures due to the viscosity of the fluid decreases.

Table 2 Size degradation of LCM particle at elevated temperatures

LCM	Rotation speed (rpm)	t (min)	Fluid	T (°C)	D_{90} (μm)	Size degradation rate (%)	References

Mechanical properties of geomaterials are reported to be sensitive to temperature. The most critical and typical mechanical properties of LCMs are their compressive strength, Young's modulus, Poisson's ratio and friction coefficient. The experimental results of carbonatite (limestone and marble) show that compressive strength, elastic modulus, and Poisson's ratio generally decrease at elevated temperatures (Fig. 1). The uniaxial compressive strength can reduce from 120 MPa to 86MPa after heating up to 300 °C, the elastic modulus can reduce from 22 GPa to 7 GPa after heating at 300 °C, and the Poisson's ratio can reduce from 0.3 to 0.1 after heating at 300 °C (Brotóns et al. 2013; Zhang et al. 2009). Kang et al. (2019) found that the friction coefficient of walnut shell and calcium carbonate reduces to 28% and 1% of the original value after heating to 180 °C, respectively. The carbonatite is the natural source of calcium carbonate, which is the most popular LCM used in drilling operations. In other words, the compressive strength, elastic modulus, Poisson's ratio and friction coefficient of LCMs generally decrease as temperature increases.

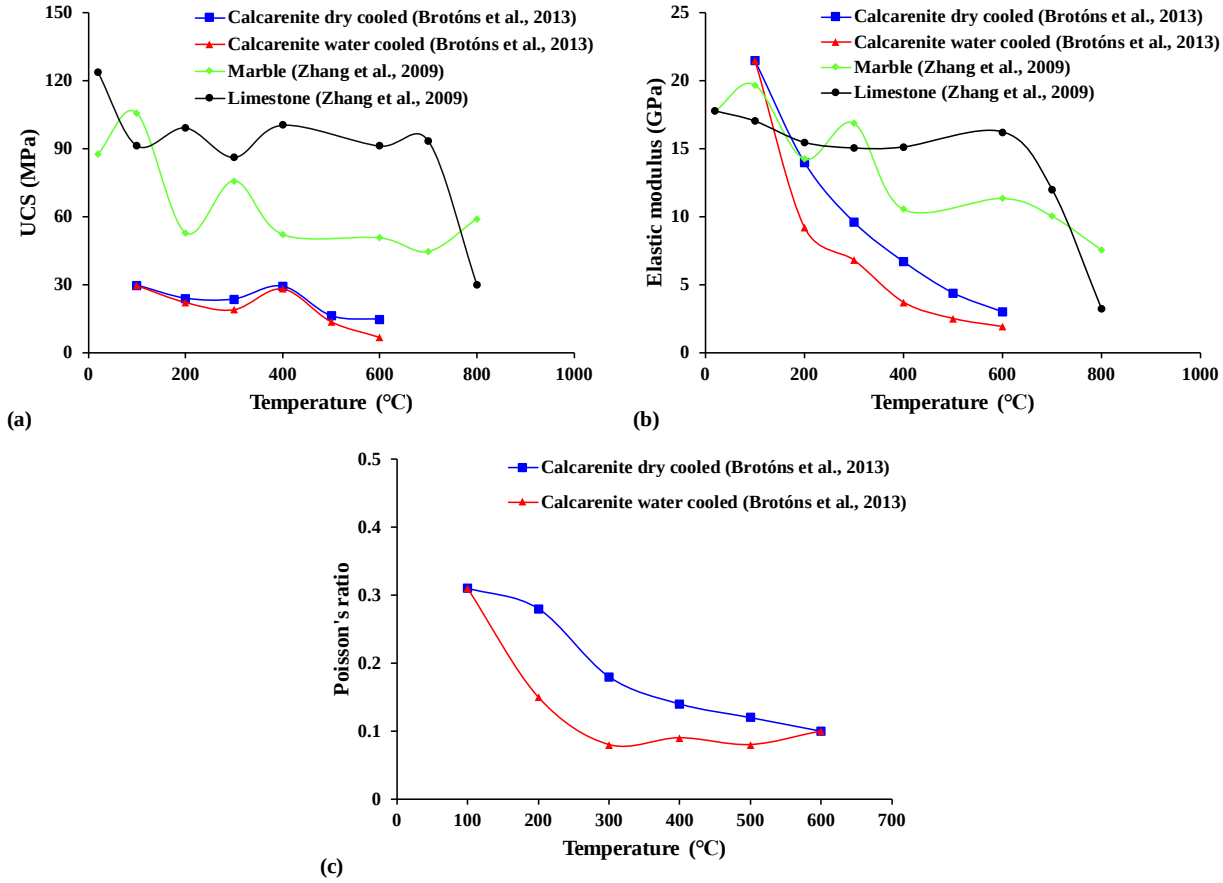

Fig.1 Mechanical properties of carbonatite change at elevated temperatures, e.g. (a) uniaxial compression strength (UCS) ; (b) Elastic modulus; and (c) Poisson's ratio.

3. Methodology

The goal is to simulate the flow of LCM laden drilling fluid and the sealing process driven by bridging of LCM particles in a vertical fracture. We mainly investigate the effect of variations in mechanical properties at elevated temperatures on the sealing process. The fracture geometry used here is a vertical wedge shown in Fig. 2. The modelled fracture has a length of 100 mm, a height of 25.4 mm, and width varying gradually from 1 mm to 0.33 mm from the inlet to the outlet (the fracture inlet width, W_{fi}=1mm). We assumed that formation is very stiff so the fracture walls are assumed to be rigid smooth surfaces, although the fracture roughness may help the bridging process. Hence, this model can be a simplified representation of a part or whole of the real fracture in the subsurface.

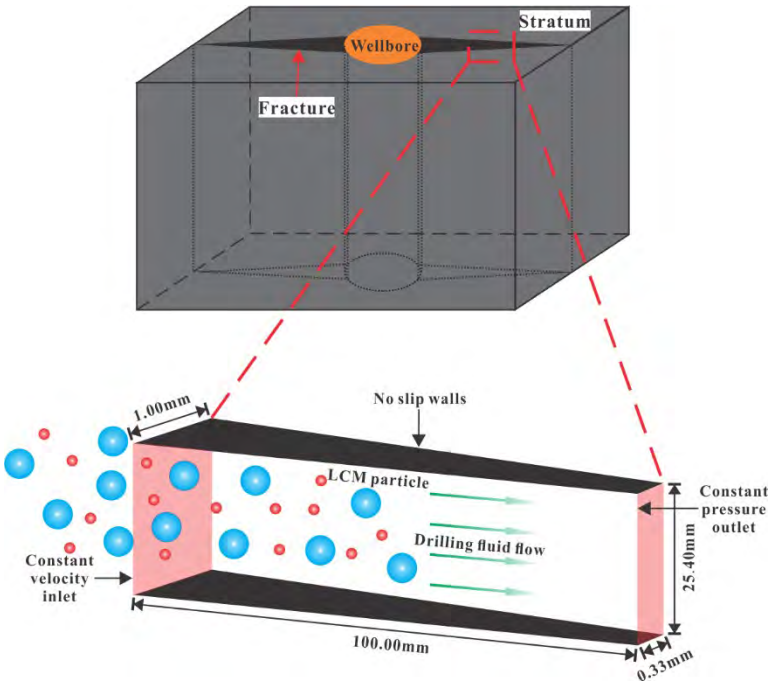

Fig. 2 A schematic diagram of fracture geometry used in the simulation.

The coupled CFD-DEM model of fracture sealing by LCMs is developed based on the open source CFDEM®coupling (Kloss et al. 2012; Hager et al. 2018). The number of particles used in the simulation is about 100, 000, the unresolved CFD-DEM method (Hager, 2014) is utilized to simulate the considerable number of particles' involved in the fracture sealing process. In the CFD-DEM, the fluid phase is assumed to be a continuum and its meso-scale motion is described by the volume-averaged Navier-Stokes equation, while the micro-scale motion of the solid phase is described by Newton's and Euler's second laws. The motion of an incompressible-fluid phase in the presence of a secondary particulate phase is governed by the volume-averaged Navier–Stokes equations (Zhou et al. 2010)

The DEM used here is a Lagrangian method. The trajectory of each particle is calculated under the consideration of influences by other particles, walls or present forces. The motion of a particle consists of a rotational component and a translational component. The translational and angular accelerations of a sphere are based on the corresponding momentum balances.

The CFD domain is gridded into hexahedral mesh cell with size of 2mm×2mm×(0.34~1)mm. The characterized length of a single cell is at least 3 times larger than particle diameter, which can obtain accurate and convergent results (Peng et al., 2015). Besides, this size also ensures the porosity changes gently. A constant injection rate, constant pressure and a no-slip wall were set as the boundary conditions at the inlet, outlet and fracture walls, respectively. A linear velocity of 1m/s along the fracture direction is the initial velocity condition at the inlet. The pressure at the outlet is considered to be zero. The gravity is 9.81 m/s^2 in the direction of fracture height. Other field data will be calculated based on these velocity and pressure field data. The solver cfdemSolverPiso provided by CFDEM® coupling for handling unresolved CFD-DEM problems is used to solve the governing equations. The implementation of the solvers is based on OpenFOAM's pisoFoam. The Reynolds Number (*Re*) is a non-dimensional parameter which indicates whether the flow follows the laminar or turbulent regime. According to the Reynolds number of the non-circular duct calculated by the hydraulic diameter, the Reynolds Number in our study remains less than 100, which indicates a laminar flow inside the fracture. Although drilling fluids are typically non-Newtonian fluids, the shear thinning behavior can be approximated as Newtonian fluid due to the relatively low flow rate in this problem. Thus, the drilling fluid flow is treated as a laminar flow of incompressible Newtonian fluid, here. After a comprehensive consideration of Courant number for CFD calculation, Rayleigh time, Hertz time and particle relaxation time for DEM calculations, and response time of fluid and particle, the time step of CFD and DEM was chosen 10^{-5} and 10^{-7}s, respectively. Therefore, the coupling time steps are every 100 DEM time steps.

For the next sections, we have designed a series of numerical experiments to understand the effect of mechanical property variations at elevated temperatures on the fracture sealing process. The basic parameters used in the simulation are shown in Table 3.

Table 3. Parameters of the fluid phase and solid phase used in the simulation

Phase	Property parameter	Value
Fluid	Density, kg/cm^3	1700
	Dynamic viscosity, Pa·s	0.0001/0.01/0.05/0.1/0.15
Solid	Density, kg/cm^3	2700
	Diameter, mm	0.1/0.2/0.33/0.4/0.5/0.6/0.7/0.8/0.9/1.0
	Young's modulus, GPa	0.1/1/10/30/50/70/100
	Poisons ratio	0.1/0.2/0.3/0.4/0.5
	Restitution coefficient	0.5

	The friction coefficient of particle and fracture surface	0/0.2/0.4/0.6/0.8/1.0

4 Results and Discussion

4.1 Effect of thermally reduced viscosity of drilling fluid on fracture sealing

Fig. 3 to Fig.4 show that the formation of a sealing zone by LCMs can be significantly influenced by the reduction of drilling fluid viscosity at elevated temperatures. The volume concentration of the LCMs is 10% in all simulations. A sealing situation is when particles stop and accumulate in a cross-section of the fracture, and the pressure of the fracture inlet builds up simultaneously. First of all, any reduction of the drilling fluid viscosity changes the velocity of LCM particles at high

temperatures. In low-viscosity drilling fluid, LCM particles move faster but with a lower local concentration compared to that in the high-viscosity drilling fluid. LCM particles move further and bridge faster at low viscosity (Fig. 3). However, the settlement of particles in the fracture is inconspicuous because of the insertion velocity, fracture length and particle concentration. Reduction of the drilling fluid viscosity has significantly shortened the sealing zone depth, in other words, sealing occurs earlier inside the fracture. When the viscosity of drilling fluid drops from 150 to 0.1 mPa·s, the sealing zone depth decreases initially and then changes little after 10 mPa·s (Fig. 4). Results of μ=0.1 and 1 mPa·s are similar while results of μ=10, 50, 100 and 150 mPa·s are similar. It is notable that the viscosity of the particle-laden fluid cannot change with various volume fractions of particles in the unresolved CFD–DEM model (Blais et al., 2016). Therefore, the viscosity here is only the viscosity of the pure fluid phase.

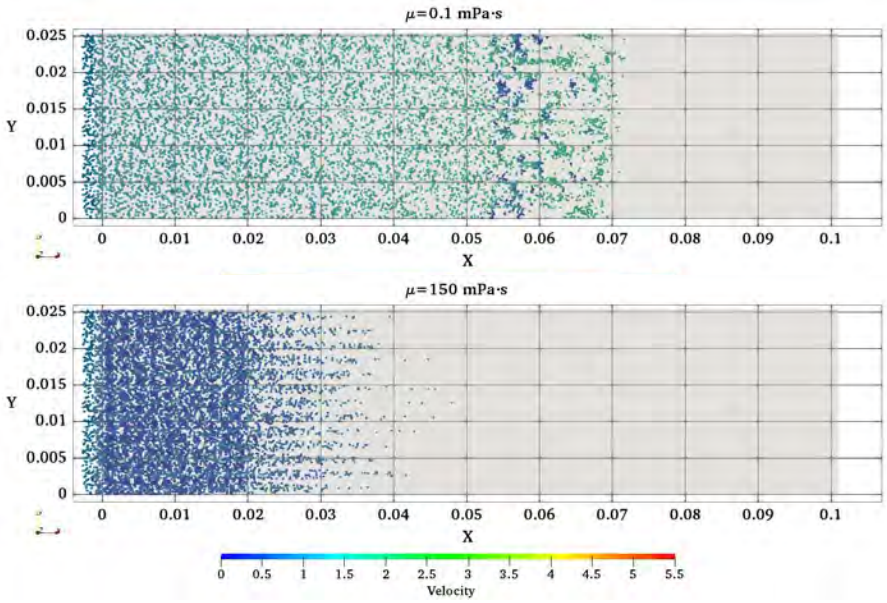

Fig. 3 Snapshots of LCM particles in motion under various drilling fluid viscosity after 0.6~0.8 $V_{fracture}$ drilling fluid is moved through the fracture. LCM particles moves along the fracture length direction with few particle bridges in low viscosity drilling fluid. The color means the velocity magnitude of the particle, which reflects the movement state of particles. The velocity increases gradually as color changes from blue to red.

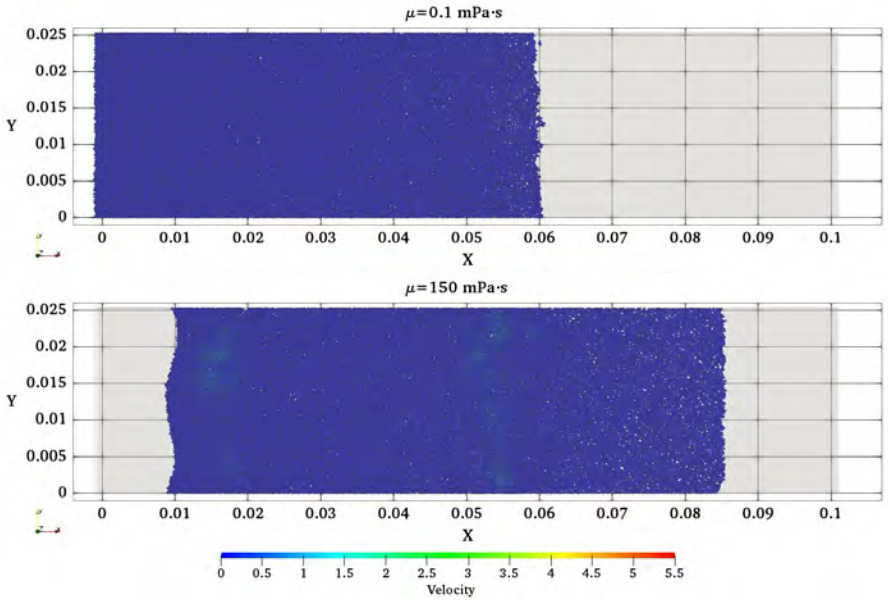

Fig. 4 Final fracture sealing state of LCMs under various drilling fluid viscosity after about 10 $V_{fracture}$ drilling fluid is moved through the fracture. The dark blue color means all particles in the figure has been immobile under drilling fluid flow, which indicates a seal.

In addition to changes in the location of the formation of the sealing zone, a reduction of drilling fluid viscosity also affects the quality of the formed seal. Fig. 5a shows that both the maximum and the stable pressure difference between the inlet and outlet of the fracture decreases as the viscosity of the drilling fluid reduces. The pressure difference is 33 MPa at the viscosity of 150 mPa·s while it reduces to 0.17 MPa at the viscosity of 0.1 mPa·s. According to the Kozeny-Carman equation (Carrier, 2003), the pressure difference of a laminar and steady-state fluid flow through a random packing is directly proportional to the viscosity of the fluid. However, the ratio of pressure difference is not equal to that of the corresponding viscosity. It means that the pressure difference variation is also impacted by other factors except for viscosity variation. Simulation results show that the porosity of the sealing zone under decreasing drilling fluid viscosity is 0.461, 0.469, 0.481, 0.489, 0.477 and 0.475, respectively. Porosity increases as viscosity reduces from 150 to 10 mPa·s and decreases as viscosity reduces from 10 to 0.1 mPa·s. In other words, the sealing zone becomes looser as viscosity drops. The flowrate at the fracture outlet continuously decreases from 2.50×10^{-5} to 1.16×10^{-5} m^3/s as the viscosity of drilling fluid reduces from 150 to 0.1 mPa·s (Fig. 5b). The cumulative drilling fluid volume passing through the fracture before sealing initially decreases and then slightly increases as viscosity of drilling fluid reduces. The smallest lost, *i.e.* lowest cumulative drilling fluid volume, is obtained by the drilling fluid with a viscosity of 10 mPa·s (Fig. 5c). This trend is consistent with that of the porosity of the sealing zone. It is noticeable that the major change in pressure difference, flow rate, and cumulative fluid loss volume occurs when the viscosity of the drilling fluid drops from 150 to 100 mPa·s. Below this limit, these three parameters change slightly by viscosity changes (Fig. 5d), as the viscosity of 150 mPa·s is high enough to continually destroy the initially formed sealing zone and push them back into deeper position until a stable seal forms. Therefore, the flow rate at the outlet and cumulative fluid loss are much higher than in the other cases. The large pressure difference is the result of combining the effect of the highest viscosity and flow rate of drilling fluid and the lowest porosity of the sealing zone.

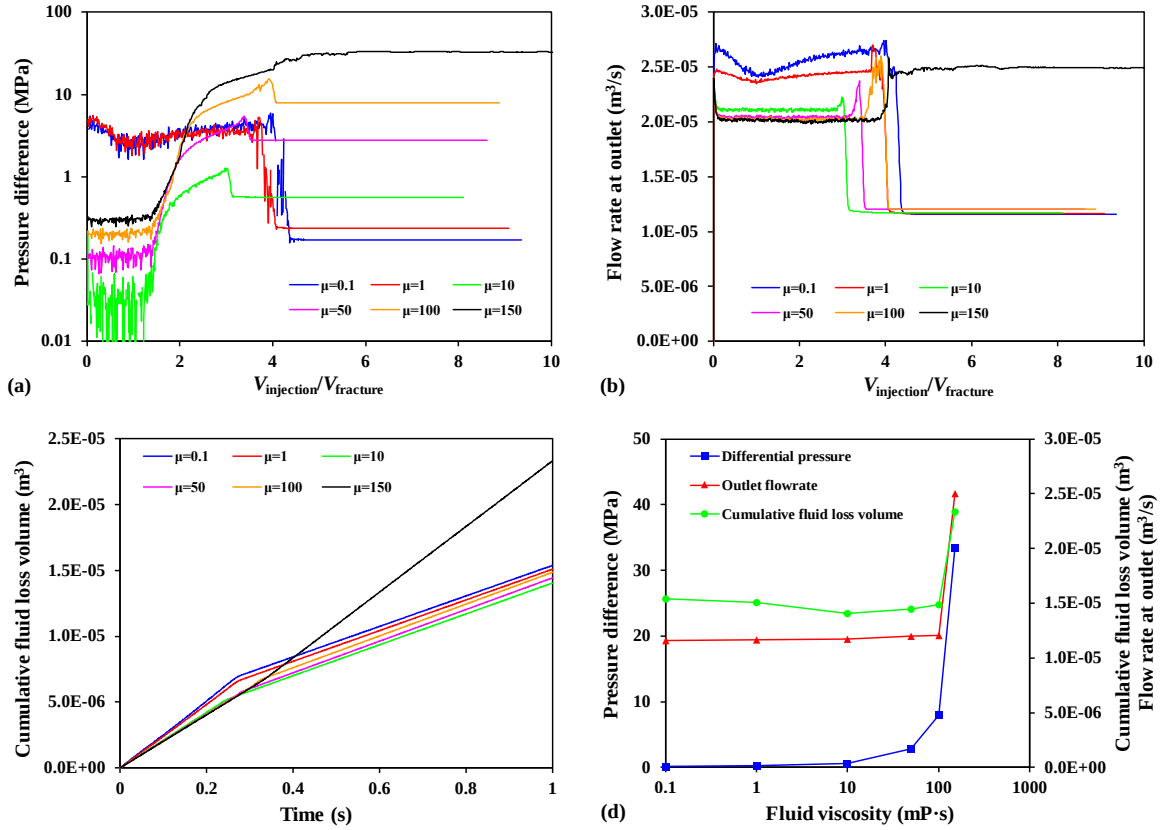

Fig. 5 Variation of the flowing parameter inside the fracture at various viscosities of the drilling fluid: (a) pressure difference; (b) flow rate at the outlet; (c) cumulative drilling fluid loss volume; (d) flowing parameter at the final state.

According to the simulation results, it is evident that as the temperature rises, the viscosity of the drilling fluid reduces affecting fracture sealing by LCM. LCM particles bridge faster and form a shallower sealing zone with less fluid loss and lower pressure difference in the fracture. The low viscosity of drilling fluid means low resistance for a particle moving. The particle can move faster to reach a suitable position to bridge in low viscous drilling fluid than higher ones. Reduction of drilling fluid viscosity seems to be positive for a rapid formation of the sealing zone. However, low viscous drilling fluids lead to more settlement of LCM particles in the bottom of the fracture. It is unfavorable for fracture sealing if the concentration of LCMs is lower than the critical value.

4.2 Effect of thermally induced particle size degradation on fracture sealing

Particle size is one of the essential properties of LCM design for sealing a fracture. Size degradation of LCM particles, which is driven by thermal expansion rupture and thermal abrasion (Scott *et al*. 2012; Grant 2016; Kang *et al*. 2019), has a significant impact on fracture sealing efficiency. Particle size can reduce to 20% of its original value in a downhole elevated temperatures circulation environment. As shown in Fig. 6 (the last two figures), in the size of

1.0~0.6 W_{fi}, the formation process of the sealing zone is dominated by the single-particle bridging mechanism. For particle diameter, D=1.0 W_{fi}, LCM particles seal outside the inlet due to wedge shape and size of fracture. For D=0.6 W_{fi}, LCM particles seal inside the fracture, which is similar to that of D=0.7, 0.8 and 0.9 W_{fi}. As particle size decreases from 1.0 to 0.6 W_{fi}, both bridging initiation time and bridging depth increase. For D=0.4 and 0.5 W_{fi}, the sealing process is dominated by a dual-particle bridging mechanism in the near field and a single-particle bridging mechanism in the far field. The LCM particles bridge at a short distance from the inlet by the dual-particle bridging mechanism and the escaping particles bridge again at a deeper position by the single-particle bridging mechanism, leaving a space between these two sealing zones (Fig. 6, the middle figure). However, the stability of the sealing zone formed by the dual-particle bridging mechanism is weaker than the one formed by the single-particle bridging mechanism. The initial bridging zone may crush in the middle (Fig. 7). It may be because particles can easily bridge at the top and bottom of the fracture, where three walls provide a sort of confinement for the particle flow. The later-coming particles pack at the previous bridge and extend to the middle gradually. Therefore, in the initial stage of the formation of the sealing zone, the middle part is the weakest part. For LCM particle size less than 0.3 W_{fi}, the process of the sealing formation is dominated by a dual-particle bridging mechanism (Fig. 6, the first two figures). However, when the particle sizes are smaller than 0.2 W_{fi}, the LCM particles cannot seal the fracture through the whole fracture height at this concentration. Moreover, the formed incomplete sealing zone will crash eventually. Besides, when the dual-particle bridging mechanism begins to work in the size range of 0.5~0.2 W_{fi}, both dual-particle bridging initiation time and bridging depth increase as the particle size decreases. Since the outlet width of the fracture is 0.34mm, LCM particles with a size smaller than 0.17 W_{fi} can barely bridge to seal the fracture.

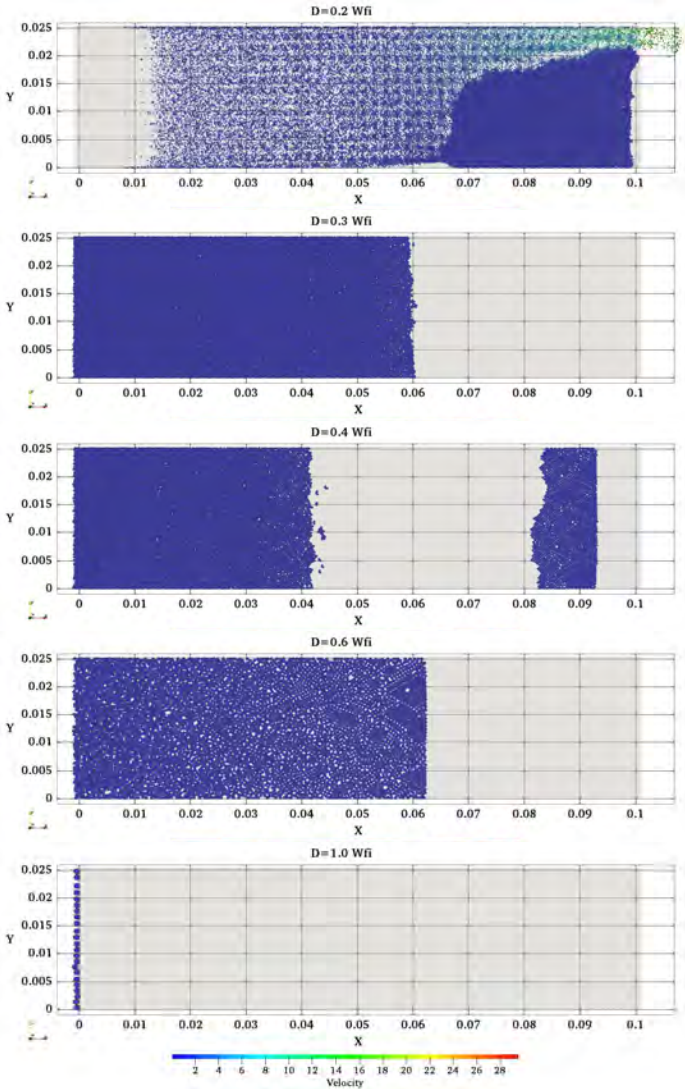

Fig. 6 Final fracture sealing states by LCMs under conditions defined by various ratios of LCM particle diameters to the width of fracture inlet after about 10 $V_{fracture}$ drilling fluid is injected.

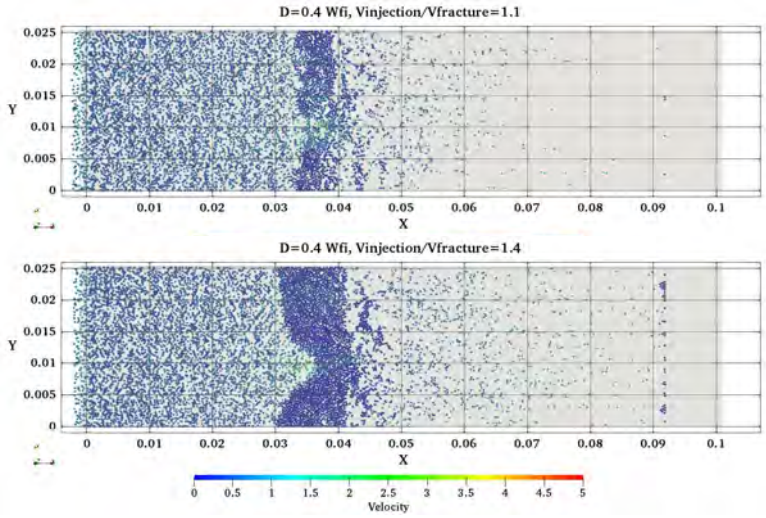

Fig. 7 Evolution of sealing zone by LCMs particle with size D=0.4 W_{fi}.

The quality of the sealing zone is also significantly affected by the particle size (Fig. 8). As particle size reduces from 1 W_{fi} to 0.3 W_{fi}, the pressure difference gradually increases except for D=0.5 W_{fi}. This is because particle with D=0.5 W_{fi} forms two thin sealing zones compared to the other particle sizes, which results in a lower differential pressure. Considering the fact that the injection rate is kept constant in our simulations, the pressure difference can be an indicator of the permeability of the sealing zone, which means that finer particles can form a tighter sealing zone. The final flow rate and cumulative fluid loss volume change slightly as particle size varies. However, D=0.2 W_{fi} and D=1.0 W_{fi} obtain larger flow rate and cumulative fluid loss than the other particle sizes, as no complete sealing zone formed.

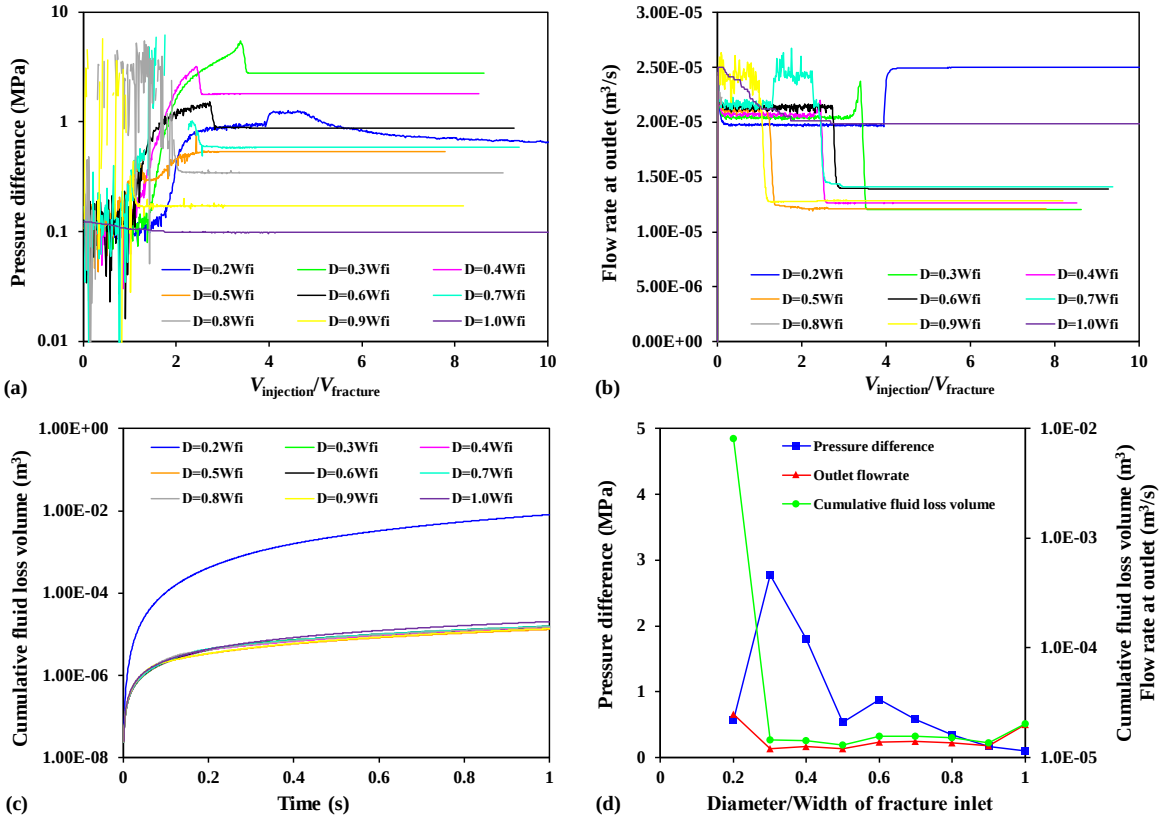

Fig. 8 Variation of different flow parameters for various ratios of LCM diameter to the inlet width of the fracture is shown, these parameters are (a) pressure difference; (b) flow rate at the outlet; (c) cumulative drilling fluid loss volume; (d) flowing parameter at the final state.

Therefore, the reduced particle size due to the thermal degradation can increase the bridging time and the bridging depth. Moreover, the bridging mechanism also switches from a single-particle bridging mechanism to a dual-particle bridging mechanism. However, the reduced particle size can form a tighter sealing zone.

5. Conclusions

A coupled CFD-DEM model is developed to simulate the sealing process of LCM particles in wedge-shaped fractures. Variations of drilling fluids and LCMs at elevated temperatures is summarized. Simulation of the fracture sealing process by LCMs particles is conducted using various parameters of drilling fluid and LCMs.

The elevated temperature usually leads to the decline of size, strength and friction coefficient of LCMs and reduction of drilling fluid viscosity. The bridging mechanism also changes from single-particle bridging to dual-particle bridging as particle size reduces. As a result of the combining effect of variations in drilling fluid and LCM properties at elevated temperatures, a successful fracture sealing case by conventional LCMs may become unstable and even completely fail at elevated temperatures.

hard rock drilling, downhole anchoring, long horizontal wells

ABSTRACT

An increasing number of geothermal projects require long horizontal well sections to be drilled through hard rock formations. Among these projects are those from well-known industry frontrunners that drill sets of inclined or horizontal wells to form downhole heat exchangers (closed loop Advanced Geothermal Systems – AGS) or Enhanced Geothermal Systems (EGS). These, and many other geothermal drilling scenarios, suffer from dysfunctions like insufficient transfer of weight on bit (WOB), drillstring buckling, and stick-slip that significantly impact cost and, ultimately, the feasibility of the project.

An innovative Downhole Anchoring and Drive (DAD) system will tackle the challenges associated with drilling long wells through hard rock and enhance especially those with long highly inclined sections. The DAD system grips the wellbore in close proximity to the drill bit and is designed to reduce damaging and inefficient drilling dysfunctions. The system includes smart control and actuation systems along with sensor feedback to autonomously drive the drilling process at the drill bit rather than at the surface. Moreover, it has the capability of applying significant axial push and pull forces to the drilling assembly and drillstring which enables additional WOB (essential for efficient drilling in hard rock) and dynamically optimizes it to dramatically improve drill bit and drill motor life and performance.

The first version of the tool was tested in Q2/2023 in a shallow test well of a leading rig contractor in Houston, TX. This paper summarizes the development and testing activities undertaken in 2024.

1. Introduction

The emerging concepts of AGS or EGS require drilling a significant quantity of long inclined or horizontal sections through challenging environments resulting from a combination of their high vertical depth (between 10,000 to 20,000 ft), hard crystalline rock formations with high friction factors (high drillstring torque and drag), and high formation temperature (a reliability challenge for downhole tools). The length of the horizontal section currently ranges from 5,000 (El-Sadi, 2024) to 9,000 ft (Longfield, 2022). The ability to drill long(er) horizontal sections cost effectively is essential for project economics (White, 2023). However, in practice, this is difficult to achieve because of the drilling dysfunctions that result when using conventional drilling technologies and processes in these applications.

The Downhole Anchoring and Drive (DAD) system currently under development will be a key component of future hard rock drilling systems and will eliminate and/or overcome the common drilling dysfunctions plaguing the cost-effective drilling of hard rock. It will reduce geothermal well construction costs through the application of significant and optimized downhole thrust force to the drill bit and allow faster and/or longer wells to be drilled than currently possible with today's conventional technologies. What follows is an overview of the problems typically encountered while drilling hard rock, what the DAD system is, how it eliminates these, and ultimately how it is a key enabler to future Autonomous Reeled Drilling Systems (ARDS).

2. Challenges related to geothermal well construction

Challenges related to well construction of long horizontal sections include drilling dysfunctions which consume significant amounts of energy that could otherwise be used to drill rock faster. They take many forms but ultimately increase drilling cost and risk through elevated downhole tool wear and damage, reduced Rate of Penetration (ROP), increased number of trips in and out of the hole, and potentially, in the case of lost in-hole event, the loss of a well.

A typical example of dysfunction is torsional vibration – large fluctuations, usually periodic, in the drill-bit rotation rate despite a constant rotation rate at the surface. Torsional vibration ultimately stems from the inverse relationship between drilling torque and the rotation speed of the now ubiquitous PDC drill bit. This results in negative damping and a tendency for the drill bit's rotary speed (and the drillstring connected to it) to oscillate when perturbed (Richard, 2007).

Another example of dynamic dysfunction is lateral vibration whereby the lateral stabilization of the drilling assembly and/or the engagement of the drill bit with the rock (a large component of drill bit lateral stability is the result of PDC cutter force balancing that relies on sufficient cutter engagement with the rock face) is insufficient to constrain lateral force instability or acceleration of the drill bit or other components within the drilling assembly. Not only can this form of dysfunction result in damage to downhole tools, but it can also cause significant irregularity in the wellbore path (tortuosity) that can then result in poor weight transfer to the drill bit (and further lateral vibration issues) as drilling progresses (Dupriest, 2013). Two common types of lateral vibration are forward whirl – typically occurs with limber drillpipe/collars that process in the same direction and similar frequency to drillstring rotation – and backward whirl – typically occurs on the drill bit and stabilizers whereby the rotation of the component within the wellbore is in the opposite direction to drillstring/bit rotation and at much higher frequency (Stroud, 2011). Both

result in high-impact shock and vibration damage along with rapid accumulation of bending fatigue (especially in the case of backward whirl).

Dynamic stability plots show the relationship of the above dysfunctions to drilling parameters (Figure 1). For maximum performance, it's desirable to work toward the upper right of the stability plot using the highest WOB along with the highest RPM while avoiding adverse dynamics – staying in the optimum zone. Watson (2013) confirmed through fundamental cutter testing that PDC drill bit ROP and life are maximized in hard rock by drilling at high WOBs.

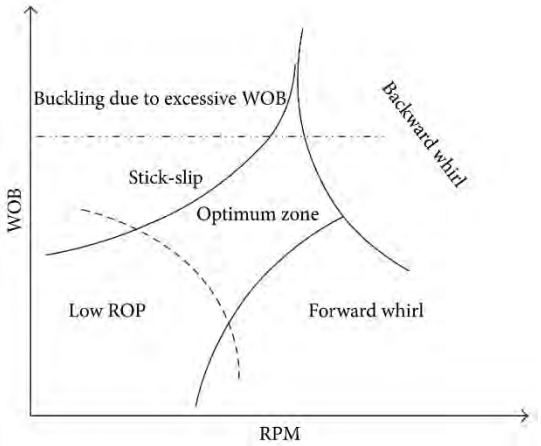

Figure 1: Typical Stability Diagram for Drilling (Wu, et al. 2010)

Avoidance and/or mitigation of dysfunction is challenging. Typically, the cause of the dysfunction is at the bottom end of the drilling assembly (for instance, the PDC drill bit) whereas the control and actuation system is many kilometers away on the top side. This results in a severely underactuated drilling system that can be very challenging to control (Krstic, 2022 & Auriol, 2022).

Figure 2 shows a drillstring drag analysis for the longest 3D granite well drilled in Thailand (Thai, 2022). This well reached a Total Depth (TD) of 22,200 ft with a circa 11,480 ft horizontal section. The cumulative drag at TD at 0 rpm (sliding) was predicted at 185,200 lbs. with approximately 25 lb./m rate of increase in the horizontal section. The DAD system can apply up to 60,000 lbs. of extra WOB in this hole size. In this well, that would have resulted in an extra 7,874 ft or 77% more horizontal footage before the same drillstring drag and levels of buckling would have been encountered.

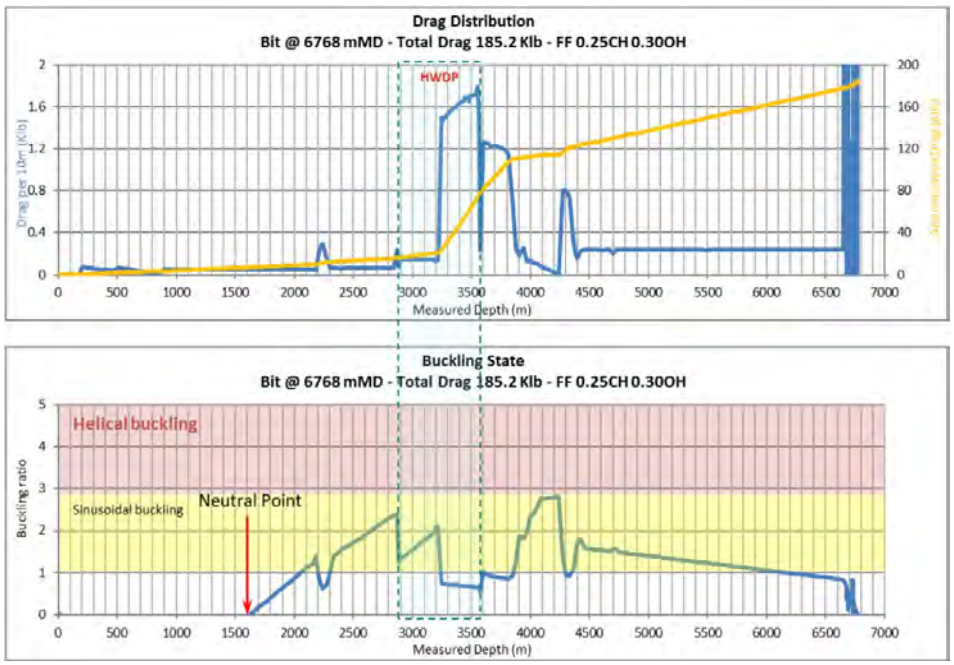

Figure 2: Drag Plot for Long Granite Well in Thailand (Thai, 2022)

What if the control and actuation system responsible for the drilling process were placed downhole in proximity (within 100 ft) of the source of instability e.g., the drill bit? What if it could apply significant and controlled downhole WOB to counteract the inverse bit torque to rotary speed relationship/negative damping and keep the drill bit cutters consistently engaged with the rock face to improve lateral stability and cutter life? What if this system could apply a significant WOB downhole directly to the drill bit to eliminate drillstring buckling and maximize reach? The answer is a more efficient drilling system that can drill both further and faster than the incumbent technology and ultimately reduces well construction cost and risk. This is what the DAD system offers the global drilling industry.

3. Downhole Anchoring and Drive (DAD) System

The DAD system is positioned within the bottom hole assembly (BHA) and contains hydraulically actuated gripping elements that anchor the BHA to the borehole wall and allow torsional and/or axial load to be reacted directly into the borehole rather than conveyed many thousands of feet above. The system contains a hydraulic thrusting unit that can apply significant and controlled thrust to the drill bit to both drill faster and actively reduce drilling dysfunction. The drilling process is controlled from the bottom of the hole with real-time sensor feedback to aid in optimization and includes many of the control modes that Drillers are accustomed to with the latest surface-based Automatic Drillers (ROP, WOB, Torque, etc.).

Dupriest and Noynaert (2022) showed that high WOB combined with more aggressive PDC cutters reduced drill bit wear rates and increased footage drilled in hard and abrasive formations. However, the same paper showed that this set-up generated stick-slip, an abrupt change in drill bit rotation rate, which had a very negative impact on the drill bit.

The resulting stability plot with the DAD system in the BHA can be seen in Figure 3. The threshold for buckling has shifted upward resulting from the ability of the DAD system to apply WOB

downhole and require less compression in the drillstring above (compression causes buckling). The stability resulting from local gripping of the wellbore has eliminated forward whirl and the ability to increase WOB and drill bit cutter engagement with the rock reduces the tendency to backward whirl. Ultimately, this extends the optimum zone, allowing higher WOBs and higher RPMs to be used, resulting in faster ROPs with fewer occurrences of damaging dynamics and adverse PDC cutter wear.

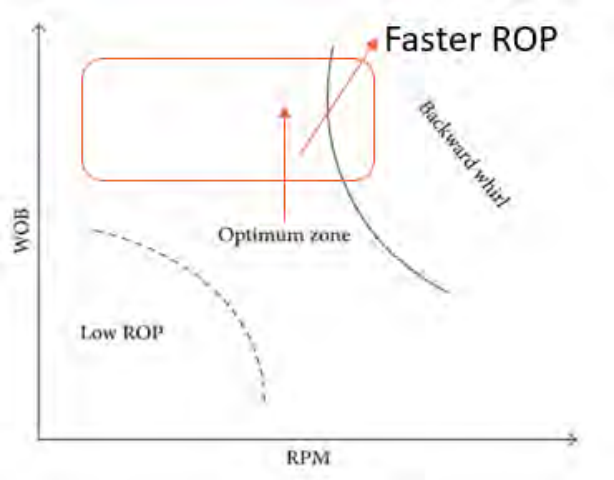

Figure 3 Modified Stability Plot Showing the Impact of the DAD System

3.1 Testing of the Anchoring Functionality

The predecessor to the DAD system focused on mechanically isolating the drill bit from the 'spring' of the drillstring to provide a rigid torsional anchor point above the drill bit to react with the torque output from the drilling motor/drill bit and allows maximum weight to be applied without triggering stick-slip.

The Concept Prototype (CP) utilized hydraulic oil to energize gripper pistons. The gripper pistons extended to grip the wellbore wall and transmit torque. The tool comprised two anchoring units connected via a closed hydraulic circuit. This hydraulic circuit synchronized the movement of the two anchors such that while one was gripping the wellbore the other unit was resetting position to take over from the gripping unit when it reached the end of its travel. The target was to continuously react torque to the formation via the grippers up to the maximum ROP – 70 ft/hr. for the CP.

The CP tool had no means of applying thrust to the drill bit and relied on it being applied by conventional means – heavy weight or drill collars in the BHA and the Driller controlling hook load/slack off weight to apply force to the drill bit. This CP was tested at the facility of a major drilling contractor in Houston, Texas, where they drilled a shallow cased hole filled with cement. The specifics of the test and results are described in Gajdos (2024). The shake-down test was successfully concluded with two main achievements:

1. The CP tool reliably gripped the wellbore while drilling and the movement of the two anchoring units was sufficiently synchronized (via the closed hydraulic circuit connecting them) to ensure continuous gripping during the test. The CP achieved the

required 70 ft/hr. with testing not able to reach the maximum limit of the tool´s capability.

2. Downhole drilling dynamic subs located above and below the downhole motor detected vibrations reduced by up to 35% when compared to drilling without the CP in the drillstring.

Despite the successes, there were two notable challenges faced by the CP tool:

1. On the trip out of hole one, one of the hoses connecting the tool's hydraulic circuits to the surface hydraulic power pack – the CP tool relied on surface-based equipment for hydraulic power – was damaged. This damage allowed cement and casing debris to enter the tool's hydraulic circuits (see Figure 4) and this required a full disassembly of the tool to remove prior to rebuild. Additional filtration was placed on the hydraulic circuits to prevent the spread and migration of debris throughout the system, in the case of infiltration, although the commercial version of the tool was not envisaged to require hydraulic lines to be run between the tool and surface and hence this particular failure mechanism – debris ingress through damaged hydraulic hose – would not exist.

Figure 4: Collected Cuttings

2. Figure 5 shows edge damage to the carbide gripping surface on the anchoring pistons. Minor surface damage was reported after interaction with hard rock (Gajdos, 2024). There is also the situation when the grippers interact with steel casing. The damage to the grippers after such a situation can be seen in Figure 5.

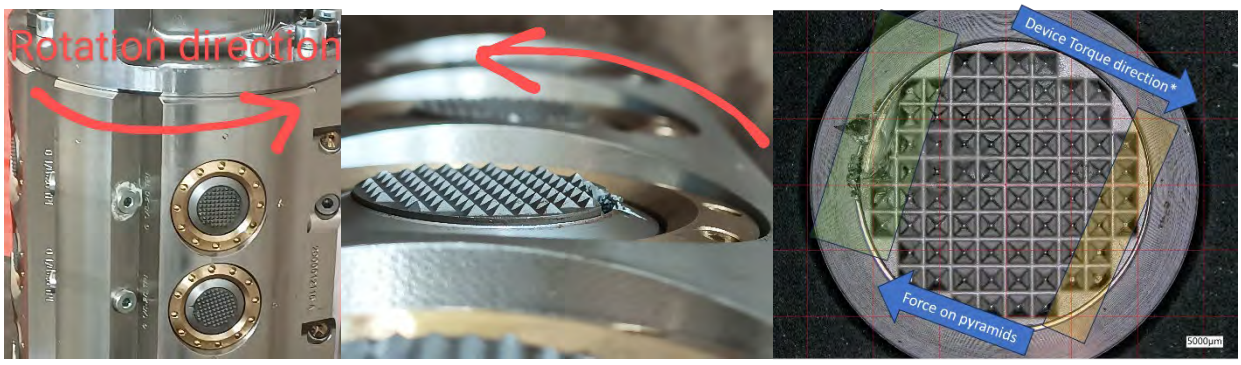

Figure 5: Damage on the Grippers after the Testing of Gripping in Steel Casing and Increasing Torque until the Tool Starts to Slip (left and center); Microscopy View on the Gripper with Highlighted Sections of Damage (at right).

The grippers were analyzed and several interesting conclusions were made:

1. Most damage occurs on one side of the gripper (green rectangle in Figure 5 right and Figure 6). These are brittle fractures in the case of the carbide gripper element. Subsequent damage to the piston body from the carbide fragments can be seen as a scratch in the direction of rotation/forces acting on the gripper piston.
2. The fractures were identified to be caused dominantly by tensile stresses because of one or more of the following:
   a. The carbide inserts do not conform to the inside of the casing/borehole (the gripper is planar vs. curved) – the edge stressed by tension fractured down to the brazed interface. The edge stressed in compression was found to have blunted gripper tips (in these materials, the tensile strength limit is several times lower than compressive).
   b. Incomplete circumferential mechanical support of gripper pad in the gripper pistons – the braze filler sits sub-flush to the top surface of the counterbore in the piston. This results in poor load transfer from the gripper pad into the piston and results in increased tensile loading.

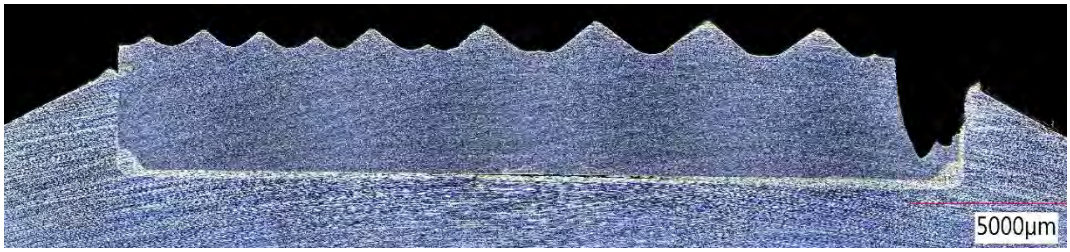

Figure 6: Cross Section of the Gripper Top with Visible Damage on the Right-hand Side

Based on this testing, it was concluded that the gripper elements must be curved to more closely conform to the shape of the casing's inside surface. This improvement will also benefit gripping in hard rock, although the small amount of deformation, penetration, and/or crushing that occurs between the gripper element and the rock reduces the susceptibility to this issue and helps more evenly distribute the stress in the gripper.

3.2 DAD Design and Configuration

A requirement for the original anchoring concept was for a purely hydro-mechanical tool with no electrical or electronic systems. This resulted from the desire for ultra-high temperature operations (350°C) for geothermal applications. As a drive to simplify the hydromechanical controls and modularize the design, it was decided to 'electrify' the anchoring tool with the addition of electronic actuation and control and, at the same time, add extra capabilities such as the application of controlled axial thrust/WOB to the drilling assembly and implementation of autonomous control loops similar to those in today´s cutting-edge automated drilling systems – these enhancements resulted in the DAD system as shown in Figure 7.

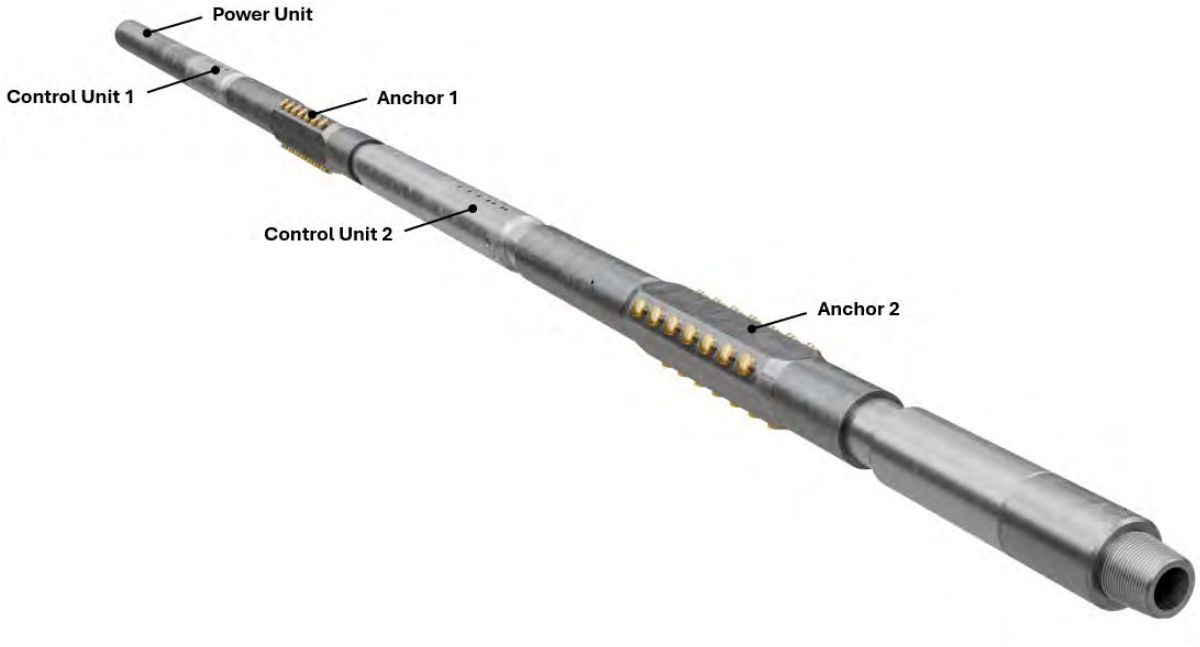

Figure 7: Visualization of the Downhole Anchoring and Drive (DAD) system

A summary of the enhancements of the DAD system over the CP tested at the drilling contractor's facility in Houston:

1. It incorporates an electronic/electrical control and actuation system to allow enhanced active control mechanisms to optimize the drilling process and reduce dysfunction.
2. Allows the drillstring to be rotated through the anchors to minimize drillstring drag and allow the use of conventional directional drilling motors and processes (e.g., slide and rotate).
3. Includes a comprehensive set of sensors and diagnostic data – e.g., pressure, torque, WOB, temperature, RPM, shock, and vibration.
4. Utilizes pressurized drilling fluid to reduce tool complexity and cost and will follow a similar design ethos to the most commercially successful RSS tools.
5. It includes an axial push/pull capability which can be used to apply additional WOB to improve ROP through higher depth of cut and/or reduced drillstring buckling/drag.
6. The modular design allows multiple anchors and thrusting units to be stacked in series should higher forces be required.
7. Utilizes a common electrical architecture that facilitates power and communications exchange between multiple modules and other third-party tools in the BHA creating the potential for a true integrated and autonomous drilling system.

The DAD System has two main tool configurations:

1. Axial anchoring only allows the central shaft to rotate through the anchoring modules and for true "plug and play" into conventional bent motors and jointed-pipe applications without the need for extra tools in the drillstring. The system utilizes modulation of axial thrust to mitigate stick-slip (and other dysfunctions).

2. Axial and Torsional anchoring – Torsionally locks the central shaft running through the system to the anchors such that when the anchors engage the borehole wall the drillstring above the DAD system cannot be rotated. Drilling motor torque reacts into the borehole wall (via the anchors) rather than into the drillstring. Allows high torque and extended reach drilling with coil tubing.

The DAD system comes equipped with the following control modes:

1. ROP Mode – This mode utilizes anchor traverse speed to control ROP, allowing for much more consistent drilling, eliminating common dysfunctions (e.g., axial stick-slip), and well control issues.
2. Bit Torque Mode – Utilizes torque feedback to stabilize drilling torque, significantly improving motor and drill-bit life and allowing motors to be run closer to maximum power (faster ROP) without risk of damage.
3. WOB Mode – This mode utilizes feedback from the WOB sensor to control axial thrust to stabilize WOB for a more consistent drilling process.

The commercial tool is undergoing development and testing for planned deployments towards the end of 2025.

4. Autonomous Reeled Drilling System (ARDS)

In addition to optimization of the drilling process through the proximity of the DAD system to the drill bit and its advanced control and actuation system, its ability to react torque and axial force into the formation is a critical enabler for drilling large diameter, hard rock wells with reeled pipe and/or coiled tubing. Coiled tubing is typically used for small diameter, low-cost well intervention and workover operations which require low torque and pull/weight capacity (compared to conventional jointed pipe in drilling applications). The ability to drill large hole diameter holes through hard rock with coiled tubing offers immense cost savings over conventional jointed pipe operations:

1. Smaller, lower-cost drilling rig due to reduced derrick capacity and tubular handling requirements.
2. Faster drilling and tripping times due to not needing to make/break rotary connections and pick-up/rack-back pipe (typically 3-4x the tripping speed compared to conventional jointed pipe).
3. Improved well control through the ability to continuously circulate while tripping in/out of the hole.
4. Reduced workplace hazards due to the elimination of rotary-shouldered connections made/broken on the rig floor.
5. Improved command and control of the downhole tools through a continuous data link to the surface via wireline.

A schematic overview of the ARDS with the DAD system can be seen in Figure 8.

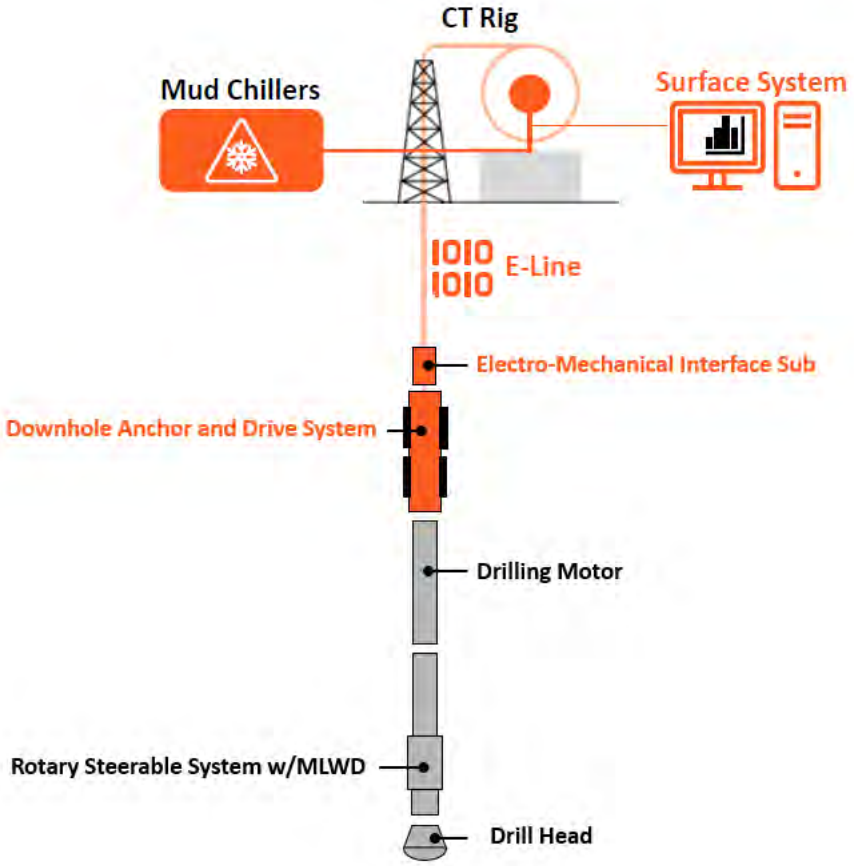

Figure 8: The Main Components of ARDS

The components of the Autonomous Reeled Drilling System are as follows:

1. Drill Head – conventional PDC, roller cone, or alternative rock destruction methods e.g., plasma.
2. Directional Drilling Assembly – allows steering of wellbore along with navigational and petrophysical logging measurements. Pictured above with Rotary Steerable System (RSS).
3. Drilling Motor – converts hydraulic energy in drilling fluid into mechanical energy for rotating the drilling assembly.
4. DAD System – the anchoring system reacts to the drilling motor torque into the formation to avoid damage and twisting of the coiled tubing string. The 700 series DAD can react to the stall torque of the heaviest duty 7-in OD drilling motors (for drilling 8.5-in to 8.75-in nominal hole size).
5. Coiled Tubing Interface – electromechanical connection of DAD system and BHA to coil tubing.
6. Coiled Tubing – customized coil tubing with improved fatigue properties and mechanical/hydraulic capacities.
7. E-Line – provides power and communications conduit between surface and downhole tools.
8. Rig – standard CT/intervention rig.

9. Surface System – this system allows data visualization, bidirectional communications, and control of the DAD system. It is also possible to receive MWD and LWD data.

5. Conclusion

This paper describes the innovative new Downhole Anchoring and Drive System proposed for hard rock drilling in geothermal applications. Typical forms of drilling dysfunction are discussed, along with the ability of the DAD system to mitigate these along with its ability to extend drilling distances through the application of downhole thrust. The DAD system will be commercially deployed in 2025 for geothermal applications. DAD system is also presented as the critical enabler of an Autonomous Reeled Drilling System, introducing a complete paradigm change in geothermal well construction.

Confining pressure, Mechanical specific energy, Interfacial friction angle, Hard rock drilling, Geothermal

ABSTRACT

Interfacial Friction Angle (IFA) is the frictional resistance experienced at the interface between the PDC cutters and the formation. Mechanical specific energy (MSE) is the energy required to remove a unit volume of rock during drilling. IFA is affected by normal and drag forces, including depth of cut (DOC) and rate of penetration (ROP), which also impacts MSE. Accurate interpretation of IFA and MSE in hard rock is crucial and can be used to optimize hard rock and geothermal drilling. This study used an in-house rig to test two 3¾" PDC bits (4 and 5-blade designs) to characterize IFA and MSE under hydrostatic pressures of 0 psi, 1000 psi, and 2000 psi. Tests were conducted in Sierra White Granite (SWG) using water as the drilling fluid at constant rotational speeds of 80 and 150 RPM, and the weight on bit (WOB) was incrementally increased while ROP and bit torque (T) were recorded. Results showed that the impact of hydrostatic pressure on MSE becomes distinctly evident at WOB values greater than 4000 lbs for both bits. Beyond this threshold, the effect on MSE is decreased for the tests under confinement, suggesting a change in rock failure criteria from elastic to more plastic deformation. The MSE for the unconfined tests (0 psi) decreases substantially after 4000 lbs, whereas this decrease is not observed in the tests under confinement (1000 psi and 2000 psi). The unconfined tests showed a more apparent decrease in MSE in Phase 2 (the efficient drilling phase) with increasing WOB, where the most effective drilling is seen when MSE values approach the rock's unconfined compressive strength (UCS). The values for MSE at a given confinement show the same trend for MSE but with a different low limit, indicating a distinctly different failure mode criterion. Results also showed that IFA becomes nearly constant in the efficient cutting phase of the drilling process. It was observed that increased confinement increases IFA during Phase 2 of the drilling process. During the inefficient phase of drilling (Phase 1), a higher IFA was observed due to insufficient WOB.

1. Introduction

When drilling in impermeable formations, hydrostatic pressure from the weight of the drilling fluid acts as confining pressure by uniformly applying force to the rock being penetrated at the bottom of the wellbore (Rampersad et al., 1994). Enhanced or deep geothermal wells are characterized by hard abrasive impermeable rock without formation fluids. This study assumes hydrostatic pressure as the confining pressure without considering pore pressure. Understanding the impact of confining pressure (i.e., hydrostatic pressure from the drilling fluid column) on IFA and MSE is crucial for optimizing drilling efficiency and reducing overall costs.

1.1 Mechanical Specific Energy (MSE)

Mechanical Specific Energy (MSE) is simplified as the energy required to cut a volume of rock, as depicted by Equation 1.

$$\text{MSE} = \frac{\text{Work done in cutting action}}{\text{Volume of rock removed}} \quad (1)$$

MSE has been widely used to measure drilling efficiency and maximize rate of penetration (ROP). While previous literature discusses the effects of MSE on drilling performance under atmospheric conditions, very little information is provided on the effects of confining pressure on MSE and its impact on drilling efficiency. Models have been established to calculate the specific energy required to remove a specific volume of rock. Teale (1965) proposed a model for calculating MSE in rotary drilling, which uses measurements of torque, weight on bit (WOB), and rotational speed (RPM). Teale's studies also demonstrated that maximum drilling efficiency occurs when MSE equals the unconfined compressive strength (UCS) of the formation being drilled; therefore, MSE can be used to identify optimal drilling efficiency. By comparing MSE to the formation's UCS in real-time, drilling performance can be evaluated, and drilling parameters can be adjusted accordingly to achieve the best results.

Pessier and Fear (1992) modified Teale's (1965) model and provided a way to calculate torque at the bit without reliable torque measurements where torque is calculated from the weight on bit (WOB). Even though Pessier and Fear's (1992) model uses WOB to calculate torque, the WOB is still based on surface measurements. Wellbore friction and inclination in directional drilling greatly influence WOB and torque values. This causes a deviation in the surface read WOB and torque values from actual downhole values. This limitation is not accounted for in Teale's (1965) and Pessier and Fear (1992) models. Dupriest and Koederitz (2005) later proposed an MSE model based on Teale's (1965) model incorporating mechanical bit efficiency. Dupriest and Koederitz (2005) assumed a mechanical bit efficiency of 35%. However, researchers (Hammoutene and Bits, 2012; Amadi and Iyalla, 2012) argued that the mechanical bit efficiency is bit specific and also differs based on the formation being drilled, which poses limitations on Dupriest and Koederitz's (2005) model.

Researchers have since sought to incorporate hydraulic energy into the MSE function to account for bit cleaning and removing cuttings from the hole (Mohan et al. 2009). Rajabov et al. (2012) studied the effects of back rake and side rake angles on the MSE of single PDC cutters with selected rocks at varying depths of cut (DOC) and confining pressures. It was found that the MSE decreases with increasing DOC up to 0.08" under both atmospheric and confining pressures in

Carthage Marble, Mancos Shale, and Torrey Buff Sandstone and then starts to increase slightly at DOC above 0.08". Rajabov et al. (2012) results suggested that the MSE increases significantly at low confining pressures and that the cutting mechanism changes at high confining pressures. Tests conducted by Rajabov et al. (2012) also showed that increasing confining pressure from 250 psi to 500 psi did not affect the MSE as opposed to increasing from atmospheric pressure to 250 psi, which indicates that most of the increase in MSE and decrease in cutting efficiency occurs at low confining pressures.

1.2 Interfacial friction angle (IFA)

The interaction between the rock and the cutter generates a frictional force at the cutter interface, which is characterized by the Interfacial Friction Angle (IFA). This angle represents the resistance encountered by the cutter as it penetrates and shears the rock, influencing the efficiency and effectiveness of the drilling process. IFA significantly affects the cutter's horizontal and vertical force components. Figure 1 shows the forces acting on a sharp cutter as reported by Detournay and Defourny (1992), where F_n is the normal force, F_d is the drag force, θ is the back rake angle, and ψ is the IFA. The IFA interaction between the rock and drill bit cutters plays a key role in the bit's response and overall performance.

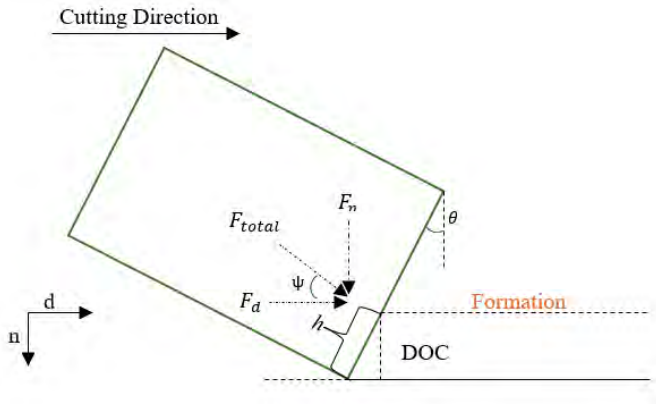

Figure 1: Force balance for sharp cutters (Detournay and Defourny, 1992)

IFA models derived from single cutter analysis are used with ROP models to improve ROP estimation and aid in drilling efficiency, improving overall drilling costs. The complexity of the cutting mechanism involving hard formations at high confining pressures is one of the primary sources of inaccurate ROP predictions in hard rock drilling; therefore, it is essential to estimate IFA as accurately as possible to optimize ROP successfully. Atashnezhad et al. (2020) developed an empirical model for PDC cutter rock IFA estimation to estimate different phases of drilling using a Differential Evolution Algorithm (DEA) where single cutter analysis was used. The IFA model includes the cutter velocity, PDC cutter back rake, rock's unconfined compressive strength (UCS), PDC cutter diameter, and DOC. Figure 2 shows an example of the IFA general trend for hard and soft rocks with increasing DOC, where two distinct drilling phases can be seen. IFA values are higher in Phase 1 and decrease as DOC is increased significantly for hard rock until Phase 2 is reached. At this point, the decrease in IFA becomes less steep, and the effect of DOC is

minimal. A horizontal trend is observed for soft rocks, signifying little to no effect on IFA with increasing DOC.

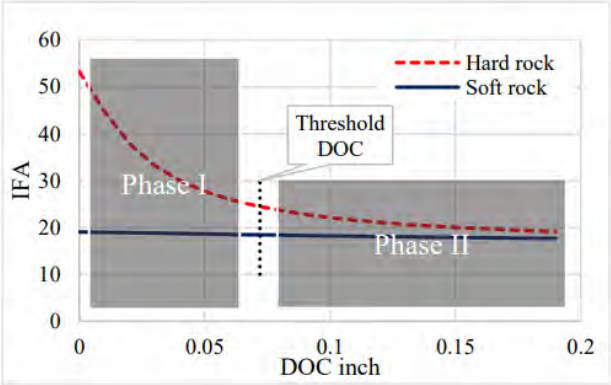

Figure 2: IFA trend for hard and soft rocks showing two phases of drilling (Atashnezhad et al., 2020)

This paper aims to analyze the direct effect of hydrostatic pressure from the drilling fluid at the bottom of the wellbore while drilling on MSE and IFA in Sierra White Granite (SWG) and discuss the impact of MSE and IFA on drilling efficiency in hard rock drilling.

2. Methodology and Testing

2.1 Bit Information

Two polycrystalline diamond compact (PDC) bits, 4-bladed and 5-bladed, each with a diameter of 3¾ inches, were used for laboratory testing. The front and side profiles of the 4-bladed and 5-bladed bits are shown in Figures 3 and 4, respectively. The properties of these bits are detailed in Table 1.

Figure 3: Bit 1- Four Bladed PDC bit front and side profile

Figure 4: Bit 2- Five Bladed PDC bit front and side profile

Table 1: Bit Properties

	Bit 1	Bit 2
Bit Diameter (inch)	3-¾	3-¾
Number of Face Cutters	11	19
Number of Blades	4	5
Cutter Diameter (mm)	13	11

2.2 Experimental

An indoor drilling rig, designed to simulate typical field conditions under both atmospheric and confining pressures was employed for testing. The experimental procedure followed was consistent with the methodology reported by Mayibeki et al., 2023. The experiments were performed at atmospheric and confining pressures of 1000 and 2000 psi. The tests were performed at 80 and 150 RPM rotational speeds, with the weight on bit (WOB) gradually increasing to approximately 6500 lbf. Sierra White Granite (SWG) was used with an unconfined compressive strength (UCS) of 28,000 psi, bulk density of 165.4 lb/ft^{-3}, and Young's Modulus of 6×10^{6} psi. The permeability and porosity of the granite were assumed to be negligible.

The indoor rig features a drill string powered by hydraulic energy. The WOB is electronically controlled, while the torque necessary for rotating the drill string is generated by a belt drive system connected to an electric motor, which is also hydraulically powered. The drilling fluid used in the testing was water, maintained at a flow rate of 100 gallons per minute and a constant temperature of 60 °F.

The rock sample was lowered into a confinement cell, which was pressurized using water to conduct the confinement testing. A back pressure regulator adjusted the pressure setting for a specific test. Sensors were placed at the drill string to monitor ROP, WOB, and rotational speed, where the sampling rate of the measured data was set to 100 Hz for the tests under atmospheric conditions and 2000 Hz for the tests under confinement.

3. Results and Discussion

3.1 MSE Analysis

MSE was calculated using Teale's (1965) model, as shown in Equation 2. In this model, WOB is measured in pound-force (lbf), the bit area (Ab) is measured in square inches (in²), RPM is measured in revolutions per minute (rev/min), the torque generated at the bit (T) is measured in foot-pound-force (ft-lbf), and ROP is measured in feet per hour (ft/hr).

$$\mathrm{MSE} = \left(\frac{\mathrm{WOB}}{\mathrm{Ab}}\right) + \frac{120\pi\times\mathrm{RPM}\times\mathrm{T}}{\mathrm{Ab}\times\mathrm{ROP}} \quad (2)$$

3.1.1 Four-Bladed Bit MSE Analysis

MSE results were initially analyzed as a function of the applied WOB to observe how MSE changes when the WOB is gradually increased from 2 klbf to 6.5 klbf at confining pressures of 0, 1000, and 2000 psi. Figures 5a and 5b illustrate the effect of incremental WOB on MSE at rotational speeds of 80 and 150 RPM, respectively.

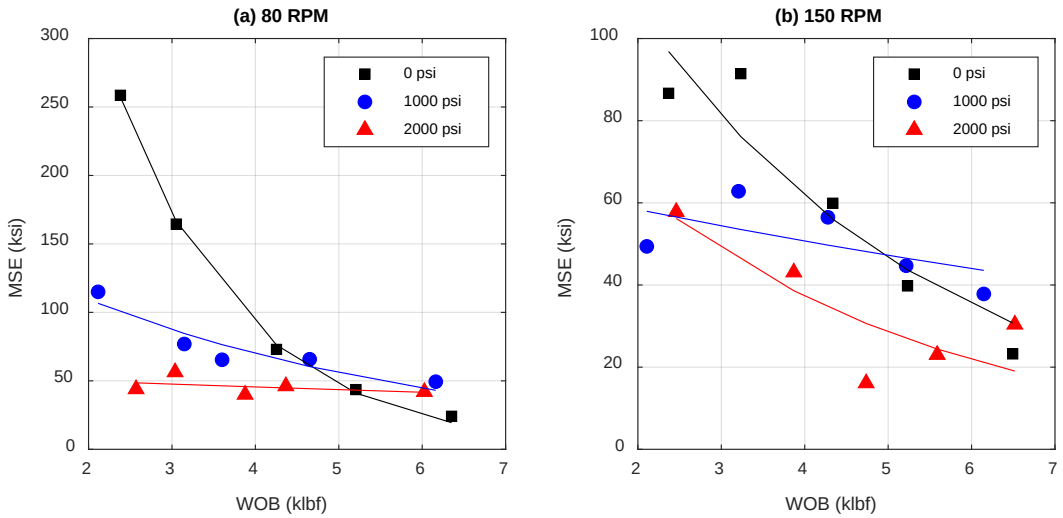

Figure 5: MSE as a Function of WOB Under Confining Pressures of 0, 1000, and 2000 psi at (a) 80 RPM and (b) 150 RPM

At lower WOB or during Phase 1 of drilling, the 0 psi tests exhibit higher MSE values than those under confinement. In the absence of confining pressure at lower WOB, fractures can propagate uncontrollably and irregularly due to the lack of external pressure. Confining pressure helps to maintain stress concentration around the drill bit cutters, enhancing its efficiency. Additionally, confining pressure contributes to the stability of the rock, creating a more localized stress concentration that ensures the applied energy is used effectively to remove a volume of rock. Without confinement, applied stress is more likely to disperse, reducing the efficiency of the rock-breaking process. This means more energy is required to achieve the same penetration rate compared to confined conditions. However, as WOB values exceed 4 klbf, the MSE for the 0 psi tests continues to decrease significantly, while the tests under confinement show nearly constant MSE values with a slight increase for the tests at 2000 psi.

At higher confining pressures, the rock failure mechanism appears to shift from brittle to ductile failure. Tests conducted by (He & Xu, 2015) reported a critical depth (i.e., hydrostatic pressure) beyond which the rock shifts from brittle to ductile failure. This transitional phase occurs at higher confining pressures, causing MSE to remain nearly constant or increase slightly for tests under confinement. This makes it more challenging to determine the most efficient drilling conditions at high confining pressures. Under confinement, the MSE requirement is more consistent and sustained due to the continuous shearing process. Because the rock has more of a ductile cutting action at high confining pressures, the energy required in the drilling process remains stable and does not fluctuate as much. Unlike brittle failure, where energy spikes might be observed, ductile deformation requires a constant energy supply, as observed in He and Xu's (2015) experiments.

As a result of the consistent and sustained MSE requirement, achieving the most efficient drilling parameters becomes more challenging. When drilling with higher weight on bit (WOB) at high confining pressures, the rock becomes harder due to increased stress, requiring more energy to drill it. Hydrostatic or confining pressure inhibits the formation of macro cracks and increases the rock's strength (Liu et al., 2021). As a result, the MSE also increases, especially in the tests conducted at 2000 psi confining pressure. However, the tests with 1000 psi confinement display a higher average MSE than the 2000 psi test, suggesting that the transition from brittle to ductile rock failure mode may occur around 1000 psi, increasing energy requirements at this pressure. Rajabov et al. (2012) observed a similar behavior where most of the MSE increase and energy consumption was seen at lower confining pressures.

Additional optimization techniques must be explored to achieve efficient drilling in hard rock under high confining pressures to reduce MSE. A higher RPM can lower MSE values due to the faster cutting action from the bit's rotation. However, real-time optimization methods are crucial for monitoring key parameters such as WOB, RPM, ROP, torque, and MSE to ensure an efficient and cost-effective drilling operation without excessively wearing the bit. The effect of confining pressure on MSE was also analyzed for constant WOB values of 2, 4, and 6 klbf to observe how MSE changes under varying confining pressures while maintaining constant WOB. Results are displayed in Figures 6a and 6b, illustrating the findings at (a) 80 RPM and (b) 150 RPM.

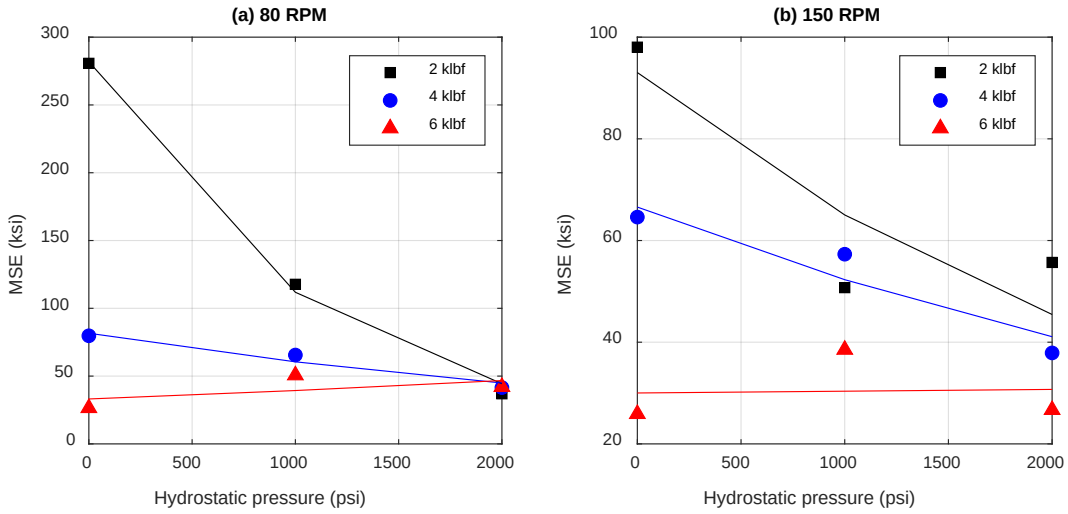

Figure 6: MSE vs Confining Pressure for a Constant WOB at (a) 80 RPM and (b) 150 RPM

The tests with the highest WOB show the lowest overall MSE at atmospheric pressure and under confinement, except for the test at 80 RPM and 2000 psi, where the lowest WOB shows the lowest MSE. A higher WOB ensures improved bit-rock contact, better cutter engagement, consistent cutting action, and enhanced energy transfer and utilization. These factors collectively reduce the MSE required to drill the rock, improving drilling efficiency. Drilling with a lower WOB is inefficient for hard rock at high confining pressures. An optimum WOB is necessary to lower MSE without excessively wearing out the bit.

The effect of confining pressure on MSE was also analyzed for constant DOC values of 0.01, 0.03, 0.06, and 0.1 inches/rev to observe how DOC influences MSE under varying confining pressures.

DOC (inches/rev) was calculated using Equation 3, where ROP (ft/hr) represents the penetration rate and RPM signifies revolutions per minute. Figures 7a and 7b show the effect of confining pressure on MSE based on DOC for 80 and 150 RPM, respectively.

$$\mathrm{DOC} = \frac{\mathrm{ROP}}{\mathrm{RPM}} \tag{3}$$

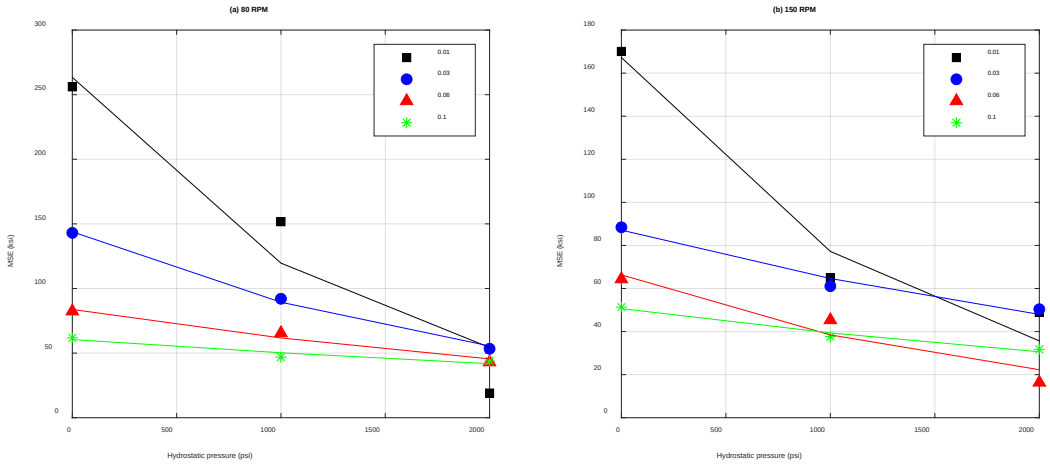

Figure 7: MSE vs Confining Pressure for a Constant DOC at (a) 80 RPM and (b) 150 RPM

Higher MSE values are observed at lower DOC and lower confining pressures due to reduced cutting efficiency and poor bit-rock interaction. When confining pressure exceeds 1000 psi, MSE significantly decreases for the test conducted at 0.01 inches/rev DOC and 80 RPM. At higher confining pressures, lower MSE values are observed at lower DOC values and 80 RPM due to the rock deforming plastically and undergoing shear failure. This suggests that a lower DOC facilitates more efficient drilling than a higher DOC when drilling hard rock under high confining pressures and low RPM.

However, a lower DOC and low RPM can result in lower ROP, making optimization techniques crucial for effective drilling. When drilling with a higher RPM, a higher DOC of 0.06 inches/rev is preferred, resulting in the lowest MSE, as shown in Figure 7b. A higher DOC tends to have lower MSE values at lower confining pressures due to increased penetration and easier fracture propagation from the brittle failure mechanism. In contrast, lower DOC values are more effective at higher confining pressures, where ductile failure dominates, as Richard et al. (1999) and He and Xu (2015) reported.

3.1.2 Five-Bladed Bit MSE Analysis

Results for MSE versus confining pressure at incremental WOB were analyzed for the 5-bladed bit. The WOB was gradually increased from 2 klbf to 6.5 klbf at (a) 80 RPM and (b) 150 RPM under confining pressures of 0, 1000, and 2000 psi. Figures 8a and 8b display the results at 80 RPM and 150 RPM, respectively.

Similar to the 4-bladed bit, tests with a lower WOB observed higher MSE at lower confining pressures, except for the test at 2000 psi and 80 RPM, which showed a continuous increase in MSE (Figure 8a). At higher confining pressures where plastic behavior is prevalent, the rock absorbs more energy as the rock deforms continuously without fracturing (He & Xu, 2015). At WOB values greater than 4 klbf, the MSE for the 0 psi test continues to decrease significantly, a trend not observed in the other tests. An increase in MSE is seen for the test under 2000 psi at 80 RPM, as more energy is required to break the rock at higher confining pressures. The increased pressure compresses the rock more tightly around the drill bit, requiring more energy to achieve effective penetration. Consequently, higher confining pressures demand a more significant input of energy to overcome the rock's increased resistance, resulting in higher MSE values. The increased confining pressure and plastic deformation increase the overall energy demand, leading to higher MSE values.

Increasing WOB can achieve Minimum MSE at a lower value in unconfined conditions. However, reaching the minimum MSE requires a greater WOB under higher confining pressures. This indicates that the MSE and energy consumption in drilling vary with confining pressure, with optimal drilling efficiency being easier to achieve in unconfined environments. As confining pressure increases, the rock's resistance to drilling also increases, necessitating higher WOB to attain the minimum MSE. Moreover, this trend suggests that there is a point beyond which further increases in WOB might not significantly reduce MSE or may even increase it due to the complexities of rock deformation and failure mechanisms under high pressure, as observed in the tests at 2000 psi and 80 RPM for both bits. This emphasizes optimizing WOB based on the specific confining pressure conditions to achieve the most efficient drilling performance.

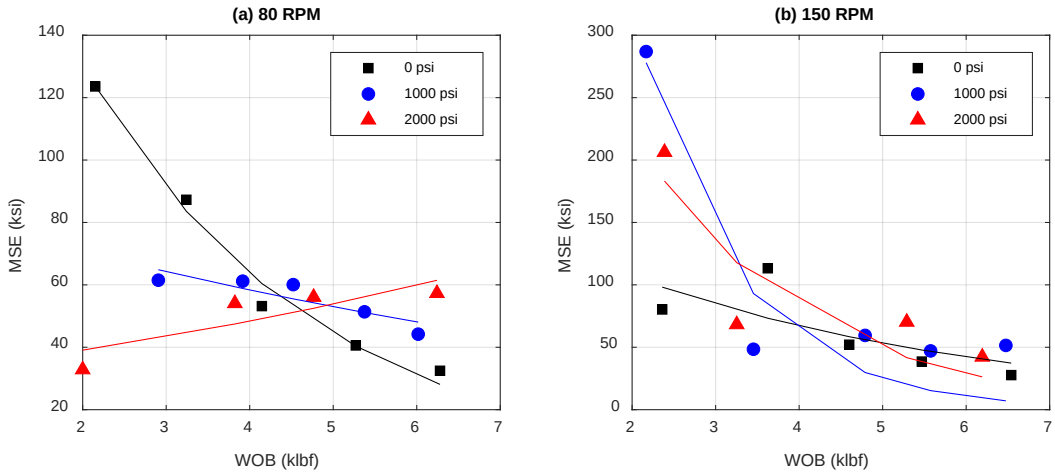

Figure 8: MSE as a Function of WOB Under Confining Pressures of 0, 1000, and 2000 psi at (a) 80 RPM and (b) 150 RPM for the 5-bladed PDC bit

Figures 9a and 9b illustrate the effect of confining pressure on MSE under constant WOB values of 2, 4, and 6 klbf at (a) 80 RPM and (b) 150 RPM. Unlike the 4-bladed bit, tests at higher WOB values exhibit the lowest MSE, only up to 1000 psi for the tests conducted at 80 RPM. The MSE for the 2 klbf test shows a continuous decrease in MSE, a trend not observed in the other tests. This observation suggests that for the 5-bladed bit, drilling with a lower WOB and a lower RPM under high confining pressures might be optimal for efficient drilling, but this will result in reduced

ROP and increased rotating time. However, tests conducted with higher WOB at higher RPM achieved the lowest MSE, as shown in Figure 9b. Drilling with a high RPM can cause vibrations and stability issues, therefore, a higher WOB may be necessary to maintain bit stability, reduce vibrations, and ensure a smoother drilling process.

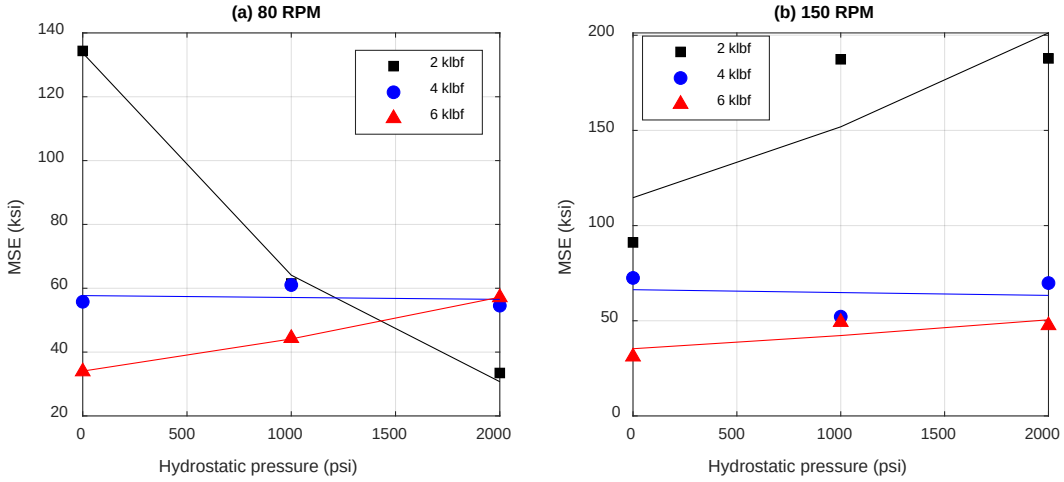

Figure 9: MSE vs Confining Pressure for a Constant WOB at (a) 80 RPM and (b) 150 RPM

The effect of confining pressure on MSE at different DOC was also analyzed at 80 and 150 RPM for the 5-bladed bit. Figures 10a and 10b present the results at 80 and 150 RPM, respectively.

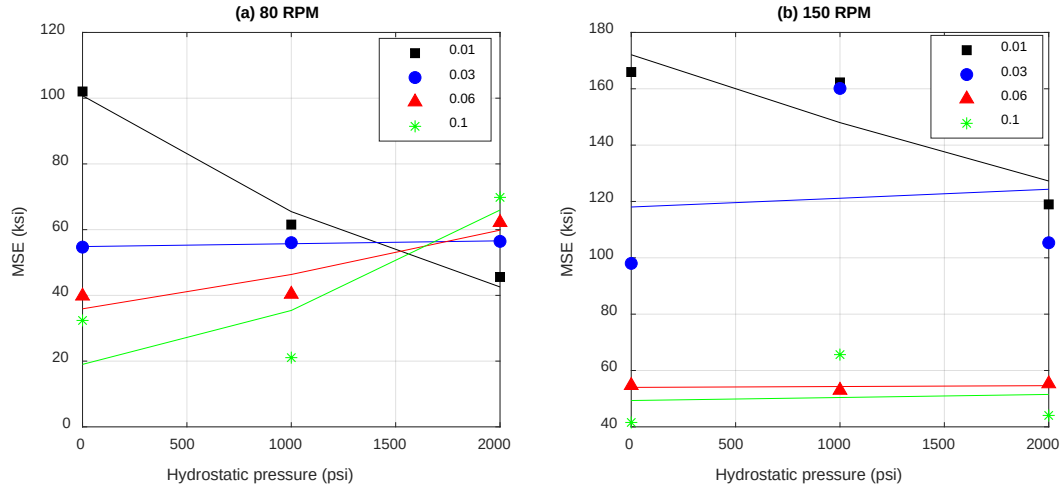

Figure 10: MSE vs Confining Pressure for a Constant DOC at (a) 80 RPM and (b) 150 RPM

Similar to the 4-bladed bit, tests with a lower DOC exhibit higher MSE values at lower confining pressures due to poor bit-rock interaction. At 80 RPM, as confining pressure increases, the MSE for the test with the lowest DOC of 0.01 inches/rev continues to decrease significantly, while the other tests show a steady increase in MSE. This observation further reinforces that a lower RPM and DOC of 0.01 inches/rev are optimal for drilling hard rock at high confining pressures. However, at 150 RPM, tests with a higher DOC demonstrate the lowest MSE, indicating that

drilling with a higher DOC is most effective at higher rotational speeds, as observed with the 4-bladed bit.

3.2 IFA Analysis

Principles from Detournay and Defourny's (1992) IFA model were used to create a correlation shown in Equation 7, to calculate the equivalent bit IFA values. Hareland & Rampersad's (1994) equivalent radius concept was also used to calculate the drag force on a cutter (DFOC). In Equation 7, ψ denotes the IFA (deg), WOC is the weight on cutter (klbf), DFOC is the drag force generated at the cutter (klbf), and BR is the cutter back rake (deg). WOC and DFOC can be calculated from Equations 4 and 5 respectively. The equivalent bit radius (Re) measured in inches can be calculated from Equation 6.

$$\mathrm{WOC} = \frac{\mathrm{WOB}}{\mathrm{Nc}} \tag{4}$$

$$DFOC = \frac{\frac{\text{Measured Torque}}{\mathrm{Re}}}{\mathrm{Nc}} \tag{5}$$

$$\mathrm{Re} = \frac{\mathrm{Db}}{\sqrt[2]{2}} \tag{6}$$

$$\psi = \mathrm{Tan}^{-1}\left(\frac{\mathrm{WOC}}{\mathrm{DFOC}}\right) - \mathrm{BR} \tag{7}$$

3.2.1 Four-Bladed Bit IFA Analysis

Figures 11a and 11b illustrate the effect of confining pressure on IFA as a function of the applied WOB and RPM. For a constant WOB, increasing confining pressure results in a higher IFA at both rotational speeds. This is mainly due to the increased normal forces at the contact interface between the drill bit and the rock, which results in greater frictional resistance. The lower WOB tests show the highest average IFA at both rotational speeds. Lower WOB results in decreased penetration rates, causing the drill bit to remain in contact with the rock for a longer duration. This extended contact increases the likelihood of higher frictional resistance, leading to a higher observed IFA.

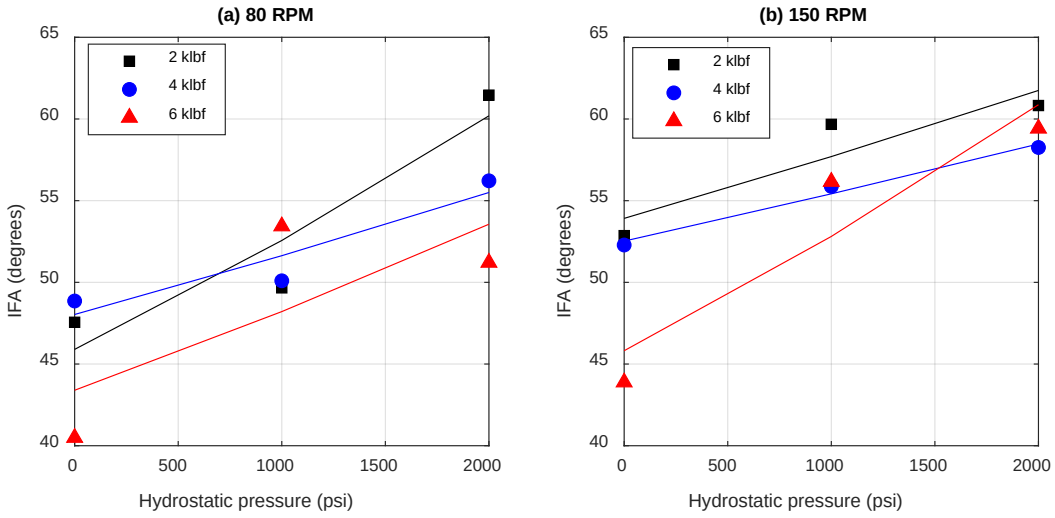

Figure 11: IFA vs Confining pressure for a constant WOB at (a) 80 RPM and (b) 150 RPM

The relationship between specific energy and drilling strength is given by the ratio shown in Equation 8 where E is the specific energy (lb/in^2), S is the drilling strength (lb/in^2), Fn is the normal force (lbf), Fd is the drag force (lbf), θ is the back rake angle (deg) and ψ is the IFA (deg)

$$E \cdot S = \frac{F_n}{F_d} = \tan(\theta + \psi) \tag{8}$$

The ratio of the normal force to the drag force changes with varying angles, affecting the efficiency and mode of drilling. Consequently, the normal force to drag force ratio also affects the IFA. As seen from the results, drilling at higher confinement requires more WOB to overcome the rock's resistance to fracture. While WOB increased with higher confinement, the required torque did not increase proportionally and decreased in some cases. The observed increase in WOB without a proportional increase in torque under higher confining pressures implies a transition in the cutting mode. During this transitional phase, spikes in IFA can be observed in some tests. This suggests that higher normal forces are needed to initiate and sustain cutting in more ductile conditions where plastic flow occurs more smoothly compared to brittle failure mode. Brittle failure results in rough fracture surfaces, causing spikes in IFA when the rock fractures and breaks away. However, in ductile mode, where the rock tends to flow and deform plastically, lower IFA values are observed.

The transition from brittle to plastic cutting modes highlights the need to adjust WOB and monitor torque to maintain drilling efficiency. Optimization of drilling parameters for different confining pressure conditions is necessary to improve rock penetration and drilling efficiency.

3.2.2 Five-Bladed Bit IFA Analysis

The effect of confining pressure on IFA for the 5-bladed bit is illustrated in Figures 12a and 12b, for rotational speeds of 80 RPM and 150 RPM, respectively. The 5-bladed bit generally exhibits lower average IFA values at higher confining pressures when compared to the 4-bladed bit. This is due to the improved weight distribution and reduced stress concentration resulting from the

increased contact area with the rock formation. At a constant WOB and 80 RPM, the IFA steadily increases from 0 to 1000 psi across all WOB levels. However, when confining pressure is increased from 1000 to 2000 psi, the 2 klbf test shows a slight decrease in IFA due to lower contact pressure and less friction. For the tests under 150 RPM, the IFA shows an increase in the 2 klbf and 6 klbf tests when the confining pressure is increased from 0 to 1000 psi and a decrease in the 4 klbf test. Again, this decrease can also be attributed to the change in rock failure mechanism from brittle to ductile experienced at higher confining pressures. Plastic deformation experienced in ductile mode results in smoother surfaces and reduced resistance at the interface between the drill bit and the rock. This can cause a decrease in IFA values at higher confining pressures.

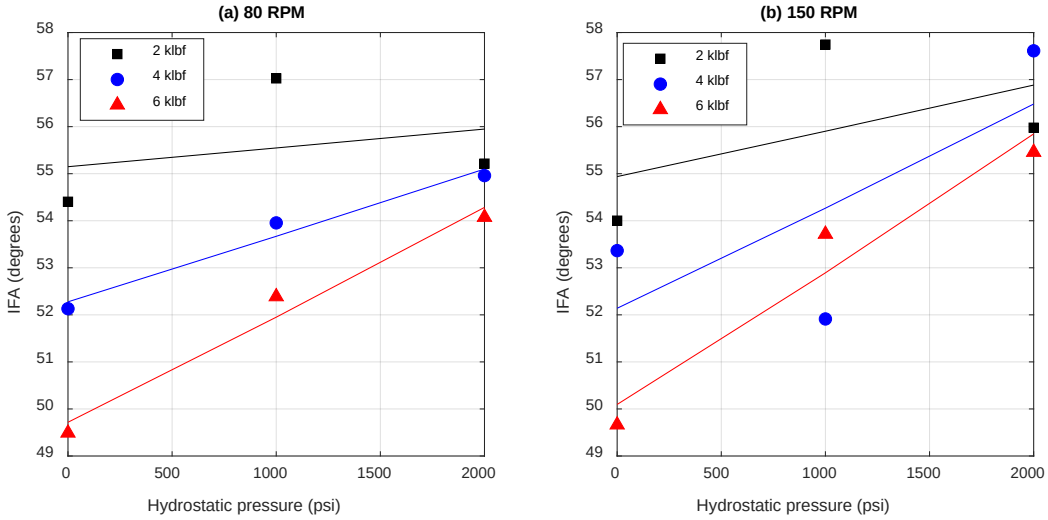

Figure 12: IFA vs Confining pressure for a Constant WOB at (a) 80 RPM and (b) 150 RPM

4. Conclusions

- Higher confining pressures significantly enhance the rock's strength by increasing its resistance to fracturing. This means that more energy and WOB are required to achieve the same rate of penetration or depth of cut, impacting drilling costs and operational efficiency. Optimizing drilling parameters becomes crucial to balance MSE and ensure an economical drilling operation.
- The results from the presented drill bit testing agree with previous studies that show that as confining pressure increases, a transition in rock failure modes occurs in hard rock. At lower confining pressures, brittle failure is dominant and involves sudden fracturing and higher specific energies. In comparison, at higher confining pressures, ductile failure dominates and requires sustained energy input due to gradual deformation. This transition complicates drilling efficiency, necessitating adjustments in drilling parameters to achieve drilling efficiency.
- Drilling with a higher WOB typically yields the lowest MSE, indicating efficient rock removal. However, tests at 2000 psi confining pressure and 80 RPM reveal that using a lower WOB achieves the lowest MSE, highlighting a subtle relationship influenced by confining pressure and RPM. This variability further proves the need to tailor drilling

parameters to specific operational contexts, particularly under high confining pressures, for optimal efficiency and performance.

- Tests conducted at 1000 psi and 80 RPM with a 0.01 inches/rev DOC show a significant decrease in MSE, suggesting that lower DOC values are more efficient under high confining pressures. This means that energy consumption is reduced at lower DOC, and penetration rates are improved due to the rock's plastic deformation and shear failure characteristics.
- The Interfacial Friction Angle (IFA) increases with increasing confining pressure for a given WOB due to higher normal forces at the drill bit-rock interface, resulting in greater frictional resistance. During the transition from brittle to ductile failure modes, spikes in IFA occur due to rougher fracture surfaces in brittle failure. In contrast, ductile deformation leads to lower IFA values as the rock undergoes plastic flow. Understanding these dynamics enables informed decision-making in drilling operations, enhancing overall efficiency and performance.

ABSTRACT

Geothermal drilling has become more and more attractive as an option in the search for new green-energy exploration and production. This activity has been driven by the demand for new energy and the existence of technological advances. However geothermal drilling operations have unique challenges, which need to be carefully addressed. These environments will challenge the equipment to be exposed to high downhole temperatures which will exceeds the standard temperature equipment and tool ratings, risking burning the drilling tools which result in costly equipment damage and non-productive drilling time.

The effort of designing and developing equipment to be operated in high temperature conditions continually happen. However, this effort will increase the production cost and limit the availability of equipment deployment to operate in another environment. As alternative, drilling through high temperature volcanic formations up to 250°C using standard temperature tools (150°C rating) will requires specific drilling practices to keep the tools survive and reduce the risk of failures. To overcome the associated challenges, field experience introduces a flexible engineered approach to avoid any non-productive time (NPT) that is associated due to tools failure.

This paper will present a systematic approach to overcome volcanic geothermal drilling challenges associated with high temperatures. Hence the goal is to have an optimum, safe, efficient drilling operations and emphasize in drilling practice with standard temperature tools (150°C rating) in formation temperatures up to 250°C.All the paragraphs of the paper are set in <Normal Style>. The paragraphs should not have line breaks between them – the GRC Normal Style will space the paragraphs automatically. Please be very careful to use styles throughout the document, so that all the papers will have a similar appearance.

1. Introduction

Indonesia is renowned for its significant geothermal potential, boasting an estimated 29,000 MW of geothermal resources, making it one of the top geothermal energy reserves in the world. Positioned on the Pacific Ring of Fire, Indonesia benefits from abundant geothermal activity due to its numerous volcanoes, offering a substantial and largely untapped energy resource.

As of 2024, Indonesia's installed geothermal capacity stands at approximately 2,133 MW, which is about 7% of its total potential. This positions Indonesia as the second-largest producer of geothermal energy globally, after the United States. The current utilization of this resource, however, represents only a fraction of what is feasible, highlighting a significant opportunity for expansion.

The Indonesian government has set ambitious goals to increase the country's geothermal capacity as part of its broader strategy to transition to renewable energy sources. By 2030, the government aims to boost the installed geothermal capacity to 8,000 MW. This plan is part of Indonesia’s commitment to reduce greenhouse gas emissions and decrease reliance on fossil fuels, thereby promoting a sustainable energy future.

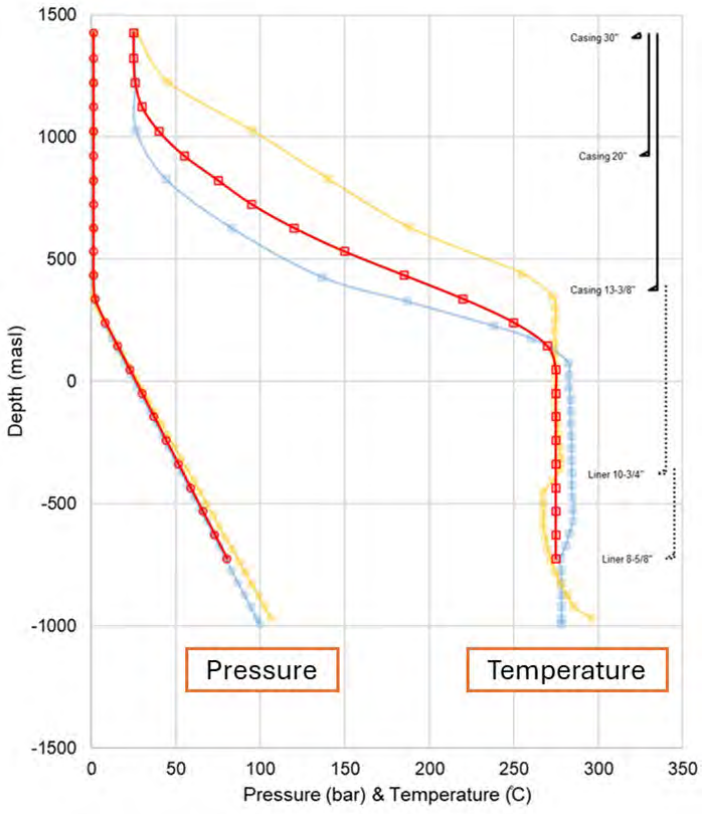

Figure 1. Temperature and pressure prediction.

Geothermal drilling in Indonesia, unlike conventional oil and gas drilling, involves penetrating through volcanic formations characterized by extremely high temperatures. Standard drilling equipment is typically rated for temperatures up to 150°C, but geothermal formations can reach temperatures of 250°C or higher as shown at Figure 1. This disparity presents a risk of equipment

failure, leading to costly downtime and equipment replacement. The challenge is to conduct efficient and safe drilling operations while minimizing risks associated with high-temperature environments.

2. Methodology

Geothermal drilling in Indonesia is particularly challenging due to the high-temperature reservoirs found throughout the country's geothermal fields. These fields are located in diverse geological settings, each presenting unique difficulties for drilling operations. The key geothermal fields span from North Sumatra to East Java, and their reservoir temperatures can reach up to 250°C.

Specific Challenges in High-Temperature Reservoirs

1. Equipment Durability and Performance
    a. High-Temperature Exposure: Standard drilling tools are typically rated for temperatures up to 150°C. However, the reservoir temperatures in many Indonesian geothermal fields can exceed this limit, reaching up to 250°C as shown at Figure 2. Prolonged exposure to such high temperatures can cause thermal degradation of drilling tools, leading to frequent failures and costly replacements.

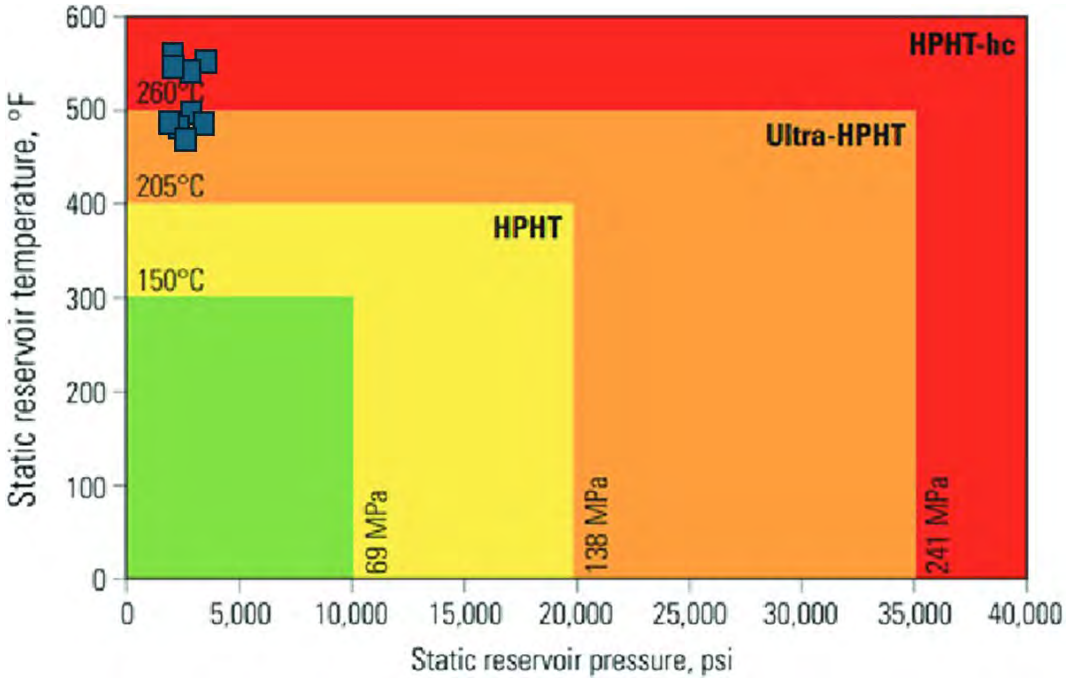

Figure 2. High temperature low pressure geothermal in Indonesia.

    b. Corrosion and Erosion: The geothermal fluids in these high-temperature reservoirs are often corrosive, containing dissolved gases like CO_2 and H_2S, which can corrode metal components of the drilling tools and equipment. Additionally, the abrasive nature of geothermal fluids can cause erosion, further reducing the lifespan of drilling tools.
2. Operational Efficiency

a. Non-Productive Time (NPT): Equipment failures due to high temperatures and corrosion can lead to significant non-productive time (NPT), where drilling operations are halted for tool replacement or repair. This not only increases operational costs but also delays project timelines.
b. Cooling Requirements: Managing the high downhole temperatures requires effective cooling strategies, such as optimizing mud circulation rates and using cooling fluids. These measures are essential to maintain the integrity of the drilling tools but can complicate the drilling process and increase operational complexity.

3. Safety Concerns
   a. High-Pressure Steam Zones: Many geothermal fields have high-pressure steam zones, which pose significant safety risks. Blowouts and uncontrolled releases of steam can endanger the safety of the drilling crew and equipment.

Figure 3. Equipment damage after exposed to steam kick

   b. Acidic Fluids: The presence of acidic fluids in some geothermal reservoirs requires the use of specialized materials and coatings to protect the drilling tools and equipment. Failure to adequately address these conditions can result in rapid deterioration of the drilling infrastructure.

4. Cost Implications
   a. High-Cost Equipment: The development and deployment of high-temperature-resistant tools are expensive, increasing the overall cost of geothermal drilling projects. This cost factor is a major consideration, especially for projects with limited budgets.
   b. Maintenance and Replacement: Frequent maintenance and replacement of drilling tools due to high-temperature exposure and corrosion add to the operational costs. Ensuring a steady supply of spare parts and maintaining an efficient maintenance schedule are critical for managing these expenses.

2.1 Conventional approach, using High Temp Tools

Given above challenges in drilling high temperature reservoir, the conventional approach will be

Pros of Using High-Temperature Tools

- Reliability: High-temperature tools are engineered specifically for the harsh conditions of geothermal drilling, ensuring better performance and reduced risk of failure.

- Durability: These tools are made from materials that can endure prolonged exposure to high temperatures, resulting in longer operational life.

Cons of Using High-Temperature Tools

- Cost: High-temperature tools are significantly more expensive to manufacture and procure.
- Limited Availability: Due to their specialized nature, these tools are not as readily available as standard temperature tools, potentially leading to delays in operations.
- Increased Production Costs: The cost of designing, developing, and deploying these tools increases the overall production costs, making the operation less economically viable.

Alternative Approach: Using Standard Temperature Tools

Given the high costs and limited availability of high-temperature tools, an alternative approach is to use standard temperature tools (rated up to 150°C) with specific drilling practices designed to mitigate the risks associated with high-temperature environments.

Pros of Using Standard Temperature Tools

- Cost-Effective: Standard temperature tools are less expensive and more readily available.
- Flexibility: These tools can be deployed in a variety of drilling environments, not just high-temperature geothermal formations.
- Cons of Using Standard Temperature Tools
- Risk of Failure: Standard tools are not designed for high-temperature conditions, increasing the risk of equipment failure.
- Operational Challenges: Using standard tools in high-temperature environments requires careful planning and execution to avoid non-productive time (NPT).

Drilling Practice and Risk Mitigation Using Standard Temperature Tools

To successfully use standard temperature tools in high-temperature environments, specific drilling practices must be implemented. These practices include:

- Circulation Management: Maintaining an optimal mud circulation rate to cool down the drill bit and other downhole tools.
- Heat Dissipation: Utilizing techniques such as intermittent drilling to allow the equipment to cool down.
- Monitoring: Continuous monitoring of downhole temperatures and tool conditions to anticipate and address potential failures before they occur.
- Adaptive Strategies: Implementing flexible drilling strategies that can be adjusted based on real-time data from the drilling operation.

3. Results and Discussion

3.1 Prediction VS Simulation Circulating Temperature Profile

The simulation data derived from prognostic profiles and optimized using offset well data provides a detailed circulation temperature profile during drilling operations, as illustrated in Figure 4.

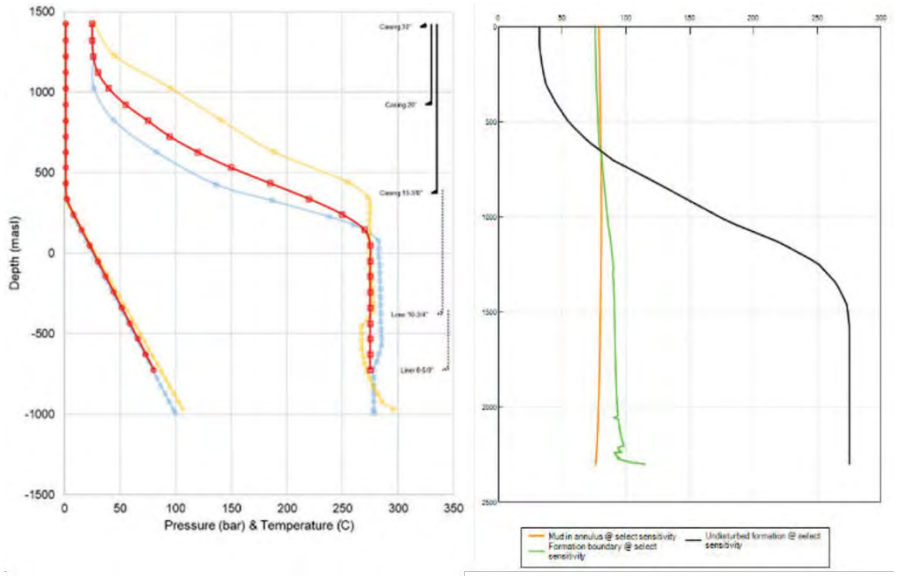

Figure 4. Prediction and simulation temperature profile.

Accurate simulation outcomes play a crucial role in assessing the feasibility of tool selection and funding allocation for successful geothermal drilling operations. By leveraging advanced modeling techniques, such as those integrating historical data from offset wells, stakeholders can make informed decisions that mitigate risks and optimize operational efficiency.

Furthermore, these precise simulations not only enhance operational planning but also contribute to cost-effectiveness and project viability. They enable stakeholders to anticipate challenges and adjust strategies preemptively, thereby improving overall project outcomes. This proactive approach not only instills confidence in investors and partners but also positions the project favorably for securing future funding and expanding its operational footprint. As the industry continues to evolve, the integration of robust simulation methodologies remains essential for driving innovation and achieving sustainable success in geothermal drilling.

3.2 Actual Circulating Temperature Profile

Field data shows that maintaining an optimal circulating temperature profile is crucial for the success of geothermal drilling operations as shown at Figure 5.

By carefully managing the circulation rate, combination on pump rate of Mud and Air it is possible to keep the temperature of the drilling fluid within a range that is safe for standard temperature tools. This practice helps in preventing overheating and potential steam kick.

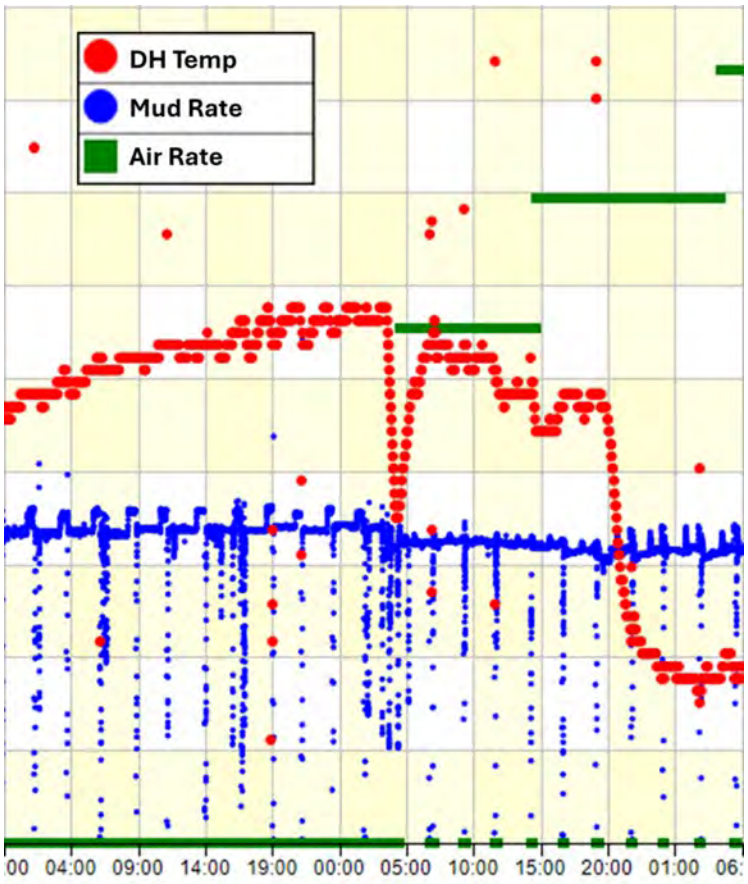

Figure 5. Managing down hole temperature.

3.3 Drilling Strategies in Hot Reservoir Sections

Effective drilling strategies are essential when operating in hot reservoir sections. One approach is to use a combination of high-viscosity drilling mud and cooling fluids to protect the drilling tools. Another strategy involves intermittent drilling, where the operation is paused periodically to allow the tools to cool down, thereby extending their operational life.

Key strategy in drilling ultra high temperature section with standard temperature equipment.

- Bottom Hole Assembly Selection
  Start from trajectory planning and decide either smart tools required to drill the section or rotary with dumb irons will be sufficient.
- Staging In and Out Procedure
  Prior to tripping into the hot reservoir zone, frequent temperature check is required and circulate if the temperature is close to 90% of equipment temperature ratings.
- High Temp Connection Practice
  Minimize static time without pumping in the hot reservoir zone, E-Mag MWD with fast surveying method is an advantage.
- Air to Fluid Ratio Management
  Balancing the ratio is crucial, too high on one side could lead to overheating or steam kick.

- Water Supply Management
  Continuous water supply is mandatory when drilling the hot zone. Whenever there is indication of shortage water supply, the bottom hole assembly need to be secured in safe zone.

3.4 Contract Requirements as Supporting Operation

To ensure smooth and efficient drilling operations, it is essential to have clear contract requirements that support the use of standard temperature tools in high-temperature environments. These requirements should include provisions for:

- Tool Replacement: Agreements on rapid replacement of tools in case of failure.
- Operational Flexibility: Allowances for adaptive drilling strategies based on real-time data.
- Risk Sharing: Clear delineation of responsibilities and risk-sharing between the operator and the drilling contractor.

4. Discussion and Conclusion

Drilling Ultra High Temperature Geothermal using Alternative Approach, standard temperature rating tools, has advantages in reducing overall drilling cost. This approach is proven to be successful in Indonesia geothermal wells. Over the years geothermal drilling cost in Indonesia become more efficient, where the equipment selection is one of the key contributors.

Risk of using standard temperature can be managed with proper drilling practice. If the drilling practice is not followed, it will be result in equipment damage that can increase the well cost by 20%. Project briefing to address the strategy need to involve all stakeholder to ensure smooth and safe operation execution.

Drilling with standard temperature tools unlock the opportunity for further understanding of geothermal reservoir, by potentially using the Logging While Drilling equipment where it has broad selection in standard temperature rating. At the moment the reservoir characterization mainly done with only Pressure and Temperature Logging. Some of the wells can be logged with quenching method to obtain Image and Sonic data, however if the wells is too hot and quenching method not successful, the logging attempt will be canceled.

Geothermal drilling in high-temperature volcanic formations presents unique challenges that require innovative approaches and robust risk mitigation strategies. While high-temperature tools offer reliability, their high cost and limited availability necessitate the exploration of alternative methods. Using standard temperature tools with specific drilling practices provides a viable solution, enabling efficient and safe operations while controlling costs. By adopting a flexible, engineered approach and implementing comprehensive risk mitigation strategies, it is possible to overcome the challenges of geothermal drilling and unlock the vast potential of geothermal energy.

ABSTRACT

Geothermal drilling operations face inherent challenges, with stuck-pipe incidents posing significant risks to both safety and project success. In this paper, we introduce a groundbreaking stuck-pipe risk advisor (SPRA) that integrates causal artificial intelligence (AI) and semantic web technologies to provide explainable real-time decision support and enhance drilling performance.

Our causal-AI model uses advanced machine-learning algorithms to analyze historical drilling data, identifying complex relationships and potential risk factors which may lead to stuck-pipe incidents. By leveraging causal relationships, the SPRA can proactively assess the likelihood of a stuck-pipe occurrence based on current drilling conditions.

To enhance transparency and trust in the decision-making process, our system incorporates semantic web technologies to generate explainable outputs. The SPRA generates detailed explanations of its predictions, using semantic annotations to link specific risk factors through causal relationships. This not only aids drilling operators in understanding the basis of the system's reported risk levels but also facilitates continuous learning and improvement of drilling practices.

In addition, the SPRA has a flow-diagram-based interface for drilling operators that shows risk factors, possible solutions, and interactive explanations in real time. By empowering operators with actionable insights, the SPRA aims to support the wellsite team in reducing the frequency of stuck-pipe incidents, enhancing drilling efficiency, and ultimately contributing to the overall safety and success of geothermal drilling projects.

We present the development, validation, and practical application of the SPRA, demonstrating its potential to revolutionize geothermal drilling performance through causal AI and semantic web technologies.

1. Introduction

Indonesia is located among three active tectonic plates and has more than 80 active volcanoes, contributing to Indonesia's wealth of geothermal potential (Nasruddin et al. 2016). Improving the efficiency of geothermal well drilling is viewed as a key enabler for continued development of this potential. Several challenges have been identified in geothermal drilling; for example, the lithology is predominantly igneous rock, which is hard and abrasive. Geothermal facies are dominated by a wide and complex range of fractures and faults, which act as primary drilling targets but also cause lost circulation, which is a common issue in geothermal drilling. The lithology encountered in geothermal drilling also includes paleosols rich in smectite and illite, along with tuffaceous siltstones, which bring the added challenge of swelling or reactive clays. These conditions can lead to wellbore instability and severe hole problems during drilling.

Negotiating the combined challenges of lost circulation, swelling clays, and unstable formations is recognized in Star Energy Geothermal (SEG) as fundamental to avoiding stuck pipe incidents. Stuck pipe refers to a situation in drilling where the drill string cannot rotate, move up, or move down. There are several types of stuck pipe based on a variety of root causes: mechanical sticking, differential sticking, and hole geometry. In geothermal, the most common cause of stuck pipe is mechanical sticking, resulting from combinations of factors such as hole cleaning, unconsolidated formations, fractured-faulted formations, and reactive clays.

Current SEG drilling practice involves post-job studies of previous stuck pipe incidents, identification of subsurface hazards from offset well analysis, and continuous monitoring of drilling parameters by wellsite geologists and drilling engineers in a Real-Time Decision Center (RTDC). When situations and conditions indicate increased risk of stuck pipe, appropriate mitigating practices are implemented.

Our delivered solution augments, streamlines, and automates the SEG approach through detection of key decision points, an automated population of questionnaires, AI-accelerated identification of root causes and the explanations for them, and the gathering of the relevant related scenarios for review. This review is examined by the SEG decision makers, who direct a mitigation response if one is warranted.

As an example, through this raised level of automation, SEG's knowledge of subsurface hazards is supported by real-time detection of fractures encountered during drilling. Since SEG's previous wells information and experience have been used to fine-tune the AI, and each example is also available for direct comparison to the generated explanation for the current situation, the system provides a consistent and repeatable high level of process adherence, analysis, and best practice.

All steps in the deliberate, review and collate sequence are automated using causal artificial intelligence (casual AI) (for an introduction to causal AI see Hurwitz and Thompson, 2023). Within the workflow, the geologist and engineers interact with the system following a RACI (Responsible, Accountable, Consulted, Informed) matrix and operational sequence.

To develop the causal-AI, extensive workshops involving well engineers and geologists conducted iterative reviews between engineering and AI interpretation definitions of stuck pipe incident events. A semantic web risk ontology encodes this mapping between human and machine-readable statements that are causally consistent; the causal network is built by inferring interconnections in a guided causal discovery (Pfaff-Kastner et al., 2024). Questionnaires covering geological, well

engineering, and drilling practice encompass the complete system, including aspects where real-time sensors do not yet provide the input. Where real-time sensor data and machine learning can provide an answer, the system can accept it (autofill). Taking this “whole problem” approach, automating a system that supports the full engineering requirements rather than trying to extract information from the more limited set of things that are already available as data streams, differentiates our approach.

The estimated risk is reported relative to both the current state on the ground and uncertainty around it. Review of historical cases and possible future scenarios train and fine-tune the causal network, extending a consistent collaborative framework from desktop to Edge Internet of Things (IoT).

Estimating the risk of stuck pipe comprises an analysis of drilling parameters, real-time measurements, and domain knowledge from geologists and engineers. Additionally, understanding the causal path of stuck pipe events in geothermal wells helps to trace a direct line between the potential event and the preventative and mitigation measures. All these aspects are addressed in the solution that we propose.

2. Challenge of stuck pipe in Geothermal Drilling operation

Generally, stuck pipe events have been one of the biggest problems impacting geothermal drilling operations worldwide. Particularly for geothermal drilling in Indonesia, factors that enhance the risk of stuck pipe in geothermal wells include drilling fluid losses and the presence of reactive clays.

Severe fluid losses ranging from partial to total losses cause problems removing the cuttings from the wellbore. The use of aerated fluid drilling is a common mitigation practice in these areas. When total fluid losses are encountered, there is no knowledge of drill cutting behavior within the borehole. In the presence of fractured formations, the cuttings could move into the formation, but also the cuttings could accumulate near the bottom hole assembly (BHA) and create restrictions in the annular space. This can lead to stuck pipe events due to the presence of solids in the borehole.

As mentioned before, aerated drilling is a common practice in geothermal well drilling. This practice brings complexities in the management of pressures in the system, the control of solids, and the modeling of the hydraulics. Those elements increase the complexity of stuck pipe prevention management.

Furthermore, geological hazards such as reactive clays and tuffaceous siltstones can cause hole instability due to the clays' reaction with water, which worsens over time. Reactive clays can also cause sticky conditions, leading to stuck pipe events. Another risk aspect of geothermal reservoirs is the presence of naturally unconsolidated formations. Those formations can cause caving into the annulus and, together with cuttings, increase the number of solids in the borehole.

2.1 Risk of Stuck pipe in Geothermal Drilling

Drilling geothermal wells presents a unique challenge due to the inherent risk of encountering fractured formations with low reservoir pressures. When the drill bit intersects these fractures, the wellbore fluid pressure can exceed the reservoir pressure. Aerated mud drilling addresses this issue by injecting air into the drilling fluid to lighten the fluid column. However, this technique comes with its own drawbacks. The drill cuttings may not effectively circulate out, accumulating in the wellbore or within the fractures themselves. This accumulation of cuttings, along with the inherent friction of the drill pipe against the wellbore, makes it difficult to accurately predict torque and drag. As a result, the increased drag caused by the cuttings can lead to situations where the drill pipe becomes stuck.

2.1.1 Formation-related Risks in Geothermal Drilling through Volcanic Rock

For geothermal applications, drilling through volcanic rock presents several formation-related risks that can significantly impact wellbore stability and drilling efficiency. Here is a breakdown and illustration of several key risks (Figure 1):

1. **Clay Swelling:** Volcanic formations often contain highly reactive clays, notably paleosols and tuffaceous siltstones. These clays can absorb water from water-based drilling muds, causing them to swell and potentially stick the drill pipe. Prolonged exposure to drilling fluids can exacerbate this issue, making it critical to manage drilling times and potentially use alternative mud systems that are less likely to cause swelling.
2. **Unconsolidated Formations:** Certain volcanic rock formations, particularly ash deposits or breccia, may be poorly consolidated or unconsolidated. This means the rock lacks sufficient cohesion and can crumble easily during drilling. The resulting loose gravel and rock fragments can significantly increase the number of cuttings generated within the wellbore. Excessive cuttings can hinder circulation, impede accurate torque and drag calculations, and ultimately lead to stuck pipe incidents.
3. **Drilling near Faults and Fractures:** Faults and natural fractures frequently litter volcanic landscapes. When drilling close to these geological features, especially in the direction of maximum stress, the wellbore can encounter zones of weakness. These weak zones can collapse or cave in during drilling, potentially trapping the drill pipe and causing significant wellbore instability. Careful wellbore planning and monitoring are essential to mitigate the risks associated with drilling near faults and fractures.

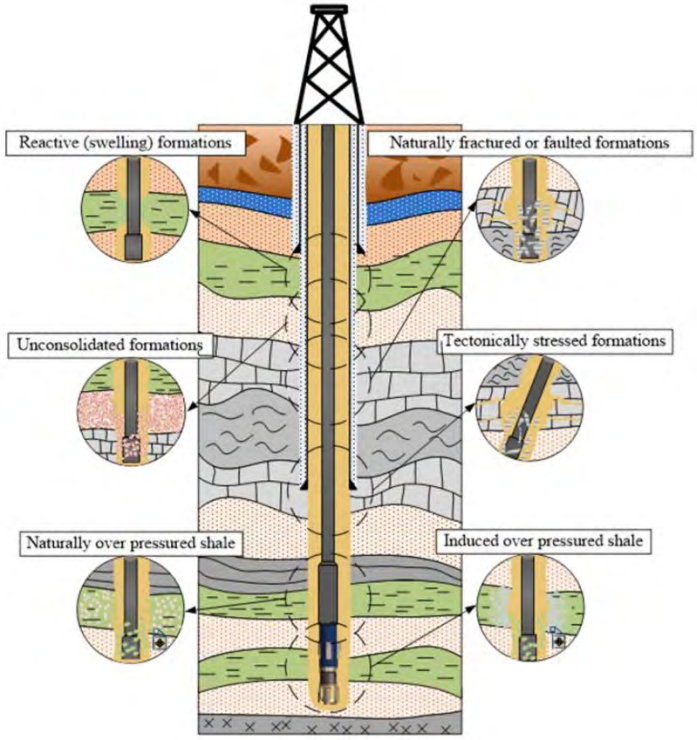

Figure 1: Clay Swelling formation and Unconsolidated Formation can be potential of geothermal hydrothermal system stuck pipe. (Pašić, 2020)

2.1.2 Stuck Pipe Risk from Downward Annular Flow in Geothermal Drilling

Encountering natural fractures while drilling geothermal wells presents a significant risk of stuck pipe due to a phenomenon that results in downward annular flow. In normal drilling scenarios, circulation ensures fluid travels down the drill pipe and returns upwards through the annulus, carrying cuttings out of the wellbore. However, when the drill bit intersects a natural fracture, the pressure dynamics change. Following is a description and illustration of this phenomenon (Figures 2 and 3):

1. **Pressure Differential:** Natural fractures within geothermal formations often possess much lower pressure compared to the pressurized drilling fluid circulating in the wellbore. This creates a pressure imbalance.
2. **Fluid Loss and Downward Movement:** When a fracture occurs, the annulus may divert some or all of the pressurized drilling fluid and the suspended cuttings into it. This loss of fluid disrupts the normal upward flow in the annulus.
3. **Downward Annular Flow and Cutting Accumulation:** In some situations, the pressure differential can be so significant that it can cause a reversal of flow within the annulus. The drilling fluid and cuttings, instead of traveling upwards can flow downwards due to the pressure differential. This downward movement of solids can lead to a situation where cuttings accumulate or pack off around the stabilizers and bottom hole assembly (BHA).
4. **Increased Friction and Stuck Pipe:** The stabilizers on the BHA are critical for maintaining the wellbore condition and directional control. However, a buildup of cuttings around the stabilizers due to downward flow significantly increases friction between the

drill string and the wellbore wall. This increased friction can lead to the drill pipe becoming stuck, potentially requiring complex and expensive operations to free it.

In conclusion, natural fractures encountered during geothermal drilling require a proactive approach to reduce the risk of stuck pipe due to downward annular flow. Real-time monitoring of drilling parameters and adjustments to drilling practices, such as reducing pump pressure, can help prevent this issue and ensure smooth wellbore completion.

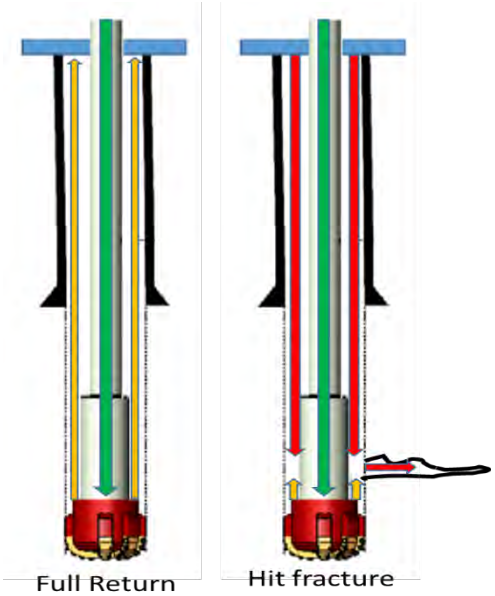

Figure 2. Drilling with full return can cause solids to rise, but impact fractures can cause fluid in the annulus to go downward and any solid that remains in the annulus can obstruct the stabilizer.

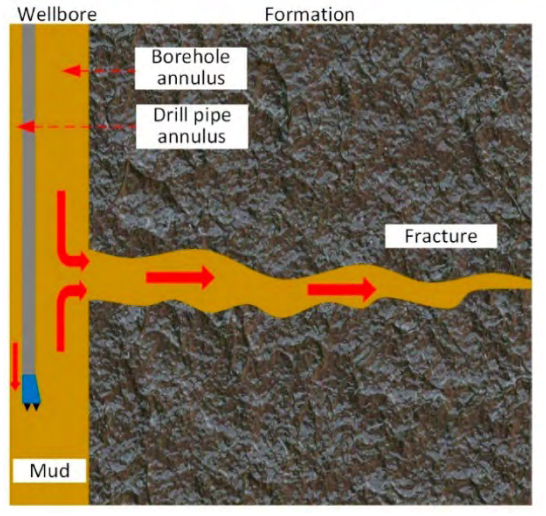

Figure 3: Drilling fluid losses. (Yi, 2018)

2.1.3 Stuck Pipe Risk due to cutting size, well inclination and aerated drilling to hole cleaning

Ensuring proper hole cleaning becomes a paramount concern during geothermal drilling when encountering natural fractures. The drill bit and the Bottom Hole Assembly (BHA) can shear larger cuttings. Large cutting presence necessitates a high annular velocity to overcome the settling velocity of the cuttings and prevent them from accumulating in the wellbore. However, achieving this optimal velocity presents a challenge.

Hole cleaning issues can significantly increase the risk of stuck pipe, and the carrying capacity of drilling fluid is reduced by aerated drilling. Drilling naturally fractured geothermal formations commonly employs this strategy, which involves injecting air into the drilling fluid to reduce its density. While this technique helps maintain circulation, the increased air content significantly reduces the fluid's carrying capacity for cuttings. This creates a trade-off: maintaining circulation while potentially compromising the ability to remove cuttings effectively (Figure 4).

Impact of Wellbore Inclination: Hole cleaning efficiency is further complicated by wellbore inclination. In deviated wells, particularly those with high inclination angles, cuttings tend to settle on the low side of the wellbore due to gravity. This can create a layer of cuttings that hinders circulation and increases the risk of pack-off, a situation where cuttings become lodged and prevent further drilling progress (Figure 4).

Friction Build-up and Stuck Pipe: The combined effects of reduced carrying capacity and hindered cuttings removal due to inclination can lead to a risky buildup of cuttings in the wellbore. This accumulation increases friction between the drill string and the wellbore wall. When this friction becomes excessive, the drill pipe can become stuck, requiring complex and costly operations to free it (Figure 5).

Therefore, meticulous hole cleaning practices are crucial in geothermal drilling, particularly in fractured zones. Balancing pressure control with proper fluid rheology and optimizing drilling parameters based on wellbore inclination are vital to ensure efficient cutting removal and minimize the risk of stuck pipe incidents (Figure 4).

3. Solution

The significant benefits of reducing the frequency of stuck pipe incidents have inspired the creation of an innovative early detection system and risk advisor, specifically designed to enhance geothermal drilling applications. This system will leverage a robust knowledge base constructed upon causal relationships and historical drilling data. Employing causal AI through a powerful probabilistic graphical model, this system will perform real-time analysis and risk assessment during drilling operations. By implementing this intelligent system, geothermal drilling can benefit from several key advantages:

- **Early Warnings for Natural Fractures:** Natural fractures encountered during drilling are a leading cause of stuck pipes. The knowledge base, built upon historical data and expert knowledge, will identify key indicators and patterns associated with encountering fractures. The causal framework will then analyze real-time drilling parameters, such as pump pressure, flow rate, and drilling vibrations, and provide early warnings before the drill bit hits a major fracture. This allows for proactive adjustments to drilling practices, potentially mitigating stuck pipe incidents altogether.
- **Improved Decision-Making:** The system's real-time risk assessment capabilities will empower drilling personnel to make informed decisions throughout the drilling process. By quantifying the likelihood of encountering stuck pipe based on current drilling conditions, the system can recommend adjustments to drilling parameters, such as reducing pump pressure or modifying drilling fluid properties. This data-driven approach fosters proactive risk management, leading to safer and more efficient drilling operations.
- **Knowledge Capture and Continuous Improvement:** We designed the developed system to continuously learn and improve its risk assessment capabilities. The integration of new drilling data into the semantic web knowledge base refines the causal model, resulting in a more accurate and reliable prediction of stuck pipe risks. This continuous learning process ensures the system remains effective over time, adapting to changing geological conditions and evolving drilling practices.

This knowledge-based early warning system, powered by causal-AI, presents a promising solution for mitigating stuck pipe risk in geothermal drilling. By providing early warnings and facilitating informed decision-making, this system can significantly improve the safety and efficiency of geothermal well development.

The development of the stuck-pipe risk advisor (SPRA) is being implemented through a collaborative effort between Star Energy and SLB, as follows:

3.1 Causal-AI Concept

Causal artificial intelligence addresses an issue in machine learning, namely that identifying and understanding causal relationships is a barrier for correlation-based systems (Pearl, 2009). Our method uses a Shapes Constraint Language-based semantic web reasoner (see Pareti & Konstantinidis, 2021) to make sure that the causal relationships found in geological and well engineering contexts are fully consistent across a knowledge graph representation. The relationships form a directed acyclic graph (DAG), identifying each node with a concept and representing a cause-to-effect relationship between a pair of nodes through each directed edge. In addition to nodes in the Bayesian sense (observable properties, latent variables, unknown parameters, or hypotheses), we additionally represent actions. In terms of cause-effect relationships, we recognize both that actions may be interventions (Pearl, 2009); our actions can be recognized as those of temporal AI planning, which may also require certain preconditions to be met before taking action (e.g., Fox & Long, 2003). This offers a pathway to autonomous operations (Liu et al., 2024) and dynamic configuration, which are the key enabling technologies for the real-time use case proposed here.

Within the network, a risk may be assessed using the well-known techniques of belief propagation (Pearl, 1982); with the role of actions handled using the do-calculus (Pearl, 2009; Pearl & Mackenzie, 2018).

One recognized advantage of both semantic web technologies and causal AI directed graphs is their capability to inform explanations (Clinciu et al., 2021). We combine these explainable artificial intelligence (XAI) techniques with the well-known capabilities of knowledge graph-led search for semantic web technologies (Dong et al. 2009) to provide enhanced validation, digital reporting, and offset well analysis.

Our explainable AI causal network (XAI-CN) system represents a neuro-symbolic artificial intelligence system (Sarker et al., 2022) which can organically develop and extend its automation capabilities as the digital well-site operations mature.

3.2 Alarm System Concept

The dynamic configuration and automated execution provided by XAI-CN empower the network to be seamlessly triggered by a data-driven ML agent. Automatic detection of fractures, using the

signature of increasing ROP and flowrate combined with a drop in pump pressure, will generate a fracture alarm that the smart system will swiftly and efficiently identify.

In the use case of geothermal stuck-pipe, SEG Well Engineers have identified a “golden window” in the drilling process that is key to the timing of stuck-pipe risk evaluation. We will develop a data-driven ML agent to identify the "golden window" from time-series data in real-time, which will then initiate a server call to the XAI-CN system, triggering the full risk assessment process.

3.3 Autofill (Time Series) Concept

A unique aspect of XAI-CN is the ability to dynamically configure to accept real-time inputs as an alternative to having human experts answer questions within the questionnaire. When a full risk assessment is triggered, the XAI-CN system will explore the available “auto-fill” agents to gain as much information as possible; a reduced form questionnaire is then presented to the Well Engineer. The autofill feature will automatically populate the indicators for fracture, which include a bump in ROP and a loss in flowrate due to a decrease in pump pressure. Drilling parameters response [Standpipe pressure trend, ROP trend, WOB trend, ROP range, and RPM range], depth from last fracture, and mud flow rate range will also be auto filled based on sensor information parsed with proprietary SLB algorithms.

3.4 Deployment

The sensors on the drilling rig stream real-time drilling data to the company's drilling platform. Evaluating risks using a causal knowledge graph that captures well engineering domain knowledge and experience. Explanation for the estimated risk level, including preliminary root-cause suggestions. User will have immediate access to comprehensive information that captures risks from similar jobs. Forecasting scenarios enables the evaluation of potential mitigation methods.

4. Result and Discussion

The tool itself contains two software products: Drilling log monitoring for automatically detecting potential risk zones early and an AI-based semantic web to analyze the risk in each potential risk zone more deeply using a causal AI network.

4.1. Real-time delivery system

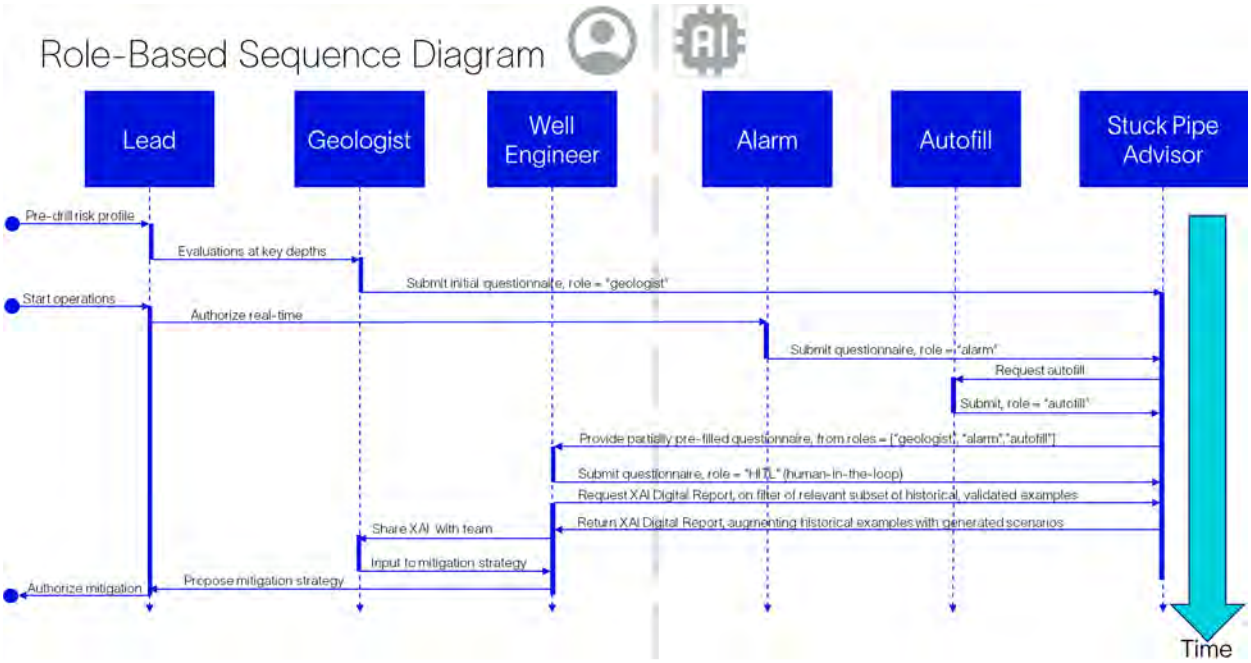

Figure 8 Example operations sequence diagram.

We recognize the roles of three (3) nominal team members: the team lead, the geologist, and the well engineer. This team collaborates with XAI-CN (designated as Stuck Pipe Advisor) and the AI/ML alarm and autofill. We recognize that some information is available ahead of on-bottom drilling; in particular, the expectations around geology may be pre-populated. When drilling commences, the alarm is continually monitoring the real-time signals to detect fractures and identify the "golden window." On recognizing this "golden window", the autofill elements are triggered to provide automated supporting information before the well engineer and geologist are presented with the partially filled questionnaire. The review and update of the questionnaire by the well engineer and geologist allows the system to operate with an up-to-date information set. The XAI-CN can then provide the root-cause analysis and off-set well analysis that informs the whole team, enabling the team lead to make their decisions on prevention and mitigation (Figure 8).

The presentation of the digital results combines the current risk profile, its explanation, and the relevant offset well information. Figure 9 shows an example flow chart, where the system has identified five (5) primary features that contribute to the assessment that there is currently a risk of stuck pipe due to wellbore geometry. Four of the identified key contributors are observations, and one is an action, namely that the BHA had to be changed, which, combined with recent observations of tight spots when pulling out of a hole (POOH), and previous albeit minor sticking, raises awareness of potential risk. A hole caliper measurement, the path shown in yellow in Figure 9, was the primary contributor to this understanding of risk, but the context is provided by the rest of the diagram. Importantly, this allows the search to share a set of nearby cases with similar risks, which the team can further filter to match the field and hole size, just as in conventional offset well analysis. These nearby cases may include suggestions for preventive or mitigation measures. It is

this access to combined knowledge at the time of decision-making that enables the team to make informed choices, ultimately avoiding stuck pipe incidents.

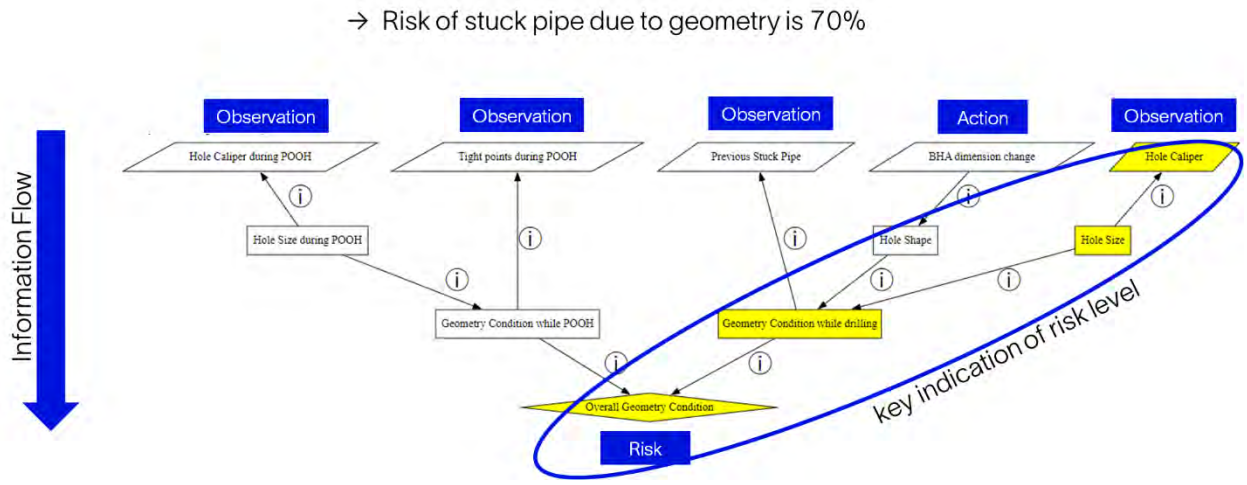

Figure 9. An example explanation flow chart.

4.2 Early Detection system

4.2.1 Automated Potential Risk Zone Detection

In geothermal drilling operations, the early detection of fracture zones is crucial for mitigating the risks associated with stuck pipe, a common challenge that can lead to significant operational delays and increased costs. As described previously, fracture zones can cause partial or total loss of circulation, leading to hole cleaning problems and cuttings pack-off. These zones, if not identified and managed promptly, can cause the drill string to become stuck, necessitating costly retrieval operations or even abandonment of the well.

Real-time monitoring systems, developed to address this challenge, enhance the predictive capabilities and operational safety of drilling in geothermal fields. The inclusion of a traffic light flagging system in these monitoring solutions represents a significant advancement in risk management. This system employs a color-coded alert mechanism to indicate the proximity to potential feed zones, thus enabling on-site engineers to take timely preventative actions.

The flagging system utilizes real-time data from drilling parameters such as measured depth, bit depth, rate of penetration (ROP), standpipe pressure (SPP), and weight on bit (WOB). We closely monitor these parameters for specific changes that signal approaching fracture zones, also known as the "golden window". Based on the data collected from several wells across multiple fields, the system classifies the level of potential risk into five color codes: Red indicates a very high risk where ROP increases sharply and SPP drops rapidly; orange signifies a high risk with moderate changes in ROP or SPP; blue represents a medium risk with moderate changes in both parameters; yellow and green denote lower risks with gradual changes.

This system's effectiveness in geothermal drilling lies in its ability to provide a clear, real-time visualization of risk levels through an intuitive color-coded scheme. By enabling better

anticipation of feed zones, the system aids in proactive decision-making and risk mitigation. Additionally, a semantic web interface enhances the system during medium- to high-risk scenarios, providing a transparent analysis of the risks within the golden window. This technological integration not only improves safety, but it also optimizes drilling efficiency by reducing non-productive time due to stuck pipe incidents. We enhance the real-time monitoring of drilling logs by incorporating a traffic light flagging system into the mud log data time series. This system alerts us whenever a potential risk zone, also known as the "golden window," approaches.

Oil and gas companies have explored time-series-based identification of open fractures (Al-Adwani et al., 2012), in this project, we defined a completely new identifier for the 'golden window' based on several drilling parameters. We create flagging based on changes in values over the last 2 hours for several drilling parameters, such as measured depth, bit depth, rate of penetration (ROP), standpipe pressure (SPP), and weight on bit (WOB), which closely correlate to the potential risk of stuck pipe.

There are basically five color codes in the traffic light (Figure 10), depending on the level or potential risk. Red for very high potential risk when ROP is highly increasing and SPP is rapidly dropping. Orange for high potential risk, when either ROP is moderately increasing or SPP is slightly dropping, and the other one is changing extremely. Blue for medium potential risk when both ROP is moderately increasing or SPP is slightly dropping. Yellow and green for low potential risk, when both ROP is slowly increasing and SPP is slowly dropping.

We set up cut-off values as boundaries for each of the categories based on the existing value on the dataset. There are thousands of time series drilling log data from hundreds of wells covering three geothermal fields as the dataset that we used for observation for creating the cut-off logic of color codes mentioned above. Therefore, these color codes help on-site engineers identify an upcoming potential risk zone for risk mitigation before it happens. In addition, starting with blue code, orange code, and red code will trigger the system to show up the semantic web for transparent risk analysis within the golden window.

Overall, the traffic light flagging system represents a transformative approach to managing drilling risks in geothermal operations, underscoring the importance of technological innovation in the pursuit of energy resource extraction.

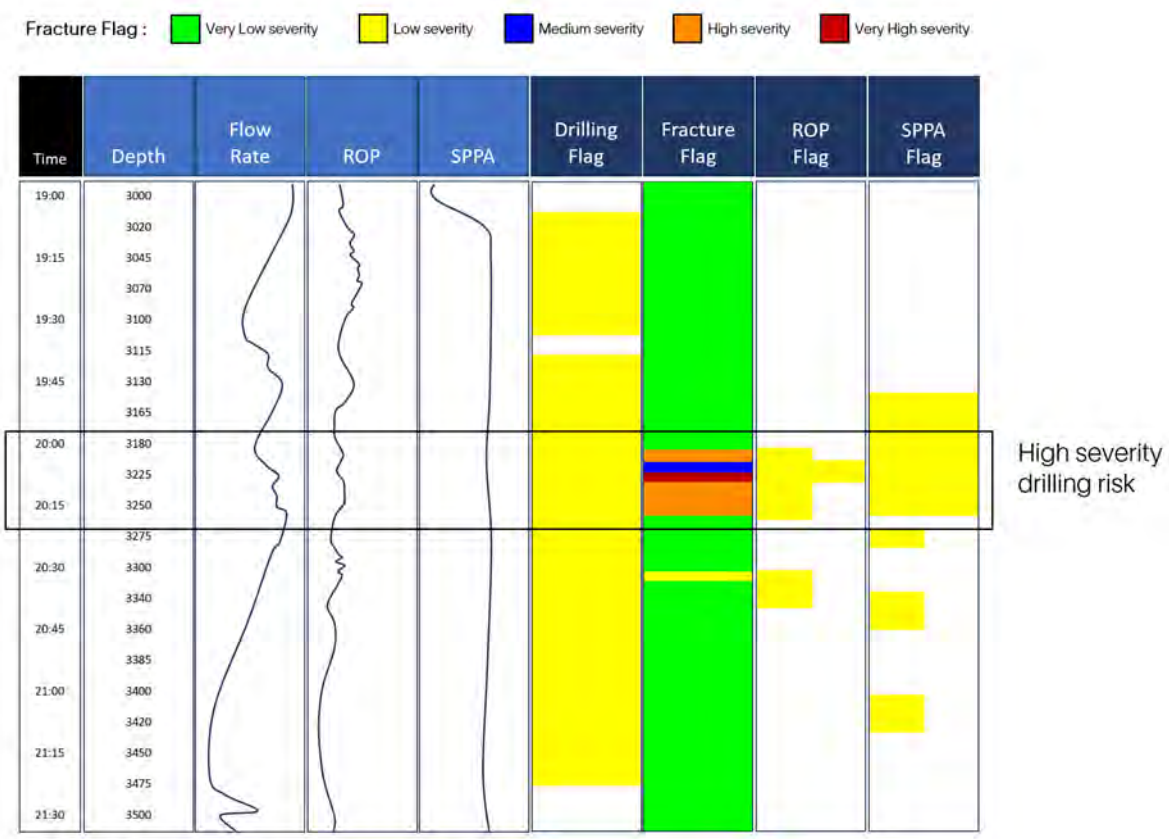

Figure 10. Sample of fracture risk "golden window" flagging

4.2.2 Semantic Web Risk Ontology

Our semantic web risk ontology provides transparent and trustworthy inferences about risk relationships (Figure 11). We have a core set of relationships that support application development by combining publicly available ontologies for sensors (Janowicz et al., 2019) with internally developed ontologies, which we will detail in a future paper[1] .

The relationships play two key roles in the system: firstly, after the AI has identified the key relationships that explain the current risk, the machine representation needs to be mapped to natural language and diagrams that the team facing the decision-making can explore.

In mapping to a machine representation, a causal reasoner continually checks the latest information for circularity (cause-effect reasoning errors) and missing or duplicate nodes. Subject matter experts' flag and debate and review the knowledge to resolve flagged inconsistencies or omissions.

To establish the explanation, we first perform a calculation step that uses an information criterion to identify the most significant paths through the knowledge graph. This is achieved by combining a mutual information entropy measure (Kjærulff & Madsen, 2012) Using a shortest path algorithm,

[1] Pers. Comm. Peter Gregory

we extract the graph's subsection using the do-calculus approach (Pearl, 2009). We then translate this machine-readable output into an explanation flow chart (Clinciu et al., 2021) described by semantic web relationships (Figure 11), which in turn can be translated into human-readable text using an LLM, which is known to outperform solutions relying on LLM alone (Allemang and Sequeda, 2024).

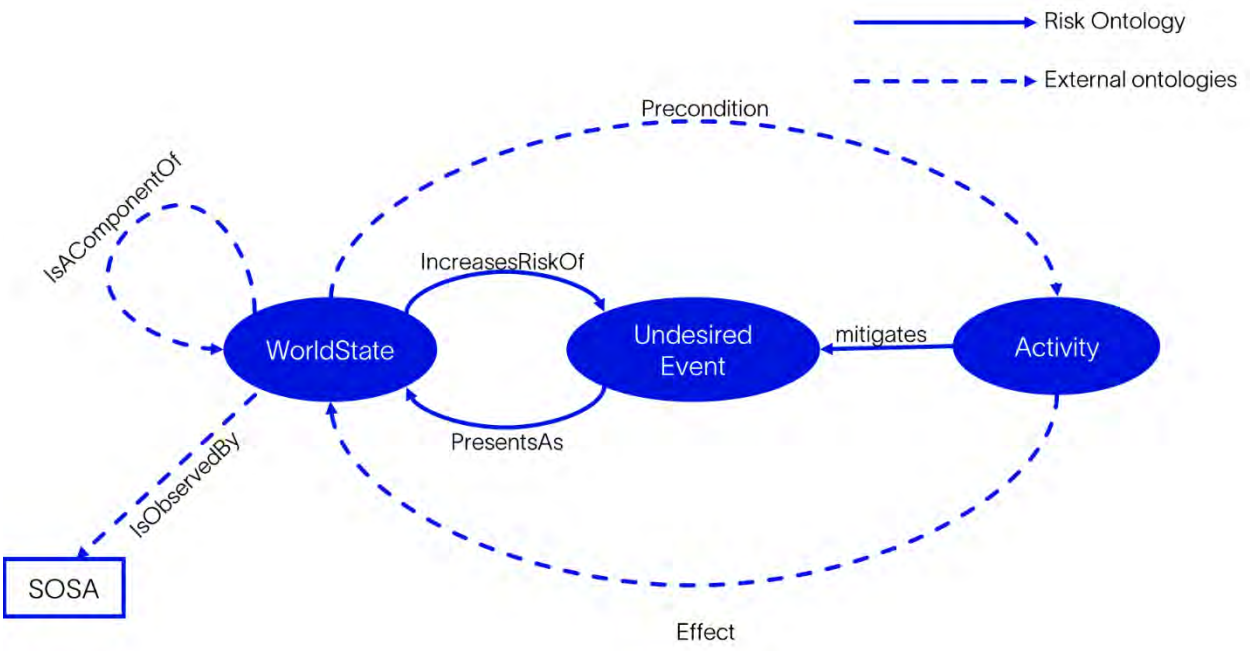

Figure 11 The risk ontology (personal communication from P. Gregory)

Our causal AI model uses advanced machine-learning algorithms to analyze historical drilling data, identifying complex relationships and potential risk factors leading to stuck-pipe incidents. By leveraging causal relationships, the SPRA can proactively assess the likelihood of a stuck-pipe occurrence based on current drilling conditions.

The SPRA generates detailed explanations of its predictions, using semantic annotations to link specific risk factors and causal relationships. This not only assists drilling operators in understanding the basis of the system's reported risk levels, but also facilitates continuous learning and improvement of drilling practices. In addition, the SPRA has a flow-diagram-based interface for drilling operators that shows risk factors, possible solutions, and interactive explanations in real time.

5. Conclusions

Because stuck pipes directly affect the total cost of drilling a well, prevention and mitigation are essential. For a long time, the stuck pipe problem has been a major issue in the industry. Traditional procedures for predicting stuck pipe incidents, on the other hand, leave room for digital innovation because most current methods are susceptible to human bias.

The artificial intelligence process has the potential to drastically reduce the problem of stuck pipes. We can construct the AI from historical occurrences to predict downhole issues in advance, giving the operation crew ample time to take preventative and mitigation measures. This can significantly reduce the consequences of NPT and other failures in wells. Furthermore, AI workflows can limit human error in interpretation.

Causal AI powers this knowledge-based early warning system, providing a viable solution to mitigate the risk of stuck pipes in geothermal drilling. This method has the potential to dramatically improve the safety and efficiency of geothermal well development by providing early warnings and allowing informed decision-making.

Optimizing Hard Rock Geothermal Drilling Efficiency With PDC Bits: A Comprehensive Study

Conner Richardson-Fervo Energy; Elliot Howard-Fervo Energy; Jordan Self-Ulterra Drilling Technologies; Shana Larson-Ulterra Drilling Technologies; Charles Douglas-Ulterra Drilling Technologies; David Cormier-Ulterra Drilling Technologies; William Dubose-Ulterra Drilling Technologies

Keywords

Fervro Energy, Ulterra Drilling Technologies, Geothermal, Horizontal, Granite, PDC Drill Bit

ABSTRACT

This paper presents a comprehensive analysis of the application of Polycrystalline Diamond Compact (PDC) bits in geothermal drilling operations, aiming to enhance overall drilling efficiency and geothermal wellbore performance when drilling hard and abrasive granite. Additionally, it explores the unique challenges associated with geothermal drilling in granite and evaluates the suitability of PDC bits in addressing these challenges.

Key aspects covered in the paper include the engineering, design, and optimization of PDC drill bits tailored for hard and abrasive rock in geothermal environments, with a focus on factors such as cutter geometry, cutting structure design and bit body material composition.

This paper provides insights into the implementation of PDC bits in geothermal projects that drill hard and abrasive granite lateral intervals. Learnings from traditional oil and gas drilling methods shed light on the potential advantages, such as increased penetration rates, increased run lengths and reduced drilling costs.

The findings of this study contribute valuable knowledge to the geothermal drilling community, offering a roadmap for optimizing drilling practices through the utilization of advanced PDC bit technology. This paper concludes with recommendations for future research directions and the continued advancement of geothermal drilling techniques to support the sustainable development of clean, renewable geothermal energy resources.

Unlocking geothermal energy from some of the most challenging geologic production zones below the Earth’s surface utilizing the latest technologies and drilling techniques has proven to demonstrate the economic viability of this type of clean energy extraction. These innovations can be used as building blocks for future innovations and technologies to unlock the Earth’s geothermal potential even more efficiently.

1. Introduction

Geothermal drilling is a means of harnessing clean, renewable energy from the Earth which is available 24 hours per day, 7 days per week. Tungsten carbide (TCI) and milled tooth (MT) roller cone drill bits, while effective, have certain limitations, such as higher wear rates, seal or bearing related failures, slower penetration rates (ROP) and increased downtime for trips related to the cutting structure degradation or seal/bearing related issues. The adoption of PDC drill bits presents an opportunity to address these challenges and achieve substantial cost savings in geothermal drilling projects.

PDC drill bits feature a fixed cutting structure (no moving components) equipped with synthetic diamond cutters, providing improved hardness, thermal and abrasion resistance. These features enable faster penetration rates through various geological formations, reducing the overall drilling time and well construction cost. The enhanced drilling efficiency of PDC bits directly translates to cost savings by minimizing rig operational costs and accelerating project timelines.

This paper includes a case study highlighting the successful application of PDC drill bits in a geothermal drilling project in southwest Utah. This case study highlights specific instances where cost savings were realized through improved drilling efficiency, reduced downtime, and extended bit life.

The implementation of PDC drill bits in geothermal drilling operations offers a reliable solution for achieving cost savings. Enhanced drilling efficiency, reduced downtime, and extended bit life contribute to overall project economics, making PDC drill bits one of the key technologies in the pursuit of clean, sustainable geothermal energy extraction.

With the introduction of PDC bits along with subsequent improvements to the bit design, PDC cutter technology, bit body materials changes along with increased gauge pad length the performance in the 8.75” lateral section (±30ksi granite) of the geothermal wells has increased performance from 1,172’ to 2,911’ drilled with a single bit (148%). The respective ROP followed suit with an 11% increase.

The foundation of the overall success of innovative new projects is the working partnership between the service companies and the operators executing the drilling campaign.

Application Definition

- Rock Properties and Challenges
- Drive Type (Top Drive, PDM)
- Rig Capabilities

Bit Design Selection and Criteria

- Blade Count, Cutter Size, Cutter Technology, CFD
- Bit Body Material (Steel or Matrix)

Field Test Trials

- Drill Bit Performance (EDR Data Analysis)
- Dull Bit Evaluation

2. The Value of Partnership Between Operator and Service Provider

A good partnership between an operator and a service provider involves clear communication, mutual trust, and shared goals. The operator relies on the service provider for specialized expertise and equipment, while the service provider relies on the operator for detailed information and clear feedback to efficiently deliver services or products that meet the operator's objectives. Both parties work collaboratively to optimize operations. Regular feedback and performance evaluations help maintain the partnership's effectiveness and drive continuous improvement. When operators and service providers form a solid partnership through mutual sharing of knowledge and expertise, significant benefits and advantages are realized by both parties. By working closely with the operator, the service provider gains access to a higher level of detail regarding the operator's specific needs, challenges, and operational requirements. This deeper understanding allows the service provider to tailor more effective solutions in a timelier manner. The operator can then realize more frequent and more significant step changes in performance.

Partnering with a service provider enables the operator to engage in more meaningful interactions throughout the project lifecycle. With regular interaction, time spent with a service provider becomes more valuable with less time required for each interaction. The operator achieves better results in less time. This close collaboration fosters a dynamic feedback loop wherein the service provider can quickly iterate on their solutions based on real-time feedback from the operator and detailed historical understanding. By maintaining open lines of communication and actively soliciting input from the operator, the service provider can ensure that their solutions remain aligned with ever-evolving needs and priorities, delivering greater value for the operator. Trust between the two parties must be established as well because data shared from either side may be sensitive. An understanding of allowed and disallowed uses of shared information must be determined and understood. However, the sharing of this detailed information from both parties is vital to maximize the speed and effectiveness of solutions.

Optimizing drill bit design for hard rock drilling in an effective and timely matter required significant communication, data-sharing, and feedback between the operator and the drill bit company. It required a trusting partnership. Initially, the drill bit company shared lessons learned and expertise from previous hard rock applications such as the Utah FORGE project. The operator trusted the bit company with proprietary access to their specific geology, wellbore geometry, bottom-hole assemblies (BHA), and drilling parameters. The drill bit company and operator used the data to understand differences and similarities leading to initial bit designs selected and agreed upon for trial.

After initial trials with the service provider's bit, the iterative process of improvement began. The drill bit company was able to review drilling parameters and dull conditions of the bits with the operator and apply their suggestion for improvement in design. The operator was able to express honest and constructive feedback on performance. The drill bit company trusted the operator with proprietary details on proposed drill bit cutting structure design and bit material changes that could be made to increase performance. The operator was able to express their opinion and expertise to mold and shift recommendations to better fit their operational goals and requirements. Each drill bit run was a learning opportunity for the partnership to better understand and overcome the limiting factors together to iterate and improve. The partnership improved the operator's performance from expecting less than 1,000-ft per bit run to achieving multiple single-bit runs

over 2,000-ft, reducing the number of bits/BHA's required per well and reducing the overall cost while reducing NPT time.

3. PDC Drill Bit Design

An 8.75", 7 bladed-13mm cutter matrix body PDC bit (**Bit-A**) was initially designed to drill the challenging granite formation in Utah – specifically for the Fervo Energy Cape Station project in Milford, Utah. The interval of interest was the 4,500' to 5000' lateral section in the ±30ksi compressive strength abrasive granite. The formation TVD is ±8700'. Over a 7-month period several design and materials changes were implemented to improve the drilling efficiency and dull condition of the drill bit which resulted in a new PDC bit product line (**Bit-B**). **Figure 1** below shows the baseline bit alongside the modifications made after the first field trials. Modifications including an increased gauge pad length, cutter geometry shape change and matrix body materials change.

Figure 1: Bit-A (7 blades, 13mm cutters), Bit-B (7 blades, 13mm cutter)

PDC drill bits feature diamond-enhanced cutters that are highly resistant to wear and abrasion. Granite's hardness is well-suited for PDC bits, allowing them to maintain their cutting effectiveness over extended drilling periods.

The inherent hardness of PDC bits enables efficient penetration through granite formations. The PDC drill bits provide a continuous and consistent cutting action, resulting in faster drilling rates compared to conventional roller cone bits. **Figure 2** below shows the drilling mechanics of a roller cone insert versus a PDC cutter.

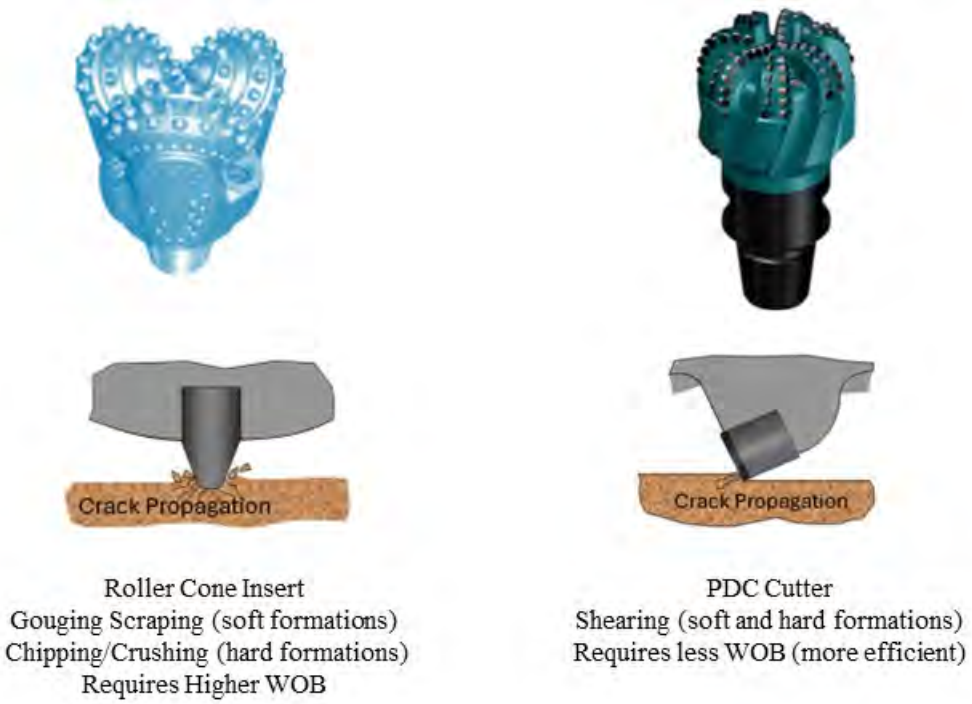

Figure 2: Roller cone insert vs PDC cutter Rock Mechanics

PDC bits contribute to reduced cycle time as they withstand the abrasive nature of granite, minimizing the need for frequent bit changes. This characteristic enhances operational efficiency and reduces overall drilling costs. The robust design of PDC bits leads to an extended lifespan in granite drilling applications. This longevity not only reduces the frequency of bit replacements but also contributes to cost savings by minimizing equipment mobilization and demobilization.

Adjusting drilling parameters, such as weight on bit (WOB) and rotational speed (RPM), can further optimize the performance of PDC bits in granite formations. Proper drilling practices ensure maximum efficiency and longevity of the bits.

Granite drilling generates significant heat at the rock and cutter interface, therefore adequate cooling mechanisms must be implemented to prevent overheating of PDC bits. The bottom hole temperature in the Cape Station project ranges between 400°-425°F. The temperature does not pose a significant challenge for the PDC bits as proper fluid circulation helps dissipate heat and maintains optimal drilling conditions. Although elevated temperature environments can affect downhole tool life, the high downhole temperature has been proven to not drastically affect PDC bit performance.

PDC cutting structure changes are generally made after dull trends are identified on the drill bit. It generally takes between three to five runs on a cutting structure to identify dull trends if all the other variables are held constant (WOB, RPM, flow rate, geology). Materials changes (matrix body, cutters) can be made after one run if an undesirable dull condition exists such as bit body erosion and/or impact/thermal/abrasive wear on cutters.

In summary, PDC drill bits paired with a drilling rig with adequate capabilities are well-suited for drilling granite due to their hardness, thermal and abrasion resistance, and efficient cutting action. Implementing PDC technology in granite drilling operations enhances overall drilling performance, reduces downtime, and contributes to cost-effective and successful projects.

4. PDC Cutter Development

Before the release/commercialization of any new PDC cutters to the field, there is extensive and time-consuming collaboration with the vendors' engineers. Prior to a cutter making it to the field, extensive lab cutter tests are performed to ensure the best product is ready for field trials. After the new cutter designs pass the rigorous field tests and evaluation (performance and dull condition) the cutters then progress to commercialization or, if required are sent back to the vendors' development teams for modifications. Each cutter being tested undergoes extensive post run evaluation to understand the observed dull conditions for future design improvements.

The first step, prior to any modification to the bit design, was to investigate and test new cutter technology. The transition from traditional round PDC cutters to multi-dimensional shaped PDC cutters to improve the cutting efficiency was made after the initial field trials. Scribe cutters (**Figure 3**) are the embodiment of a force multiplier. Like a knife-edge, they feature a prominent cutting edge that reduces the exposed cut face by 36% to improve the cut-crush ratio while drilling. The result is a cutter that focuses the maximum available weight transfer into challenging formations. The same force is applied across a smaller area, increasing the load per unit area (PSI).

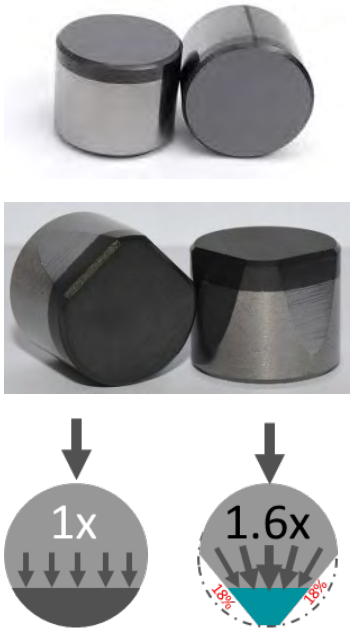

Figure 3: Round Cutters and Scribe Cutters

When selecting a scribe cutter attention must be paid to how "sharp" the cutting tip is. Small tip widths generally increase drilling efficiency but may result in a reduction in durability. A "blunter" tip results in a reduction in drilling efficiency but increases in durability.

When drilling at a moderate to high depth of cut the PDC cutters oftentimes get buried to >0.100" depth of cut (DOC). The high depth of cut places a force surface on the cutting edge, resulting in a gradient of loads and forces on the cutting face. This gradient of forces places a moment arm on the cutter, a compressive force on the tip and a neutral state away from the edge, putting a tensile load on the diamond table. Hard composite materials such as PDC cutters perform better in compression than tension.

PDC cutters are comprised of two primary materials, synthetic diamond and a tungsten carbide substrate. The synthetic diamond must be engineered to withstand the application that it is targeting. The key considerations for the selection of the diamond include impact resistance, wear resistance and thermal resistance. Most applications around the world require the proper balance of these three material properties based on the rock properties/lithology, drive system and drilling fluid. The tungsten carbide substrate is the supporting structure for the diamond table and is needed to attach the cutters to the PDC bit body with the use of a braze material. The tungsten carbide substrate is also a component that is modified/engineered to increase its erosion and corrosion resistance. **Figure 4** below shows the diamond grit, tungsten carbide substrate, HTHP cubic press and resulting PDC cutter.

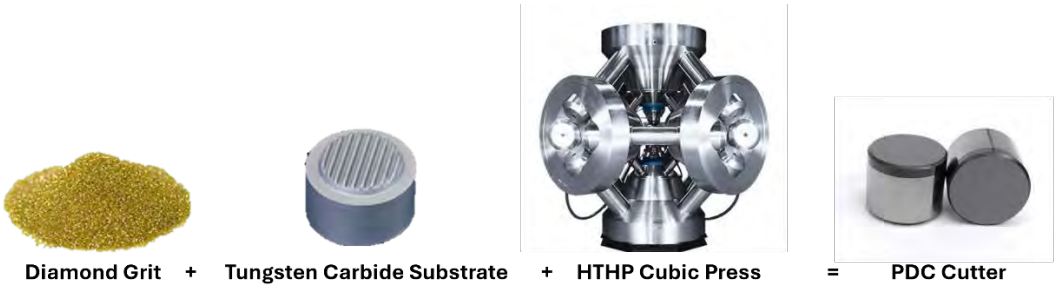

Figure 4: PDC Cutter (synthetic diamond and tungsten carbide substrate)

The system that is a PDC cutter must balance the various parameters and components that go into its creation. The crux of a PDC cutter is internal stresses, both mechanical and thermal. Interface patterns must distribute the internal compression/tension stresses efficiently to mitigate stress risers (failure initiation points). Lower interface heights result in higher thermal stability but results in lower strength of the compact. Tall interfaces enable higher strength but interferes with the maximum leach depth and braze thermal stability.

Higher pressure sintering allows for higher diamond packing density but creates a more fragile crack-prone diamond table. Higher density diamond also limits the leach ability of diamond, which can limit the effective thermal stability of the PDC cutter.

Lab development of PDC cutters typically revolves around milling granite, which for general geothermal environments is a similar pairing versus "producing" formations. The typical UCS of the granite used on the Vertical Turret Lathe (VTL) tests is around 20-25ksi. Parameters can be adjusted on the VTL to simulate downhole dysfunction, such as vibration. Through iterative tests evaluating single variable changes, the engineers can develop trade-off curves on development levers. It is critical that the rock of the VTL remain consistent to ensure like-like development comparisons.

Since drilling is a multimodal loading and failure mechanism environment, PDC cutters must be designed to service the primary modes of failure. Abrasion is caused by conventional shearing of formation. Thermal degradation by the bearing surface and friction caused by the shearing mechanism. Impact by either the formation (chert, dolomite, anhydride, etc.) or by parameter selection leading to vibration (axial or horizontal) or tangentially (stick-slip, HFTO). Because of these multi-modal loading scenarios, cutters must be designed to be off-center balanced, otherwise any one of these failure modes can exploit the designed product weakness.

5. PDC Gauge Pad Length Change

Gauge pad length was increased to improve tracking capabilities in the lateral interval, which inherently improves borehole quality, thereby reducing cycle time. The initial field trial was done with bits equipped with 3.0” gauge pad lengths (**Bit-A**), which transitioned over the project to bits re-designed with 6.0” gauge pad lengths (**Bit-B**). The transition to the longer gauge bit was on the third well on the Cape Station project and was set as the standard gauge pad length for all subsequent 8.75” designs. **Figure 5** shows the 7 bladed – 13mm cutter bit with different gauge pad lengths.

Figure 5: 8.75” Bit-A with 3.0” Gauge Pad on the Left and 8.75” Bit-B with 6.0” Gauge Pad on the Right

6. Matrix Bit Body Materials Development

A new matrix body material (tungsten carbide and binder) was incorporated to survive the erosion in the abrasive granite formation/environment encountered when drilling in this area in Utah. The abrasive nature of the granite had a negative effect on the matrix bit body of the PDC bit resulting in non-rerunnable bits due to erosion/abrasion on the bit body near the bit/rock interface. As the footage drilled over the span of the project increased due to drilling efficiency and drill bit improvements (cutter shape and design changes), the number of hours on bottom has also increased, exposing the limitation of the standard matrix powder used. Knowing that limitation on erosion/abrasion resistance was going to result in bit bodies being damaged beyond repair, a new matrix powder was deployed on all future bits manufactured for the application. **Figure 6** below shows the reduction in erosion/abrasion on the blades by moving to new matrix powder.

Some of the material properties of the matrix powder are listed below:

60% Increase in TRS (Base Strength)

50% Increase in fatigue life

25% Increase in thermal resistance

95% Increase in abrasion resistance

Figure 6: Original Matrix Powder (left) vs New Matrix Powder (right)

7. Dull PDC Bit Study

The dull photos in **Figure 7** are from the original design with standard round cutters, the original bit body matrix powder and the original 3.0” gauge pad length. The longest run on that frame was 1,172’ and it had an ROP of 44 feet/hour. **Figure 8** is the modified bit design with shaped cutters, new more erosion resistant matrix powder and was equipped with a 6.0” gauge pad length. This

bit drilled 2,911’ and it had an ROP of 49 feet/hour. This represents an increase in footage drilled of over 148% with an ROP increase of 11%. Although the dull state of the bit is worse than the previous best run on the original bit, the performance trade-off was substantial. This performance significantly improved upon the prior performance of the competitor PDC bits that on average drilled 531’ at an ROP of 55 feet/hour.

Figure 7: Bit-A, PDC1, MP1 (1,172’ @ 33.0 fph)

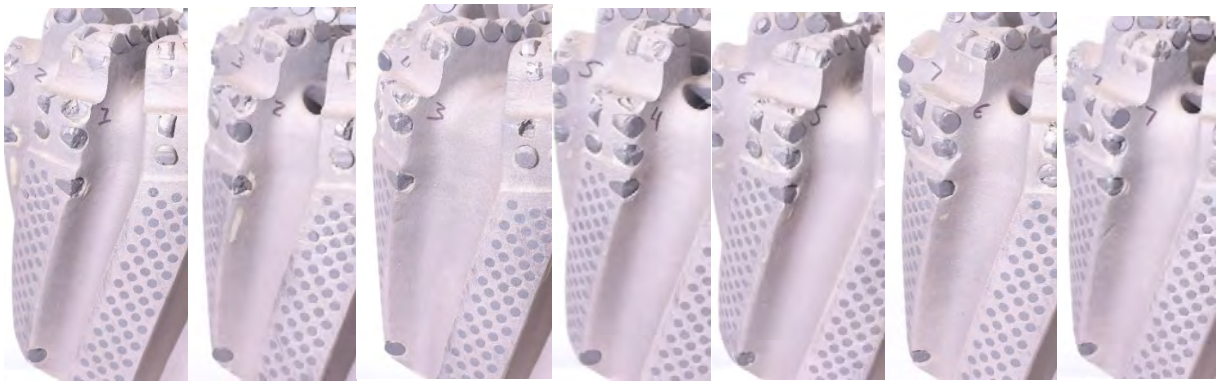

Figure 8: Bit-B, PDC2, MP2, GPL2 (2,911’ @ 37.0 fph)

8. PDC Drill Bit Design Changes

After initial PDC bit and PDC cutter field trials, each dull bit underwent dull evaluation by both the local applications engineers, Cutter R&D engineers as well as other PDC experts in the organization to identify where design and/or cutter improvements could be made to enhance the drill bit performance (footage and/or ROP) and dull condition.

Figure 9 shows design changes regarding the bits profile to address a dull characteristic limiting the performance of the original field trial PDC bit. In this case, the profile and back rakes were changed to lower the amount of work each cutter saw starting at the nose location on bit profile.

9. Improved Drilling Efficiency in The Lateral: 6 Well Case Study

The graph below (Figure 10) shows all the 8.75” bit runs in the lateral section. Both Ulterra (bit provider-A) and competitor bits are included. Although the scope of this paper is focused on the design and materials changes to the PDC bit itself, there were drilling efficiency gains made by changes to the bottom hole assembly and operating parameter optimization. The bits in the lateral section were all run on steerable PDM’s (Positive Displacement Motors). Run parameter changes were made based on the previous wells and bit dulls analyzing the EDR Data (Electronic Drilling Recorder Data) and adjusting the WOB, RPM and Flow Rate accordingly to improve both footage drilled and ROP.

- Well #1: 9 PDC bits used in the lateral (364 hours + Trips)
- Well #6: 2 PDC bits used in the lateral (144 hours + Trips)
- Reduced well time in the lateral by 9 days over the span of 6 wells (a 7 month time period)
- 78% decrease in bit runs – 60% decrease in drilling time in the lateral

Figure 10: Days vs Depth Chart

The graph below (**Figure 11**) represents the six subject horizontal wells and the drilling efficiency gains in footage and ROP in the lateral interval. The graph clearly shows the increased footage drilled per bit over the initial six wells of the drilling program. The wells are listed in chronological order from left to right on the graph.

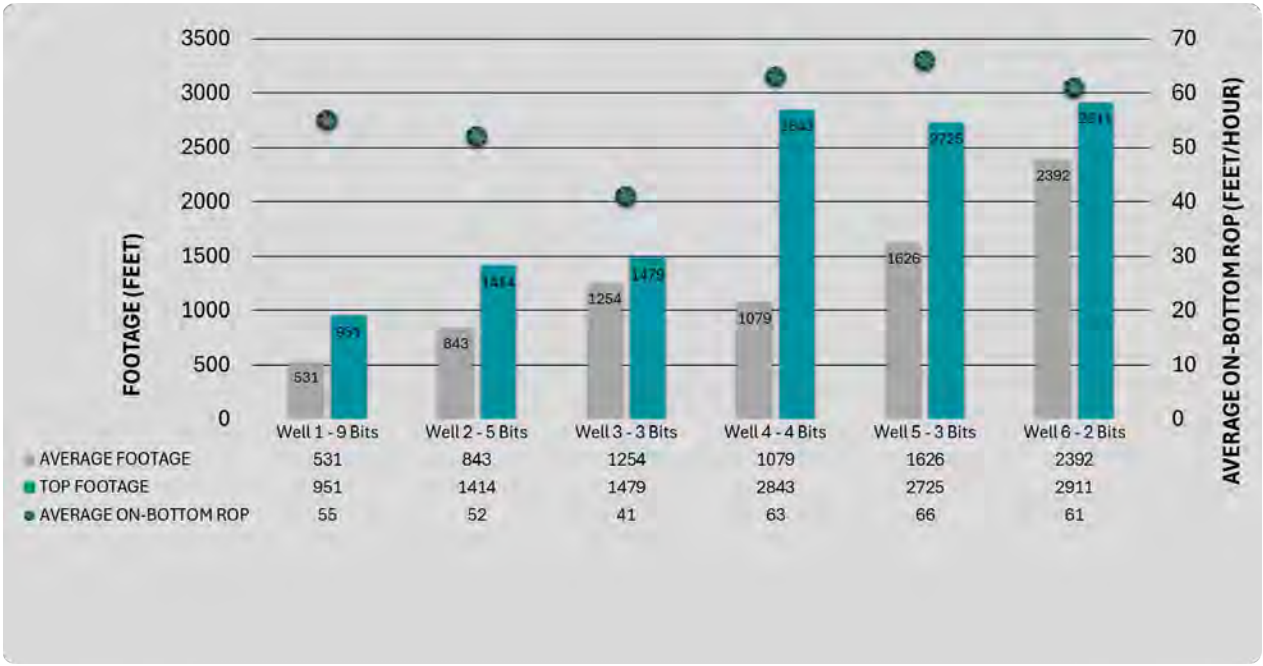

Figure 11: Metrics (Average Footage and Average om-bottom ROP) by Well – Lateral Interval

The table below (**Figure 12**) only represents bit povider-A's PDC runs shown on the chart above (**Figure 11**). The changes to the PDC Bit include cutting structure changes, PDC cutter changes, matrix powder changes and gauge pad length changes.

10. Wellbore Design and Geometry

The Cape Station wells in Beaver County, Utah in this study all consist of wellbores that include a lateral section of around ±5000’ at a true vertical depth (TVD) around ±8700’. The heat map scale on the right side of the plot shows the on bottom ROP (**Figure 13**).

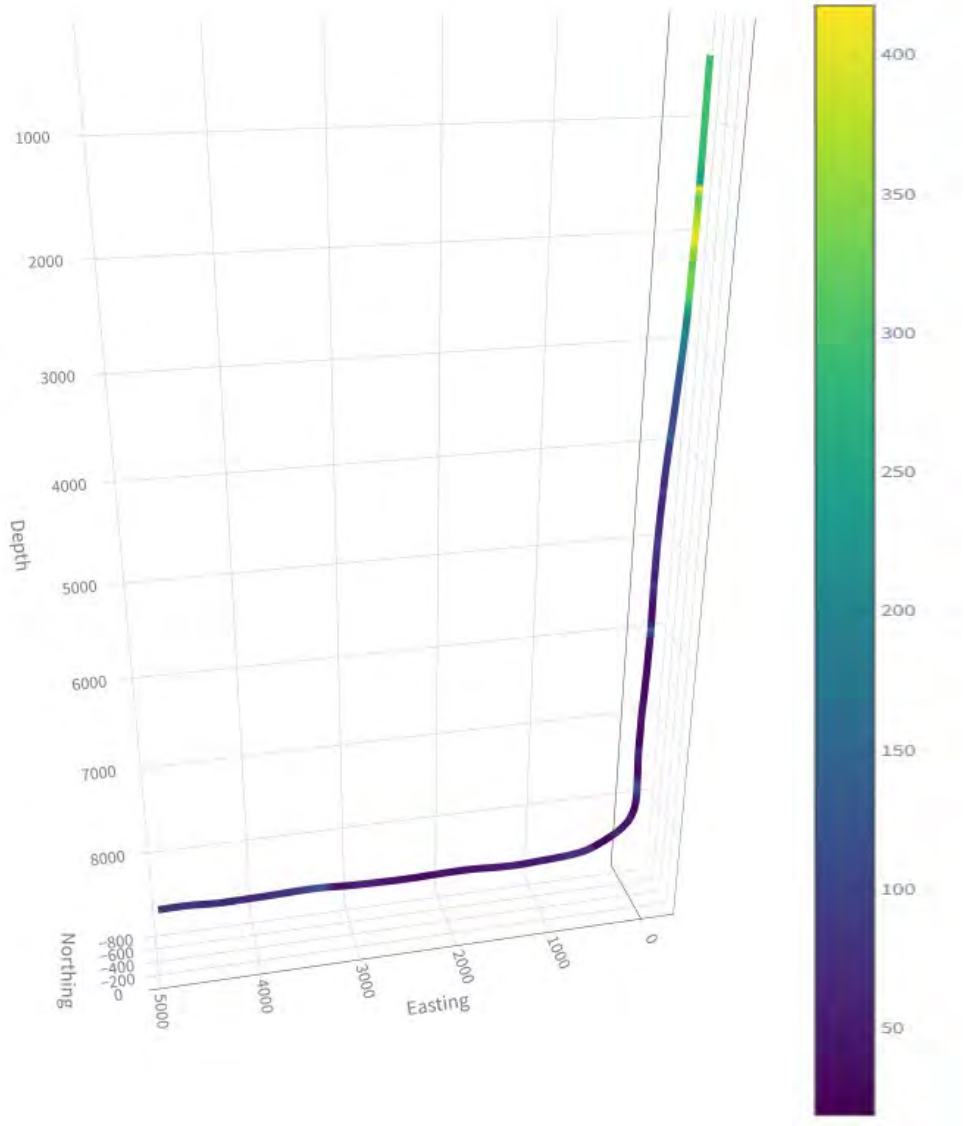

Figure 13: W3P Sample Geothermal Wellbore Trajectory with ROP

11. Present and Future Geothermal Opportunities

Although there is potential to drill Geothermal wells in many areas of the United States, this paper is focused on geothermal activity in Beaver County, Utah. This is one of the more challenging areas/formations in the United States to extract the energy from the earth due to the lithology (granite) being drilled in the lateral section. **Figure 14** below shows the location of the Cape Station project in Utah.

Figure 14: Cape Station: Beaver County, Utah Geothermal Location

The map below (**Figure 15**) shows the proximity of the Utah FORGE geothermal project relative to the Cape Station project.

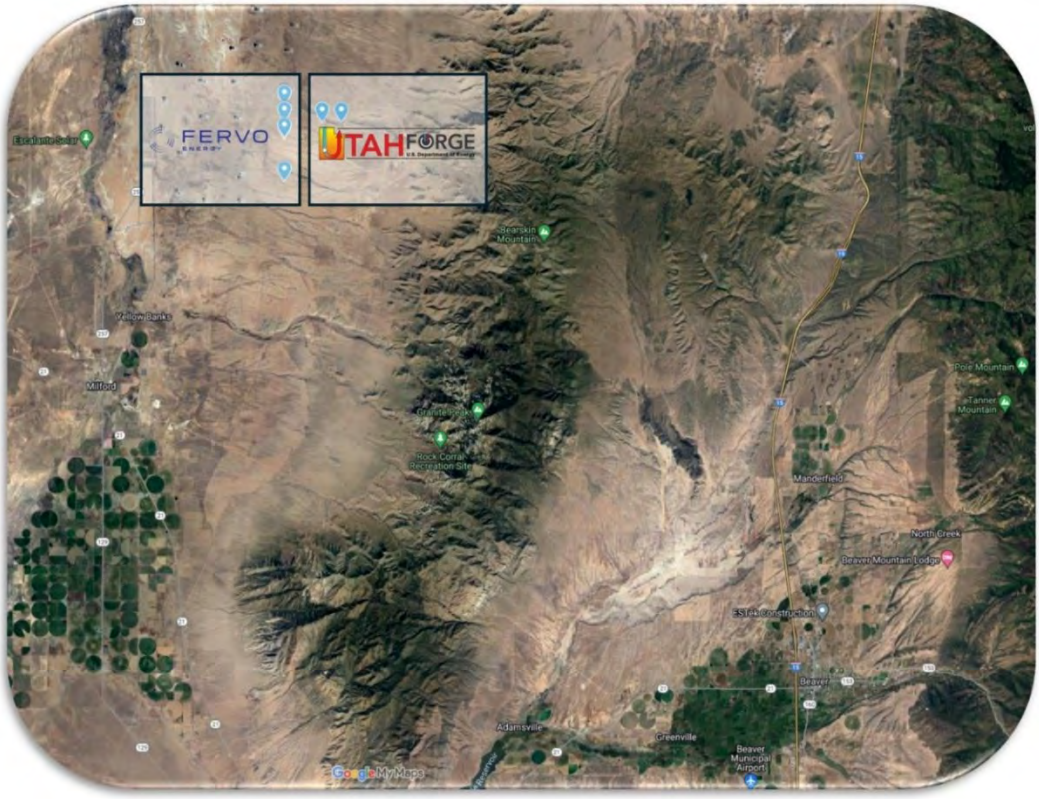

Figure 15: Cape Station and Utah FORGE Geothermal Well Locations

Figure 16 shows the areas in the United States and potential areas for future geothermal projects. The state of Utah is highlighted as it is the current focus of this paper and PDC development for the hard rock (granite) being drilled in the lateral.

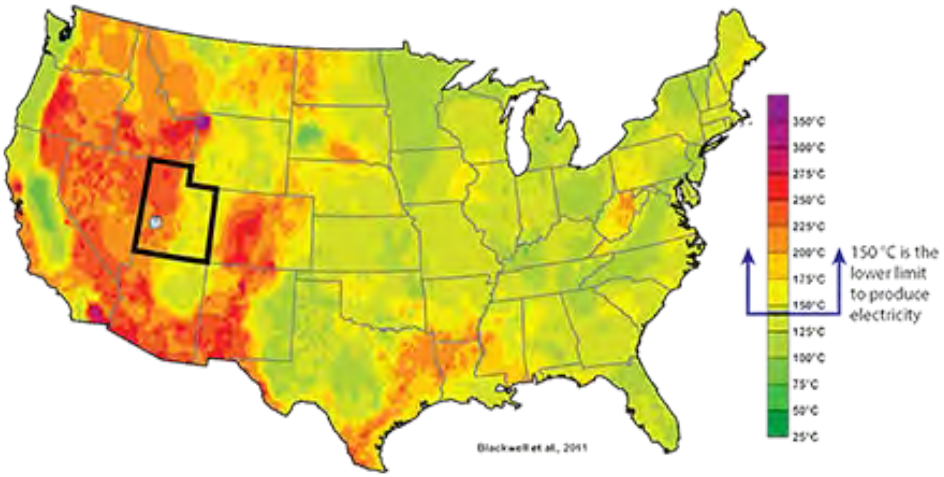

Figure 16: Potential Future Geothermal Operations (Blackwell et al., 2011)

12. Formation Characteristics

Most granite is a medium to coarsely crystalline igneous rock. Its color and texture depends largely on the relative abundance of quarts,feldspar (a family of rock-forming minerals), and mica.

Granite, one of the hardest, least brittle rocks on the planet (on the Mohs scale of mineral hardness, it generally falls between about 6 and 7). This translates into 25 to 30ksi unconfined compressive strength rock ('unconfined' is how the equivalent measure is presented in the drill bit industry, developing bits for the oil and gas industry).

Granite's density is high when compared to other, similarly drilled rock such as limestone or shale. Its density can range from 2.63 to 2.75 g/cm³ – which contributes heavily to its strength and durability.

Pore spaces make rock more vulnerable to substances penetrating it by capillary attraction or macroscopic flow. Granite'sporosity is so low that it is almost completely immune to water absorption and weathering.

Granites great stength can be attributed to it's granular texture. This quality is invariable due to granite being formed via interlocking, mineral crystals.

These specific properties might not apply to all granite formations in Utah. That depends on geological conditions and the mineral content of the rock. Very specific properties of granite in certain locations in Utah will have to be investigated on-site. The properties of the rock can also be tested off-site through the use of core samples that can be sent out to a lab for detailed testing of the mechanical properties. In fact, samples of the granite formation from the adjacent Utah FORGE project were sent out for analysis and the information gatherered is available on their website. The compressive strength of the rock can also be calculted utilizing electronic log data (such as gamma ray and sonic) and a mathematical model.

Figure 17 below shows properties of rock material in terms of unconfined compressive strenght (UCS) in kpsi.

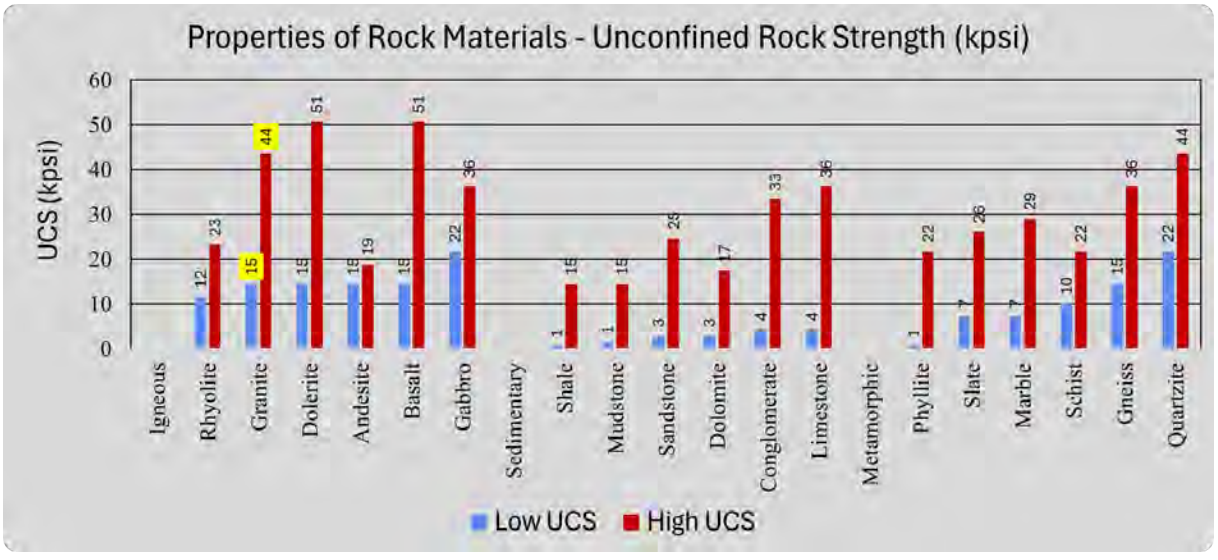

Figure 17: Unconfined Compress Strength of Various Rock Types

13. Conclusion

Our mission and the primary goal of these types of conference is to collaborate on technologies and techniques that allow us to produce clean and affordable energy.

One of the primary goals is to increase drilling efficiency that enables operators to tap into energy sources in the least amount of time and capital. Drilling efficiency gains alone, reduces the overall “unavoidable” carbon footprint of tapping into these energy sources.

The PDC bit manufacturers contribution is small in stature, a PDC drill bit measures around one foot in height, but monumental on the overall efficiency.

The Operator is currently drilling a 100 well project in Beaver County, Utah with the end goal of producing 400 MW of 24/7 carbon-free energy. At the time of writing this paper the team has already reduced the time in the ±5000’ lateral section from 15 days to 6 days and from 9 bit runs to 2 bits runs.

To put this into perspective, in 7 months, the team has reduced the drilling time in the lateral section alone from 1500 days to 600 days (extrapolated over the 100 well drilling program). This translates into a 60% reduction in time in the lateral section.

The geothermal community can further minimize its carbon footprint by its individual and group efforts to increase efficiency through collaboration.

Future development in the Utah geothermal application will include further development of PDC cutting structures, PDC cutters as well as parameter roadmaps. Other drilling related practices that affect PDC bit performance (such as connection and off bottom practices) are continually being reviewed and optimized by the operator.

Acknowledgements

We would like to acknowledge the great people involved in the Cape Station geothermal project in Utah, both in the office and in the field. The entire team on H&P 492, including all onsite service providers, all played a major role on the project. There are so many support people behind the scenes that contribute to the success of these types of projects it is hard to name them all. So, to those people, we offer our sincere gratitude to those that put their fingerprint on the success that all of us enjoy due to your commitment and contribution to being the best at what you do daily.

Managed Temperature Drilling, Insulated Drill Pipes, Automatic Temperature Controller

ABSTRACT

Drill pipe insulation is an effective method for downhole temperature management in high-temperature wells. Of late, the most popular pipe insulation method has been the application of a coating of low thermal conductivity to the inner wall of the drill pipe. When the coating is damaged, the insulation is also partially breached, leading to temperature management disruptions and higher downhole temperature.

Detection and prediction of coating damage is thus pivotal to successful downhole temperature management. There is currently no approach for the evaluation and detection of insulation coating damage. In this paper, we first propose a method to estimate drill pipe insulation integrity and then describe an automatic controller to account for the negative effects.

The insulation coating integrity evaluation workflow involves first using an advanced thermo-hydraulics model of the well to perform simulations of the planned drilling operations. From the simulation results, the relation between the bottom hole circulating temperature (BHCT) (and the surface temperature) and the drill pipe's average apparent thermal conductivity is established. We then use this relationship and compare it to the relationship between BHCT and surface temperature during actual drilling operations to determine damage (this is reflected as a change in the apparent thermal conductivity).

Next, to control the well's bottomhole temperature, a feedforward proportional, integral, derivative (PID) controller is used. In this study, the surface inlet temperature and the pump flow rate are used as the control inputs. Data from high-temperature land wells in the US using insulated drill pipes were used for the study. The effect of peeling and thinning of the insulation (the two prominent types of insulation damage) and its negative temperature effects were investigated.

This is the first study that demonstrates an approach to estimate the integrity of the drill pipe coating during actual drilling operation. In addition, a controller is suggested to automatically control /recommend flow rate and inlet temperature changes.

1. Introduction

When drilling geothermal wells, the high downhole temperature is a critical issue that lowers the life of the drilling tools, alters the fluid properties, and increases drilling risks and costs (van Oort et al., 2021). The development of high-temperature tools, drilling fluids, and cements have enabled drilling in extreme downhole conditions, but the increased cost from applying these advanced tools impair the profitability of many geothermal projects.

The fundamental premise behind managed temperature drilling (MTD) is to optimize the drilling plan and operation to maintain the downhole temperature within the working limit of the drilling tools and the drilling fluid. It aims to balance the capability of all components in the drilling system to optimize the drilling cost and performance in extreme downhole temperature conditions. By utilizing MTD, the drillable formation temperature of the drilling system can be expanded beyond the limits of each of the components in the drilling system.

One approach to keeping the downhole temperature within limits is to constrain the temperature increase of the drilling mud pumped into the drill pipe until it reaches the bottom of the hole. The mud traveling through the drill pipe is typically cooler than the mud in the annulus returning to the surface. The steel which is between the mud in the drill pipe (DP) and the annulus has a high thermal conductivity of 45 W/m/K. Under normal circumstances, the thermal energy flows from the annulus to the inside of the drill pipe, heating the mud, and in effect reducing the mud's ability to cool the bottomhole assembly. To suppress the heat transfer across the drill pipe, the drill pipe may be insulated. Among the MTD tools, insulated drill pipes are shown to be particularly effective, especially in deeper wells. Simulations show that drill pipe insulation is very effective for temperature management at depth, while the impact of surface mud cooling on the downhole temperature decreases in deeper wells (Khaled et al., 2023).

Tubing and pipeline insulation have been studied in the past with respect to heavy oil production and transportation (Lombard et al., 2008; Bell et al., 2021). To mobilize the heavy oil, hot steam is injected into the reservoir to heat the oil and thus decrease its viscosity. To keep the steam's high temperature and preserve the thermal energy carried by the steam, the steam is injected through insulated tubings. Once the heavy oil is produced and pumped into the transmission pipeline, pipeline insulation is used to suppress the heat dissipation from the oil to the environment to maintain the temperature and viscosity of the crude oil. In general, two types of insulation technology have been applied in the field, including insulation layers made of low-thermal-conductivity materials (Bell et al., 2021), and vacuum insulation (Singh et al., 2007).

Compared to production tubing and the transmission pipeline, DP works under more dynamic conditions. The alternating torques, the ever-changing axial load and the vibrations along with the impact forces challenge the robustness of the insulation structure. Furthermore, the thickness of the DP is strictly limited to allow more mud to flow through the DP and the annulus.

Between the two most popular DP insulation approaches, vacuum insulation is expensive and prone to damages by downhole impact and vibration, while the low-conductivity coating insulation

has a much lower installation cost and is less sensitive to impact and vibration. These advantages made insulative coating the prevailing DP insulation technology. However these insulations also fail, and there is as yet, no research on the real-time diagnosis and evaluation of the health of the DP insulation coating.

In this paper, we propose a method and procedure to diagnose the health of the insulation coating during drilling and introduce an automatic controller for downhole temperature maintenance in case of insulation failure. In the proposed method, a thermo-hydraulic model of the well is established and the relation between the circulating temperature and the coating health is first acquired. Then, using the measured surface and downhole temperature, the insulation health can be determined, and the remaining lifespan of the coating estimated. A PID controller is developed to maintain the downhole temperature when the insulation coating fails. The proposed procedure and the controller are demonstrated using simulated case studies.

2. Insulation Health Diagnosis

During drilling, the bottomhole circulating temperature (BHCT) and the surface temperature of the returning mud in the annulus are functions of formation properties, wellbore geometry, operational parameters, drillstring geometry, and drillstring properties including the DP apparent thermal conductivity. Assuming other parameters are unchanged, the BHCT and the surface temperature are functions of the DP apparent radial thermal conductivity k_{app}.

To get the relation between the mud circulating temperature and k_{app}, a thermo-hydraulic model of the well is established using the model developed by van Oort et al. (Fallah, 2021; Khaled et al., 2023; Wang et al., 2023). Based on the model, we assume the k_{app} and simulate the downhole temperature until steady state to get the BHCT. The BHCT at different assumed k_{app} is calculated and the BHCT-k_{app} curve is plotted (see Fig. 2). We will show in the case study that k_{app} is in fact a function of BHCT if the DP is sufficiently insulated.

The cross-section of the DP is a circular ring. Since the outer surface of the DP contacts the wellbore and suffers wear and impact, the insulation coating is on the inner surface to maximize the coating's life. Assuming the coating has a uniform thickness, the cross-section of the coating is also a circular ring. The k_{app} of the DP-coating system can be represented by (Bird et al., 2009)

$$k_{app} = \frac{\left(\ln\frac{r_{out}}{r_{in}}\right)_{DP+coating}}{2\pi L} \cdot \frac{1}{\frac{\left(\ln\frac{r_{out}}{r_{in}}\right)_{coating}}{2\pi L k_{coating}} + \frac{\left(\ln\frac{r_{out}}{r_{in}}\right)_{DP}}{2\pi L k_{DP}}} = \frac{\left(\ln\frac{r_{out}}{r_{in}}\right)_{DP+coating}}{\frac{\left(\ln\frac{r_{out}}{r_{in}}\right)_{coating}}{k_{coating}} + \frac{\left(\ln\frac{r_{out}}{r_{in}}\right)_{DP}}{k_{DP}}} \quad (1)$$

where r_{in} and r_{out} are the inner and outer radii of the corresponding layer, L is the unit length, k is the thermal conductivity, subscript $coating$ refers to the coating layer, and subscript DP refers to the steel part of the DP.

There are two typical damage modes for the coating: peeling, where part of the coating peels off the DP while the remaining coating keeps the thickness; thinning is when the coating is worn out uniformly. In this study, we assume that the coating damage is uniform along the drillstring, which means the coating health for each stand of DP is the same.

The DP insulation coating process is in its early stage of development and not all damage modes are properly documented. In this paper, we assume that there can be two damage modes: peeling or (and) thinning.

If peeling is the dominant coating damage mode, k_{app} is a function of the ratio of the remaining coating, α, and the thermal conductivity of the steel and the coating.

$$k_{app} = \alpha k_{steel} + (1-\alpha) k_{perfect} \tag{2}$$

$$\alpha = \frac{k_{app} - k_{perfect}}{k_{steel} - k_{perfect}} \tag{3}$$

where $k_{perfect}$ is the apparent radial thermal conductivity when there is no coating damage, and k_{steel} is the thermal conductivity of steel/non-coated DP.

If thinning is the dominant coating damage mode, we can derive the relation between the remaining ratio of coating thickness, β.

Assuming the initial thickness of the coating is $t_{coating}$, the inner radius of the coating is

$$(r_{in})_{coating} = (r_{in})_{DP} - \beta t_{coating} \tag{4}$$

Substituting Eq. (4) into Eq. (1) and expanding the log terms, we get

$$k_{app} = \frac{\ln r_{out,DP} - \ln\left(r_{in,DP} - \beta t_{coating}\right)}{\frac{\ln r_{in,DP} - \ln\left(r_{in,DP} - \beta t_{coating}\right)}{k_{coating}} + \frac{\left(\ln \frac{r_{out}}{r_{in}}\right)_{DP}}{k_{DP}}} \tag{5}$$

Eq. (5) can be rearranged to obtain the below.

$$\left(\frac{k_{app}}{k_{coating}} - 1\right) \cdot \ln\left(r_{in,DP} - \beta t_{coating}\right) = \frac{k_{app}}{k_{coating}} \ln r_{in,DP} + \frac{k_{app}}{k_{DP}} \left(\ln \frac{r_{out}}{r_{in}}\right)_{DP} - \ln r_{out,DP} \tag{6}$$

$$\beta = \frac{1}{t_{coating}} \left(r_{in,DP} - \exp\left[\frac{1}{\frac{k_{app}}{k_{coating}} - 1} \cdot \left(\left(\frac{k_{app}}{k_{coating}} - \frac{k_{app}}{k_{DP}} \right) \ln r_{in,DP} + \left(\frac{k_{app}}{k_{DP}} - 1 \right) \ln r_{out,DP} \right) \right] \right) \tag{7}$$

In practice, the k_{app} of the DP-coating system can be plotted against the BHCT. The k_{app} can then be easily looked up from the curve using the measured BHCT. Eq. (3) and Eq. (7) can also be plotted for easy reference.

In summary, the apparent thermal conductivity k_{app} is first calculated via simulation. If the dominant coating damage mode is peeling, the remaining coating area ratio α can be calculated using Eq. (3); if the dominant coating damage mode is thinning, the remaining coating thickness ratio can be calculated using Eq. (7). By monitoring and extrapolating how α and β decrease during drilling, the remaining lifespan of the insulation coating may be estimated.

3. Case Study

For the case study we use a representative L-shape horizontal well in the Haynesville basin. The well trajectory is shown in Fig. 1. The well has a true vertical depth (TVD) of 12,000 ft and the formation temperature at that depth is 385°F. A coating is painted on the inner surface of the 4.5" DP for insulation purpose.

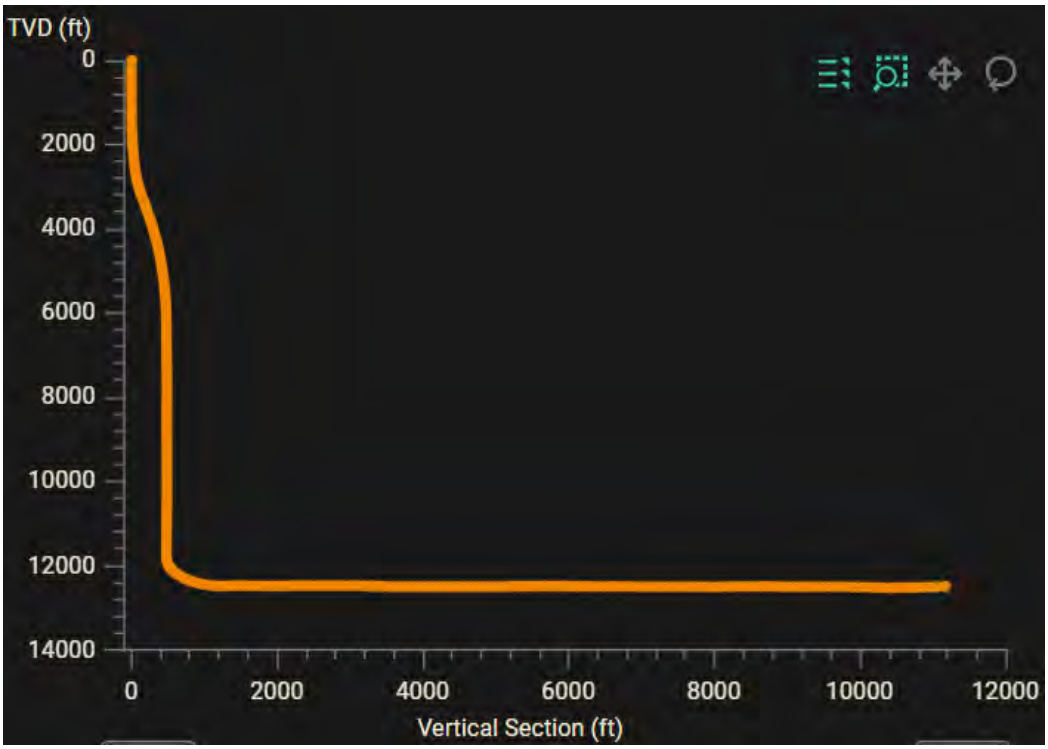

Figure 1: Case study well trajectory.

The well is modeled using the advanced hydraulics software developed by van Oort et al. (Fallah, 2021; Khaled et al., 2023; Wang et al., 2023). The DP is modeled as a uniform material of k_{app} which is calculated using Eq. 1.

Even with the mud cooler and the insulated DP, the downhole temperature became challenging for the downhole tools even before reaching the designed total depth. At measured depth (MD) 19,000 ft, which is in the middle of the lateral section, the BCHT for different k_{app} is modeled and simulated. The BHCT and mud temperature at the outlet are plotted in Fig. 2. According to Fig. 2, BHCT can be significantly decreased by as much as 100° F if k_{app} is sufficiently low. When the normalized k_{app} increases to about 30%, the BHCT is almost as high as that of using a non-insulated DP. In a field application, the BHCT can be measured and k_{app} can then be looked up using Fig. 2.

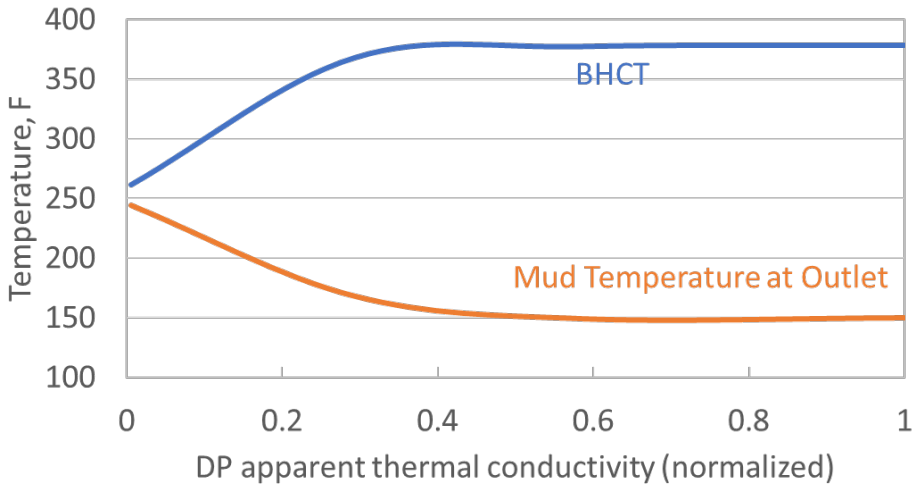

Figure 2: Relation between the mud temperature and the DP apparent thermal conductivity, k_{app}.

Fig. 3 shows the k_{app}-α curve calculated from Eq. 3. The k_{app} increases linearly as α drops. To achieve a normalized k_{app} of above 30%, the remaining coating area ratio required is $\alpha > 70\%$. Assuming peeling is the dominant damage mode of this DP, if the measured BHCT is 300 F, we look up Fig. 2 to get $k_{app} = 0.1$, and look up Fig. 3 to get $\alpha = 0.9$. By calculating α at different MD, the speed of coating damage can be calculated, and the remaining lifespan of the coating can be estimated.

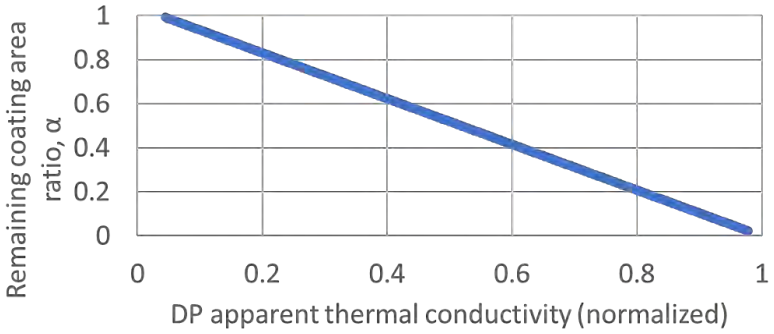

Figure 3: Relation between the remaining coating area ratio, α, and the DP apparent thermal conductivity, k_{app}.

Fig. 4 shows the k_{app}-β curve calculated using Eq. 6. Here, k_{app} grows nonlinearly as β drops. To achieve a normalized k_{app} of above 30%, the required remaining coating thickness ratio is 18% ($\beta > 18\%$). Assuming thinning is the dominant damage mode of this DP, if the measured BHCT is 300 F, we look up Fig. 2 to get $k_{app} = 0.1$, and then look up Fig. 4 to get $\beta = 0.7$. Here again, by calculating β at different MD, the speed of coating damage can be calculated, and the remaining lifespan of the coating can be estimated.

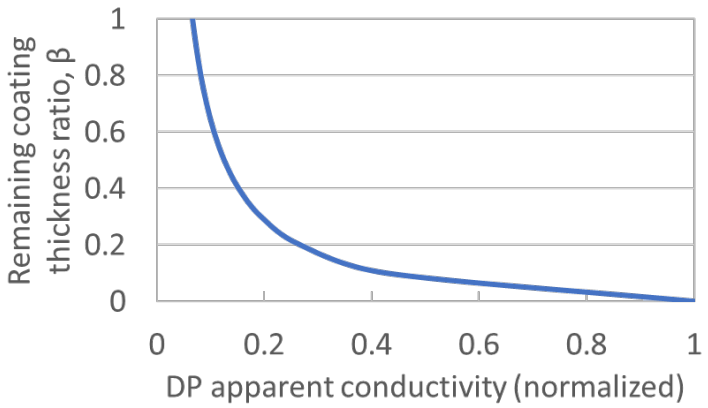

Figure 4: Relation between the remaining coating thickness ratio, β, and the DP apparent thermal conductivity, k_{app}.

The above method enables online diagnosis of the DP insulation coating without pull-out-of-hole. Based on the calculated coating damage speed and remaining coating lifespan, the driller can better plan the maintenance of the DP and decide when to switch to a new set of DPs. Figures 2-4 are based on the specific well data but can be used as a reference for general wells.

4. Automated Downhole Temperature Control System

If the insulation coating is damaged, the mud flowing through the DP receives excessive heat and may not sufficiently cool the bottom hole regions of the well. The BHCT is then increased and may lead to BHA components' accelerated aging or even sudden failure.

To mitigate the impact of the coating damage and maintain the BHCT, a feedforward PID controller is developed, as shown in Fig. 5. The controller controls the pump and the mud cooler. When the BHCT exceeds $BHCT_{max}$, the difference between $BHCT_{max}$ and BCHT is calculated and fed into the PID controller to get the control signal u_{PID}. At the same time, a feedforward block calculates the feedforward control signal u_{ff}. The total control signal u_{tot} is a weighed sum of u_{PID} and u_{ff}. The plant can be either the pump or the mud cooler. A higher pump rate and a lower inlet mud temperature will, in most cases, restore the BHCT to within the limit of the downhole tools.

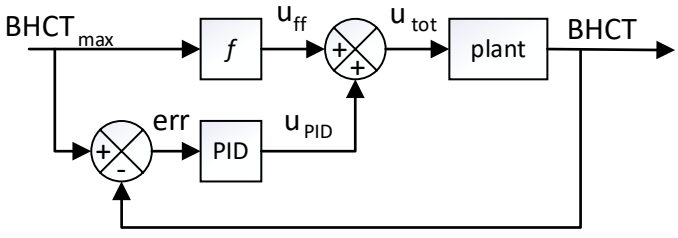

Figure 5: Feedforward PID controller.

This controller is demonstrated via a simulation based on the Utah FORGE dataset. The Utah FORGE 16A78-32 well at 5,900 ft is simulated using the model developed by van Oort et al. (Fallah, 2021; Khaled et al., 2023; Wang et al., 2023). The parameters of the well are listed in Tables 1-3. The insulation coating is assumed to be 0.02 inch thick with a thermal conductivity of 0.116 BTU/(h.ft.°F)

Table 1. Drilling fluid properties for Utah FORGE 16A78-32 well

Drilling Fluid Properties	
Fluid density (ppg)	8.9
Fluid plastic viscosity (lbf.s/100ft^2)	41771
Specific heat capacity (BTU/(lb.°F))	0.896
Thermal conductivity ((BTU.in)/(hr.ft^2.°F))	5.200

Table 2. Formation geothermal properties for Utah FORGE 16A78-32 well

Formation Geothermal Properties	
Formation surface temperature (°F)	67.85
Formation temperature gradient (°F/ft)	0.041
Rock density (ppg)	23.367
Formation specific heat capacity (BTU/(lb.°F))	0.222
Formation thermal conductivity ((BTU.in)/(hr.ft^2.°F)	16.016

Table 3. Wellbore configuration for Utah FORGE 16A78-32 well

Wellbore Configuration	
Wellbore depth (ft)	5900
Wellbore inclination (deg)	0

At the beginning of the simulation, the temperature in the well is at static equilibrium with the formation temperature. The pump is then turned on for 500 min to reach a steady state. Then, the DP apparent thermal conductivity k_{app} is increased from 4.585 BTU/(h.ft.°F) to 26.017 BTU/(h.ft.°F). The increase in k_{app} immediately increases the BHCT from 264°F to 290°F. The controller is then activated and the results for using the pump, and the mud cooler independently are shown in Figs. 6 and 7.

Fig. 6 shows the performance of the controller when only the pump rate, Q is changed. As the BHCT increases above the preset goal, the controller increases the mud pump rate from 400 gpm to 550 gpm. As a result, the BHCT decreases to below the preset limit of 290°F within a few minutes.

Fig. 7 shows the performance of the controller when controlling only the mud inlet temperature, T_{in}. As the BHCT increases above the preset goal, the controller forces the mud cooler to decrease the mud inlet temperature from 120°F to about 90°F.

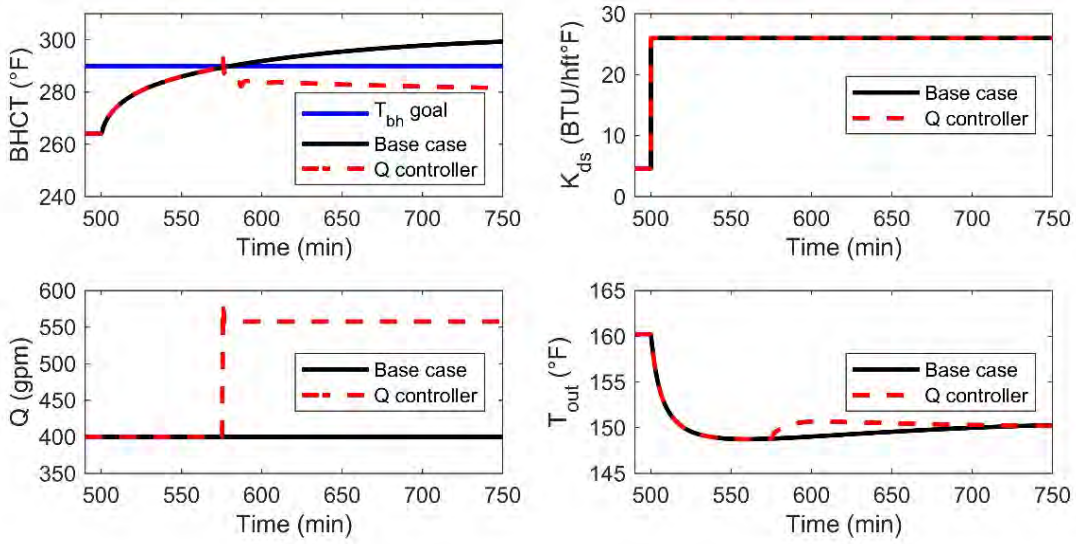

Figure 6: Performance of the controller when coating is damaged using only the pump.

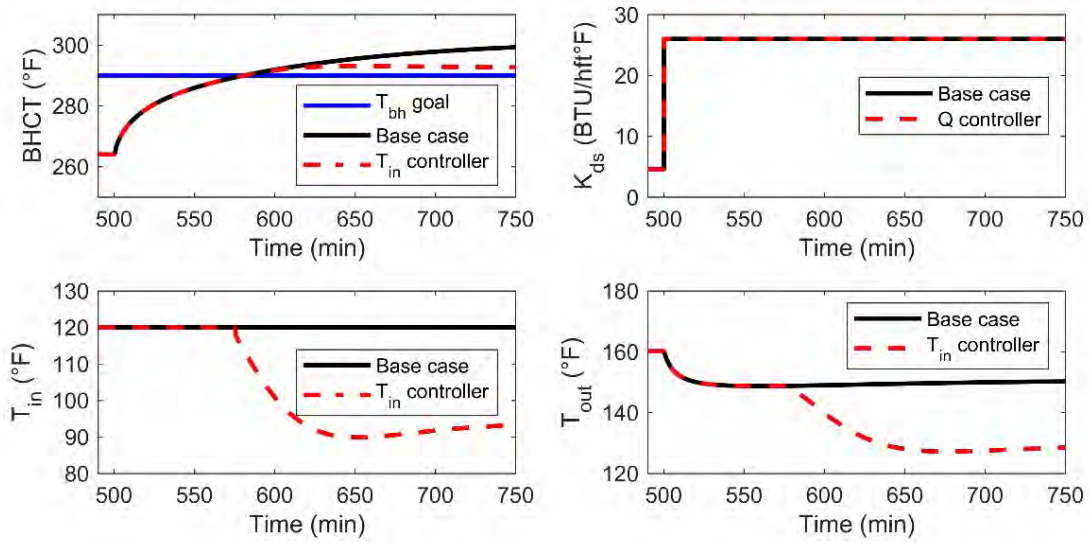

Figure 7: Performance of the controller when coating is damaged using only the mud cooler.

5. Conclusion

In this paper, we proposed a method and procedure to diagnose the insulation coating of insulated DP in real-time. To maintain the downhole temperature even when the coating is damaged, we developed a PID controller that uses the mud pump and the mud cooler to manage the downhole temperature.

(1) We used a validated thermo-hydraulic model to study the impact of apparent DP thermal conductivity on surface and downhole temperature.

(2) Assuming uniform coating damage along the drillstring, the relationship between apparent DP thermal conductivity and coating damage is derived.

(3) We proposed a method and procedure for online diagnosis of the health of DP insulation coating and showcased the method in a case study. If the dominant damage mode of the coating is peeling, the remaining coating area ratio can be determined. If the dominant damage mode of the coating is thinning, the remaining coating thickness ratio can be determined. The speed of coating damage can be calculated, and the remaining lifespan of the insulation coating can be estimated.

(4) A PID controller is developed to mitigate the impact on BHCT from sudden coating damage. The controller controls the mud pump and the mud cooler. The controller is demonstrated using a validated thermo-hydraulic model on the Utah FORGE dataset.

Glossary

k_{app}	-apparent thermal conductivity
$k_{coating}$	-insulation coating thermal conductivity
k_{steel}	-steel thermal conductivity
$k_{perfect}$	-apparent DP-coating system thermal conductivity when there is no coating damage
r_{out}	-outer radius
r_{in}	-inner radius
$t_{coating}$	-coating thickness
α	-ratio of the remaining coating if the dominant damage mode is peeling
β	-ratio of the remaining coating thickness if the dominant damage mode is thinning

Drill Bits, hybrid, volcanic

ABSTRACT

Geothermal power in Indonesia is an increasingly significant source of renewable energy as a result of its volcanic geology. A case study from Indonesia is presented on reducing drilling days on geothermal applications in North Sumatra using innovative hybrid polycrystalline diamond compact (PDC) and roller cone drill bit technology. Results of distance drilled and drilling penetration rates are compared to offsets.

The primary obstacle in the Sorik Marapi field is formation drillability. The lithology is a mixture of multiple hard volcanic formations consisting of breccia, tuff and andesite. The coarse rock fragments cemented together can damage and wear down the cutters and inserts on drill bits. And the interbedded nature of the formations create non-homogenous drilling which can also damage drill bits. The operator began working closely with a service provider to re-imagine how a well can be put on production faster in order to return value for stakeholder quicker. The continuous improvement process led to a partnership in innovation for the 17.5-in and 12.25-in. sections.

Consistent introduction of new drill bit technology has allowed this operator to complete wells faster by reducing drilling days. The solution was to deploy the hybrid drill bit which is more efficient, capable of producing higher penetration rates and smoother drilling. By combining the efficient shearing of PDCs and the crushing strength of roller cones the hybrid bit has the potential to maintain higher overall rate of penetration (ROP) for more distance than a roller cone or PDC bit could individually. The roller cone inserts pre-fracture the hard lithologies, making it easier for the PDC cutters to plow away the formation. And the combined crushing and shearing cutting structure provides improved overall stability when drilling through interbedded formations. In addition the smooth drilling nature of the hybrid bit perfectly maintained the tangent well trajectory.

This paper describes the partnership between the operator and bit service provider that led to the success in developing the optimal technology to deliver superior performance in igneous

formations. The collaboration in technology development contributed to drilling wells more efficiently and more accurately and enabling the operator to reach total depth (TD) reliably in the most challenging and complex geothermal drilling environments.

1. Geothermal Power in Indonesia

Many countries have been investing in geothermal power for decades. This is the case for the Asian Pacific countries located along the Ring of Fire. On the Indonesian island of Sumatra is a stratovolcano which is a significant source of renewable energy. The rock formations in this application are highly interbedded extrusive magma (lava) which is composed of rhyolite and andesite. Breccia, tuff, metamorphic phyllite and quartzite are also found in the lithology. The fractured nature of the formation leads to partial and total lost circulation.

An operator faced challenges while drilling the 17.5-in and 12.25-in sections of geothermal wells. The hard, abrasive and interbedded formations generate significant drilling dysfunctions (torque and vibrations) that quickly dulled PDC drill bits, leading to low ROP. For PDC bits, durability on the shoulder profile is the primary weak point. This limits the ability of PDCs to complete the section in one run, and results in higher costs from additional bits and delays from additional trips to change bits.

Figure 1 – West coast of Island of Sumatra, near capital city of Padang (black dot)
(Source: Wikipedia.org)

2. Drilling Simulation Software

The three dimensional bit drilling simulation software is the first step to creating a robust and durable cutting structure for geothermal applications in volcanic applications. A primary feature of the design methodology, the software creates advanced simulations that guide the selection, manufacture, and deployment of the optimal drill bit for specific hard and abrasive well conditions. By providing both full bit response and individual cutting element analysis, the bit drilling simulation affords more informed design decisions, shorter development cycles, and reduced need for costly lab or field testing. The value proposition for the drilling simulation software are further documented by Duffy et al, 2022 and Russell et al, 2022. The software uses a polygonal surface

mesh to accurately simulate bit-rock interactions under downhole drilling conditions and analyze the hybrid bit's PDC and TCI (tungsten carbide insert) dual-cutting mechanism together in one model. Performing design iterations to optimize these values—the software helps pinpoint a bit design that offers improved durability and higher ROP at a lower cost per foot.

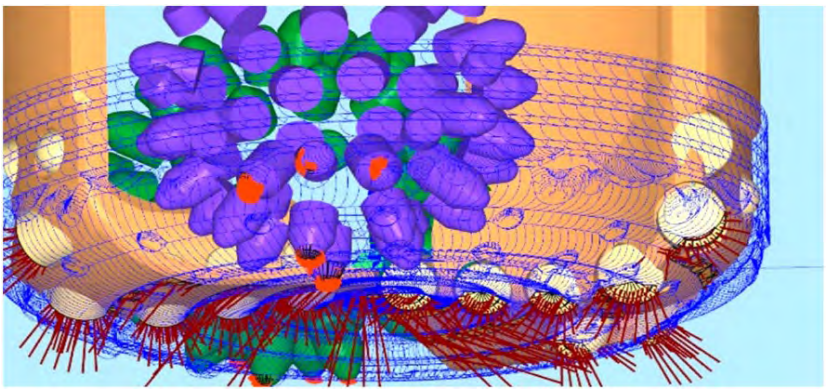

Figure 2 - Modeling drill bit-rock interactions using a polygonal surface mesh and cutter stress loading display

3. PDC & Roller Cone Hybrid Drill Bit Design

Unique drill bit solutions are needed for the most challenging applications. Since their introduction to the drilling industry in 2011, the hybrid drill bit have met this need with a dual cutting mechanism that combines the crushing action of a roller cone with the shearing action of a PDC. These designs leverage roller cone and PDC cutting elements to minimize vibrations, improve drilling efficiency and extend run length in difficult applications. In non-homogenous extrusive rocks it delivers improved drilling rates of penetration over Tricone drill bits, and is more consistent than PDC drill bits which are susceptible to impact damage. Additional case studies of hybrid performance in Asia Pacific have been documented by Lockwood et al (2021) and Wan et al (2015).

For this application, the hybrid design package featured precision balanced blade count and cone optimization, resulting in a proven performance step-change. Increased blade counts improved lateral stability while making the bit more aggressive to stand up to wear and tear. Recessed shoulder cutters increased diamond volume, which improved durability to keep the bit engaged and extend distance drilled. Sharp, dense cones further allowed improved rates of penetration. Cutter selection options included impact resistant dual-chamfer cutters specifically selected to handle increased loads of challenging drilling environments to improve drilling speed and efficiency.

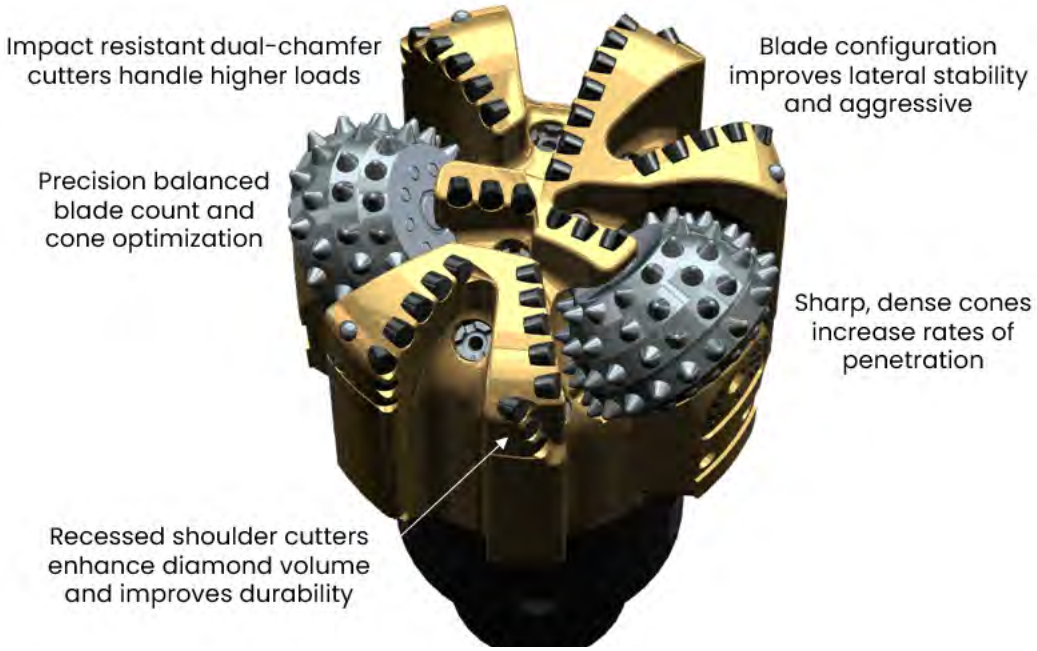

Figure 3 – Hybrid drill bit features

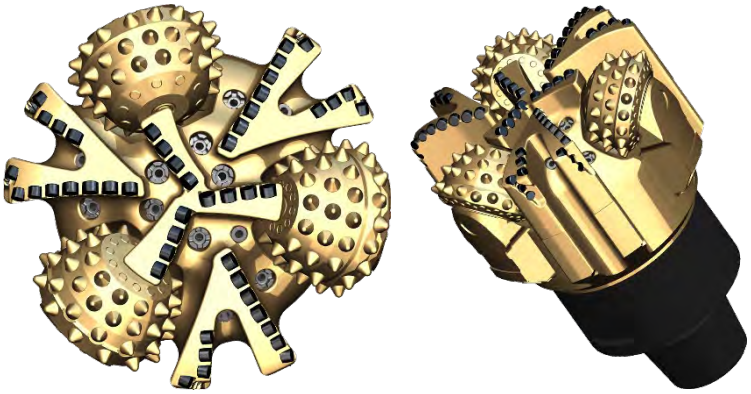

Figure 4 – 17.5-in Hybrid, 6-Blades, 3-Cones,
19mm (3/4-in) cutters, Conic Inserts for Aggressiveness

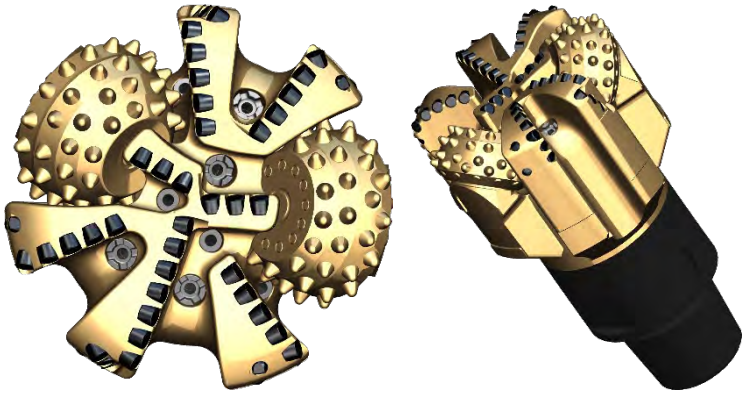

Figure 5 – 12.25-in Hybrid, 5-Blades, 2-Cones,
16mm (5/8-in) cutters, Conic Inserts for Aggressiveness

4. General Performance Results

Data from over forty wells were analyzed. In the 17.5-in section, the hybrid (designated as KM in graph) delivered 27% improvement in distance drilled and 74% improvement in ROP over roller cones. In the 12.25-in section, the hybrid delivered 105% improvement in distance drilled and 45% improvement in ROP over roller cones.

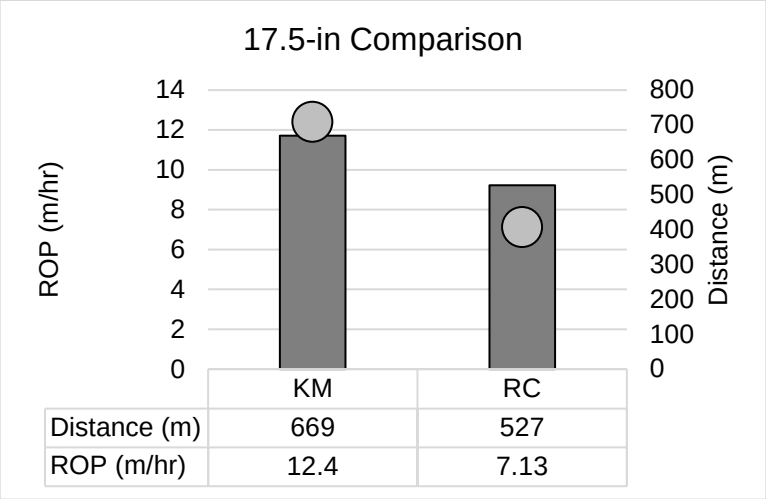

Figure 6 – Performance comparison for 17.5-in sections: 27% improvement in distance drilled (bars), 74% improvement in penetration rate (circles).

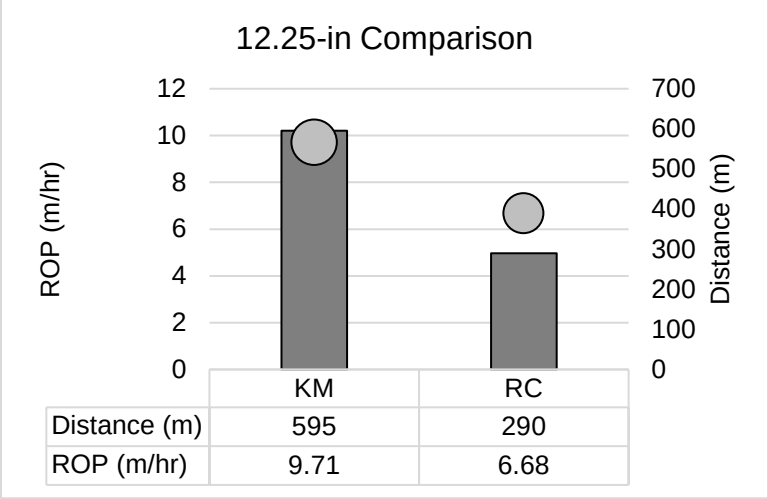

Figure 7 – Performance comparison for 12.25-in sections: 105% improvement in distance drilled (bars), 45% improvement in penetration rate (circle).

5. Detailed Performance from 17.5-in Section

The 17.5-in section is drilled with one bit to section total depth (TD). The average hybrid distance drilled of 669 meters is 27% farther than the average roller cone distance drilled of 527 meters. The hybrid achieved a maximum distance drilled of 876 meters in one run. The average ROP of 12.40 m/hr is 74% faster than the average roller cone ROP of 7.13 m/hr. The hybrid achieved a maximum ROP of 15.36 m/hr in one run. The hybrid averages 56 hours of drilling, with maximum of 82 hours.

The 17.5-in hybrid are comprised of 6-Blades, 3-Cones, with 19mm (3/4-in) PDC cutters. The 17.5-in roller cones are classified as IADC 435 – 515.

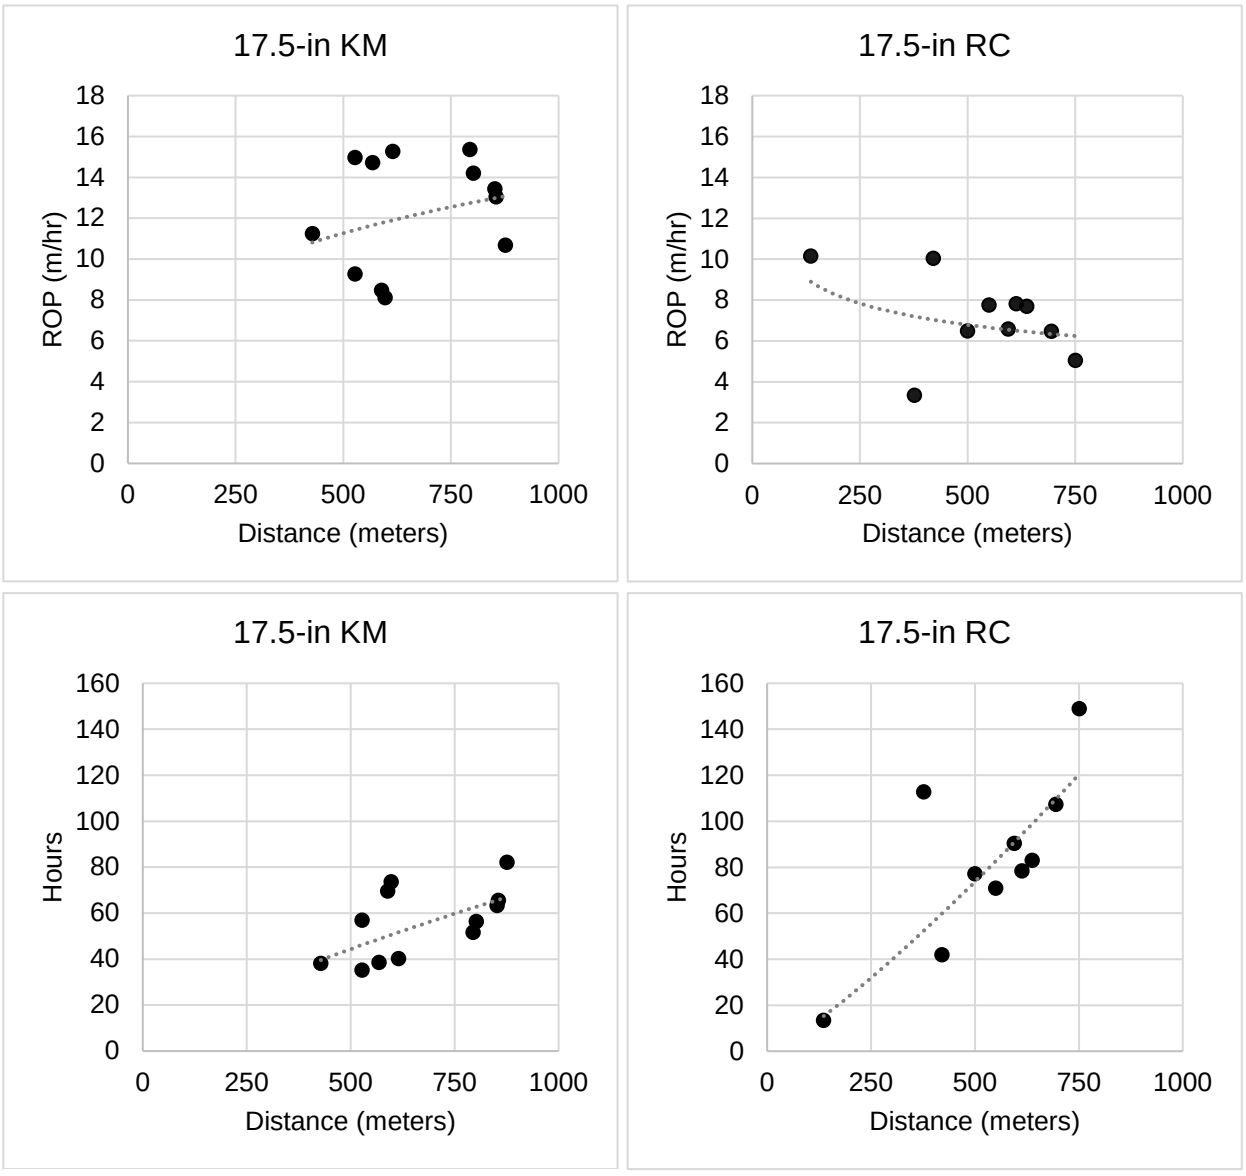

Figure 8 – Detailed performance comparison for 17.5-in sections

6. Detailed Performance from 12.25-in Section

The 12.25-in section is drilled with one bit to section TD. The average hybrid distance drilled of 595 meters is 105% farther than the average roller cone distance drilled of 290 meter. The average ROP of 9.71 m/hr is 45% faster than the average roller cone ROP of 6.68 m/hr. The hybrid achieved a maximum ROP of 14.98 m/hr in one run. The hybrid achieved a maximum distance drilled of 1030 meters in one run. The hybrid averages 63.6 hours of drilling, with maximum 87 hours.

The 12.25-in hybrid are comprised of 5-Blades, 2-Cones with 16mm (5/8-in) PDC cutters. The 12.25-in roller cones are classified as IADC 437 – 537.

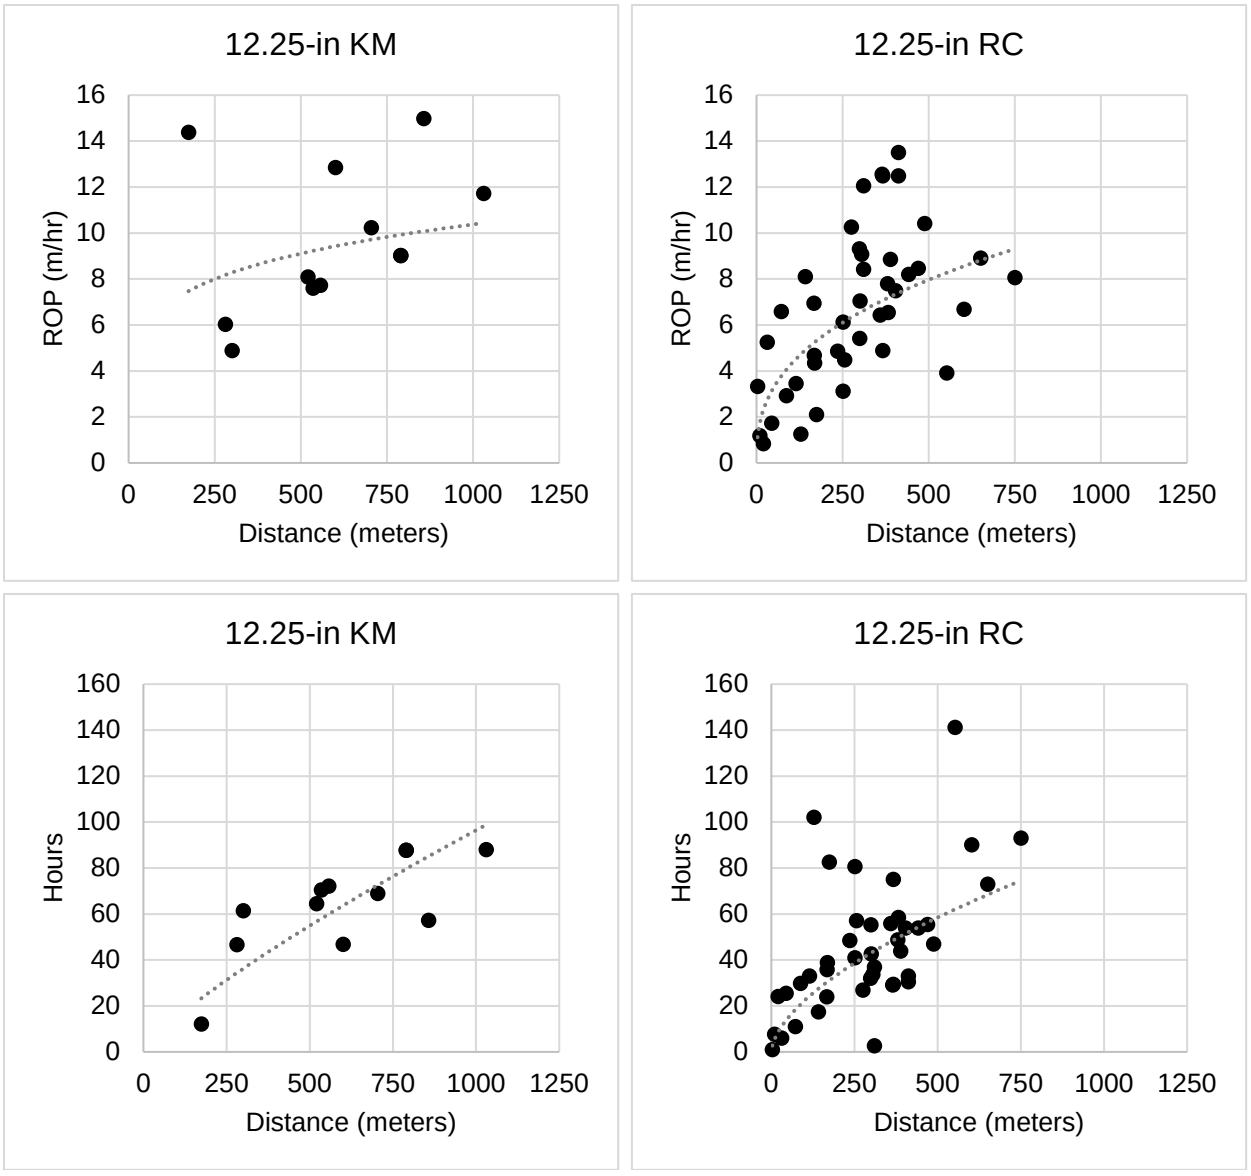

Figure 9 – Detailed performance comparison for 12.25-in sections

7. Conclusions

For decades, legacy roller cone drill bits have been used to drill geothermal wells at slow penetration rates. The learnings from this Indonesia application are chartering a new path of exceptional drilling performance utilizing hybrid drill bits. As stated by Oueslati et al in 2019, the transfer of innovation and best practices from the established oil & gas industry is key to reducing the risk and cost of geothermal projects. The application of this technology is enabling faster delivery of geothermal wells in Indonesia.

ABSTRACT

Geothermal cost and performance evaluation implemented via techno-economic assessment (TEA) modeling is critical for the U.S. Department of Energy (DOE) and other geothermal industry stakeholders in assessing the current state of geothermal technologies and to identify existing hurdles to commercially viable geothermal development. The Geothermal Electricity Technology Evaluation Model (GETEM) is a major TEA tool used in estimating the economic feasibility and levelized cost of energy (LCOE) of conventional hydrothermal systems and enhanced geothermal systems (EGS). Since 2021, GETEM has been transitioning from an intricate spreadsheet model to a user-friendly tool within the System Advisor Model (SAM) developed by the National Renewable Energy Laboratory (NREL). Apart from enabling an expanded visibility of the geothermal model among other renewable resources, having GETEM in SAM has the advantage of simulation automation, better usability, updates tracking, active user inputs/feedback, and extended financial modeling. GETEM is used in developing supply curves for NREL's Annual Technology Baseline (ATB), which provides inputs to the Renewable Energy Potential (reV) and the Regional Energy Deployment System (ReEDS) models. The geothermal module in NREL's reV model assesses the geothermal energy potential in the conterminous United States by defining the geospatial intersection of geothermal resources with existing grid infrastructure within the constraint of land use characteristics. The ReEDS model is a capacity expansion model used for simulating the long-term build-out and operation of the U.S. generation and transmission system based on current energy costs and policies. To ensure enhanced representation of current industry trends in our model transitions and development, we organized a two-day virtual workshop to elicit geothermal industry stakeholder input and recommendations on our current approaches and assumptions on techno-economic, resource assessment, and deployment scenarios modeling of geothermal technologies. Participants included developers, operators, investors, regulatory agencies, system modelers, national laboratory researchers, consultants, and other stakeholders. In this workshop, we gained stakeholder insights on current geothermal plant performance (i.e., capacity factors), updated drilling costs and learning curves, and next-generation technologies such as closed-loop and superhot rock geothermal. Other outcomes from this workshop and its impact on future geothermal development feasibility, resource availability, and capacity expansion studies are compiled and discussed.

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

1. Introduction

The geothermal energy industry in the United States has seen a significant increase in technology advancements and public and private sector interests in recent years. Substantial investments in next-generation geothermal technologies have been reported, with an estimated $396 million invested in next-generation companies between 2021 and 2023 (DOE, 2024a). These have translated to a record number of power purchase agreements (PPAs) since 2020 (Robins et al., 2021; DOE, 2024a). Simultaneously, technological improvements are being made in multiple phases of geothermal power development such as drilling and completion, power plant design, and optimization. These innovations are being accelerated by technology demonstration projects like FORGE and the EGS Pilot Demonstrations specifically targeted at de-risking next-generation geothermal technologies.

The National Renewable Energy Laboratory (NREL) has supported the U.S. Department of Energy's (DOE's) effort in de-risking geothermal power projects. Through its Geothermal Technologies Office (GTO), the DOE previously engaged NREL in developing the GeoVision report. The GeoVison report describes a pathways and scenarios for technology advancement (DOE, 2019). Other efforts such as the Geothermal Earthshot analysis have been used to determine the pathway to get to low-cost enhanced geothermal systems development (Augustine et al., 2023). In these studies, NREL has provided business as usual and scenario-based analyses to the DOE using a defined methodology. First, base cases for resource (e.g., hydrothermal or EGS) and technology (flash or binary) pairs are determined using the Geothermal Electricity Technology Evaluation Model (GETEM) (DOE, 2016). This bottom-up techno-economic assessment (TEA) model estimates the lifecycle performance and cost of a geothermal project based on predefined assumptions for each project development phase. The outputs from this model are used to develop supply curves (i.e., cost versus cumulative resource capacity plots) that can be used for future deployment planning. GETEM is the primary model used in the geothermal technology representation in NREL's Annual Technology Baseline (ATB) that defines the current and future costs and performance levels for multiple renewable energy technologies (NREL, 2024). Supply curves developed primarily with GETEM are used in ReEDS for capacity expansion modeling of geothermal deployments into the future relative to other electricity generation technologies, policies, decarbonization goals, and other constraints (Gagnon et al., 2024). Figure 1 illustrates the interrelationship between GETEM, the ATB, and ReEDS. Recently, GETEM has been transitioning from an Excel-based workbook to a user-friendly model within NREL's System Advisor Model (SAM) tool. This transition is at its last stage of model alignment. GETEM in SAM is available both as a module in the Graphic User Interface (GUI)-enabled SAM model and the Python code-based PySAM available on GitHub. Having GETEM in SAM will enable a wider outreach beyond traditional users, incorporation of other geothermal next-generation technologies (including closed-loop and superhot rock geothermal), comparability with other renewable energy technologies, and a robust financial modeling capability (*System Advisor Model (SAM)*, 2022).

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

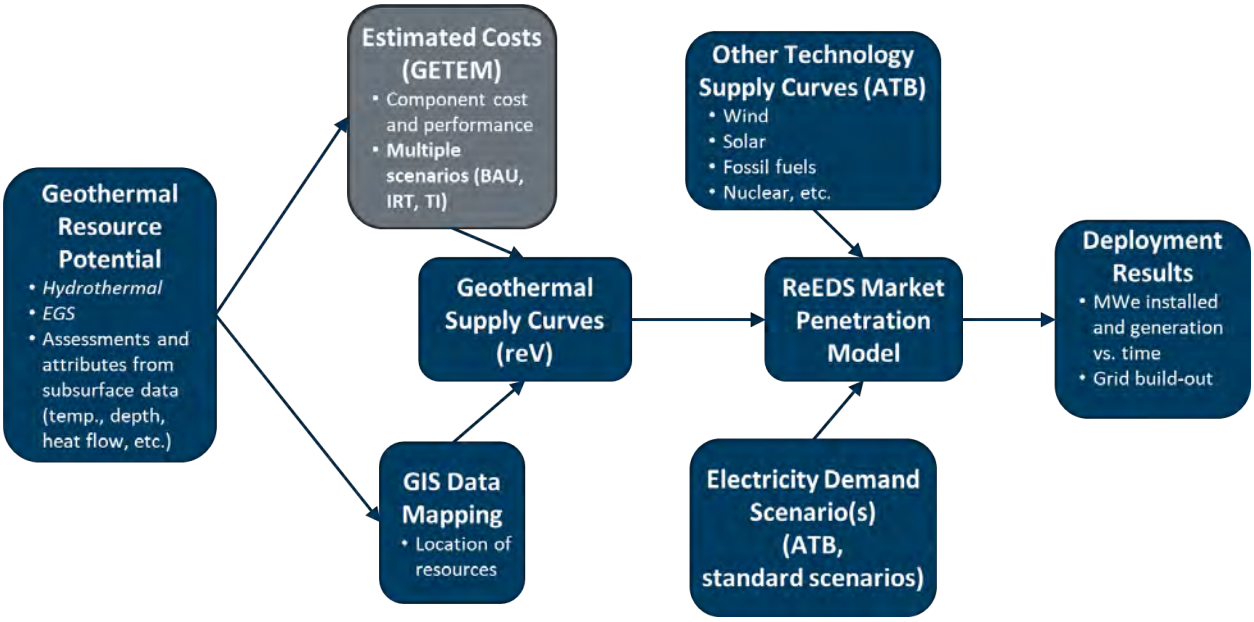

Figure 1: The interrelationship between GETEM, the ATB, reV, and ReEDS in determining future technology deployment scenarios. BAU= Business As Usual, IRT = Improve Regulatory Timeline, TI = Technology Improvement scenarios used in the GeoVision study (DOE, 2019)

The Renewable Energy Potential (reV) model is another NREL tool that has been recently adapted with capabilities to estimate and geospatially represent, with multiple levels of uncertainty, the available geothermal resources in the conterminous United States (Pinchuk et al., 2023). In developing these estimates, the reV model uses geospatial datasets, including heat flow and temperature at depth maps, grid infrastructure data, and geographical constraints (e.g., land use characteristics) to determine geothermal resource availability down to a 1-km^2 spatial resolution (Pinchuk et al., 2023). The model also takes in installation cost inputs from PySAM and in-built spur line transmission (or grid connection) cost model to develop supply curves for both hydrothermal and EGS technologies. The model methodology is shown in Figure 2.

On January 9-10, 2024, NREL gathered 66 geothermal industry stakeholders from around the country to discuss progress made in making our models more representative of the state-of-the-art and future expectations of the geothermal industry. This virtual workshop was titled the "NREL Geothermal Power Systems Analysis Workshop." Participants represented geothermal developers, operators, state agencies, non-profit organizations, investors, power system modelers, subject matter experts, the DOE-GTO, and national laboratories. Over the two days, NREL presented ongoing work in GETEM, SAM, reV and ReEDS and their anticipated impacts on future ATB and capacity expansion and scenario modeling. Breakout sessions also gave room for participants to identify and discuss gaps in our model assumptions and methods to ensure better representation of the performance, cost, and value of geothermal power systems. In this article, we summarize the major takeaways from the workshop discussions.

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

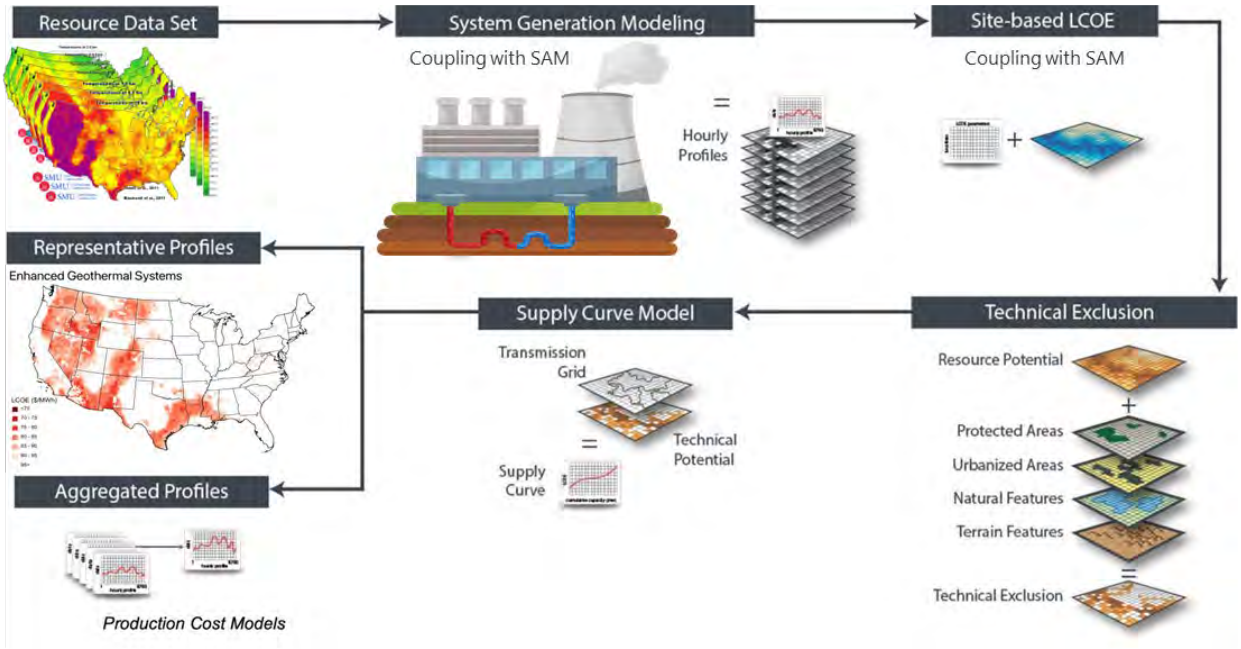

Figure 2: The reV model methodology implemented to estimate resource potential and generate geospatially-distributed cost profiles

2. Workshop Discussions

The NREL Geothermal Power Systems Analysis Workshop discussions were centered on four main topics:

- GETEM and SAM model updates
- The ATB process and geothermal representation in the ATB
- Geothermal representation in ReEDS
- Geothermal resource potential estimation with reV

The following subsections describe the major talking points around the highlighted topics.

2.1 GETEM and SAM Model Updates

2.1.1 Resource Temperature Limit on Binary Cycles

A major technical consideration that was discussed is how the GETEM model implements binary plant operations. The Excel-based GETEM model intrinsically assumes that binary plants do not operate beyond 200°C (G. L. Mines, 2016). Hence, once a system specification greater than 200°C is imputed into the model, it assumes a flash-based power cycle. According to Mines (2016), the reason for this restriction is that downhole production pump technology at the time GETEM was developed had a 200°C operational limit (G. L. Mines, 2016). GETEM assumes that flash plants have sufficient reservoir pressure and do not require production pumps. Also, the temperature-based correlations for the binary plant cost estimation in GETEM has this same 200°C limit. This temperature-based partitioning between flash and binary cycles is not an actual physical constraint. Multiple plants worldwide run on organic Rankine cycles (ORCs) that utilize geothermal energy resources above 200°C. Therefore, Excel-GETEM appears to characteristically underestimate the

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

potential of binary cycles at high temperatures. The GETEM in SAM model accommodates simulations of binary power plants with resource temperatures above 200°C. It also accommodates flash plant operations at temperatures below this threshold. However, since it is inherently based on GETEM, there is a need to update the plant cost correlations in SAM to accommodate higher resource temperatures.

2.1.2 Exploration Drilling Success Rates

Hydrothermal resource exploration comes with its inherent resource confirmation uncertainty. In the western U.S, a vast number of convection-dominated hydrothermal plays that can be traced back to surface expressions (e.g., geysers, fumaroles, and hot springs) have been discovered. Hence, to increase the potential for resource discovery, drilling for "blind" resources is set to become the norm in future hydrothermal exploration, just as in the oil and gas industry today. This comes with an increased requirement for exploration (geological, geochemical, and geophysical) data acquisition that culminates in a test drilling phase where full-size wells are drilled to confirm resource availability (heat, permeability, and suitable reservoir fluid volume) and productivity. Generally, for hydrothermal systems, the global average historical success rate for the first full-size well has been reported as 50%, increasing to 59% for the first five wells (Allen et al., 2013). GETEM currently defaults to a 50% success rate (53% was used in the 2023 ATB). Wells are deemed unsuccessful for several reasons, including drilling dry holes, loss of mechanical integrity during drilling, inadequate pressure and temperature, low productivity, and geochemical considerations (corrosion and scaling tendencies) (Allen et al., 2013). With significant improvement in data collection before test well drilling, data-enhanced conceptual model development, and advancements in drilling technology (e.g., sidetracking), success rate estimations for hydrothermal, and by extension EGS, projects need to be revisited. Determining a representative value for exploration drilling success may require an updated study similar to Allen et al. (2013) and expert consultation on additional costs incurred to reducing well failure rates.

2.1.3 Beyond the Levelized Cost of Electricity (LCOE)

The LCOE is a metric that expresses the discounted cost to install and operate a geothermal plant over its generation life cycle. It is typically used to compare cost competitiveness from one geothermal project to another and between geothermal and other renewable energy technologies. It is also used to determine the contract electricity price for a PPA. Because it is strictly project-based, it does not account for the system value of the plant as a service provider to the electric grid (Mai et al., 2021; DOE, 2024a). Specifically, the ability of geothermal plants to offer both firm and dispatchable electricity (among other ancillary services) to the grid is not captured within the definition of the LCOE. The LCOE does not also account for avoided costs (e.g., additional generation and transmission costs) that could have been incurred to meet demand. Other metrics that have been proposed include the Levelized Value of Electricity (LVOE), Net Value of Electricity (NVOE), Net Value of Capacity (NVOC), Profitability-Adjusted LCOE, Levelized Avoided Cost of Electricity (LACE) and Cost of Valued Energy (COVE) (EIA, 2017; Simpson et al., 2020; Mai et al., 2021; Loth et al., 2022). Both NVOE and LACE account for only the system value leaving out the effect of cost. Others account for both system cost and value with varying degrees of complexity in their estimation. GETEM only considers LCOE and does not have the capability to estimate value-derived revenues. Although SAM calculates LCOE, it also has a robust financial model that can estimate cost- versus value-derived metrics such as return on investment

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

(ROI). Therefore, once a suitable metric beyond LCOE is established for geothermal, it should be implementable in SAM.

2.1.4 Other Discussion Points

We have summarized other discussion points that were raised during the GETEM in SAM session in Table 1. These relate to both performance- and cost-based parameters.

Table 1: Summary of other discussion points in the GETEM in SAM session

Discussion Point	Excel-GETEM	GETEM in SAM
Investment tax credits (ITC) and production tax credit (PTC)	Not accounted for	ITC and PTC can be included in the estimation of LCOE and in financial modeling. Other similar tax credits and incentives can be accommodated.
Reservoir modeling	No capabilities	No implicit reservoir model. However, SAM has the Gringarten model for fractured systems that can be used to determine EGS reservoir performance. Reservoir simulation results (pressure and temperature timeseries) can be imported as CSV files from other modeling software.
Ability to incorporate hybrid models e.g., solar photovoltaic (PV) /concentrating solar thermal-geothermal hybrids	No direct capabilities. Can model the geothermal part of a hybrid system	The current hybrid model just implemented in the latest SAM version is for PV-wind-battery hybrid systems. Future SAM versions could incorporate hybrid models by leveraging TEA models developed within GTO's Hybrids Portfolio.
Imputing actual reservoir performance and plant generation data	No capabilities	SAM has an additional module for a "Generic" system. In the current Geothermal module, reservoir temperature timeseries can be uploaded into SAM.
Estimating the system value of carbon emissions reduction	Determining the cost of carbon and carbon offsets is beyond the TEA scope of the model	Determining the cost of carbon and carbon offsets is beyond the TEA scope of the model. However, SAM is sufficiently flexible to accommodate financial calculations that include cashflows from carbon credits.

2.2 Geothermal Representation in the ATB

2.2.1 Next-Generation Technologies

Next-generation geothermal technologies like EGS and closed-loop geothermal (CLG) are gaining traction in terms of technology development and a defined pathway towards commercialization. Currently, the ATB accounts for conventional hydrothermal systems and next-generation EGS (as Near-Field and Deep EGS). Near-Field EGS resources are defined as brownfields that are proximal to an existing hydrothermal resource. A case in point is Fervo's EGS development in the Blue

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

Mountain Geothermal field in Nevada (Norbeck & Latimer, 2023). Deep EGS resources in the ATB are defined as greenfields that have not been previously developed and are geologically conduction-dominated plays.

CLG systems are not currently represented in the ATB. Several factors have constrained their inclusion in the ATB. The first is technology standardization. Multiple CLG system designs have been proposed and have been broadly categorized based on the loop design into coaxial/pipe-pipe/downhole heat exchanger (with or without a lateral), U-loop (single-, double-, or multi-lateral), and the Eavor Loop. Technology categorization that is strictly based on loop design may create standardization complexities as new loop designs emerge. The second factor is the definition of a representative plant size for each loop design. Can we assume similar plants sizes as in hydrothermal and EGS? A third factor is that, based on previous results from past TEA, LCOE for CLG systems could range from 2,200 $/MWh for the coaxial loop to 70 $/MWh for the Eavor Loop (Beckers et al., 2022; Beckers & Johnston, 2022). There may be a requirement to prioritize more competitive designs for representation in the ATB.

Superhot rock/supercritical geothermal, which targets resources above 375°C, is also not currently represented in the ATB. The technology is still emerging with the first-of-a-kind (FOAK) demonstration to be implemented in Newberry, Oregon as part of GTO's EGS Pilot Demonstrations portfolio (DOE, 2024b). There is presently no comprehensive TEA model for superhot systems due to the uncertainty in assessing costs for major project phases including drilling and completion, stimulation, and power plant construction. Future iterations of the ATB will accommodate superhot rock geothermal as data from the Newberry project and other pilot projects become available.

2.2.2 Effect of Plant Size

Plant size is an important factor in the estimation of lifecycle costs of a geothermal project. Generally, larger power plants tend to enjoy the benefits of economies of scale. Allowing for less intensive costs (on a per-kW basis) for leasing and permitting, project infrastructure, project financing, and operation and maintenance. From a thermodynamic perspective, larger plants could also benefit from higher energy conversion efficiency (at higher resource temperatures) and better overall plant efficiency. The economics of next-generation technologies like EGS can be improved at larger plant size deployments. The 2023 ATB assumes the following plant sizes for EGS technologies: Deep EGS = 25 MW (Binary) and 30 MW (Flash); Near-Field EGS = 30 MW (Binary) and 40 MW (Flash) based on the classification by Mines (2013). EGS developers are targeting 100-MW commercial plant build outs. Although a 100-MW plant size is used in the EGS Advanced Scenario ATB for a 2035 deployment year, it is currently too aggressive for a mid-case (Moderate) scenario. However, it may be considered in a future ATB once a FOAK 100-MW EGS plant is operational. In the 2024 ATB, we will revise the EGS plant sizes to 40 MW for both Deep and Near-Field EGS to keep pace with technology trends.

2.2.3 Capacity Factor

The capacity factor is a major plant performance indicator in the ATB and a direct input to the calculation of project capital expenditure (CAPEX). In the ATB, geothermal capacity factor is assumed to be constant throughout the project lifecycle but differs by plant technology (80% for binary for 90% for flash) (NREL, 2024). These capacity factor estimations are based on historical

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

plant data and may be heavily affected by the performance of legacy hydrothermal developments that are currently producing way below their designed plant output capacities. A revision of capacity factor estimation that takes account of improvement in air-cooled binary cycle technology and plant availability would require extensive input from geothermal plant operators. Further discussion on this topic is planned for a follow-on workshop this summer.

2.2.4 Technology Maturation

The ATB categorizes technologies as either "mature" or "nascent". Mature technologies are defined as those with a representative plant in operation or under construction in the United States in the base year (i.e., 2021 for the 2023 ATB) (NREL, 2023). Technologies outside the maturity definition are classified as nascent. Over time, hydrothermal technologies have been classified as mature while EGS are nascent. From an ATB perspective, the FOAK commercial EGS project developed in 2023 does not precisely fit the definition of mature technology in the ATB because it did not lead to the build out of a new power plant. Two horizontal wells were drilled, completed, and stimulated, and the resulting flow was tied back to an existing geothermal plant (Norbeck & Latimer, 2023). Future ATB iterations may need to account for this case by defining a mid-case technology definition as this may be the technology commercialization pathway for Near-Field EGS projects.

2.2.5 Geothermal Learning Rates

Since the 2023 ATB, we have adopted a learning curve approach to determining future costs of geothermal technology development scenarios. An explanation of this approach can be found in the ATB documentation (NREL, 2024). Essentially, a single factor learning curve that expresses the power-law relationship between cumulative capacity and cost was used to determined future capital costs beyond the base year to the full deployment year of the Moderate and Advanced scenarios (i.e., 2035). The learning rate, which determines the slope of the curve, expresses the rate at which technologies adopt learning by doing practices to increase capacity and reduce cost. The assumptions for geothermal learning rates are shown in Table 2. The 13% learning rate for the hydrothermal Moderate scenario was derived from historical drilling and completion learning rates in the unconventional oil and gas industry (Fukui et al., 2017). The EGS Moderate learning rate was derived from the low-end approximation for learning rates found in the study by Latimer & Meier (2017) that compiled at historical learning rates in both geothermal and oil and gas projects. The 30% rates for the Advanced EGS and hydrothermal are based on the high-end estimation of learning rates found in the same study (Latimer & Meier, 2017). In a recent paper by El-Sadi et al. (2024), a 35% in-project learning rate has been achieved so far in the Cape Station, Milford, Utah drilling campaign (El-Sadi et al., 2024). This in-project improvement can form a basis for reevaluating the inter-project learning rate assumptions in future ATB efforts.

Table 2: Learning rate assumptions used in the 2023 ATB

Scenario	Base Year–2035	2035–2050
Moderate Scenario	13% (hydrothermal), 18% (EGS)	0.5% annual cost reduction
Advanced Scenario	30%	0.5% annual cost reduction

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

2.3 Geothermal Representation in ReEDS

2.3.1 Classification of Geothermal Resources

The ATB classifies geothermal resources as hydrothermal, Near-Field EGS, and Deep EGS with a resource temperature dependent tie back to a binary or flash cycle. In capacity expansion modeling in ReEDS using defined standard scenarios (Gagnon et al., 2024), this classification obscures the high-value and low-cost sites on the supply curve that are competitive with other renewable technologies. Hence, a new temperature-based resource classification for geothermal in ReEDS that could elucidate these high-value sites was discussed at the workshop. Table 3 below shows the 10 resource classes. This applies to each resource type – hydrothermal, Near-Field EGS, and Deep EGS. A comment was made at the workshop on the skewness of the temperature bins towards higher temperature resources with lower site counts. Hence, it was recommended that the bin size should be proportional to the site counts or available resource count within each class.

Table 3: Temperature-based resource classes for geothermal in ReEDS

Resource Class	Bin Lower Bound (Resource Temp, °C)	Bin Upper Bound (Resource Temp, °C)
1	>325	None
2	>300	325
3	>275	300
4	>250	275
5	>225	250
6	>200	225
7	>175	200
8	>150	175
9	>125	150
10	0	125

2.5 Geothermal Resource Potential Estimation with reV

Discussions during the workshop on the reV model were limited to questions about understanding how the model works and how to improve data collection on estimating resource potential at higher geospatial resolution for both hydrothermal and EGS. For example, the reV model uses the temperature at depth and thermal conductivity data layers for both hydrothermal and EGS resources. Since hydrothermal units are more convection-dominated than EGS, this increases the uncertainty of estimating hydrothermal resource potential with reV since it is solely based on conductive heat flow. There is a need for more high-resolution convective heat flow data to characterize hydrothermal resource potential at national scale.

3. Outcomes and Future Plans

The NREL Geothermal Power Systems Analysis Workshop exposed areas for improvement in both modeling capabilities and scope. Discussions covered TEA modeling with GETEM and SAM, geothermal representation in the ATB, scenarios analysis modeling with ReEDS, and resource potential estimation and geospatial representation in the reV model. Participants at the workshop were fully engaged and provided suggestions on model improvement, especially in the

This report is available at no cost from the National Renewable Energy Laboratory (NREL) at www.nrel.gov/publications.

representation of next-generation geothermal systems, including closed-loop and superhot rock geothermal. As these next-generation technologies become mainstream, opening a new frontier in dispatchable and flexible geothermal operations, geothermal power analysis models will be required to represent crosscutting performance, cost, and value of geothermal to the electric grid. A follow-on workshop is planned for this summer with a focus on improving and updating assumptions on various phases of a geothermal project lifecycle in the GETEM in SAM model.

Whispers of a New Frontier for Safe and Profitable Geothermal Anywhere

Luke P. Frash

Los Alamos National Laboratory

Keywords

Fracture Caging, CGS, EGS, AGS, Reservoir Engineering

ABSTRACT

The potential of geothermal power to fulfill the energy needs for all nations persists, despite not yet having been achieved. To promote its development, attention is generally given to solving those challenges that are tractable and compatible with conventional thinking, such as decreasing the cost of drilling. Meanwhile, two of the most crucial problems are often bypassed due to their complexity: these being the need for prevention of induced seismicity and the need for predicting performance uncertainty. Recently, we developed a stochastic design tool to meet the challenge of uncertainty assessment and to investigate the potential of fracture caging to control the risk of induced seismicity. Here, we use this tool to investigate the feasibility of full-scale development of hot dry rock resources for clean baseload power generation. We investigate various strategies for development that include advanced, enhanced, and caged geothermal systems. We investigate economics with consideration of drilling depth, thermal gradient, and number of wells. Our work predicts that it is possible to safely and profitably develop geothermal nearly anywhere using the currently available tools. However, achieving this will require a shift in thinking.

1. Introduction

Numerous studies investigated the future of geothermal energy beyond conventional convective systems (Tester et al., 2006; Hamm et al., 2020). They predicted that deep hot dry rock resources (Duchane and Brown, 2002) can yield from 60 to 100 GW of electric power as long as the needed technologies could be developed and made affordable. The basis of this premise centered on the application of hydraulic fracturing to create sufficient surface area for economic heat extraction in any reservoir that otherwise would not be able to facilitate enough flow for production (Gringarten et al., 1975). In addition, this premise assumes that the required high-temperature tools for well drilling, stimulation, and flow control can be developed. More crucially, this premise requires the development of seismic risk mitigation technologies, that are currently limited to monitoring based approaches (Majer et al., 2012) and limits on injection volumes (McGarr, 2014). However, our

experience shows that these methods are unreliable even if they are considered best practices (Kim et al., 2018; Ellsworth, 2013).

Proposed new approaches to seismicity control include cyclic soft stimulation (Hofmann et al., 2019) and fracture caging (Frash et al., 2018; Frash et al., 2021). Cyclic soft stimulation involves injection with oscillating flow and applies only during fracture creation. It is based on the idea that fatigue, thermal effects, and poromechanical effects can aid fracture propagation to ultimately reduce the net pressure needed to grow fractures and hence reduce the likelihood of triggering a large seismic event. Fracture caging involves drilling an array of boundary wells around a target reservoir before fluid injection to then intercept and contain both fluid flow and seismicity. The method entails drilling multiple wells and is anticipated to be employed throughout the life of a geothermal system. Yet another proposed method to reduce the risk of seismicity is closed loop geothermal systems (Beckers et al., 2022), also called advanced geothermal systems, using a looped array of wells with fluid is circulated only through these wells. In this case, no fractures would be required but the drilling costs are likely to be high because radial heat transfer to wells is much slower than bi-linear heat transfer to fractures. This stems from the expectation that hot dry rock systems will be thermal conduction limited during long-term heat recovery.

In this study, the technoeconomic performance of deep hot dry rock systems is evaluated using a fast simplified-physics model named GeoDT (Frash, 2021). This tool enables Monte-Carlo ensemble modeling to better quantify uncertainty for the performance of various reservoir designs, all with the goal of seeking an optimized, reliable, and economic approach to harvest geothermal energy. Here, we investigate the techno-economics of closed-loop Advanced Geothermal Systems (AGS), sand-propped Enhanced Geothermal Systems (EGS), and new hydraulic fracture Caged Geothermal Systems (EGS). Our analysis considers varied well depths, thermal gradients, and numbers of wells. The model includes well placement, hydraulic stimulation, heat recovery, power conversion, and economics to then estimate the net present value for inter-design comparison. We will show that primary details for maximized performance include reservoir temperature, in-situ stress direction, proppant permeability, number of wells, well spacing, and number of fractures.

2. Model Setup

Geothermal Design Tool (GeoDT) is a fast simplified-physics screening tool that is intended for rapid assessment and design optimization for well and fracture dominated geothermal systems. It is not meant for modelling conventional convective geothermal systems. This study investigates the cost and performance of AGS, EGS, and CGS (Fig. 1).

GeoDT uses a sequentially coupled solver (Fig. 2) to estimate the impact of design elements, in-situ stress, natural fractures, hydraulic stimulation, fluid circulation, heat transfer, thermal-electric power conversion, and economics. Examples of the included physics are stress-dependent fracture conductivity, shear stimulation and dilation, induced seismicity, and transient heat flow from the rock to the fluid. The solver prioritizes speed over accuracy with the intent of informing decision making in a timely manner that requires minimal expertise and effort. Most simulations complete in less than 20 seconds using a generic desktop computer (Frash et al., 2023).

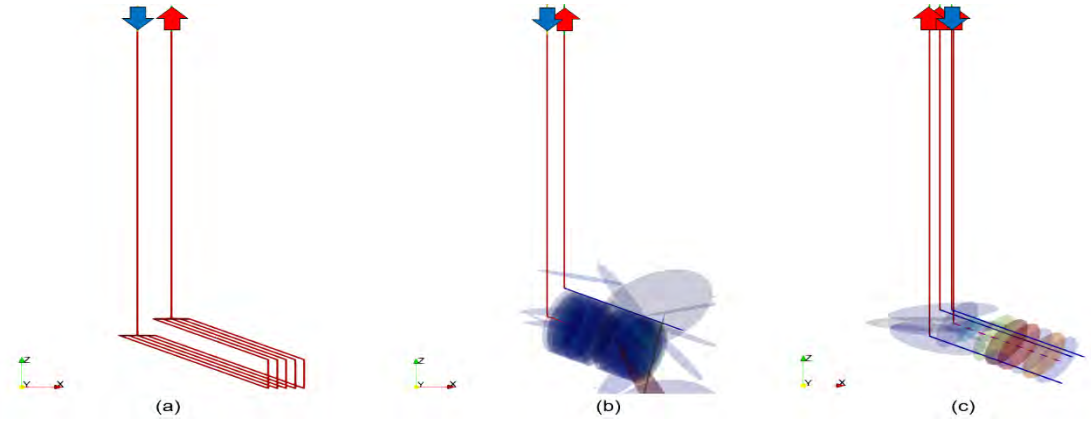

Figure 1: Model concepts for closed loop AGS, sand propped multi-stage EGS, and fracture caged CGS. The details of each design were varied to optimize performance and cost, seeking maximum net present value.

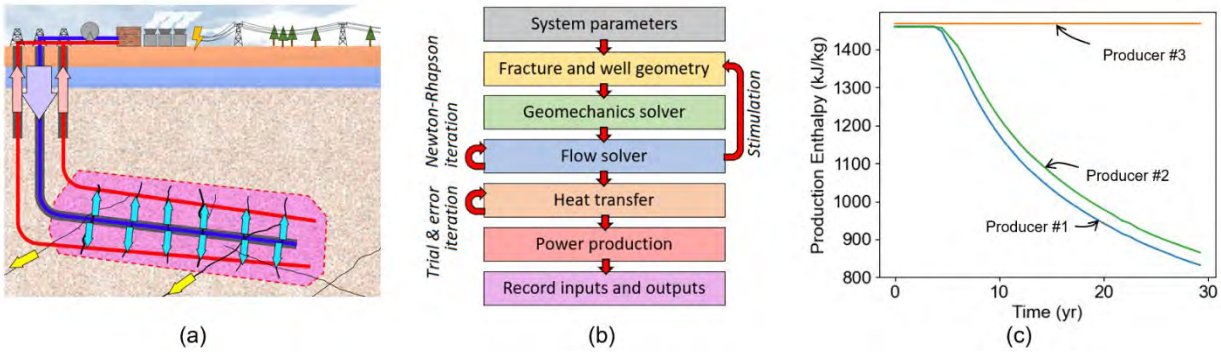

Figure 2: GeoDT solves the technoeconomic performance of AGS, EGS, and CGS using a sequentially-coupled solver (b) based on a 3D stress-dependent network of wells and fractures. Its goal is to rapidly estimate the performance curve (c) of a given design (a) in an uncertain subsurface environment.

The model parameters needed to define the wells were many (Table 1). These included number of wells, flow rates, back pressures, well diameters, lengths, depths, casing thicknesses, number of perforation clusters, perforation diameters, stimulation volume, sand concentration in the frac fluid, proppant permeability, fluid viscosity, and more. The model parameters needed to setup the reservoir were even more numerous. The included rock thermal gradient, stress regime, ambient temperature, rock density, elastic properties, fracture properties, fracture stimulation properties, and more. In comparison, the parameters for the economic model were quite simple. For our base case, we use a parameter set from an earlier study for greenfield geothermal energy development. The source of each model value is given by the references therein (Frash et al., 2024). Elaboration on the details of how GeoDT functions, its validation, and why these model parameters were selected is beyond the scope of this study but can be found in cited references. In the forthcoming sections, we combine previous findings and new results to elucidate the key reservoir parameters that control the economics of AGS, EGS, and CGS to reveal that several important and commonly held assumptions are likely to be false. This will ultimately lead to our current conclusion that a shift in thinking is needed to achieve prolific, safe, and profitable geothermal anywhere.

3. Well and Stress Orientation

One of the first studies that used GeoDT investigated the likelihood of successfully developing a reservoir using CGS without any site-specific information being known about the subsurface

(Frash, 2022). Neither AGS nor EGS had yet been implemented in this older version of GeoDT. The study completed a Monte-Carlo ensemble model of 50,000 fully random scenarios followed by 10,000 scenarios for the optimized design having 7 to 9.4 km depth, 45 to 55 °C/km gradient, injection at 0.030 to 0.046 m^3/s, 3 to 6 production wells, and wells drilled within 45° of the minimum principal stress which was set as North in this scenario set. The last detail was critical for making sense of the results and for increasing the chance of achieving high power output from

the scenario set. Note that well orientation varied randomly from North to East and from horizontal to vertical. This covers the whole 3D range of well orientations because of geometric symmetry. For interpretation, the results were filtered and interpreted using box plots. Results from successful scenarios that achieved at least 20 MWe net power output are reproduced here (Fig. 3). More recent work builds on this foundation by assuming that a developer will measure the in-situ stresses to then drill wells parallel to the minimum principal stress. This direction will likely have uncertainty around ±20° (Fu et al., 2021; Kelley et al., 2024), but this is much better than nothing.

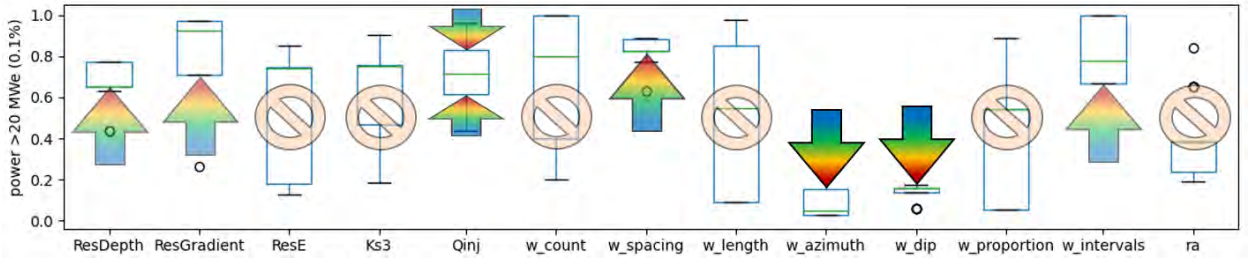

Figure 3: Boxplot showing correlations between CGS model inputs and high performance outcomes. Reservoir parameters were assumed to be unknown. The 0.1% of scenarios that achieved this performance mark showed a need for high temperatures (ResDepth and ResGradient), high injection rates (Qinj), large well spacing (w_spacing), and wells near-parallel to the minimum principal stress (w_azimuth and w_dip). Plotted values are normalized to the ranges used for model inputs (e.g., 4 km < ResDepth < 10 km). Arrows highlight trends and crosses highlight no-trends.

4. Strategy and Number of Wells

One of the top selling points for EGS is a minimized drilling effort where as few as two wells can be required to generate power. In a strong contrast, AGS proposes the opposite with maximized drilling length at depth to enhance total thermal output. In between, CGS proposes to drill a few more wells than EGS to achieve improved reservoir control and higher power output. Despite the commonly held assumptions, it is not obvious which of these three strategies will perform best. Likewise, the optimized approach for each strategy is not self-evident. Here, GeoDT is employed to investigate the optimization of each design and to compare each strategy.

To begin, let us consider a closed-loop AGS concept with a looped array of wells drilled sub-horizontally within a reservoir at 6 km depth and with 36 to 50 °C/km thermal gradient (Frash et al., 2024). This scenario is based on the greenfield GLADE geothermal drilling project near Fort Collins, CO. Next, lets fix all the well design variables except for the flow rate and the number of loops drilled into the reservoir (i.e., the number of wells). More specifically, we consider designs with 5, 13, and 25 loops (Fig. 4).

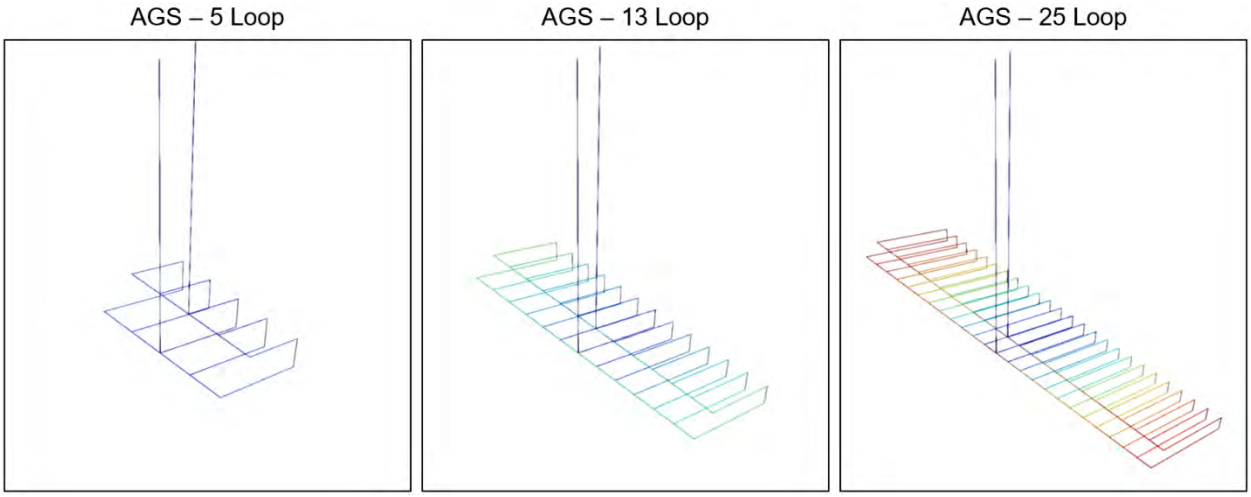

Figure 4: Closed-loop AGS designs having 5, 13, and 25 loops, 6000 m depth, and 2000 m long sub-laterals.

Each design was evaluated for 3,000 realizations to factor subsurface uncertainty into the results. These results can be displayed using color-scaled scatterplots to aid interpretation of the outputs that include timeseries data, 3D geometry, and a myriad of additional parameters (Fig. 5). Knowing that thermal performance is extremely sensitive to flow rate, these plots will all show flow on one axis. If the flow is too slow, the produced fluid will be cold by the time it reaches the surface. If the rate is increased, the fluid now becomes hot but could be uneconomic. Then if increased more, the produced fluid will cool faster over time. At the fastest rates, frictional losses become extreme so pumping power and pressures can become untenable. The optimal flow rate for peak sustained power production and peak economy will be dependent on AGS, EGS, and CGS design and the reservoir properties. In other words, a best estimate is needed to ensure that a given system performs at peak, but there will be irreducible uncertainty in this estimate. This study captures that uncertainty through its Monte-Carlo approach accompanied by design-based filtering of the results. Note that it is rarely useful to filter results by outcomes (e.g., net power production) because outcomes depend on uncontrollable rock properties. Instead, quantile statistics filtered by design decisions offer a better approach to identify promising designs (Fig. 6).

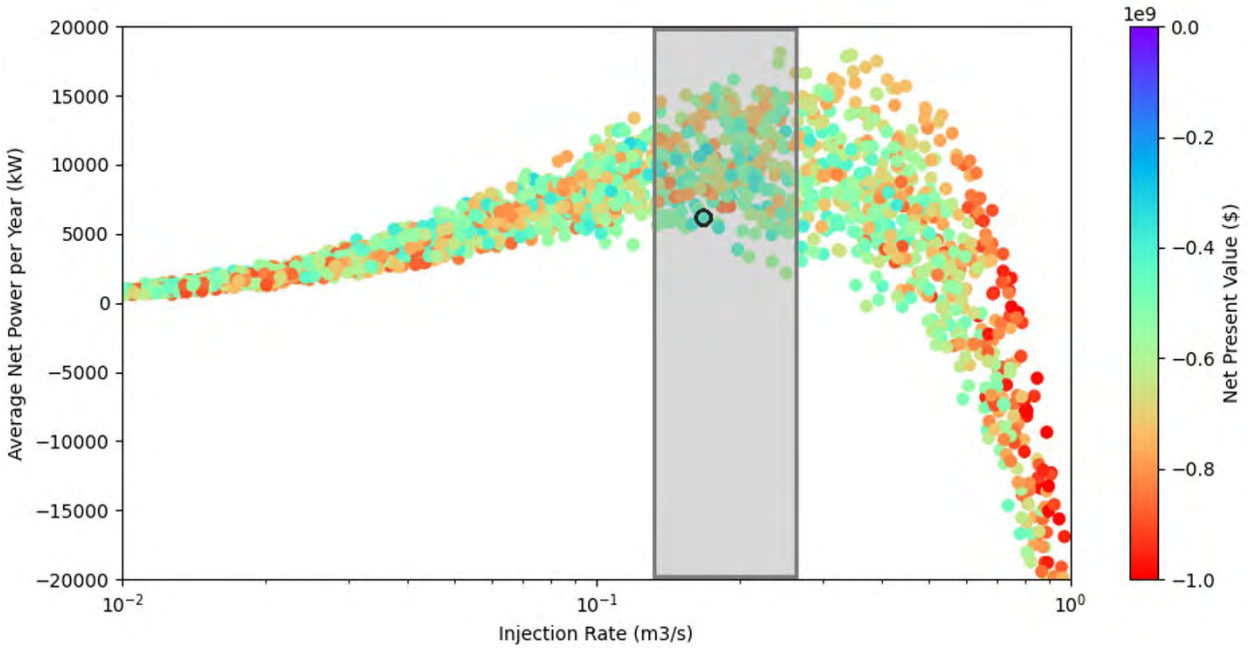

Figure 5: Example scatter plot of project net present value as a function of average net power production per year, being total generated power less pumping power over a 15 year lifespan in this example. Peak economy is achieved when the flow rate is optimized to produce the hottest fluid for the longest time at the highest rate. Optimum flow and design parameters were identified for every scenario by using model input ranges that were broad enough to assure that optima could be found.

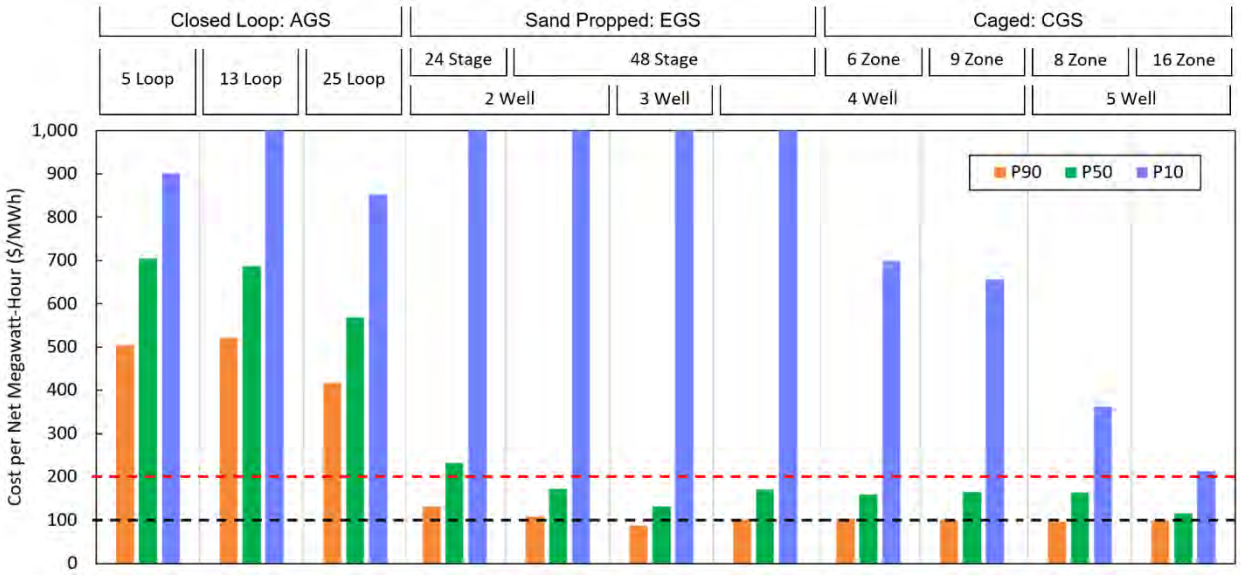

Figure 6: Comparison of the cost of electricity for AGS, EGS, and CGS with more than one design variant for each development strategy (e.g., number of wells). The lowest cost of electricity is achieved for 3-well 48-stage EGS. The most reliable and affordable cost of electricity is achieved with 5-well 16-zone CGS. The most affordable electricity from AGS is achieved with 25-loops. These quantile statistics are reaped from filtered data that isolated optimized flow rates and designs within each variant. This analysis included around 48,000 realizations, all obtained in about two weeks using GeoDT and a desktop computer. The result points a path forward to steer future high-fidelity modeling efforts by showing which development strategy is most likely to yield an economic outcome (Frash et al., 2024).

The execution of this effort yielded valuable insights regarding the potential of AGS, EGS, and CGS. At the foremost, the result shows that a minimum number of wells is not the most economic option. Instead, a low well count can actually increase the likelihood of project failure, leading to an elevated risk of the worst-case outcome. In the case of EGS, the worst-case outcome includes injection induced seismicity at larger than tolerable magnitudes. This prediction agrees with field experience where larger than tolerable earthquakes were observed in Basel, Landau, Soultz-sous-Forêts, and Pohang (Kim, 2018). Simpler models than GeoDT, such as Gringaten's, lack the ability to predict the likelihood of structural failures arising from poor fluid containment. The methods used in GeoDT permit a glimpse of these effects, but the results cannot and should not be assumed to be correct with respect to their specific values. In truth, reliable and accurate forecasts of seismic risk may never be possible because of the high uncertainty inherent to the subsurface.

Another key outcome from this effort was identification of the most promising designs for AGS, EGS, and CGS. For AGS, designs that maximized the number of loops (i.e., the length of the wells in the hot reservoir) worked best. In addition, AGS performed better when the loops were near horizontal because steeply dipping loops incur a mixture of heating and cooling effects which lowers the efficiency of the heat exchanger. However, too many loops will increase the risk of loss of access to the reservoir because a operational problems could cause damage to the vertical wells, meaning that the system has single point of failure which could result in a total loss of subsurface assets. For EGS, designs that maximized the number of stimulated fractures performed best. The models included attempts to improve flow uniformity through the fracture network using smaller casing perforations, tuned proppant permeability, and in-well zonal isolation, but these tricks came with an excessively increased pumping cost because they all required decreasing the conductivity

of the fractures. The optimized number of wells for EGS was found to be three, one injector and two producers. For CGS, four to five wells and designs that maximized the number of injection zones yield the best results. Unlike EGS, stimulation never tops in CGS so injection rates were never limited by downhole pressures. Also, unlike EGS, proppants were not injected in CGS to hold fractures open. The obvious drawback of this approach is perpetually high injection pressures and high flow rates yielding higher pumping losses, but the total achievable flow rate is higher so that makes up for the loss.

5. Depth and Thermal Gradient

Drilling for water, oil, gas, wastewater, and geothermal most often targets a specific geology at a known or estimated depth. Building on from this, it is expected that hot dry rock geothermal will do the same. However, the potential of a resource is linked to its temperature and the depth at which that temperature will be achieved may not be known, especially for greenfield resources. To investigate drilling strategy economics, we employ GeoDT to estimate the net present value of AGS, EGS, and CGS greenfield projects where the thermal gradient is unknown (Fig. 7; Fig. 8). The gradient for this analysis varies from 55 to 120 °C/km for well depths from 2 to 8 km. Results from this work reveal that flow rate and reservoir temperature have a first-order effect on economy, but well depth and geothermal gradient have a second order effect. This is intuitive in hindsight because higher temperatures are needed to achieve higher efficiency for the conversion of heat to electricity (Zarrouk and Moon, 2014). Today, only moderate drilling temperatures can be managed with a soft maximum of around 300 °C (572 °F). We note the common knowledge that elastomers tend to degrade above 200 °C and steel melts above 1300 °C, yet the model maximum temperature is 1200 °C. Thus, we can ignore results with temperatures above 300 °C for practical reasons.

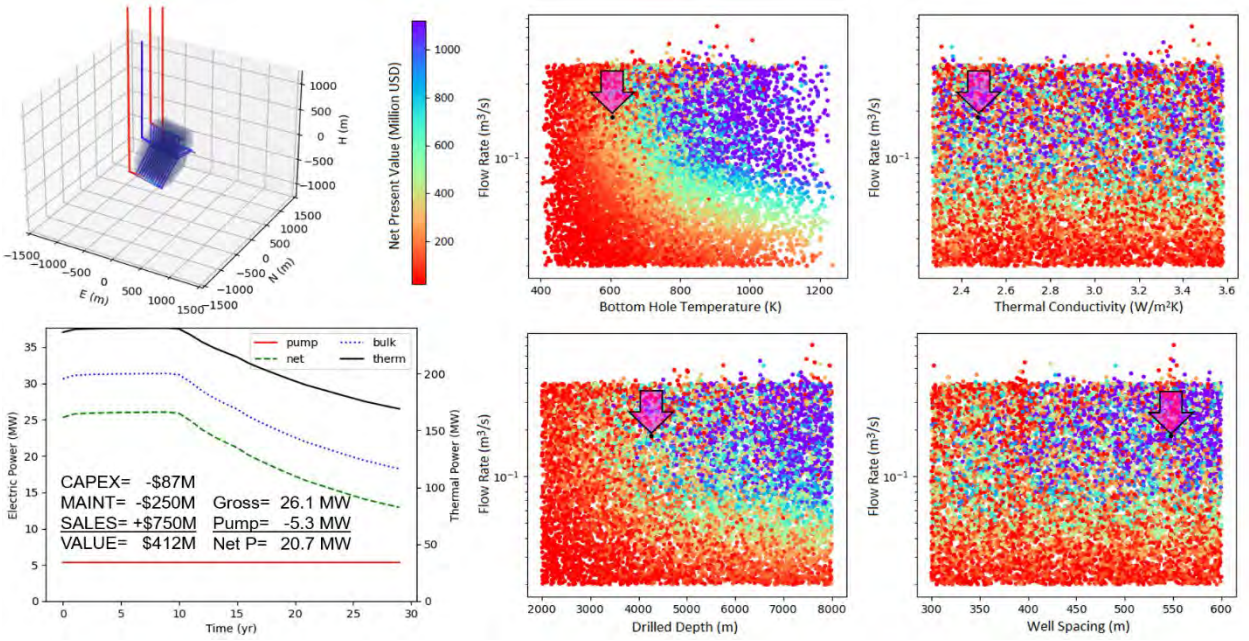

Figure 7: Net present value for 4-well 12-zone CGS showing first-order dependence on reservoir temperature and flow rate, second-order dependence on well depth, and tertiary dependence on well spacing. Thermal conductivity had no discernible effect, in part due to its low variance from 2.2 to 3.6 W/m²K.

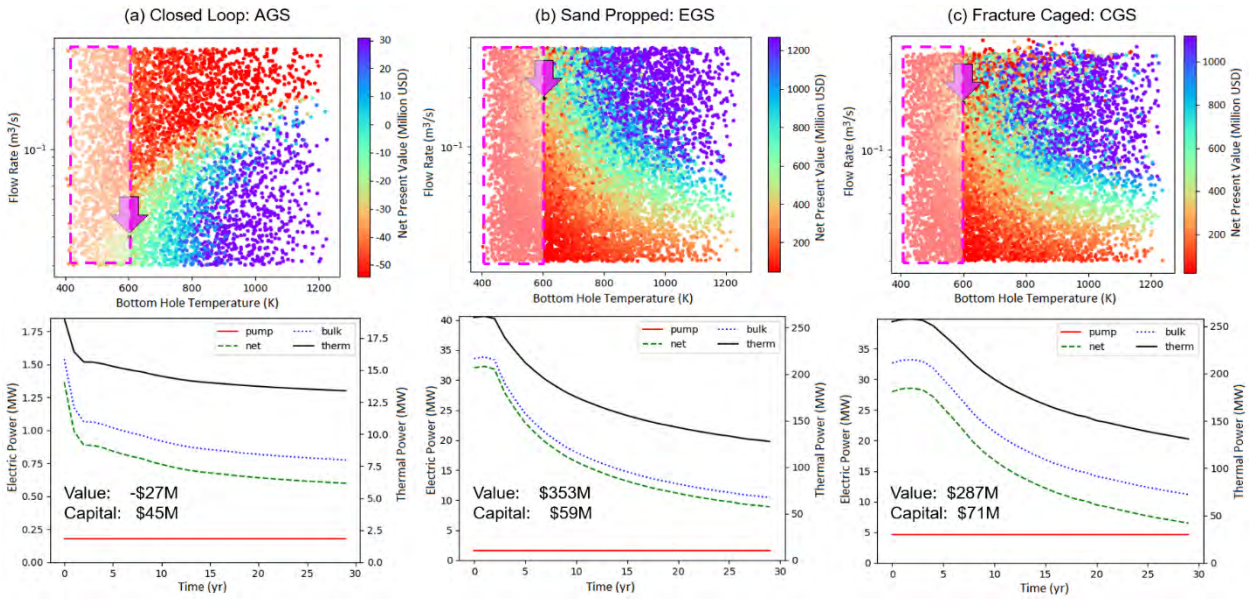

Figure 8: Net present value for optimized 13-loop AGS, 3-well 30 stage EGS, and 4-well 12-zone CGS. Higher economic flow rates for EGS and CGS is the primary reason why these systems outperform AGS. Natural shear fractures and faults were excluded from this analysis to mask their chaotic effect.

The nominal high-performance scenarios occurred with a reservoir temperature of 300 °C and at the lowest optimum flow rate. This associated with cooling over time but the increase in bulk harvestable power makes up for the losses. The lowest optimum rate helps flatten the performance curve which then simplifies the design process for surface turbomachinery. Routinely, GeoDT shows that some amount of thermal decline is favorable for peak economics because the higher temperature gradient in the conduction-dominated reservoir serves to extract heat more rapidly.

6. Natural Fractures and Seismicity

Natural fractures and faults are a source of undesirable complexity in AGS, EGS, and CGS. When drilling, these features can thief the drilling mud away from the rig, causing lost circulation and slower rates of penetration. When stimulating and circulating, these fractures can cause hydraulic fractures to coalesce. This causes premature cooling in the form of sparse flow paths (i.e., short-circuits). They can also interfere by preventing pressure buildup during well stimulation. GeoDT predicts these mechanisms with randomly placed critically stressed fractures (Fig. 9). In addition, GeoDT estimates the induced maximum seismic magnitudes as a function of fracture size, shear stress drop, and statistics (Lay and Wallace, 1995; Kanamori and Anderson, 1975; Gutenberg and Richter, 1954). This enables a first estimate of the seismic risk associated with a given geothermal reservoir design (Fig. 10).

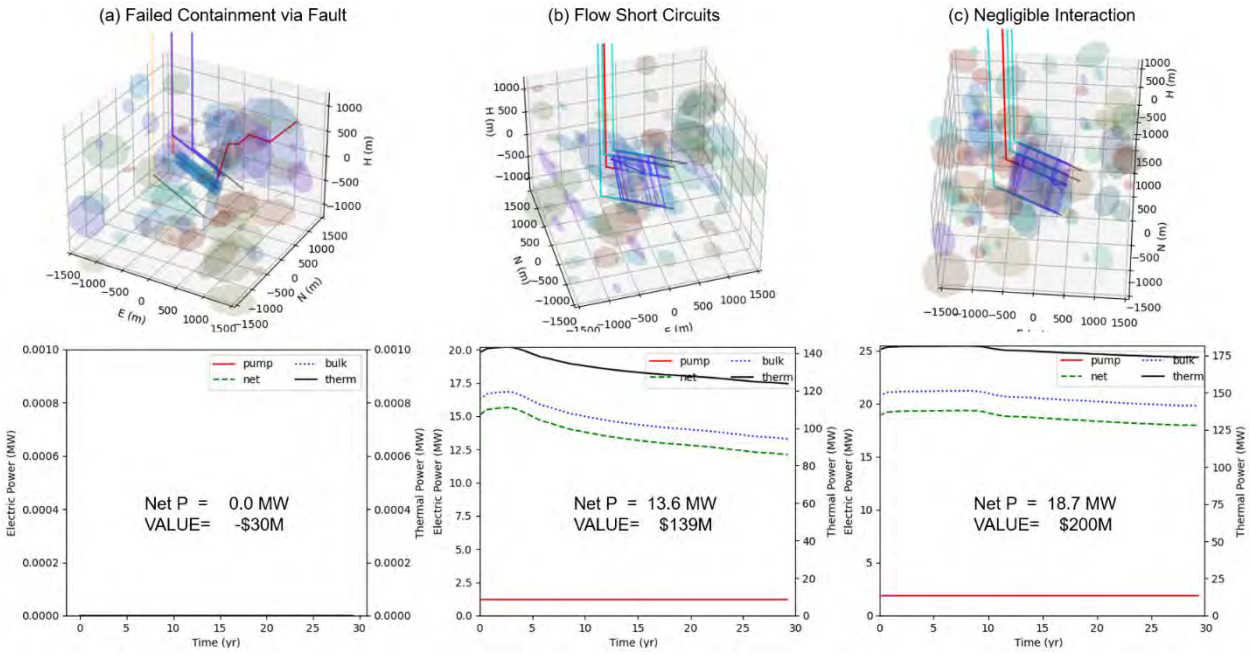

Figure 9: Faults and natural fractures introduce a mechanism for induced earthquakes and for high fluid loss. Optimized CGS designs should acknowledge that natural fractures can interfere with the system to then identify the high reliability designs that minimize the likelihood of a negative outcome.

Quantile statistics (Fig. 6) reveal the impact of design on seismics risk through a reduction in the performance uncertainty and a reduced likelihood of failure scenarios (e.g., >$300 USD/MWh for EGS and CGS). Scatterplots (Fig. 10) reveal trends in the design optimization process to identify details that should help to ensure success. A closer inspection of the results will reveal that failed containment associates with the largest magnitude seismic events for AGS, EGS, and CGS. For AGS, this will be apparent during drilling and initial fluid circulation so its diagnosis and cure (i.e., injection of cement or sealants) is straightforward. For EGS and CGS, some fluid losses should be expected during circulation and the action of faults can cause the injection and production rates to be equal despite fluid loss. This is because each well could connect to a different fracture system. Diagnosis of lost containment in EGS and CGS will require testing using methods such as tracers and microseismic monitoring. Mitigation measures could include injection of cements, gels, and diverters to clog the fast flow paths. Alternatively, additional wells could be drilled to intersect the fast flow path to then establish containment of all flow.

Unique to CGS, any natural fractures inside or interconnecting the wells are likely to have their flow contained by the fracture caging effect (Frash et al., 2021). This means that the risk of failed containment stems from the possibility of well-parallel fractures or from stimulated fractures connecting to a highly conductive fault that bypasses boundary wells (i.e., producers). Combining this process with how CGS production wells ought to be open to flow during stimulation means that a failure scenario for CGS can be identified within hours of beginning the injection. This offers an early opportunity to stop and employ seismicity mitigation measures before the fault becomes perturbed enough to trigger a large seismic event. This extra safety margin is part of what makes CGS a compelling option despite its need for more wells than the minimum EGS design. Tools such GeoDT are required to reveal these opportunities, quantify their merits, and devise mitigation options to the failure scenarios. Ultimately, the goal is to maximize the likelihood of achieving economic geothermal power.

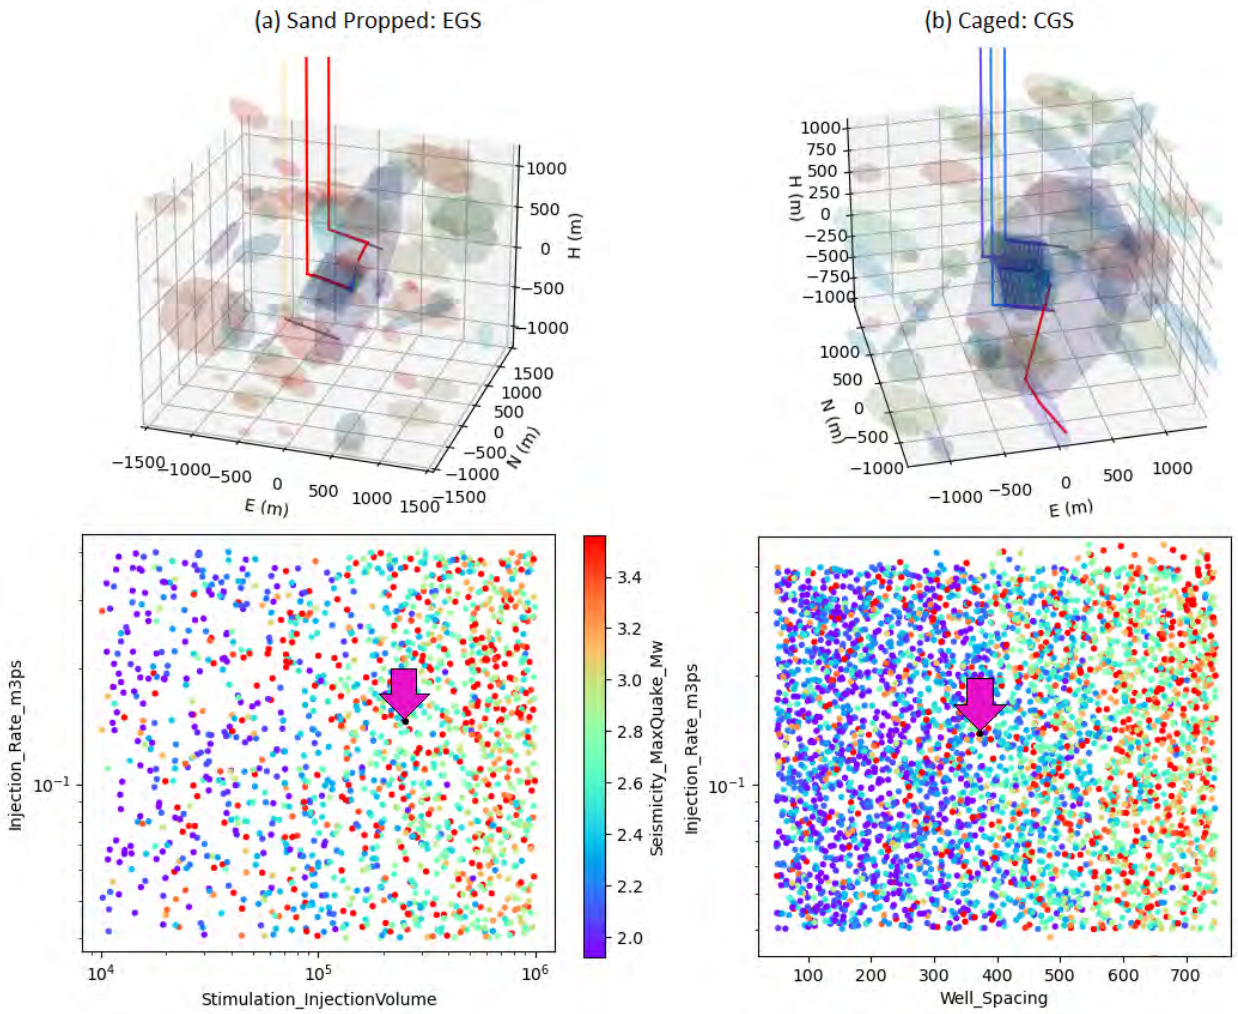

Figure 10: Maximum induced earthquake forecast by GeoDT for (a) EGS as a function of stimulation volume and (b) CGS as a function of well spacing. Mitigation measures such as the traffic-light protocol are not used in this study in order to better reveal the influence of reservoir design on seismic risk. Results from the EGS model are more sparse than for CGS because low injection volumes will fail to connect the injection well to the production well when the well spacing is too large. These failure scenarios are not shown on the plot because the circulation flow rates are too slow to plot. The same issue does not apply to CGS because the stimulation phase is the circulation stage, which never stops.

7. Economics

Recent experience drilling geothermal wells near Milford, UT and Blue Mountain, NV indicates that drilling costs could be lower than previously thought (Dupriest and Noynaert, 2022; Norbeck, et al., 2023; Lowry et al., 2017). This advancement stems from learning models, improvements in drilling methods, and the benefits of batch drilling. This information was used to update our cost model for drilling deep wells to an estimate of $1400 USD/m. This combined with the findings above leads to an updated economic estimate for the potential of CGS (Fig. 11). In short, it could be possible to generate electricity from hot dry rock at a cost point of $64 to $98 USD/MWh. This would make geothermal energy competitive to solar with energy storage at its estimated cost of $46 to $102 USD/MWh (Lazard, 2023), before government incentives.

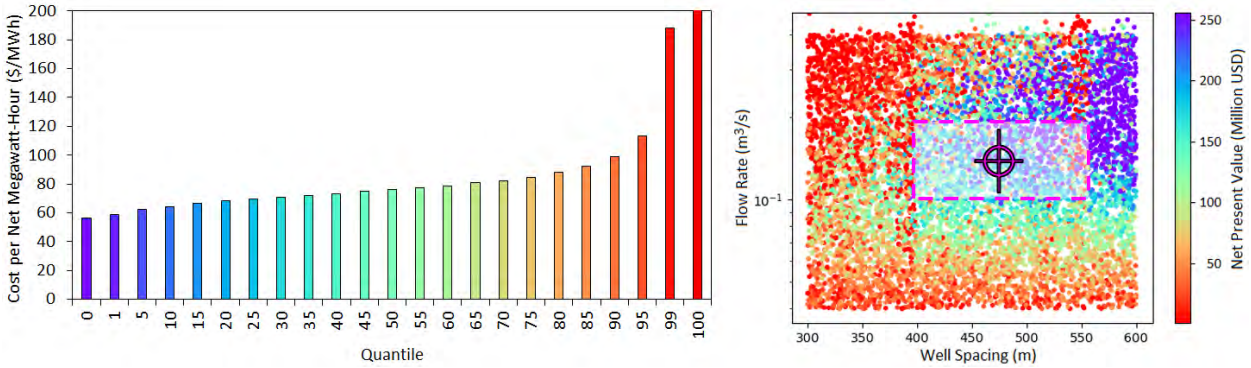

Fig. 11: Economic forecast from GeoDT for the most viable CGS design with its risk mitigation measures. The nominal cost of electricity (i.e., P50) is estimated at $75 USD/MWh.

8. Conclusions

This study investigated the technoeconomic potential of AGS, EGS, and CGS in greenfield settings where information about the subsurface is limited. The analysis is based on Monte-Carlo ensemble modeling with GeoDT to explore a large parameter space, beginning from a start scenario where no site-specific data was known. We note that GeoDT is a fast simplified physics solver that pairs measurements of complex processes, with upscaling theory, and fracture networks to estimate the energy generation and value of various geothermal reservoir designs. The analysis indicates that EGS is likely to yield the cheapest power from unconventional deep hot dry rock resources, but at a risk of triggering earthquakes. Caged Geothermal Systems (CGS) provide the next best cost at $64 to $98 USD/MWh after its initial capital investment of around $70M. AGS yields the highest cost of electricity at $275 to $560 USD/MWh and the lowest risk of induced seismicity.

Geothermal Reserves Standards: A Study of the Applicability of the SPE Petroleum Resources Management System, a Proposed Classification Framework for Geothermal Reserves and Resources

Stephen E. Gardner and D. D. Faulder

Ryder Scott Company, L.P.

Keywords

Reserves, resources, geothermal resources classification framework, thermal recovery factor, SPE, PRMS, GRMS, EGS, power density

ABSTRACT

The global geothermal industry is over 100 years old and is growing as suppliers seek to meet ever-increasing energy demands in an era of de-carbonization. Yet, unlike the petroleum industry, the geothermal industry has no universally accepted set of guidelines, standards, or protocols to guide what are called '*reserves*' in financial statements and reports. Consistency in reserves and resources classifications (wherein reserves are a subset of resources), estimation methodologies, and the related disclosures is needed by investors, regulators, and corporate management teams to compare geothermal opportunities and clearly communicate the differences in terms that are well defined and understood. Another benefit of such standards is to show value added during the exploration and early development phase of a project as resources mature from one classification to another. In this study, a literature survey was conducted of existing classification standards in order to provide the backdrop for an evaluation of a geothermal resources classification framework based on the SPE Petroleum Resources Management System (SPE-PRMS). A brief review of methodologies for estimating recoverable heat was also conducted. The SPE-PRMS is a widely recognized international standard for petroleum resources, and its applicability to the formulation of a classification framework for geothermal resources was explored. Additional terminology is introduced to define geothermal reserves, resources, and associated concepts. An initial geothermal resources management system (GRMS) is presented.

1. Introduction

As many observers are aware, the geothermal industry is poised for an investment surge due to several factors. One such factor is the continued push toward de-carbonization of energy sources driven by environmental and social concerns; another is the need for growth in base-load renewable power, and a third is the emerging economic viability of Enhanced Geothermal Systems (EGS). The large resource base in the earth's crust to 4 km depth is a major driver of EGS. New geothermal projects require capital for exploration, wellfield development, and power plant construction. Total project costs can be $4 million to $6 million per developed MWe (the electrical power output from a power plant is specified in megawatts electric, or MWe), and projects may take several years to generate first revenue. The California Public Utility Commission has called for 1000 MW of new, base-load renewable power by 2028 to help supply the state's growing needs and energy transition goals, requiring $4 billion to $6 billion, or more. In Utah, Fervo Energy is developing 400 MWe of EGS power at a reported cost of $1.1 billion (Fervo 2023). These large capital projects require outside investment from financial institutions, private equity, investment banks, and other sources.

Many of these potential new investors are likely to have experience investing in the petroleum industry and are familiar with many common and shared activities with the geothermal industry, such as subsurface geoscience evaluation, well drilling and completions (including horizontal wells), and fluid production through surface pipelines and facilities. These investors may also have experience with petroleum reserves standards and have some expectation that there are similar standards and protocols for geothermal reserves. For other new investors, geothermal projects may be their first foray into subsurface assets and development. Both types of investors are likely unfamiliar with the nuances of geothermal exploration, development, power plant operations, and selling produced power to a utility or a large power purchaser (e.g., a server farm, a mine, etc.).

At this point, it is important to note that *reserves*, whether for petroleum or geothermal, are a subset of *resources*. As such, *resources* encompass the full spectrum of estimated quantities: discovered as well as undiscovered, recoverable as well as unrecoverable, commercial as well as uneconomic, and produced as well as remaining. *Reserves*, as will be further defined in section 3.3, comprise the portion of *resources* that are discovered, recoverable, commercial, and remaining as of a given date. Throughout this work, we sometimes refer to the terms *reserves and resources* together, simply for emphasis.

The geothermal industry in the United States history is blotted by projects[1,2,3,4,5] that did not meet economic expectations. While there may be many technical reasons why a project experiences commercial difficulties, the issue often revolves around a mismatch between expectations of what the asset could produce, i.e., the asset's reserves, and the associated production profile with respect

to time, rate, pressure, and enthalpy. A review of the financial statements from domestic U.S. companies that produce geothermal energy, such as NCPA (Baker Tilly 2018-2023), Chevron (2005-2022), and Ormat (2005-2023), suggests a current capacity factor of ~52% (i.e., current electrical power production as a percentage of the initial installed plant capacity). As a project is incentivized toward profitability, the question may be asked, *why is the average project delivering only about half of its installed capacity?* At least part of the answer to that question, and others, may be found in properly understanding the uncertainty around a project's geothermal reserves and resources.

2. Literature Review

The passage of the 1970 Geothermal Steam Act by the U.S Congress, provided for the leasing of Federal lands for geothermal exploration and development. The Act defined a *known geothermal resource area* as "an area in which the geology, nearby discoveries, competitive interests, or other indicia would, in the opinion of the Secretary, engender a belief in men who are experienced in the subject matter that the prospects for extraction of geothermal steam or associated geothermal resources are good enough to warrant expenditures of money for that purpose." It should be noted that several criteria are specified: geologic favorability, subject matter experts, and commercial opportunity.

In response, the first national assessment of the domestic geothermal resource base was performed by the United States Geologic Survey, USGS (White and Williams 1975). This assessment reviewed a comprehensive catalog of hot springs and thermal features in order to estimate the size, temperature, and heat-in-place using either direct temperature measurements or inferred from geothermometry. The national assessment was updated several times by the USGS, with the last update in 2008 (Muffler 1975, 1979; Reed 1983; Williams et al. 2008). They described a volumetric methodology for calculating the usable heat-in-place above a given reject temperature using either deterministic or probabilistic methods.

These USGS studies all referred to the geothermal *resource base* as *reserves*, highlighting the differences on how to define this key term. Furthermore, the USGS did not rely on economic criteria in defining reserves, thus missing a key factor, commerciality. This is understandable, since the early years of the industry were not concerned about precise reserves definitions and protocols as the technology was still evolving, experience was being gained, and the limited number of projects worldwide were still in their infancy. This is not the case today, as the industry has matured, with over 50 U.S. domestic power projects and more than 100 globally.

2.1 An Evolution of Geothermal Reserves Classification Standards

The U.S. domestic geothermal industry experienced a number of major oil companies, new entrants, and other players leaving the space throughout the 1990s, a period characterized by industry reorganization. Serious discussion of geothermal reserves started appearing in the literature post-2000 and has advanced toward formal protocols and standards. Three stages can be discerned from the literature.

The first stage spans about 2000 to 2008, with discussion of reserves categories and estimation methods. An early paper by Sanyal et al. (2005) proposed a process for booking geothermal reserves. It provides an excellent summary of basic principles with suggested categories and a

discussion of deterministic and probabilistic reserves estimation methods. A review by Clotworthy et al. (2006) suggested reserves categories of Proven, Probable, and Inferred and included an economic test as reserves were only to be considered "that are generally accepted to be commercially extractable with existing technology and prevailing market conditions." These authors referenced the SPE/WPC guidelines for petroleum in using deterministic and probabilistic methods.

The second stage covers approximately 2008 through 2015, coinciding with the development of Enhanced Geothermal Systems (EGS) in Australia. This required Australian regulations, protocols, and standards for determining geothermal reserves for financial reporting (Australian Reporting Code Committee 2010). The code used for its conceptual basis the Joint Ore Reserves Committee (JORC) approach and was adopted with minimal changes in Canada by the Canadian Geothermal Code Committee (2010a, 2010b). These codes recommended using a thermal recovery factor of 25% based on reservoir numerical model studies or a probabilistic model with a triangular distribution of 15%, 20%, and 25% for min, median, and max. The thermal recovery factor was then used to define proven reserves for the early Australian EGS pioneers. Somewhat in contrast, Grant (2015) presented a pervasive argument that for mature hydrothermal systems, a best estimate thermal recovery factor is 8% to 10% and that the Australian Code and Lexicon overstates hydrothermal recovery factors by 75%. Since EGS developments can have lower recovery factors than traditional hydrothermal projects, the overstatement becomes even greater in those instances.

In a review of the Cooper Basin, Habanero project, Geodynamics Ltd. (2014) presents an excellent summary of said project, including geoscience and financial information with over $400 million expended. It was apparent that the *proven reserves* that were booked were an attraction for initial capital investors, based on the Australian protocols. The company was incorporated in 2000 and listed on the Australian Securities Exchange in September 2002. After extensive testing, the project demonstrated 1 MWe in October 2013. The post project study estimated capital costs of $21 million per developed MWe, which is four to six times greater than a typical 50 MWe binary power plant. One observation from this situation is that if a project is to fail financially, it is better to do so sooner than later.

The third stage started approximately 2015, with the literature providing documentation of project data from around the world. Ciriaco et al. (2020) presented an excellent summary on current methods of estimating in-place thermal resources and thermal recovery factors for over 40 fields worldwide. It is interesting to note the legacy impact of the Australian probabilistic methodology described earlier (i.e., min, median, max of 15%, 20%, and 25%), with fifteen projects using probabilistic thermal recovery factors of 20% or greater. The United Nations has published detailed classification and specifications for geothermal resources in an effort to establish an international standard (UNECE 2019, 2022). This standard has yet to gain wide use by the geothermal industry; however, it does demonstrate a maturing technical understanding and an increasing emphasis on geothermal reserves standards worldwide.

2.1 Estimation Methodologies for Geothermal Reserves

Early discussions on booking geothermal reserves included a review of existing methods conceptually based on the Society of Petroleum Engineers (SPE) and the World Petroleum Congress (WPC). Various methods including volumetric analysis, production decline curve analysis, lumped parameter modeling, numerical simulation, and the application of sophisticated

stochastic methods were reviewed. Additional authors referred to Clotworthy in 2006 for establishing a conceptual framework for geothermal reserves and sub-categories reflecting different degrees of resource confidence. They used a three-level classification system; Proven, Probable, and Inferred, based loosely on the McKelvey diagram used by SPE. A general consensus has developed since then to use proved, proved plus probable, and proved plus probable plus possible categories to represent the 90th percentile (P90), the 50th percentile or median (P50), and the 10th percentile (P10) of the cumulative probability of exceeding the reserves estimate. Deterministic methods were assumed to represent a P50 estimate.

A key difficulty in differentiating between proved and non-proved categories is the thermal recovery factor. Given a typically large heat-in-place, a small difference in the recovery factor can have a large impact on the estimated proved reserves. An excellent review of geothermal resource assessment methodologies by Ciriaco et al. (2020) summarized thermal recovery factors from the literature for a number of fields worldwide to be from 5% to 38%, with most of the fields using probabilistic methods and triangular distributions (min, median, max). This compilation included three U.S. domestic fields: Coso, Dixie Valley, and The Geysers, all very well characterized and with long production histories that exhibited thermal recovery factors of 8% to 11%. These low thermal recovery factors from large, well-managed assets with over 30 years of production history suggest that recovery factors much greater than this may be optimistic. Moreover, optimistic thermal recovery factors may be related to high porosity assumptions since they are proportional in a given analysis. Zarrouk (2013) proposed that thermal recovery factors should consider the host porosity and type of geothermal system.

Decline curve analysis (DCA) has long been used in the petroleum industry to forecast reserves from properties that are actively producing. While many geothermal fields use pumped wells at fixed rates, several geothermal fields use flowing wells and are subject to mass depletion, such as Coso and The Geysers. DCA has been used for many years at The Geysers for estimating remaining steam reserves and to estimate well flow capacity (*kh*) (Faulder 1996, 1997; Reyes 2004). In another instance, a common petroleum evaluation software was utilized to observe the historical performance trends in an established geothermal field and then apply DCA to multiple data streams, including steam and water mass, in order to forecast the future production (Ryder Scott Company 2021).

The difficulty in using strictly volumetric methods of heat-initially-in-place and a thermal recovery factor leads to considerations of how to estimate the production potential of a new prospect or a discovery without extensive geoscience and engineering data. The concept of power density has been studied by Wilmarth and Stimac (2015), Cummings (2016), Wilmarth et al. (2021), and Holmes (2024). Power density is defined as generating capacity divided by producing area. Figure 1 shows power density (MW_e/km^2) plotted vs. reservoir temperature (°C) for over a hundred fields worldwide. Distinctions were made between different tectonic environments, and an exponential regression was performed. The resulting plot showed a range of power density at each temperature, empirically representing the lognormal distribution of key underlying data, primarily area.

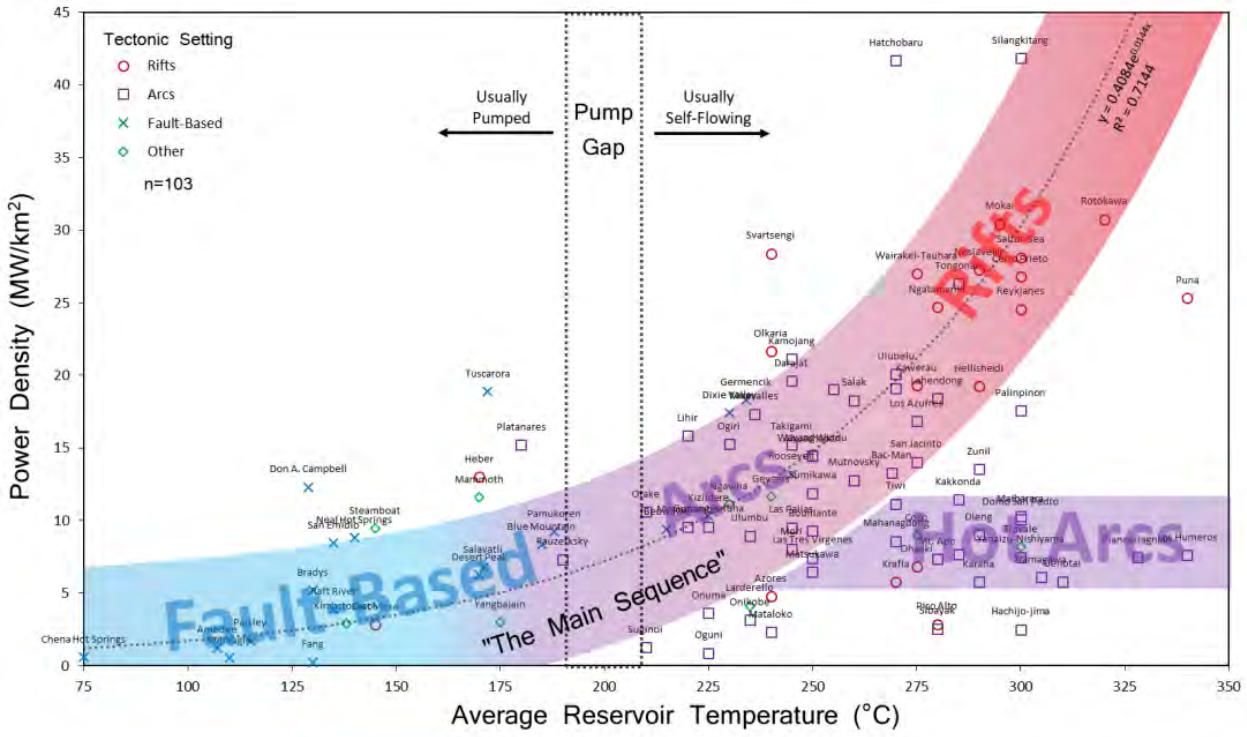

Figure 1: Power Density versus average reservoir temperature, from Wilmarth et al. (2020).

One distinct advantage of the power density method is not having to assume a thermal recovery factor, and power density increases with temperature, making intuitive sense. Another advantage is the data is based on actual operating experience for an increasing number of fields. One critique of the method is the choice of which capacity for power generation to use, the initially installed plant capacity or the actual stabilized power generation after some period of time. Another critique is the calculation of field size, since the area of the wellfield operations is dependent on the development strategy used. The power densities presented do not include a table of the underlying data used, and future work on this topic should develop a defined protocol for consistency and transparency. Yet, with refinement and an expanding data set, the power density method may provide a robust method for resource comparison using statistical methods, especially in the early appraisal stage of a project. A minimum and maximum estimated reservoir temperature can be used to bracket the power density distribution. An estimate of the defined field size multiplied by the power density provides an early estimate of the power generation potential.

A number of authors point to the evolving approach of using reservoir simulation to model the dynamic reservoir response during exploitation and to quantify heat recovery (Fang et al. 2022; Sanyal and Sarmiento 2005; Winofa et al 2020). The complex nature of modeling hydrothermal systems requires a large geoscience data set synthesized into a geologic model of the resource, such as temperature, porosity, and permeability within the structural and stratigraphic controls and open hydrologic boundaries. Mature projects typically have sufficient geologic and engineering data to construct and calibrate reservoir simulation models, and where sufficient data is available, reservoir simulation is a preferred method. To ensure their reliability, reservoir simulation models need to be regularly updated and recalibrated, taking care to understand why the forecast and actual

operations did not match, for such cases. We note that demonstrating or calculating the reliability of reservoir simulation, or any other estimation methodology, is a key criterion for assigning specific reserves categories to quantities of recoverable heat.

3. A Viable Classification Framework for Geothermal Reserves and Resources

3.1 The Need for Geothermal Reserves Standards

In general terms, reserves are the supply of a certain commodity that is available for future use, and for companies that sell commodities, reserves are a crucial measure of resource magnitude, growth (or decline), and longevity. For the energy industry, particularly for oil and natural gas, this is no exception. The establishment of standards for estimating and reporting petroleum reserves has been of great importance for many decades and is widely accepted as a critical part of carrying out business and defining the value of the company. Corporate management teams use reserves to understand their portfolio and to plan future development activities. Reserves represent an asset and are an integral part of the company's accounting to determine earnings. Regulators use reserves to plan for public energy needs and infrastructure, to predict tax revenue and inform tax incentives, and to help administer the use of natural resources. Investors use reserves to compare company performance and investment opportunities. Accordingly, reserves standards provide consistency in resource classifications, estimation methodologies, and the related disclosures. This consistency of information promotes reliable estimates and clear communication about such estimates, which then brings stability to the market place. Stakeholders are able to compare opportunities, manage portfolios, and transact with greater comprehension and confidence.

Whether for petroleum or for geothermal energy, this same reasoning and need for reserves standards applies. As discussed earlier, multiple geothermal standards have been in existence for many years (Australia, Canada, UNECE, etc.). However, a particular set of standards has yet to emerge as being widely-accepted. This reality may be at least partly due to the geothermal energy industry being something of a sleeping giant, when compared to the current mix of global energy supply. As worldwide economies continue to seek additional sources of energy to meet ever-growing demand, especially sources with a low carbon intensity, geothermal energy is positioned to become more common and to attract more investment capital. The acceptance and use of reserves standards are necessary to aid in the development and growth of geothermal energy, thus creating favorable conditions for a universal geothermal reserves standard to take hold. Yearsley (2019) discusses using the SPE framework for analyzing the transaction value of geothermal assets.

3.2 Experience from Hydrocarbons

The SPE Petroleum Resources Management System, a.k.a. SPE-PRMS or simply PRMS, is an important international standard for defining and classifying *petroleum* resources (Society of Petroleum Engineers 2018). Its principles are commonly applied to oil and gas assets around the world. Not only is the PRMS framework widespread, but many technical experts and other energy stakeholders are already highly familiar with its principles and application, having utilized it for decades. Furthermore, other standards for hydrocarbons, such as COGEH and the SEC guidelines, make reference to the PRMS. This high degree of acceptance and familiarity is important and may

help position the PRMS to be a natural bridge to a geothermal classification system, especially for stakeholders that already have some background in oil and gas.

In August of 2022, SPE issued a statement recognizing that the PRMS principles were being applied to non-hydrocarbons, including geothermal resources. SPE did not object "as long as it is made clear that while such application is outside of the PRMS, PRMS principles have been followed, while involving other subject matter expert parties as appropriate, and applied as though the extracted resources were considered as petroleum (Society of Petroleum Engineers 2022)." This statement opens the door for the acceptance and application of the principles of the PRMS for geothermal resources classification.

The technical estimation of petroleum or geothermal resources involves the assessment of quantities that have an inherent degree of uncertainty. The uncertainty in the estimates of recoverable volumes is represented by the *category* assigned to the estimates. Furthermore, these quantities are associated with exploration, appraisal, and development projects at various stages of design and implementation. The commercial aspects considered (e.g., technical, economical, regulatory, and legal) will relate the project's maturity status, or *classification*, to the chance that a technically viable project will actually be implemented. The PRMS classification framework provides a methodical approach to classify a given project according to its commercial maturity and to categorize the range of estimates according to the associated uncertainty of those estimates, for a project outcome. Since the PRMS is principles-based instead of rules-based, it inherently allows for adaptability to geothermal applications. In addition, petroleum and geothermal projects share many similarities, such as geologic and fluid flow characteristics, exploration and extraction technologies, and economic modeling. On the other hand, there are also important differences, including recovery of heat versus hydrocarbons, capital requirements and infrastructure, saleable products, and market drivers. We recognize that situations may arise requiring a departure from the PRMS as a guideline; however, our initial work has made it apparent that many reserves-related questions for geothermal energy become more straightforward by first looking for an analogy in the handling of hydrocarbon reserves. Finally, for the purposes of our discussion here, the adapted classification framework will be referred to as the Geothermal Resources Management System, or GRMS.

3.3 Important Terms and Definitions

As mentioned earlier, it is first important to distinguish between the terms *resources* and *reserves* in the context of geothermal energy. Leveraging language from the PRMS and adapting it to geothermal, the term *resources* comprises all quantities of geothermal energy, discovered and undiscovered, recoverable and unrecoverable, already produced as well as remaining, that are naturally occurring within the earth. Furthermore, Heat Initially-in-Place (HIIP) is a term that refers to a geothermal resource before any production has occurred. Again leveraging language from the PRMS, *reserves* are the portion of resources that are "commercially recoverable by application of development projects to known [sources] from a given date forward under defined conditions." Furthermore, reserves must satisfy four criteria: they must be "discovered, recoverable, commercial, and remaining based on the development project(s) applied." The exergy, or the useable portion of total energy in a system, of a geothermal project depends upon differences in temperature between the source heat and the reject, or waste, heat. Thus, the amount of geothermal reserves of a project can be different depending upon factors such as the type of

geothermal power plant, the reject temperature of the plant, or in the case of a direct heat application, whatever the minimum temperature is of the particular application.

Since geothermal reserves and resources as defined above are energy, their unit of measurement is joules, or more commonly, megawatt-hours (MWh) after the conversion to electrical energy. In the case where geothermal energy is used as direct heat, the British thermal unit (BTU) is another appropriate unit of measurement. We note that a megawatt (MW, 1 million joules per second) is a rate and is suitable to measure instantaneous energy production, such as the electrical power output from a geothermal plant, but it is not the appropriate measure for our definitions of reserves and resources. Furthermore, although geothermal energy is typically carried as heat by steam or water, which are measured in mass units such as kg or pounds-mass (lbm), the mass itself of steam or water does not represent an amount of energy nor would it qualify as geothermal reserves.

Using the PRMS as a model, we define proved, or P1, geothermal reserves as those quantities of geothermal resources that, by analysis of geoscience and engineering data, can be estimated with reasonable certainty to be commercially recoverable from a given data forward from known reservoirs and under defined economic conditions, operating methods, and government regulations. The term *reasonable certainty* means a high degree of confidence that quantities will be recovered (i.e., at least 90% probability, if probabilistic methods are used). We define probable, or P2, geothermal reserves with the same definition from the PRMS as for oil and gas: those additional reserves that analysis of geoscience and engineering data indicates are less likely to be recovered than proved reserves but more certain to be recovered than possible reserves (i.e., in a probabilistic context, there is at least 50% probability that the sum of proved plus probable (2P) reserves will be recovered). Lastly, we define possible, or P3, reserves with the same definition from the PRMS for oil and gas: those additional reserves that analysis of geoscience and engineering data indicates are less likely to be recoverable than probable reserves (i.e., in a probabilistic context, there is at least 10% probability that the sum of proved plus probable plus possible (3P) reserves will be recovered).

Beyond reserves, additional quantities of geothermal resources may be classified as contingent or prospective. Again using the PRMS as a model, we define contingent geothermal resources as those quantities estimated, as of a given date, to be potentially recoverable from known sources by application of development projects, but which are not currently considered to be commercially recoverable owing to one or more contingencies. Contingencies may include various issues, such as no available market, an operator's commitment or financial ability to proceed with development, uneconomic costs or prices, regulatory barriers, environmental opposition, etc. Similar to how the categories of reserves (i.e., proved/P1, probable/P2, and possible/P3) represent different ranges of uncertainty, contingent resources are categorized into C1, C2, and C3, where C1 corresponds to the same technical certainty as P1, C2 corresponds to P2, and C3 corresponds to P3. It is important to note that, similar to P1, P2, and P3 reserves, the terms C1, C2, and C3 are also representative of incremental quantities.

We define prospective geothermal resources as those quantities that are estimated, as of a given date, to be potentially recoverable from undiscovered sources. Prospective resources are sub-classified with the same nomenclature as the PRMS: 1U, 2U, and 3U. These categories are cumulative quantities and represent low, best, and high estimates, respectively.

As our scope with this paper is limited and the application of reserves and resources concepts to geothermal is still developing, we refer the interested reader to the current PRMS document, where additional terms and guidance are given for hydrocarbons that we believe in many instances are readily analogous to geothermal.

3.3 GRMS Classification Framework and Flowchart

As mentioned earlier, a focus of this work was to examine the suitability of adapting the PRMS to geothermal energy. The complete PRMS document is available from the Society of Petroleum Engineers. While it is beyond the scope of this paper to present every detail of our GRMS adaptation, the two figures below convey some key messages. We remind the reader that this initial GRMS may continue to evolve as more geothermal projects are encountered and evaluated.

Figure 2 below has been adapted for geothermal energy from the PRMS classification framework for hydrocarbons. The matrix shows the geothermal resource classifications and categories as were previously defined in section 3.2, the progression of commercial maturity along the y-axis, and the range of uncertainty in estimates along the x-axis. The figure allows a user to characterize where a particular project lies in terms of development maturity while simultaneously designating the uncertainty in a given estimate.

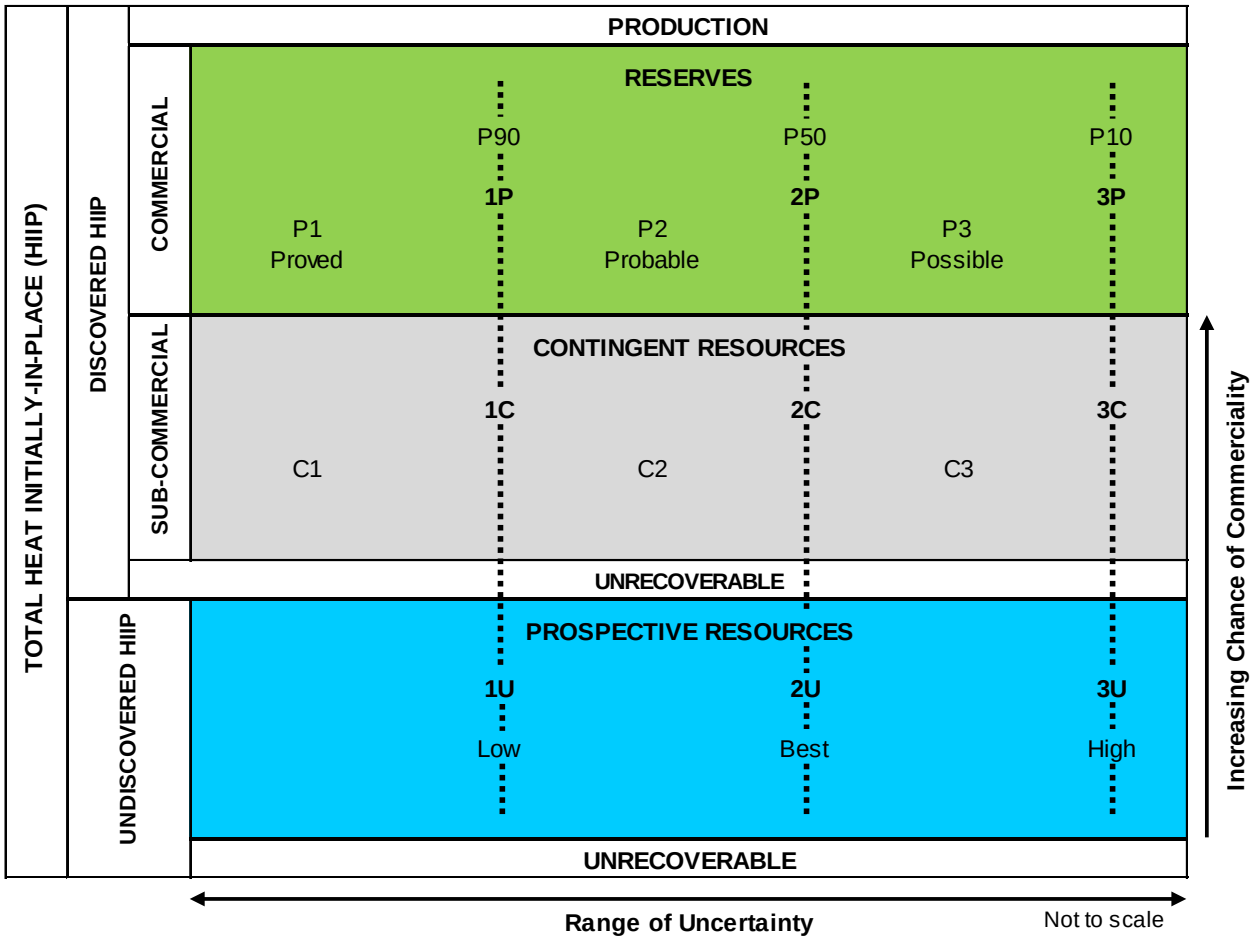

Figure 2: Geothermal resources classification framework (adapted from the SPE-PRMS, page 2).

Figure 3 is adapted for geothermal application from a concept graphic published by the Oil and Gas Climate Initiative, or OGCI (Oil and Gas Climate Initiative 2022). Based on the PRMS structure, the OGCI had originally generated the figure for application to carbon capture and storage. We have further modified it here for use with geothermal resources. The flowchart allows a user to understand and communicate the path that a project follows as it progresses, as well as what hurdles may remain to reach the next level of maturity, all the while utilizing the resource classifications and categories that were given in Figure 2.

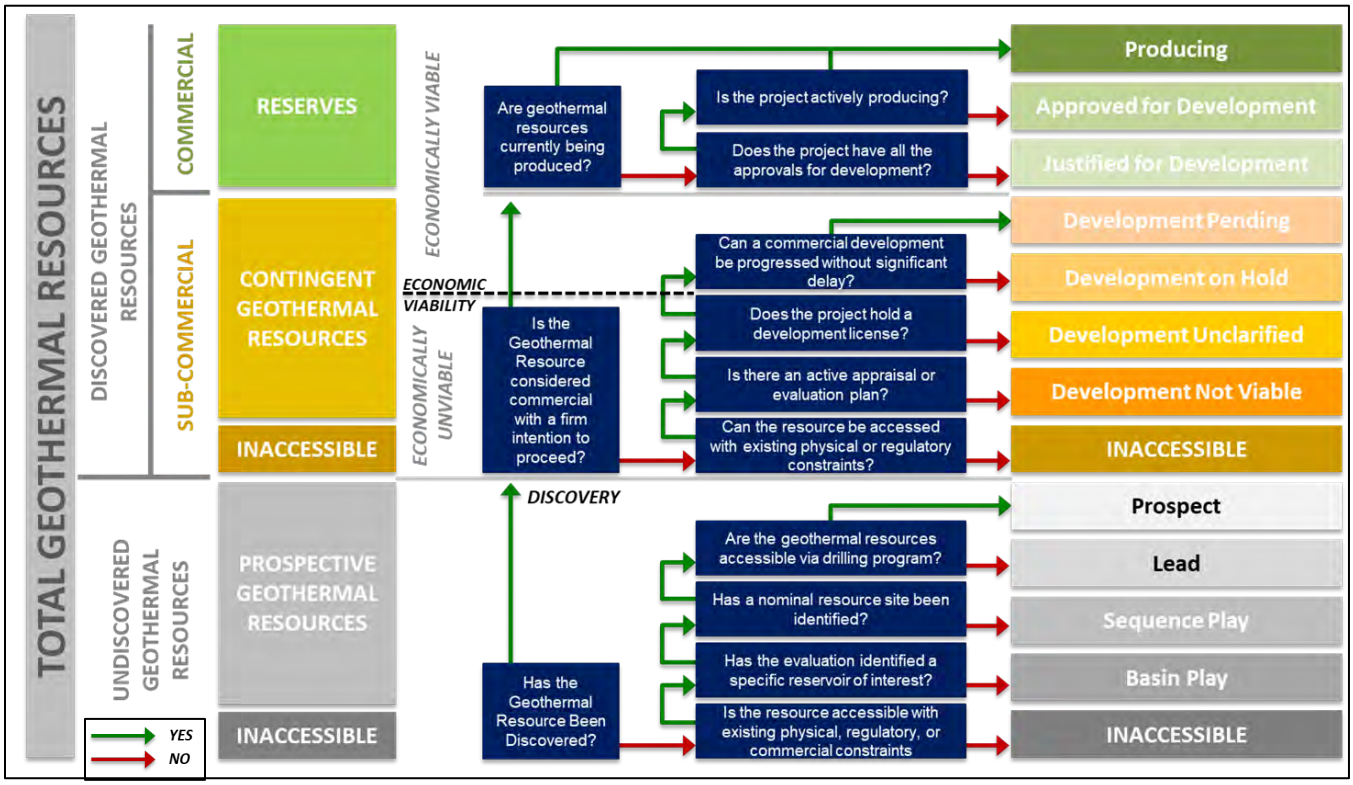

Figure 3: Flowchart for Assigning Project Sub-Classes (adapted from the OGCI CO2 Storage Resource Catalogue Cycle 3 Report, page 16).

4. Conclusions

The U.S. domestic and worldwide geothermal industries have matured with sufficient experience and data to apply formal definitions, methodologies, and protocols for estimating geothermal reserves and resources. Our literature survey and review of existing standards indicated an increasing interest and emphasis over the past two decades in the development of classification standards for geothermal reserves and resources. Yet no single set of standards has become widely accepted throughout the world. The Petroleum Resources Management System (PRMS), the common global standard for hydrocarbons, provides a good analogy for the establishment of a Geothermal Resources Management System (GRMS) and has an important advantage by being familiar to many energy stakeholders. Multiple case studies are ongoing by the authors to test the

utility of the suggested GRMS framework. Over time, additional application of the GRMS to geothermal reserves evaluations will help identify and resolve future questions or gaps in the framework.

Assessing the Economic Value of Underground Thermal Storage for Hybrid Geothermal Power

Jonathan L. Ho, Juliet Simpson, and Anne Barlas

National Renewable Energy Laboratory

Keywords

Storage, Long Duration Storage, Capacity Expansion Model, Geothermal Hybrid, Value

ABSTRACT

Solutions are needed to address resource adequacy in the electric power system for highly decarbonized systems. The storage duration, the length of time a storage device can provide continuous output at its rated capacity, must be sufficient to receive full credit toward resource adequacy. Longer peaks and high fractions of variable renewable generation have increased the required duration to potentially seasonal durations. Underground Thermal Energy Storage (UTES) can be adapted to a hybrid storage power plant or heating and cooling applications to satisfy the need for long-duration storage. In this study, we use the Renewable Energy Deployment System (ReEDS) capacity expansion model to evaluate the increase in value for an enhanced geothermal system (EGS) resources by adding UTES. In modeled scenarios, using geothermal without storage as a baseline we compare the increase in economic value for plants with a range of storage characteristics. The added value of a hybrid storage plant changes depending on assumptions including the length of storage duration, efficiency, and ability to charge storage from the grid during periods of low energy prices. Relating proposed characteristics for geothermal UTES hybrids to the modeled economic value provides insight into economically viable costs for developing UTES as well as what combination of technology characteristics and future energy and policy assumptions drive significant value increases.

1. Introduction

As a result of rapid reductions in technology costs combined with policy support, variable renewable energy (VRE), including wind and solar, are expected to represent an increasing share of U.S. power generation. Geographic and resource diversity help address generator intermittency but have declining benefits at higher penetrations. Storage is a natural complement to VREs as it addresses energy imbalances between periods of abundance and relative resource scarcity. This paper examines the added economic value of long duration Underground Thermal Energy Storage (UTES) as part of a geothermal hybrid power plant to meet.

The increasing penetration of VRE benefits from geographic and spatial diversity, which helps mitigate uncertainty in power generation, especially when coupled with flexible transmission. Due to limitations in network topology and region spanning high net demand, there remain periods when storage or peak capacity will be utilized to ensure sufficient supply. Peaking capacity often natural gas fuels, which in highly decarbonized power systems may not be possible to operate. Ensuring sufficient supply with storage necessitates longer storage durations and the length of time storage can discharge at its rated capacity to address longer net peaks associated with increasing penetrations of VRE.

One prominent well-known challenge is the diurnal mismatch exemplified by the "duck curve," where solar generation peaks during the day resulting in low net load (demand minus variable renewable generation), as the sun sets the net peak demand reflects a steep ramp as PV generation decreases. This issue is driven by a mismatch in the timing of generation availability and the demand and can be bridged using long-duration storage to shift excess daytime generation to evening peak demand. Long-duration storage is a loosely defined term but, generally refers to storage periods exceeding four hours but less than several days or weeks. This is well suited to diurnal needs as well as periods of high net load lasting for a period under a week.

Longer periods of high net load can result from high demand for space heating and cooling with wind droughts and extended periods of low wind generation. This, combined with seasonal patterns in demand and resource availability, requires storage shifting energy by periods on a seasonal basis. Seasonal storage requires substantially longer storage durations (hundreds or thousands of hours), limiting the types of technologies that could feasibly address this need.

Existing storage technologies face scalability limitations when addressing long and seasonal durations. Batteries are highly flexible but have costs that quickly scale with longer storage durations. Pumped hydro can provide long-duration storage but is constrained by geographic limitations and is less feasible for seasonal durations. Hydrogen storage offers storage capacities at a seasonal scale but remains uncertain in terms of developing a large scale production, storage, transportation, and utilization system. In contrast, when coupled with geothermal energy, UTES presents a scalable and potentially cost-effective solution for long-duration and seasonal storage. UTES systems store thermal energy in underground reservoirs, making them suitable for extensive storage periods. When integrated with geothermal plants, UTES can enhance the flexibility of traditionally baseload geothermal plants, allowing them to store excess thermal energy and dispatch it as needed. This integration transforms geothermal plants from "use-it-or-lose-it" operations to more flexible resources. Enhanced Geothermal Systems (EGS), which are not restricted to naturally occurring subsurface permeability, can be deployed throughout the U.S., further broadening the applicability of geothermal-UTES solutions.

This paper focuses on assessing the value of geothermal energy integrated with UTES as a long-duration storage solution. By examining the scalability, cost-effectiveness, and operational benefits of geothermal-UTES systems, we aim to highlight their potential to enhance the flexibility and reliability of renewable energy systems.

1.1 Geothermal UTES Background

UTES has a proven history of being used as aquifer thermal energy storage (ATES) in Europe, particularly for district heating and cooling systems (Fleuchaus et al. 2018). The subsurface can

be used for thermal storage in multiple ways including boreholes, reservoirs, or aquifers for thermal storage, and that thermal energy can be used for direct heating, direct cooling, or improved heat pump efficiency. Using UTES for heating and cooling may be most beneficial for seasonal storage when the thermal source to charge the storage is free or nearly free. UTES for heating and cooling could significantly impact the electrical grid, both to statically reduce loads on the grid and to dynamically shift when electricity is used to meet heating and cooling loads.

Geological thermal energy storage (GeoTES) (or reservoir thermal energy storage (RTES)) creates an artificial warm subsurface reservoir via heat input from the surface that can later be extracted for use to generate electricity (or be used as heat) (McTigue et al. 2023; Wendt et al. 2019; Sharan et al. 2021; Atkinson et al. 2023). Typically, the reservoir is accessed via a doublet with two wells (one "hot" and one "cold"), operated in a push/pull fashion (McTigue et al. 2023). One example of this would be to pair a concentrating solar power plant (CSP) with GeoTES. The CSP plant would then store excess heat during the day in the subsurface for later use at night (long-duration storage) or in the winter (seasonal storage). This concept is being explored by Premier Resource Group in California (Cox 2023) but has not yet been implemented in the field. GeoTES allows for significantly longer storage durations than current thermal storage technologies (molten salt tanks, packed bed, hot water tanks, etc).

Another example of UTES is in-reservoir energy storage (IRES) for enhanced geothermal systems (EGS). IRES uses pressure-based energy storage (rather than directly using thermal) within an EGS reservoir. IRES allows for a build-up of geothermal fluid in the subsurface (via either increased injection pumping while keeping outlet pumping constant or throttled output flow while keeping injection pumping constant), increasing the mass of geothermal fluid within the reservoir and thus increasing the pressure. The system can then choose to discharge additional hot fluid at a later time or discharge it at the normal rate but using less injection pumping (and thus have a higher net power production). While the energy is stored in the form of pressure, it is utilized as heat to drive a power cycle.

IRES was first defined in Ricks et al. (2022) and is being pursued for commercialization by Fervo Energy (Temple 2023) as "FervoFlex". It is currently at a low technology readiness level, and many questions remain about its potential operation, performance, and cost.

2. Methods

2.1 ReEDS Background

The Regional Energy Deployment System (ReEDS) model is NREL's flagship capacity expansion tool designed to model the evolution of the U.S. power system (Ho et al 2021). ReEDS considers the requirements of operating a power system using existing and new investments in generation storage and transmission while minimizing total operating and investment costs. ReEDS is characterized by its granular spatial and temporal resolution. It divides the U.S. into regions that preserve transmission network topology and provide detailed insights into resource and demand diversity. ReEDS utilizes consistent weather year data (2007-2013) to capture the variability and renewable energy sources and demand, ensuring a robust grid integration and reliability analysis.

The model includes a comprehensive representation of generation technologies and significant detail in characterizing renewables such as geothermal, solar, and wind. Resource supply curve information conveys cost and energy generation potential for generation technologies, including geothermal. Specific technology and year define plant capital, operating, and finance costs, with assumptions documented in NREL's Annual Technology Baseline.

ReEDS has the option to make, if necessary, new investments to ensure all system requirements are met. When selecting an investment, the mathematical optimization considers the revenue for services provided (energy, capacity, renewable portfolio) against the investment and operating costs over an economic lifetime. Investments are only selected if revenue meets or exceeds costs. This differs from metrics like Levelized Cost of Energy or Levelized Cost of Storage, which are based on cost normalized to predetermined roles. Levelized cost metrics are not able to represent a mix of services provided (e.g., energy + capacity) and do not consider the value of those services at the time they are provided, which may significantly exceed the levelized cost.

2.2 Model Expansion

The storage available with geothermal UTES is directly linked to an in-plant energy source similar to dispatchable hydroelectric power or concentrating solar power with storage. This differs from standalone storage technologies like batteries and pumped hydro storage, where energy for storage is sourced from the grid. We developed a generalized hybrid storage plant representation based upon the existing solar PV hybrid representation.

In a geothermal context, the following parameters define the operations of a hybrid storage plant with long-duration storage:

- cap: The design capacity defined for a geothermal plant relative to the size of its geothermal field that operates electricity production in equilibrium with thermal energy.
- r: The ratio between the capacity defined by size of thermal field and the size of the turbines used to produce electricity.
- eff: The round trip efficiency of energy stored in a given time period.
- dur: The length of time that the geothermal hybrid could discharge from storage at its rated capacity.

The plant has three operating decisions:

- Gen: Electricity produced from available energy from the geothermal field.
- In: Energy from geothermal field is stored through UTES in terms of electric efficiency.
- Out: Energy withdrawn from storage and used to produce electricity.

For a geothermal hybrid, the operations are defined by the following constraints:

1) Defines available geothermal energy in each time period.

$$cap = Gen_t + In_t \quad \forall t$$

2) Electricity produced cannot exceed the rated turbine capacity in each time period.

$$Gen_t + eff * Out_t \leq \frac{cap}{r} \quad \forall t$$

These equations are coupled with overarching storage equations that enforce the maximum state of charge for energy storage, defined by multiplying the storage duration by the design capacity. The storage state of charge is tracked between subsequent time periods, allowing it to increase if plant generation is lowered to increase storage or decrease if a plant withdraws energy from storage.

The addition of storage characteristics allows modeled geothermal power plants to store energy to produce during more valuable time periods, increasing the value of a prospective plant. This can allow hybrid geothermal plants the flexibility to operate responsively to grid conditions and complement the variability of solar and wind. The higher sizing of turbines relative to a conventional geothermal design allows a plant to increase its capacity contribution towards resource adequacy requirements.

2.3 Quantifying Value

Geothermal with UTES is in an early stage of commercialization with substantial uncertainty in cost. A conventional grid analysis would begin with specified costs and associated characteristics and model the investment in new capacity. Instead, we approached this by identifying how much value is added to a plant if different storage characteristics were applied. This characterizes the cost premium compared to a geothermal plant without storage, which is economically justified. The quantified added value can be calculated specific to the location and scenario to identify how geothermal UTES could specifically be applied.

ReEDS is a linear optimization model, which, while reporting investments and operations, also provides marginal prices on constraints and reduced costs on decision variables. These are a property of the relationship between the primal form (minimization) of an optimization problem and its dual form (maximization). This relationship can be utilized to calculate a reduced cost for a decision variable, which is the amount that costs would need to decrease in order for it to become part of the optimal solution. For any decision variable that is part of the optimal solution, the reduced cost must be exactly zero; otherwise, it would be possible to improve the model solution. Decision variables that do not form part of the optimal solution have negative indicating that marginal costs exceed marginal revenue. Reduced costs can indicate whether a decision variable would enter the basis if revenue increased or costs fell.

We utilize the reduced cost on the EGS investment decision variable to identify added value from adding storage characteristics utilizing methods described in Mai et al. (2021). Varying the characteristics of storage efficiency, duration, and capacity increases the marginal revenue for prospective EGS investments. Leaving cost parameters unchanged, comparing the change in reduced cost of an EGS plant with storage against a reference plant without storage provides an added economic value associated with these characteristics.

2.4 EGS IRES Parameter Range

As compared to conventional hydrothermal resources, EGS has the potential to be implemented more widely across the United States. IRES is a unique option for energy storage with EGS that

can be sited at any EGS plant with little to no additional cost. The key to IRES is not installing new storage equipment but changing how the system operates. Though IRES may incur some additional costs from oversizing the pumping or power production equipment, it otherwise does not add capital cost to the system. Thus, IRES will be investigated for its potential impacts on the electrical grid.

The operation of an IRES system was modeled for daily load shifting in (Ricks, Norbeck, and Jenkins 2022), resulting in reported annual efficiency values. It is suspected that there is potential for hundreds of hours of seasonal storage, but the roundtrip efficiency may be significantly reduced, and this seasonal storage aspect has not been investigated in detail. To provide reasonable bounds for seasonal storage, we see that (Ricks, Norbeck, and Jenkins 2022) finds a storage duration used in one of their model runs to be 450 hours, while (Ricks et al. 2024) notes a storage duration as high as 1100 hours. Corresponding seasonal storage efficiencies are never discussed, so a large range is considered. Efficiency depends on storage pressure, shut-in time, and discharge power, among other factors. Ricks found a range of roundtrip efficiencies from 60-90% for different simulations focused on diurnal storage cycling, with an average across all studied scenarios of 81% (Ricks, Norbeck, and Jenkins 2022).

For storage power, storing/discharging an extra 10-20% above the rated power for the geothermal power plant is discussed (Ricks et al. 2024; Ricks, Norbeck, and Jenkins 2022). Additionally, overrating the power cycle compared to the geothermal field is discussed up to 60% (though details to support that level of storage within that subsurface are not provided).

2.4 Modeled Scenarios

In our analysis we modeled the added value of an EGS with UTES focused on long duration storage. Modeled configurations had up to 20 hours of storage and a round-trip storage efficiency of 90%. The ratio between the design capacity and the turbine capacity was assumed to be 83%. These properties were applied to geothermal resources in the Western Interconnection and modeled in ReEDS through 2050. These properties were applied to the existing geothermal resource supply curve utilized in ReEDS. ATB moderate costs for geothermal were used, which intentionally kept EGS costs prohibitively high for investment. This ensured that in our simulations, EGS with storage would not be built and would alter the price equilibrium of the optimal solution. However, it would allow us to compare the relative shift in reduced cost.

The need for longer durations of seasonal storage is in part a function of the fraction of variable renewables deployed. In addition to a reference policy scenario, which maintains all on the books policies we also modeled a high carbon tax scenario with $600 per metric ton in 2035.

3. Results

The western U.S. has an existing higher abundance of renewable resources relative to other regions within CONUS. Under reference policies, the share of renewable energy reaches 80%, while with a CO2 tax, this increases to 98%. Adding the storage characteristics shows a significant initial increase in the added value of the plant. The most significant component of this is a result of the rise in capacity value from the oversizing of the turbines assumed in a storage configuration.

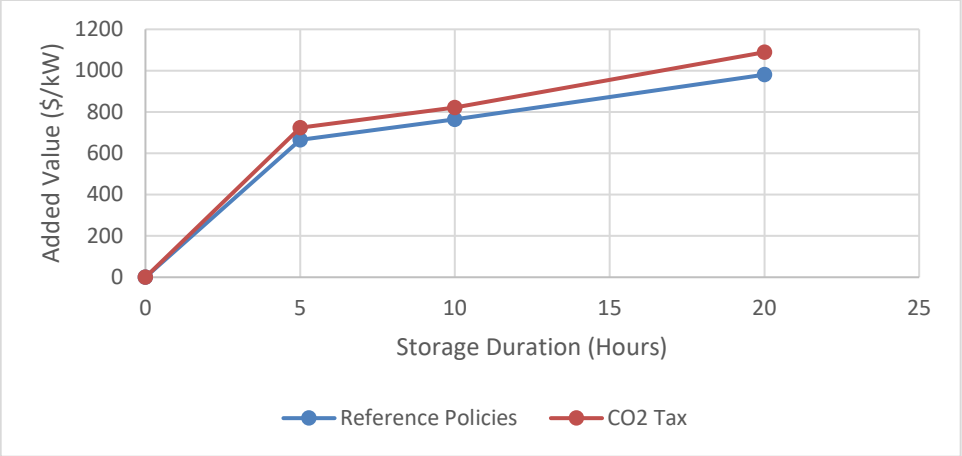

Figure 1. The average added value for EGS with UTES at different storage durations for reference policies and 100% decarbonization cases.

Increasing the storage capacity grows the plant value at a slower rate relative to the initial boost. In both cases, this increase continues through the modeled 20 hours of storage duration, suggesting that the storage duration was not saturated with 10 hours of storage duration. The gap in added value between the Reference Policies case and the CO2 Tax case increases at 20 hours of storage duration, indicating that the higher renewable penetration is associated with a greater relative need for long-duration storage.

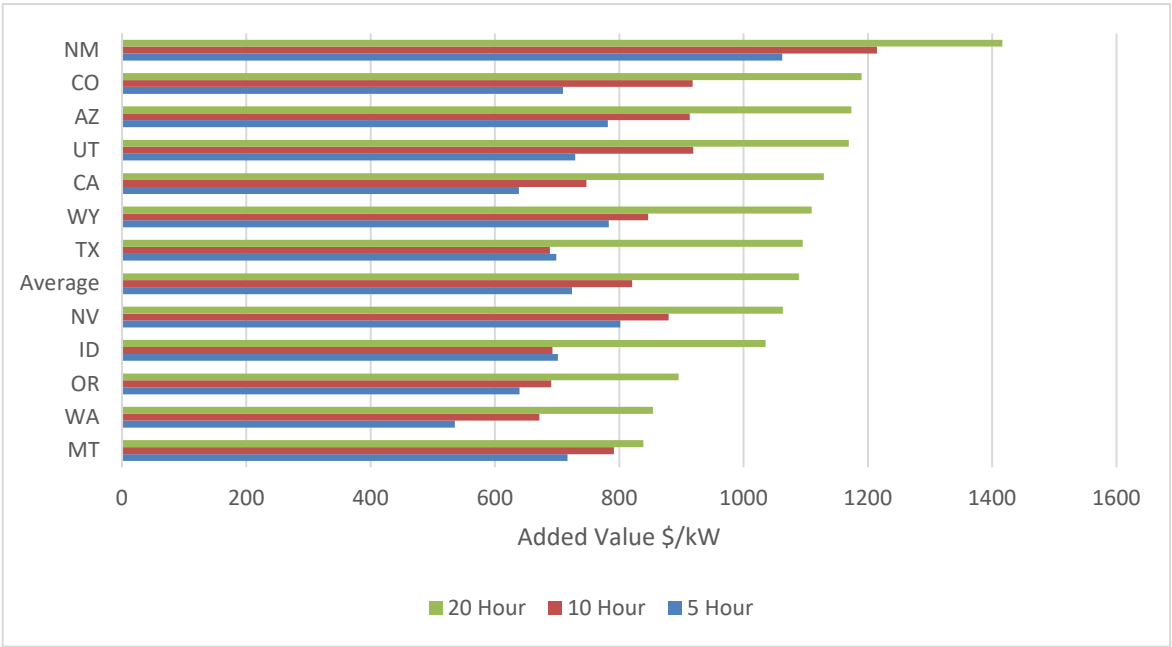

Figure 2. Average added value with by storage duration for EGS with UTES by State in CO2 Tax scenario.

The earlier west wide average added value obscures regional differences in added value for EGS with UTES. Examining the state average added value for EGS with UTES under the CO2 tax scenario reveals regional trends connected to the availability of location-specific resources. The average added value for UTES is up to 30% higher in New Mexico compared to the. Among the states, there is a north-south divide, with southern states typically recording higher added values. This is likely a combination of two effects. States below the west-wide average have significant existing hydropower capacity, while not all of this is dispatchable, with a substantial number of run-of-river hydropower plants in the Pacific Northwest, the availability of hydropower resources suppresses the economic value of UTES storage as it has significant overlap with the type of services EGS UTES could provide. Those being emissions-free storage and capacity. While regions with higher-than-average added value have hydro resources, they represent a proportionally smaller share of in-state resources.

The other factor that elevated regions with higher favorability and investment in solar PV. At 98% renewable generation, there is a limit to the load and resource diversity that can be leveraged to ensure sufficient electric power supply during periods of system stress. Low production periods can occur, requiring peaking units and energy shifting through storage, but they will occur on a more regular and predictable basis in regions with high fractions of PV due to the diurnal production cycle. For this reason, the combination of reduced dispatchable hydro and increased solar favorability form a complement with long-duration storage, increasing the value in these regions.

4. Discussion and Future Work

Using reduced costs in linear optimization to estimate the added value of adding long-duration storage characteristics to geothermal technologies offers a marked improvement over traditional metrics like LCOE and LCOS. Reduced cost metrics can directly measure the changes in revenue for hypothetical plant configurations without requiring a bottoms up calculation of construction and operating costs. The method provides insight into regional and scenario-specific revenue improvement differences for geothermal with UTES storage. While LCOE and LCOS remain useful metrics for comparing proposed technologies, they have limited insight into how a plant would operate and whether an optimal mix of services would yield a net positive value. The added value metric remains compatible with bottoms-up engineering cost analysis and can provide an economically justifiable cost premium over a more conventional design. This type of analysis scales well and allows decision-makers and designers to understand the range of grid service niches on the grid that a hypothetical UTES design could address.

Longer durations of UTES storage, less optimistic round trip efficiencies, parasitic storage losses, and larger sizing of turbines for a more rapid drawdown of stored energy are all dimensions we are interested in exploring in future analysis. Analysis of seasonal duration storage dramatically increases computation complexity but can be overcome with national scale analysis through storage with sparse chronology, linking operations in representative days to the actual days in the year to track seasonal shifts in energy. Work is being scaled up to leverage high-performance computing capabilities to extend this analysis to the national scale.

The scalability of UTES makes it a useful tool for addressing long-duration and seasonal storage needs on the grid for high-renewable and low-carbon power systems. UTES can be linked to other technologies, including Concentrating Solar Power with Geologic Thermal Energy Storage as well

as stand-alone Carnot batteries. The methods applied here to quantify added value for geothermal with UTES could be used to analyze both technologies' long and seasonal storage configurations. We are assessing the added value to CSPs of long and seasonal-duration storage using methods consistent with those discussed in this paper.

The applied methods could be implemented in other capacity expansion modeling frameworks based upon optimization with convex conditions that ensure global optimality for a solution. ReEDS is an open-source model, and the necessary metrics to calculate reduced costs for proposed technologies are built into the model. Other analysis teams could utilize this model to assess configurations and designs relevant to their design and analysis efforts.

ABSTRACT

In this paper we present a mathematical model to evaluate the economic impact of parasitic losses on electrical generation opportunity costs due to frictional pressure losses and thermal losses in an EGS system. Specifically, we will evaluate the impact of rate vs. wellbore geometry (well length, casing size, number of hydraulic fracture stages, etc.) as well as doublet and triplet well systems. The analysis will quantify the economic costs of parasitic losses of the electricity generated by the facility and equipment that circulates water through the EGS. Additionally, we will evaluate the impact of conformance control measures used in oilfield waterfloods and why these techniques would not be economical in EGS.

We have presented a mathematical model to estimate the system parasitic power losses for a given flow rate. First, the frictional loss through a given pipe diameter is calculated with the Reynolds number. This method uses the Roughness of the pipe, and the pipe diameter to determine the friction pressure loss for different wellbore geometries at varying flow rates. The method then calculates the friction (or, equivalently the effective fracture permeability) in the induced fracture system. This model provides a deterministic basis of hydraulic horsepower requirements of the circulation system and the impacts of the circulating system's parasitic losses on an EGS development's economics. This evaluation includes the traditional conformance control methods of tubing, packers, and Injection Control Devices (often called Outflow Control Devices) on the energy requirements of the EGS circulation system.

This model demonstrates that the largest operating cost of an EGS system is the "Opportunity Cost" associated with using the generated carbon-free energy to run the circulating system. If this cost is not fully understood and modeled prior to deploying the EGS, the reduction of the salable

electricity could cause a significant impact to the economics. Furthermore, if traditional 'plug and perf' completion techniques do not provide the required conformance control and traditional methods of conformance control are required to manage injection, the frictional losses could be so great that the system requires more electricity than it generates.

In the paper first we examine the relative economic effects of the system circulation rates and wellbore geometric configuration on the opportunity costs of parasitic losses including the impact of post-facto conformance control, in addition to the typical operating cost estimate based on plant and field size. Second, we illustrate the need to properly model and understand parasitic losses prior to the design of the development plan for any EGS project. Third, we discuss the impact of alternative conformance control measures on the project economics.

1. Introduction

The heat within the Earth has been used to generate carbon free electricity since 1904 when the first geothermal power plant was built at the Lardorello dry steam field in Tuscany, Italy. From a humble beginning of 10 kilowatts (kW) of energy, Lardorello Geothermal Complex has grown to a capacity of 769 megawatts (MW) and currently it is the 2nd largest geothermal power plant in the world (Statista, 2024).

The current global geothermal power generation capacity is 16 gigawatts (GW), and the United States lead the world with 3.9 GW of geothermal power (Figure 1).

In the United States the Geysers Geothermal Complex is capable of producing 900 megawatts (MW) of electricity through its 18 power plants. However, even with the tremendous resources like the Salton Sea and the Geysers Fields in California, the Mean Net Generation of geothermal electricity in the United States has stagnated between 1.5 GW and 1.9 GW since 1990 (Robins, et al. 2021).

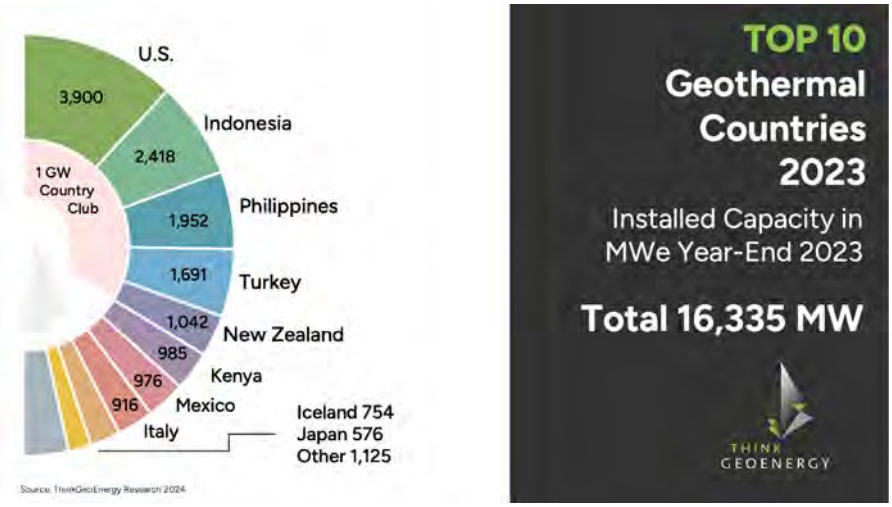

Figure 1: Top 10 geothermal countries in the world as of 2023 (ThinkGeoEnergy, January 2024).

The primary cause of this stagnation in growth is because the main source of the geothermal power in the world is from subsurface hot water reservoirs known as hydrothermal resources where the reservoirs' high temperatures and permeabilities provide natural or pumped flow of superheated

water to the surface for economical generation of electricity. Unfortunately, scarcity of hydrothermal fields and the trifling discovery of new fields that can significantly grow carbon-free power to offset current declining fields are the reasons for non-growth of hydrothermal reservoirs. It is estimated that only 2% of the geothermal resources in the world are accessible using hydrothermal technology (Geiser, Marsh and Hilpert, 2016). Between 2016 and 2021, eleven (11) plants were taken offline, removing 103.3 MW of nameplate capacity and only seven (7) new plants have gone online during this time supplying 186.3 MW of nameplate capacity (Robins, et al. 2021).

In an attempt to grow geothermal power generation beyond the limits of hydrothermal systems, there has been a great deal of research and development resulting in advances in a newer form of geothermal power generation referred to as Enhanced (or Engineered) Geothermal Systems (EGS). In contrast to the high-permeability hydrothermal systems, the EGS heat reservoirs typically consists of hot-dry-rocks with extremely low porosity, permeability; and no water is present in the limited pore spaces. This resource is referred to as Hot Dry Rock (HDR). To produce heat from an HDR, a subsurface heat exchanger must be created. Water can be injected into this subsurface heat exchanger and circulated to extract heat from the rock. Specifically, one creates an artificial link between 2 or more horizontal bore holes using hydraulic stimulation technology to allow cold water to be pumped down an "injector" well to a depth of sufficient geothermal heat. Once at depth, the water will be heated within the fracture network by the surrounding rocks to a temperature sufficient to generate electricity. The heated water will then be recovered to surface via the producer(s) and typically run through an Organic Rankin Cycle (ORC) plant to generate carbon free electricity

The key enablers to EGS are step change technology advances in extended reach, horizontal drilling and multi-stage hydraulic fracturing due to the development of shale hydrocarbon resources. Wells that with a true vertical depth (TVD) of 9,000 ft and a lateral departure of greater than 5,000 ft horizontally are now being drilled in under 25 days, in rocks that 7 years ago would have taken over 90 days to drill at 3 to 4 times the cost. In addition to drilling and stimulating the wells, the EGS systems require continuous injection of water into the target hot rock zone because of the absence of water in such systems (Mindygaliyeva, et al. 2024).

The availability of a water source for use in the EGS presents multiple challenges that must be examined for any EGS development project to be economically successful. First, access to the source and quantity of water for well stimulation (i.e., hydraulic fracturing) and fluid circulation must be established as part of project selection. Second, daily rates and volumes circulated to generate electricity to be economically viable must be understood. Third, modeling the required horsepower to run the circulation system and the potential impacts on for-sale-electricity (referred to as parasitic losses). Fourth, managing conformance control solutions (to distribute water evenly in the hydraulic fracture flow paths) and their impact on parasitic losses and thermal decline.

2. Key Variables Impacting Economics in an EGS System

Several key variables impact the economics of EGS. These variables were evaluated stochastically (Fleckenstein et al, 2023). The three dominant independent variables in EGS economics are (1) thermal decline, (2) flow rate per well, and (3) Power Purchase Agreement (PPA) pricing. It is not the intent of the current analysis to project what PPA pricing to use in economics, nor to project how long the current tax credits will last, nor whether carbon credits will enter the United States

market the same way as in the European Union. Rather, using a fixed set of assumptions for these variables, this analysis focuses on the thermal decline and flowrate per well to understand their impact on the net power production.

2.1. EGS System Heat Extraction Fundamentals

For an EGS system to successfully function, a minimum of two horizontal wellbores must be interconnected through a system of fracture stimulations. When there is one injector and one producer in a pair, the system is referred to as a "doublet" (Figure 2). It is critical that controlled water flow passed from the injection well to the production well as evenly as possible across the fracture system. As the water flows through the fracture to the production well, the geothermal energy from the Earth heats the fluid. The hot water flows up the production well and is converted into electricity at the surface using an ORC.

The alternate EGS system to the doublet is the 'triplet'. The concept of the triplet is that there is a single injector flanked on each side by a producer, creating a one injector, two producer system (Figure 3). The fractures are generated from the injector and will grow out radially in the direction of the maximum horizontal stress. If the two producers are correctly orientated on either side of the injector, perpendicular to the principal maximum stress, the fracture "wings" will intercept both producers. A properly engineered triplet system is ideal from a cost perspective, because only 1 set of stimulations from the injector can connect it to two producers, thus reducing completion costs by 50% and reducing the need to drill a second injection well.

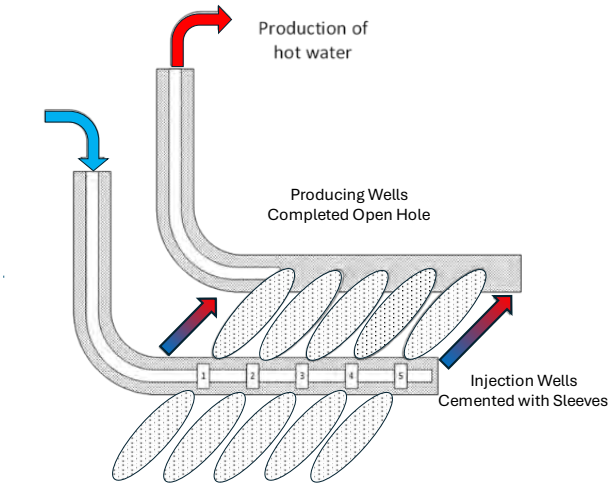

Figure 2: Doublet EGS Well System

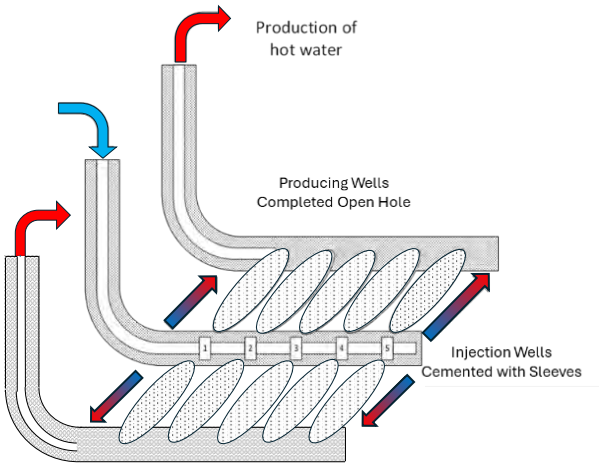

Figure 1: Triplet EGS Well System

2.2. Estimating Power Conversion and Required Flow Rate

The analysis method used starts by understanding the initial resource temperature (T_{r0}, in this analysis assumed to be the same as the plant input temperature for simplification) by drilling a regional exploration well. Once the temperature profile is understood, the required flow rate per well is calculated to design the subsurface system rate to match the power generation, in this case

the ORC. Starting with a base assumption that systems of 5 MW per doublet or 10 MW per triplet are required to be economic. Two methods were used to determine the estimated flow rate based on the resource temperature.

A common source to predict power from a binary plant (e.g., an ORC system) is to use equation 7.1 by Tester published in the 2006 MIT-led report (MIT led interdisciplinary panel 2006) where Tester extrapolated the thermal efficiency (η_{th}) based on the geofluid temperature of eight operating binary plants. Tester's linear regression resulted in the following formula for thermal efficiency (MIT led interdisciplinary panel, 2006):

$$\eta_{th} = 0.0935\,T - 2.3266 \quad (1)$$

Where,

$\eta_{th} = thermal\ efficiency,\ \%$ (For reservoir temp 90 ^{o}C - 250 ^{o}C $\Rightarrow$ 6 *to* 21%)

$T = Temperature\ of\ produced\ fluid,\ ^{o}C$

The equation for calculating electric power:

$$Q = \dot{m} c_w \Delta T \quad (2)$$

Where,

Q = electric power (J/s)

$\dot{m}$ = mass flow rate entering power generation turbine (kg/s)

c_w = specific heat of water (J/(kg·˚C)),

$$\Delta T = inlet\ T - Outlet\ T, (^{\circ}C) \quad (3)$$

Considering thermal efficiency of power plants, we can calculate the megawatt output of the plant using the following equation:

$$Q\eta_{th}/1{,}000{,}000 = plant\ power, MW \quad (4)$$

Utilizing the average plant ΔT of 73˚C (Moon et al, 2012) in plants greater than 150˚C and less than 250˚C, the required production rate to generate 5 MW can be solved for the assumed initial reservoir temperature T_{r0} of 205˚C at 60,200 BWPD per producer. Note, that the injection rate must account for formation fluid loss as documented at Blue Mountain (Norbeck and Latimer 2023). In this analysis it is assumed a fluid loss to formation of 8%.

As a validation check against Tester's formulas, the power conversions factors from Moon (Moon and Zarrouk, 2012) were evaluated for the same data set of plants greater than 150˚C and less than 250˚C. This resulted in an average power conversion factor of 4.72E-07 MW-hr / (˚C·BWPD) and a resulting rate per producer of 51,700 BWPD for 5 MW, representing a 16% difference from Tester's equation. For the Gringarten model used in this paper, the average of the two rate predictions of 56,000 BPD was used with a power conversion factor of 4.36E-07 MW-hr / (˚C·BWPD).

It is important to note that ~200˚C is recognized as a critical break over point between flash systems and binary systems. If a flash system is used, the efficiency of the plant could potentially reach 31% as documented by an MIT led interdisciplinary panel (MIT, 2006). However, this efficiency will have to be derated assuming that the cooling tower is replaced with air cooling to maintain 100% capture of the fluids for reinjection. Flashing also brings additional scaling issues for the plant depending on the water chemistry and must be evaluated on a case-by-case basis. For these reasons, all assumptions in this analysis use ORC power plants.

2.3. Modeling of a Subsurface Heat Exchanger

Modeling of subsurface heat exchanger is the same for both the 'doublet' and 'triplet'. In a typical EGS system, the wells are drilled to a formation that has a geothermal temperature of 200˚C to 260˚C. As the fluid is injected into the well it will slowly increase in temperature with depth. Once the fluid exits the wellbore the fluid is forced through the fracture where the heat from the earth will raise the temperature of the fluid to approximately the same temperature as the formation. The water will continue to the production well where it is produced back to surface for conversion to electricity. The temperature of the water will slowly decrease as it travels to the plant as a function of depth, wellbore geometry, flowrate, and ambient temperature. This can be countered through various insulation technologies in the market, such as vacuum insulated tubulars and cement with low thermal conductivity. For simplicity in this model, the bottom hole outflow temperature has been assumed as the same as the surface temperature.

The basis of modeling the heat exchanger using horizontal wells with multiple fractures in a reservoir was first developed by Gringarten, (Gringarten et al., 1975), and further advanced by Doe (Doe, McLaren and Dershowitz, 2014). Gringarten's heat extraction model was based on a set of parallel fractures with uniform properties—including fracture height (y), length (z), transmissibility (T), flow rate (q), and fracture half-spacing (xe). The length (z) represented the distance from the injector to the producer, and the total length (x) represented the horizontal length of the wellbore with the model allowing for a variable number of fractures (n) (Figure 4).

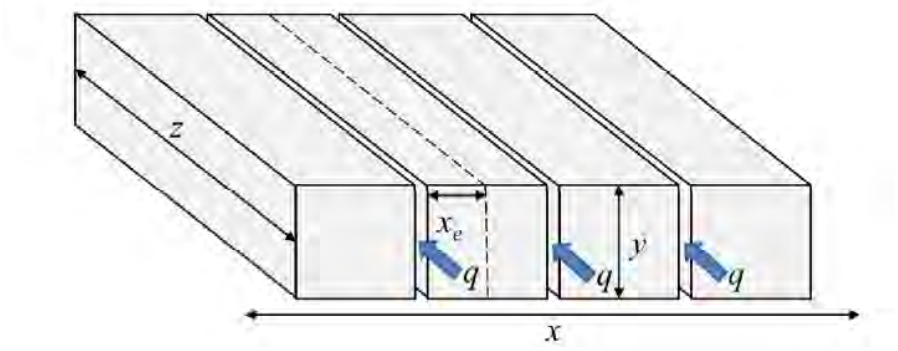

Figure 4: Gringarten et al. model, modified by Doe et al. (Augustine, 2016).

Using this model Gringarten developed a solution for thermal modeling an EGS system using dimensionless produced temperature (T_{wD}), dimensionless time (t_D), and dimensionless half-fracture spacing (X_{ED}), later simplified by Doe (Doe, McLaren and Dershowitz, 2014).

$$T_{wD} = \frac{T_{Ro} - T_w(z,t)}{T_{Ro} - T_{wo}} \tag{5}$$

Where

$T_w(z,t) =$ water temperature at z and t, ^oC
$T_{Ro} =$ intilal rock temperature at point of injection, e.g., 300^oC
$T_{wo} =$ water injection temperature, e.g., 40^oC

$$t_D = \frac{(\rho_w c_w)^2}{K_R \rho_R c_R}\left(\frac{q}{z}\right)^2 (t - \frac{z}{v}) \cong \frac{(\rho_w c_w)^2}{K_R \rho_R c_R}\left(\frac{q}{z}\right)^2 t \quad (6)$$

Where,

$q =$ volumetric flow rate per fracture per unit thickness in y direction, cm^3/s
$(e.g., 1.45 \text{ x } 10^5 cm^3/s)$
$z =$ distance above the injection point, cm
$v =$ water velocity in fracture, cm/s
$t =$ time, s
$\rho_w =$ *water* density, g/cm^3; e.g., 1.0 g/cm^3
$c_w =$ *water specific heat*, $cal/(g.^oC)$; e,g., 1.0 cal/(g.^{o}C)
$\rho_R =$ *rock* density, g/cm^3; e.g., 2.65 g/cm^3
$c_R =$ *rock specific heat*, $cal/(g.^oC)$; e,g., 0.25 cal/(g.^{o}C)
$K_R =$ *rock* thermal coductivity, cal/(cm.s.^{o}C) ; e.g., 6.2 x 10^{-3}cal/(cm.s.^{o}C)

$$x_{ED} = \frac{\rho_w c_w}{K_R}\left(\frac{q}{z}\right) x_E \quad (7)$$

Where,

$x_E =$ *fracture spacing*, *cm*; *e.g.*, $4,000$ *cm*

Using these dimensionless values and assumed uniform properties, Gringarten published these type curves for solving thermal decline based on reservoir properties and flow rates (Figure 5).

As noted by Doe, the function of thermal decline depends on the mass flow rate in the fracture vs. thermal diffusion rate from the rock matrix to the fractures (Figure 6). If the flow rate is too high within the fracture, it will travel faster than the rock matrix can supply heat to the fracture face. Alternatively, at lower flow rates, the thermal front in the matrix is better able to keep up with the rate of fluid flow in the fracture, causing a slower decline response, but steeper decline once it starts.

There must be a balance as fluid is pumped past the down hole heat exchanger to maintain the low-rate thermal front of Figure 6. Premature thermal decline from the high-rate thermal front can be caused by two events. The first event is pumping too much water down the injector compared to

the relative amount of fracture face surface area the system has, causing the entire system to prematurely decline. The second is a lack of conformance control, where the correctly calculated amount of water is pumped downhole, but it is preferentially traveling down a small subset of fractures, causing these fractures to prematurely cool, impacting the average outlet temperature's decline. This event is often referred to as '***short circuiting***'.

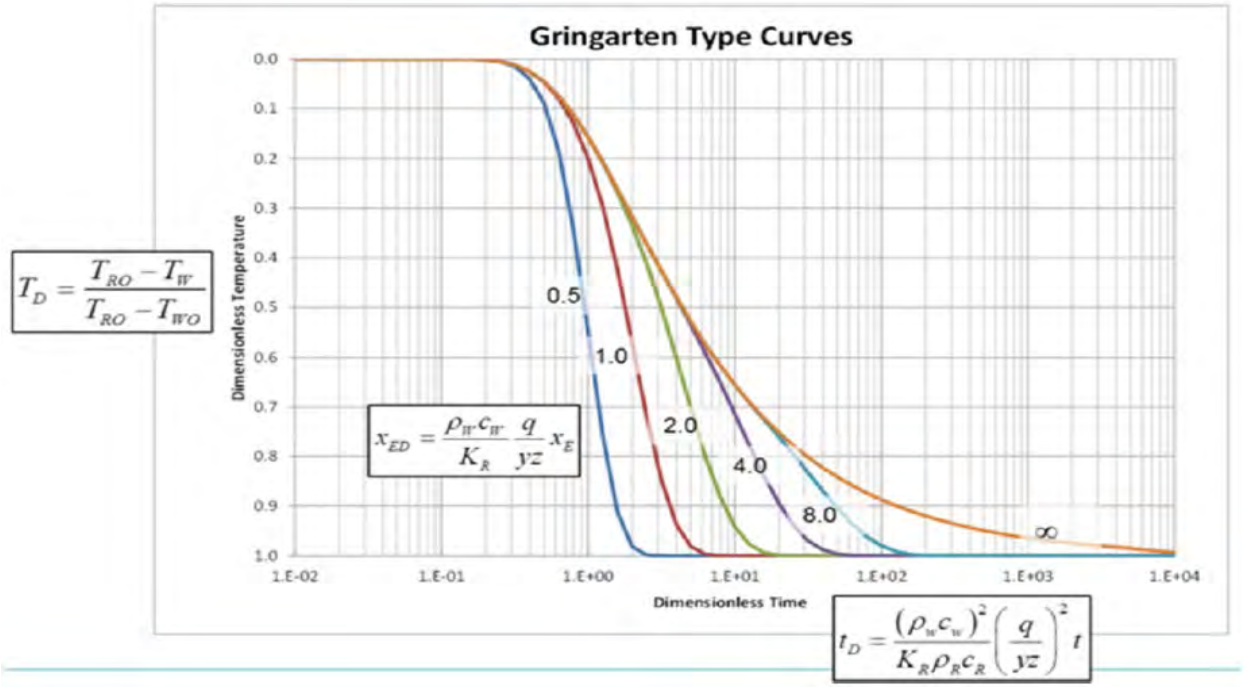

Figure 5: Gringarten type curves (Augustine, 2016).

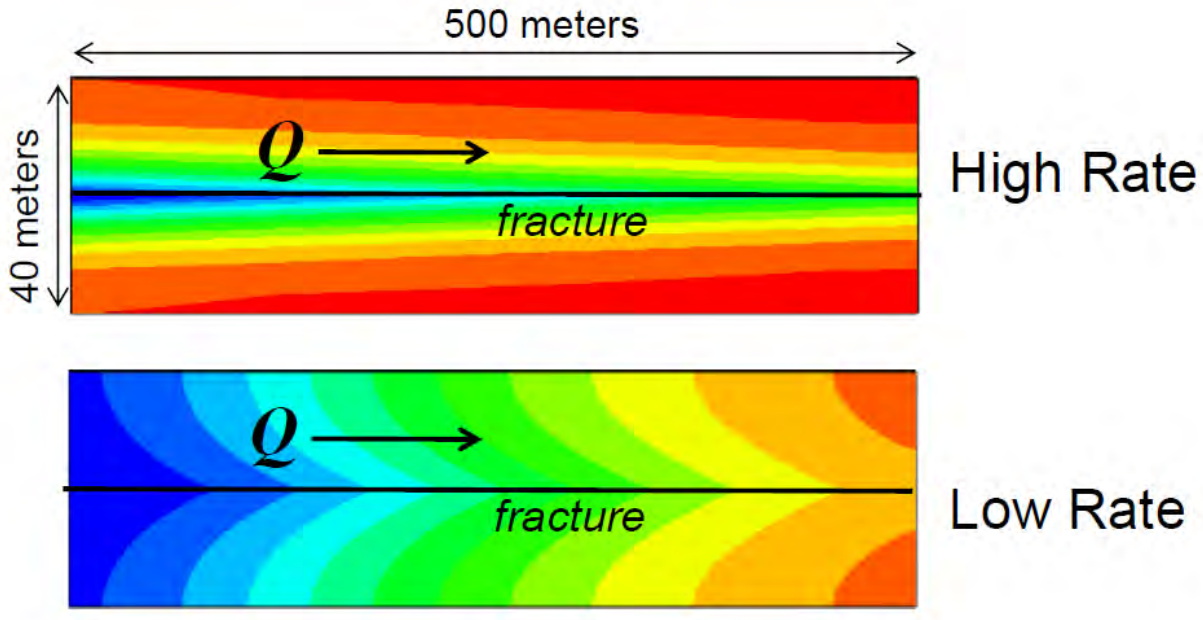

Figure 6: Diagram of thermal front vs flow rate (Doe, McLaren and Dershowitz, 2014).

Using the work established by Gringarten et al., and Doe et al. for a simplified model, a theoretical EGS was designed to model the thermal decline of a system. Using the parameters in Table 1, a "doublet" EGS system was modeled.

Table 1: EGS Parameters for Gringarten Thermal Decline

Density of Water	ρ_w	874 kg/m^3		Horizontal length	X	2414 m	7920 ft
Heat Capacity Water	c_w	4180 J/Kg˚C		spacing between horizs.	y	220 m	722 ft
Thermal Cond. Rock	K_R	3.00 J/m˙s ˚K		Frac height (penny fracs)	Z	440 m	1444 ft
Density of Rock	ρ_R	2750 kg/m^3		Total Flow Rate	q	0.103 m^3/s	56,000 BPD
Heat Capacity Rock	c_R	790 J/Kg˚C		Initial Reservoir Temp	T_{R0}	205 ˚C	478 ˚K
	C_1	2.05E+06 s/m^2		Abandonment Temp	T_w	164 ˚C	437 ˚K
	C_2	1.22E+06 s/m^2		Reinjection Temp	T_{w0}	60 ˚C	333 ˚K
				Dimensionless Outlet Tem	T_{wD}	0.28	
number of fractures	n	55		Dimensionless 1/2 space	X_{eD}	0.52	
frac 1/2 spacing	Xe	21.9 m	72 ft	Dimensionless time	t_D	0.73	
Frac spacing	2Xe	43.9 m	144 ft	Desired life	t	30 years	9.46E+08 seconds

Using the dimensionless variables, a graph of temperatures vs time was created (Figure 7); then, regression analysis was conducted to obtain Eq. 7. This equation and others were the basis for the economic model and subsequent calculations.

$$T(t) = -0.0009t^3 - 0.0279t^2 + 0.4193t + 204.06 \quad (t \text{ in years}) \tag{8}$$

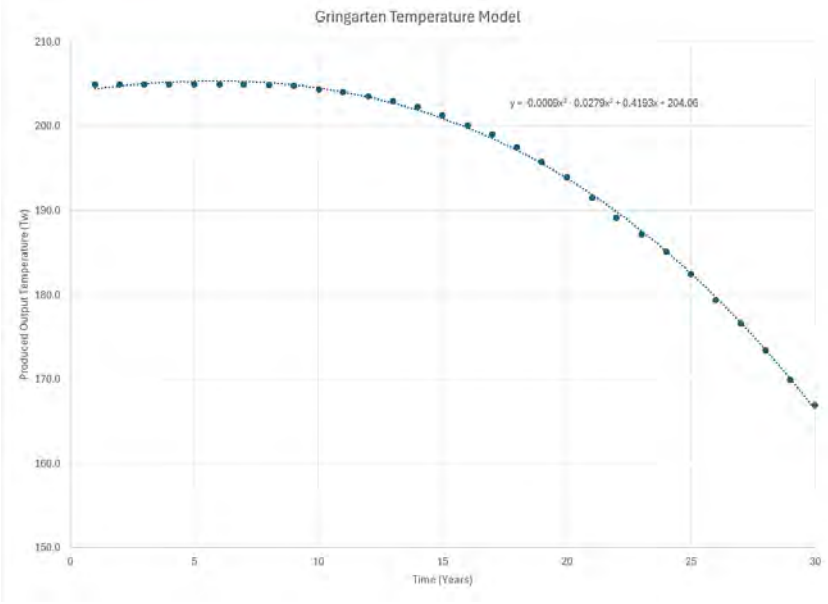

Figure 7: Thermal decline of theoretical EGS using Gringarten's model (Gringarten et. al., 1975).

There is criticality of designing an ORC to optimize the pinch point between the produced water and the working fluid. Understanding that the plant can be optimized for initial production based on the data gained in the exploration well, as the thermal decline occurs the plant efficiency will decrease, this is graphically depicted in figure 7.7 of the MIT report for flash plants. The economic model's maximum Temperature decline is 40˚C, as compared to Augustine's maximum decline (Augustine, 2011) of 32˚C. However, to account for the thermal decline and for the separation from the pinch point, the economic model assumes a linear 1.2 % loss in power generation for

every 1˚C drop in thermal decline, severely decreasing the electrical output in later years. In actual operations, similar to oil and gas fields, "infill" wells will most likely be drilled starting in year 20, to deeper, untapped resources to maintain higher heat, extending the plant life to 40+ years for a marginal cost.

2.4. Defining and Quantifying Parasitic Losses

Within the hydrothermal industry, parasitic loads are the electrical loads required to run the binary pumps, cooling tower fans, lighting, control room, and other equipment on site necessary to run the facility (DiPippo, 2016), typically around 8%. However, many economic models assume a fixed operating expense and overlook the variability of power needed (and associated costs) that EGS systems require due to the power required for the circulation of a significant amount of water. In the Gringarten model above, the required water circulation is estimated to be over 11,000 barrels of water per day (BWPD) for every MW of electricity produced at 205˚C. Previously, water circulation loads were calculated to be as high as 10% (Banks, et al., 2020) in Clarks Lake. However, this analysis was not for deep horizontal wells and considered friction loss to be insignificant. In deep, horizontal EGS systems, friction must be considered.

In this analysis, it is assumed that the resource is 9,845 ft deep, requires a horizonal lateral length of 7,920 ft, 55 frac stages, at a spacing of 144 ft between stages, with a total flow rate of 56,000 BWPD (~1,020 BWPD per frac). Later, these dimensions will be used with various wellbore architectures to demonstrate the frictional impact and resulting parasitic losses on EGS through Nodal Analysis.

Calculating the friction of the system for the parasitic losses was developed through a process of nodal analysis, using the inside diameter and the roughness of the tubulars combined with the density and viscosity of water (at temperature) and the friction within the fractures themselves. These properties were used to calculate the Reynolds numbers and Moody Friction Factors to generate the head loss in each node which was converted to psi. Six models were created for 9-5/8" 47ppf casing; 7" 35ppf casing; & 4" 11ppf tubing, each at 60˚C for injection and 205˚C for Production. These curves are identified in the appendices.

Once the friction loss models were created, the program was able to generate wellbore profiles with the following dimensions for both the producers and injectors (unless noted):

7" casing across the reservoir with 9-5/8" casing to surface

7" long string from TD to Surface

4" 'conformance string' across the reservoir with 9-5/8" casing to surface

4" 'conformance string' across the reservoir with 7" casing to surface

It is important to note that for casing burst calculations during stimulation, we required a burst strength of greater than 10,000 psi across the reservoir. Combining this requirement with the impact of thermal cycling on high strength alloys we did not evaluate 9-5/8" across the reservoir. This may be possible with special alloy tubulars.

The nodal model then calculated the frictional impact across the tubulars to the top of the reservoir, then the friction to each fracture initiation point based on the distance between stages. As the flow in the wellbore decreased at each node, the model calculated the new friction loss to the next fracture initiation point until the end of the well was reached.

To calculate the friction loss through the fractures the results from Blue Mountain were evaluated using the relationship of pressure drop/ft of fracture (modified to fracture ½ length since the project was a doublet) vs BPD fluid/ft fracture height, (Pearson, 2001). According to Titov (Titov, et al. 2023) the average fracture height was estimated at 800 ft and the average fracture half-length was estimates at 800 ft using micro seismic and fiber optic data. However, the average distance between wells was estimated at 365 ft and the effective fracture height was estimated to be 300 ft by Norbeck (Norbeck and Latimer 2023) and these numbers were used for the calculation. Using this data from Norbeck, to get the injection pressure vs rate and corresponding production rates and pressures, the model described above used nodal analysis to solve for the pressure losses in the fractures to generate Figure 8. The resulting model and regression for friction loss was history matched against Blue Mountain and found to be accurate.

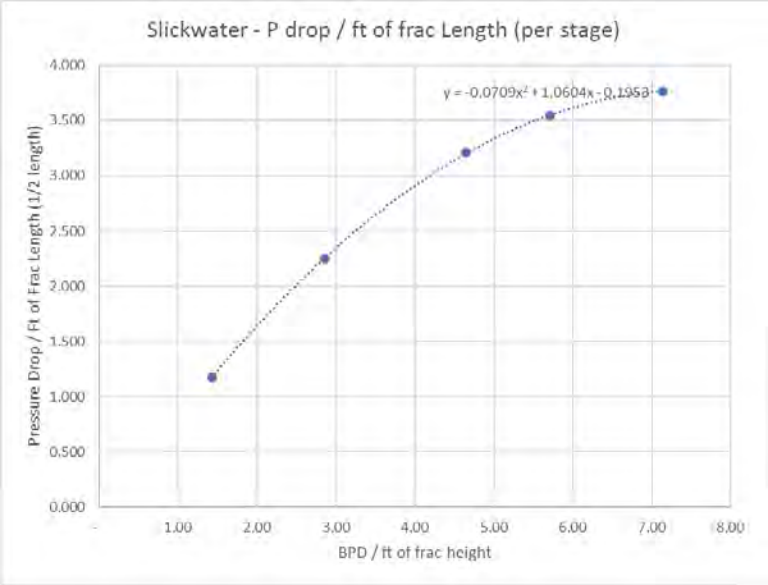

Figure 8: Calculated friction losses in the fractures of Project Red using 70/140 equivalent proppant.

Using API data, (Pearson, 2001), it is well established that the permeability of ceramic proppant, or even 30/50 Ottawa sand is significantly higher than the 70/140 equivalent sand that was pumped at Blue Mountain. At a closure stress of 5,000 psi, the API permeability of 40/70 bauxite is over 7 times greater, and 30/50 Ottawa is 2.4 times greater. One then can make a modest assumption that with improved fracturing technology the pressure losses within the fracture could be reduced by 66%. Thus, in our example with 56,000 BWPD traveling through 55 fractures, this change in proppant could have a required pressure decrease for the system of over 300 psi.

Using the same methodology outlined above for the friction losses returning up the producer, the entire pressure loss of the system can be calculated and the required HHP calculated for either a doublet or a triplet and used to define the system's parasitic losses.

Using the hypothetical doublet used in Gringarten's thermal model, and the well architecture described in Norbeck's paper (Norbeck and Latimer, 2023) on Blue Mountain, the pressure drop with a 7" long string from Surface to TD in both the injector and the producer can be calculated. Using a reservoir depth of 9,845 ft (3,000 m) and a lateral length of 7,920 ft, with 55 fractures, 144 ft between fractures and 56,000 BWPD the model can calculate the expected pressure drop in the system. In this scenario the expected pressure drop of the system is 3,104 psi.

$$HHP = \frac{P_{pump}(psi) \cdot q_{inj}(gpm)}{1714} \tag{9}$$

For example, an injection rate of 1,764 gpm and pressure drop of 3,104 psi, the required HHP to run the circulating system is 3,130 HP.

2.5. Thermal Decline

The concept of accelerated thermal decline due to "Short Circuiting" was further examined by Doe (Doe, McLaren and Dershowitz 2014). The team analyzed thermal decline using the initial Gringarten model (Gringarten, Witherspoon and Ohnishi, 1975) with 10 uniform fractures, then refined the model further by adding variations:

(a) Initial model (for direct comparison to Gringarten) :10 uniformly spaced, parallel fractures with uniform apertures.

(b) As (a), with variable fracture spacing and constant fracture transmissivity (aperture assumed based on a cubic law).

(c) As (b), Variable fracture spacing and lognormally distributed fracture transmissivity.

(d) As (c), with increased aperture coefficient of variation.

(e) As (c), with decreased aperture coefficient of variation.

(f) As (c), with fractures defined by a distribution of fracture size, orientation, and intensity based on a field case study.

The first analysis looked at 10 uniform fractures with varying fracture spacing to understand the impact on spacing assuming a total flow rate of 0.15 m3/s (81,500 bbl/day), or a rate per fracture of 0.015 m3/s (8,150 bbl/day) for 1,000 m x 1,000 m fractures (Figure 9).

Doe noted two major effects by modeling the scenarios (b) through (f) above. First, the temperature maps show that thermal interference and more rapid thermal depletion occurs in areas of great fracture density. This is independent of the aperture or fracture conductivity. The second observation was that variable apertures create variable breakthrough times or 'short circuiting' among fractures with considerably more aperture or fracture conductivity, Figure 10.

Doe found that using a variable aperture negates much of the advantage of distributing flow over multiple fractures that the Gringarten model predicts due to the second power relationship of dimensionless time to rate. This data was plotted on the familiar outlet temperature vs. time and the impact of the thermal decline from 'short circuiting' could be visualized, Figure 11.

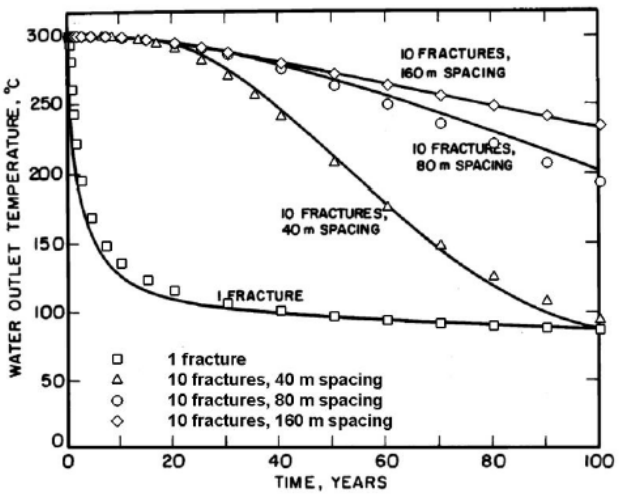

Figure 9: Water outlet temperature for Gringarten example with Frac Spacing increasing (Doe, McLaren and Dershowitz 2014).

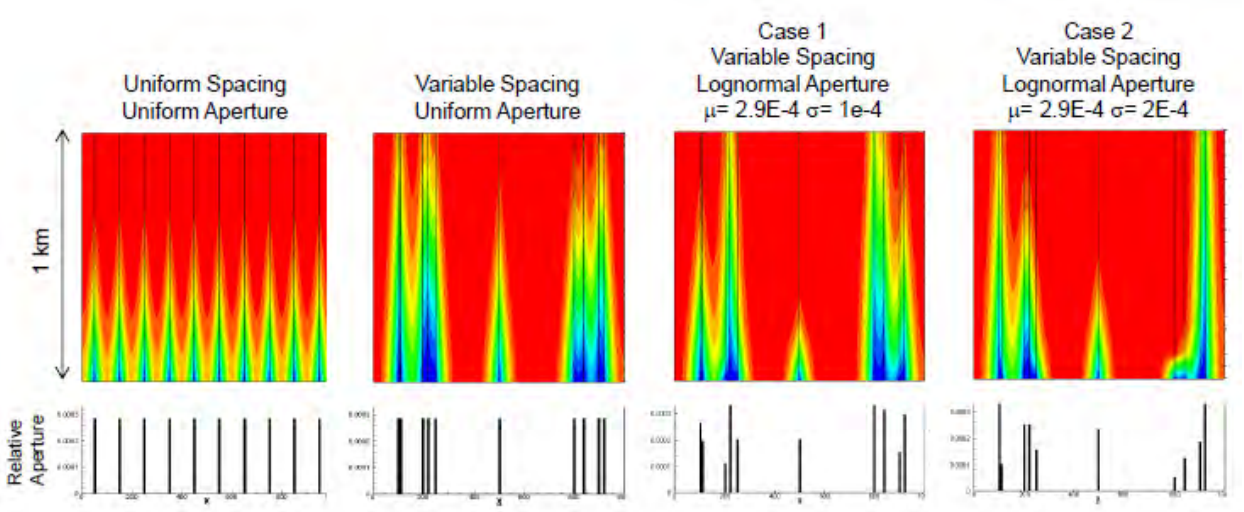

Figure 10: Heat maps for parallel fractures using variable spacing and fracture conductivity (Doe, McLaren and Dershowitz, 2014).

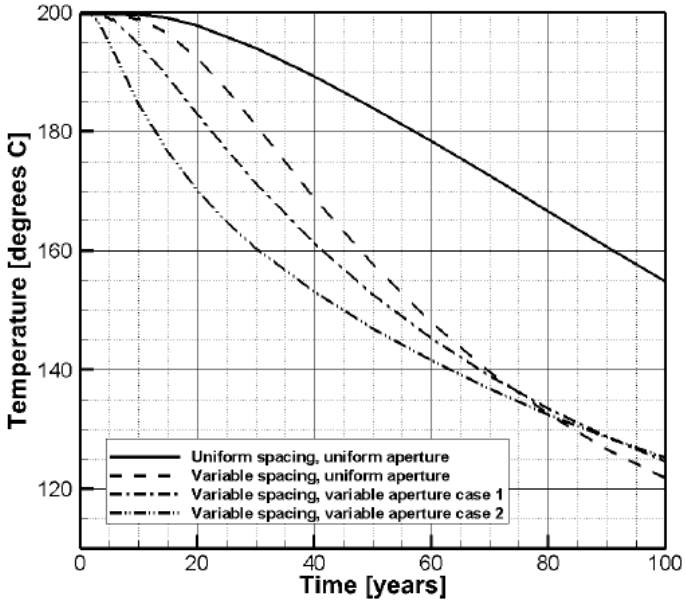

Figure 11: Impact on temperature output for variable fracture spacing and fracture conductivity (Doe, McLaren and Dershowitz, 2014).

2.6. Predicting Thermal Decline

The EGS project at Blue Mountain has fundamentally changed the EGS industry. For the first time, models created by early innovators can be compared against actual data from an EGS site that uses a horizontal injector and producer connected by multiple fracture stimulations. The two wells were drilled to a vertical depth of approximately 7,700 ft., and each had a horizontal lateral section of roughly 3,250 ft. Both wells had 7", 35 ppf, P-110 production casing run from surface to TD. The average offset spacing was 365 ft. The Injector was completed with a total of 16 stages with each stage having approximately 150 ft. All stages except stages 12 and 13 had 6 clusters per stage and 6 shots per cluster. Stages 12 & 13 had 9 clusters per stage and variable shots per cluster. The proppant was a mixture of 100 mesh and 40/70 mesh silica sand. The producer was completed in a similar technique with a total of 20 stages.

The first published injection profile from Blue Mountain showed just how different the reality of the injection profile is as compared to Gringarten's very simplified model of uniform fractures. Of approximately 18,100 BWPD of injection during the spinner survey there was a wide discrepancy of water per stage. Table 2 and Figure 12 show the stage, vs water injection allocation at Blue Mountain EGS.

Table 2: Blue Mountain Injection allocation

Stage	Approximate Injection Allocation (BWPD)
1	1,150
2	250
3	1,000
4	100
5	1,300
6	1,650
7	600
8	2,000
9	2,100
10	2,550
11	400
12	1,000
13	1,200
14	1,100
15	700
16	1,000
Total	18,100

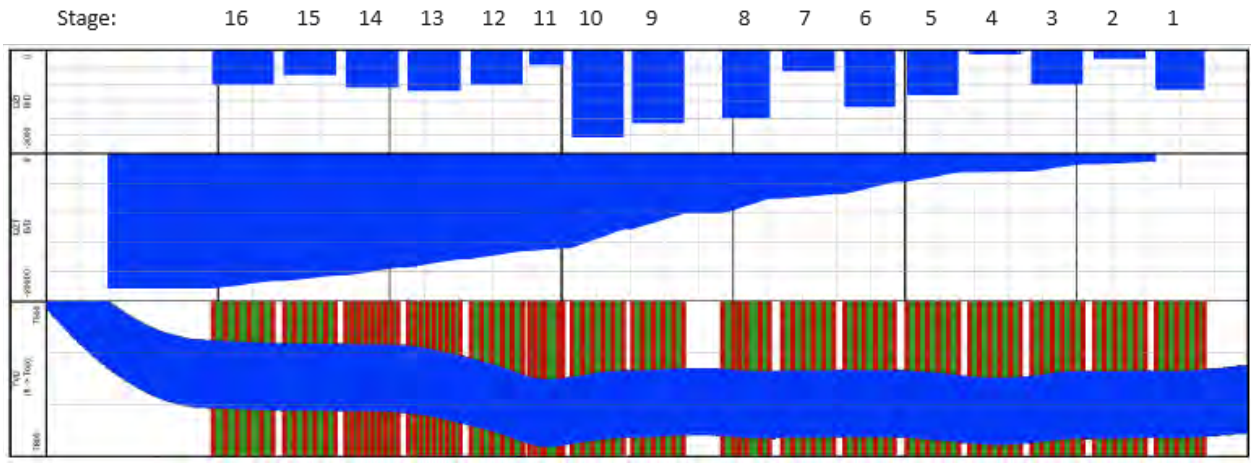

Figure 12: Blue Mountain spinner survey showing the amount of fluid allocated to each frac cluster (Norbeck and Latimer 2023).

2.7. Economic Impact from a Lack of Conformance Control

Using the data generated at the Blue Mountain site combined with the Gringarten Model, the predictions generated by Doe et al. can be evaluated and put into an economic model. The flow rates noted above were distributed into quartiles for the evaluation (Figure 13).

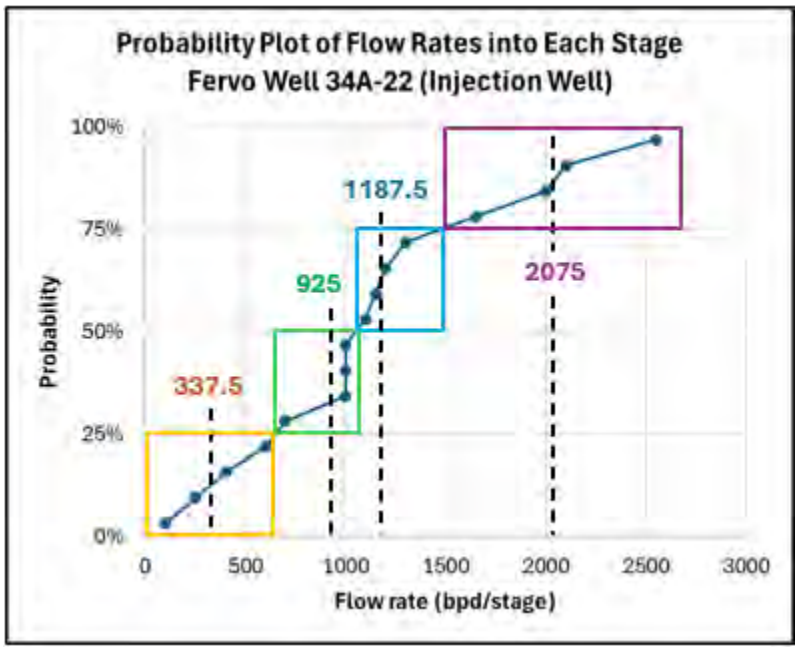

Figure 13: Flow distribution at Blue Mountain by quartiles.

Using the resulting flow rates per stage for each quartile, the flow distribution can be allocated to our theoretical well's Gringarten model using the following Table 3.

Table 3: Allocation of flow for Gringarten Model based on Blue Mountain

Flow Stream	FERVO Blue Mountain Project		This Paper
	Flow Rate (bpd/stage)	Normalized Rate (Rate/Avg. Rate)	Flow Rate (bpd/stage)
1st Quartile	338	0.298	304
2nd Quartile	925	0.818	832
3rd Quartile	1,188	1.050	1,068
4th Quartile	2,075	1.834	1,867
Average	1,131	1.000	1,018

These flow rates were then proportionally distributed into the theoretical well using Gringarten type curves. Using MATLAB, thermal decline curves were generated for each set of fracture by interpolating dimensionless time, dimensionless temperature and dimensionless half-fracture spacing. The decline for each quartile and the composite thermal decline using flow balance was plotted against the original Gringarten curve in Figure 14.

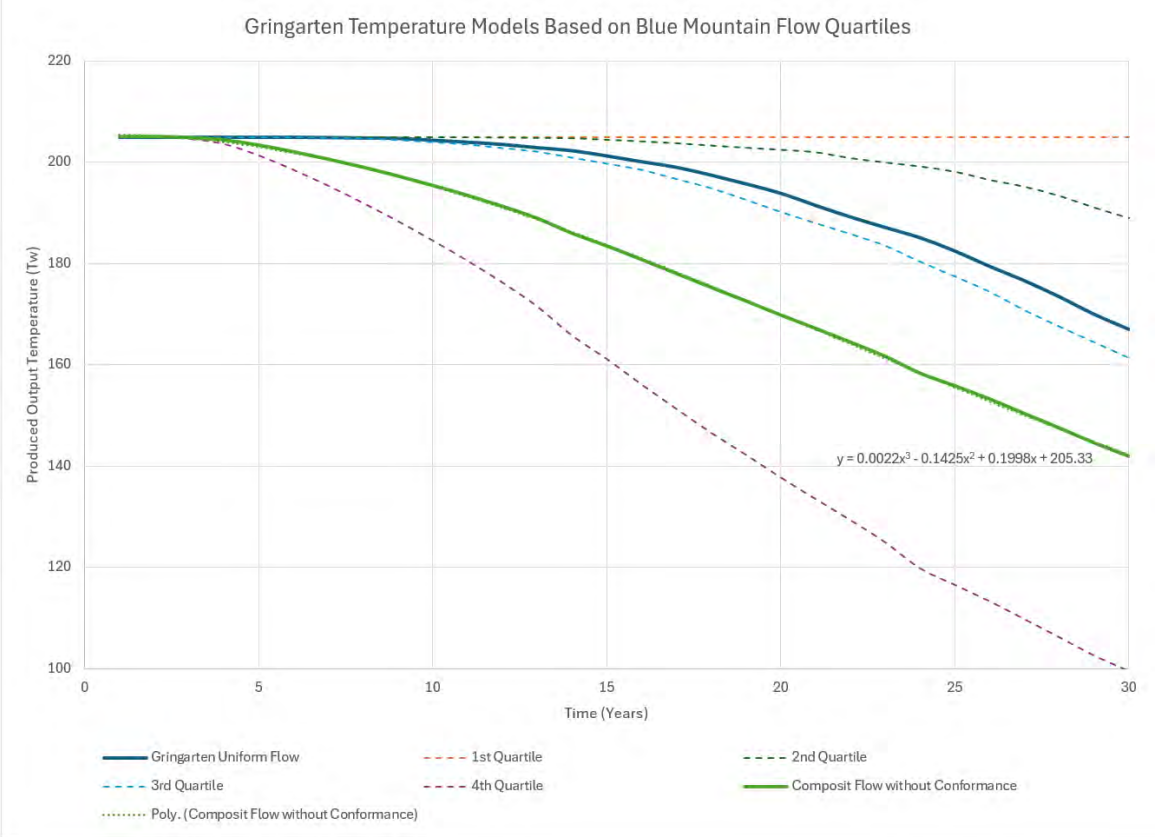

Figure 14: Gringarten temperature models based on Blue Mountain flow quartiles.

Using Figure 14, the impact of the short circuiting can be visualized with three areas that are of major concern. First, the composite decline curve for short-circuiting starts considerably earlier, in this case as early as year 3 with short-circuiting vs. year 10 with conformance control. Second, the rapid separation of the short-circuiting composite curve causes the short circuit system to reach the 25˚C decline mark 10 years earlier than conformance control curve. Third, the 1st and 2nd quartiles (50%) of the resource show limited heat harvesting in the first 20 years and essential no heat harvesting for the duration of the project in the 1st quartile.

The impact on power production follows the same trends. Figure 15 examines the Gringarten models for the system given conformance as well as short circuits. The calculations use a plant up time of 90%, the power conversion factors discussed earlier of 4.36E-07 MW-hr / (˚C·BWPD), 8% ORC plant parasitic loads, and the temperature predictions from Figure 14. The short circuit's temperature drops below the critical 3.0 MW of electricity generating capability by year 15 and generates 26% less total electricity during the 30-year life of the plant.

2.8. Introduction to "Perf and Plug" vs. Sleeves

Similar to Blue Mountain, the standard completion design for EGS has defaulted to the "Perf and Plug" technique. This has been used exclusively at Project Cape as well as all non-open hole stimulation at Forge. There are significant advantages to "Perf and Plug" that has made it a favorite among completion engineers, the largest being cost. Thanks to the advancements in the shale boom from the early 2000's through today, the cost have dropped significantly for this technique. Additionally, the reliability of the perforating guns and the plugs has improved.

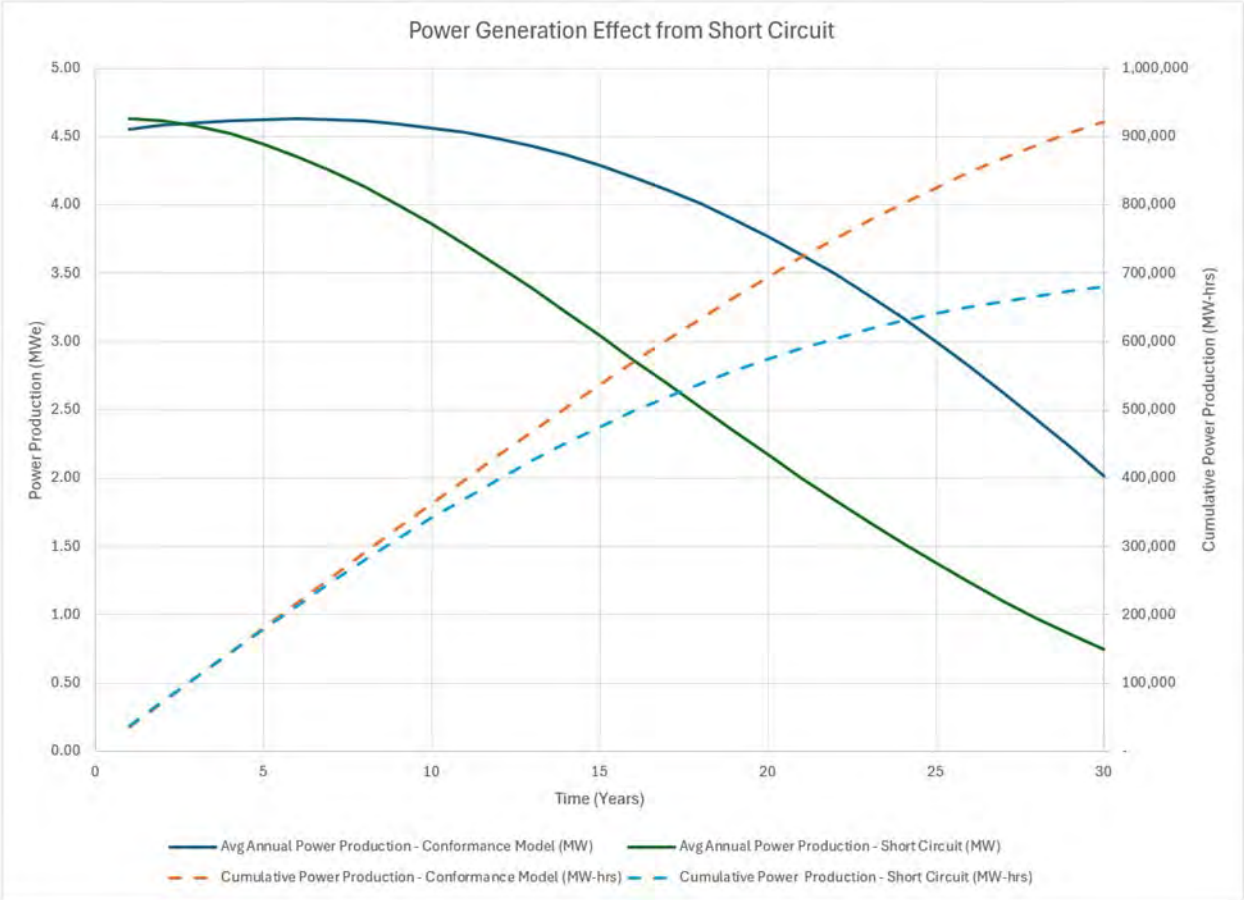

Figure 15: Power generation differences between conformance control and short circuits.

Unfortunately, "Perf and Plug" comes with a major disadvantage. Once perforations are shot through the casing and fracture stimulated, the only effective way to shut them off or slow down injection through the short circuits is to run an inner-string with multiple packers and outflow control devices (OCD). A typical conformance design using inner-string consists of the original 7" casing, perforated and stimulated in 50-150 locations down the wellbore. A 4" inner-string would be run across the injection interval using a packer to separate each stage with an OCD located between each packer to control flow into each interval where there is a short circuit.

Unfortunately, this system has two major drawbacks. First are the frictional losses described in the Nodal Analysis section increase over 17 times at injection temperatures and 1,500 gpm. Second the reliability of packers is unproven at these temperatures, compounded by the cyclic loading of cool (150˚F) injection temperature followed by 400˚F reservoir temperatures during shut in periods.

The oil and gas industry has tried to use gels, cement, and other chemicals to manage injection conformance control over the years, all with very limited success. The combination of difficulty using this technology to manage conformance in 3,000-8,000 BPD injectors at 150˚F, with the increase in difficulty of EGS requiring 60,000-120,000 BPD at temperatures in excess of 400˚F creates significant doubt in the viability of these options in EGS.

The alternative to “Perf and Plug” that is currently used in the shale market, predominately in Canada, is the frac sleeve technology. The advantage to the frac sleeve is that if the sleeve is designed properly, the sleeve and be shifted back into the closed position to shut off a short circuit without giving up internal diameter in the casing and inadvertently increasing friction pressure and parasitic losses.

Additionally, technology is being investigated that will allow for an OCD to be built directly into the sleeve allowing for a regulator position that will limit the injection into short circuits, preventing the premature cooling of the system, but still allowing for the heat to be harvested from that section of the reservoir.

2.9. Modeling the Impact of Inner-Strings on Friction

Using the same flow loop as described in the Nodal Analysis section the only realistic ability to implement conformance control in Perf and Plug is with an Inner String. Figure 16 is a graphical depiction of how a 4” Inner-String system would look in 7” casing.

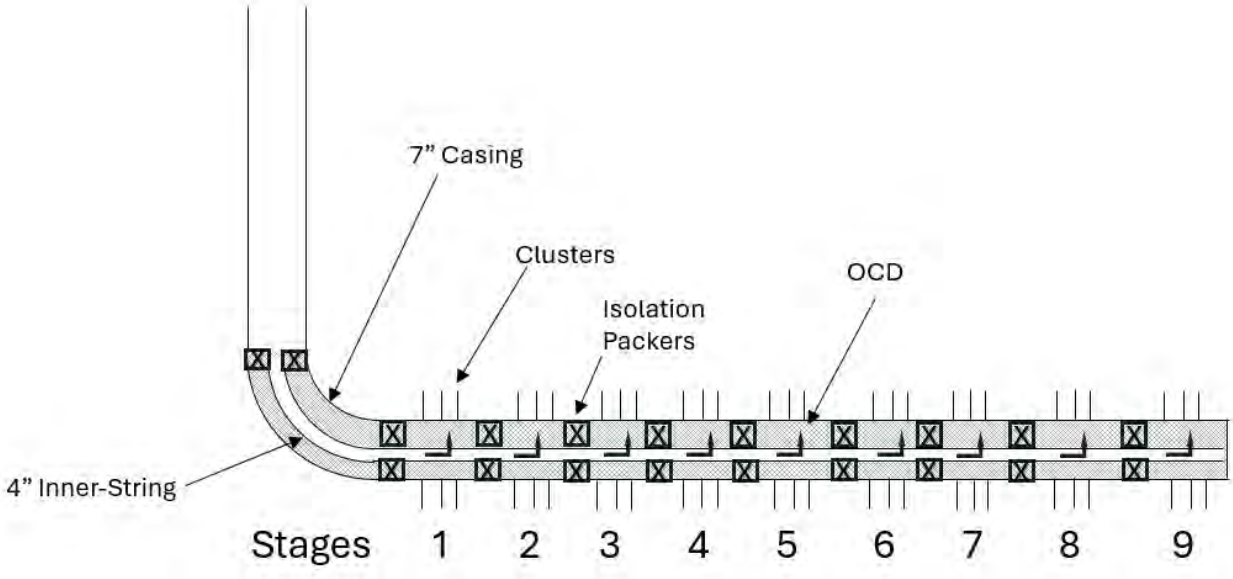

Figure 16: 4" Inner-string in 7" casing with outflow control devices.

Returning to the Nodal Analysis described earlier for the hypothetical doublet using 7” casing in both the producer and injector, 55 frac stages and 56,000 BWPD, the system required 3,130 HP. Assuming the same system, but on the injector only, there is a 4” conformance inner string run from the top of the 1st stage (10,930 ft MD) to the bottom of the well (17,765 ft MD) the power requirement to circulate the water jumps to 6,207 HP. Converting this to power with an 80% pump efficiency results in 5.8 MW, or 115% of the power produced.

$$MW_e = \frac{HHP \times 0.000745699}{\eta_{pump}} \tag{10}$$

This exercise shows quickly that if “Perf and Plug” is chosen as the completion alternative, then there is not an economic alternative for conformance control.

Alternatively, the ability to maintain full bore with the sleeves and having the ability to shut off short circuits or in the future be able to install regulator positions within the sleeves will allow for a system of conformance control without significant impact on the economics.

2.10. Parasitic Loads for Different Well Architecture

Using the same flow loop as described in the Nodal Analysis and the Impact of Inner-Strings on Friction an analysis was performed of different wellbore architectures. The reason for performing a deep dive on these variables is the theoretical EGS system that was analyzed in this paper assumed the Blue Mountain design with 7” long strings of casing in both the injector and the producer. This design indicated that to circulate 56,000 BWPD for 55 stage EGS with 144’ spacing, the system would require 3,130 HP. This is the equivalent of 2.9 MW of electricity or 58.3% of the electricity generated prior to plant parasitic losses. Table 4 examines the parasitic losses as a function of the wellbore architecture. The critical insight gained from this data is that for the required rates to generate greater than 5 MWe per well, the friction of the system becomes a dominant variable. The numbers for production and injection 7” long strings are consistent with Blue Mountain in Norbeck (Norbeck and Latimer 2023), where parasitic losses of 0.5 to 1.0MW were observed in a considerably shorter (~2,400’) injection interval and using lower rates (800 GPM or 27,000 BWPD Injected). The model used for this paper estimated 0.6 MW of parasitic losses for Blue Mountain at 800 gpm.

Table 4: Parasitic Losses as a Function of Well Design

Injector Architecture	Producer Architecture	Doublet / Triplet	Injection Rate (BWPD)	Friction Losses (psi)	Parasitic Losses (MWe)
7” Long String	7” Long String	Doublet (5MWe)	60,480 (8% fluid loss)	3,041 psi	2.9 MWe
7” Long String + 4” Inner-string	7” Long String	Doublet (5MWe)	60,480 (8% fluid loss)	6,031 psi	**5.8 MW**
9-5/8” x 7” Liner	9-5/8” x 7” Liner	Doublet (5MWe)	60,480 (8% fluid loss)	1,426 psi	1.4 MW
9-5/8” x 7” Liner + 4” Inner-string	9-5/8” x 7” Liner	Doublet (5MWe)	60,480 (8% fluid loss)	4,416 psi	4.2 MW
9-5/8” x 7” Liner	9-5/8” x 7” Liner	Triplet (10MWe)	120,960 (8% fluid loss)	2,639 psi	5.1 MW
7” Long String	7” Long String	Triplet (10MWe)	120,960 (8% fluid loss)	6,847 psi	**13.1 MW**

Critical insight gained from this modeling effort is the impact of the 7” long string as compared to using a 9-5/8” casing set above the resource with a 7” liner through the resource interval. This change in design can reduce the parasitic loads by over 50%. Additionally, without converting to

a casing / liner design or increasing bore sizes considerably to an 8-5/8” or 9-5/8” long string, the frictional impact for the triplet’s flow rate is detrimental to the economics of the project.

There are multiple reasons why casing long strings can be preferred, including operational efficiency and the ability to run fiber optics. However, all advantages of a long string over a liner must be weighed against the cost of the parasitic losses incurred with the additional friction vs. a liner.

3. Conclusions

1. Generation of geothermal electricity in the United States has stagnated between 1.5 GW and 1.9 GW since 1990. The primary cause of this stagnation is the lack of new hydrothermal reservoirs discoveries.
2. To grow geothermal power generation, geothermal power generation using Enhanced (or Engineered) Geothermal Systems (EGS) has tremendous potential. New technologies are being developed to provide economies of scale and low thermal declines needed to provide economic power generation.
3. Key variables impacting the economics of EGS power generation are the thermal decline, flowrate per well, parasitic losses and success of conformance control.
4. Parasitic losses are defined as the electricity used to power a geothermal field and power plant that does not contribute to the net electric power yield of a plant for transmission.
5. Frictional losses in the wellbore and in hydraulic fractures across various well completions geometries must be optimize for an economic EGS development.

Drill Bits, PDC, granite, ROP

ABSTRACT

Building upon successful test wells in the Utah FORGE geothermal project, a Service Company partnered with Fervo Energy to continue production wells in the application. A case study from Utah is presented on reducing drilling days on a granite geothermal well using innovative polycrystalline diamond compact (PDC) drill bit technology.

A critical deliverable in the drilling program was to increase distance drilled with PDC bits in the 12.25-in vertical and 8.75-in curve sections. Drilling through hard and abrasive formations in the Utah application can increase cutter wear and shorten bit life. The lithology consists of igneous granite with pockets of metamorphic gneiss with rock hardness unconfined compressive strengths (UCS) of 33-40k psi. The continuous improvement process led to aggressive new product development resulting in improved dulling conditions and greater distances drilled.

Reduction in drilling days from well to well was achieved in both the vertical and curve sections. The custom PDC designs were comprised of longer profiles with extended shoulders for durability and parabolic cones for high weight on bit (WOB) operating parameters. Strategic placement of multi-dimensional shaped cutters across the cutting structure provided valuable advantages to enhancing efficiency and durability. A record run drilling 936 feet was achieved in the 12.25-in vertical section. This was a fifty percent increase in distance drilled compared to the next best offset. And a benchmark was set in the 8.75-in section with one bit completing the curve. This was an improvement over the first well which required four bits to complete the curve.

For decades, legacy roller cone drill bits have been used to drill geothermal wells at slow penetration rates. The learnings from this Utah application are chartering a new path of exceptional drilling performance utilizing PDC drill bits. The application of this technology is making the uptake of geothermal wells economic and successful.

1. Background on Drilling Geothermal Wells

Geothermal applications are diverse in terms of rock hardness, temperature and overall formation drillability. Roller cone drill bits were the first to slowly hammer away at volcanic formations. In Finland the Tricone drilled a granite with UCS of 560 megapascal (MPa), equivalent to 81 kilo pound per square inch (k psi) (Cardoe et al, 2021). And in Iceland the Tricone drilled an application where the circulating temperature was 300 degrees Celsius (Stefansson et al, 2018). Next came the Kymera hybrid drill bit which quickly became the reliable choice for drilling tough, interbedded lithologies such as those found in Turkey and the Asian Pacific Ring of Fire (Oueslati et al, 2019 and Lockwood et al, 2021). In these non-homogenous extrusive rocks the Kymera delivered improved drilling rates of penetration (ROP) over the Tricone, and was more consistent than PDC drill bits which were susceptible to impact damage. The recent push by the Utah FORGE project to drill geothermal wells faster has led to developments in PDC drill bit technology. Documentation by Dupriest et al in 2022 and 2024 details the learnings and advancements to improving drilling penetration rates in igneous granite and metamorphic gneiss. Testing focused on the physics-based, limiter-redesign workflow to address specific changes in drill bit design – such as extending the safe operating limits of bits beyond the industry's common practices, and the impacts of bit aggressiveness and ROP decline.

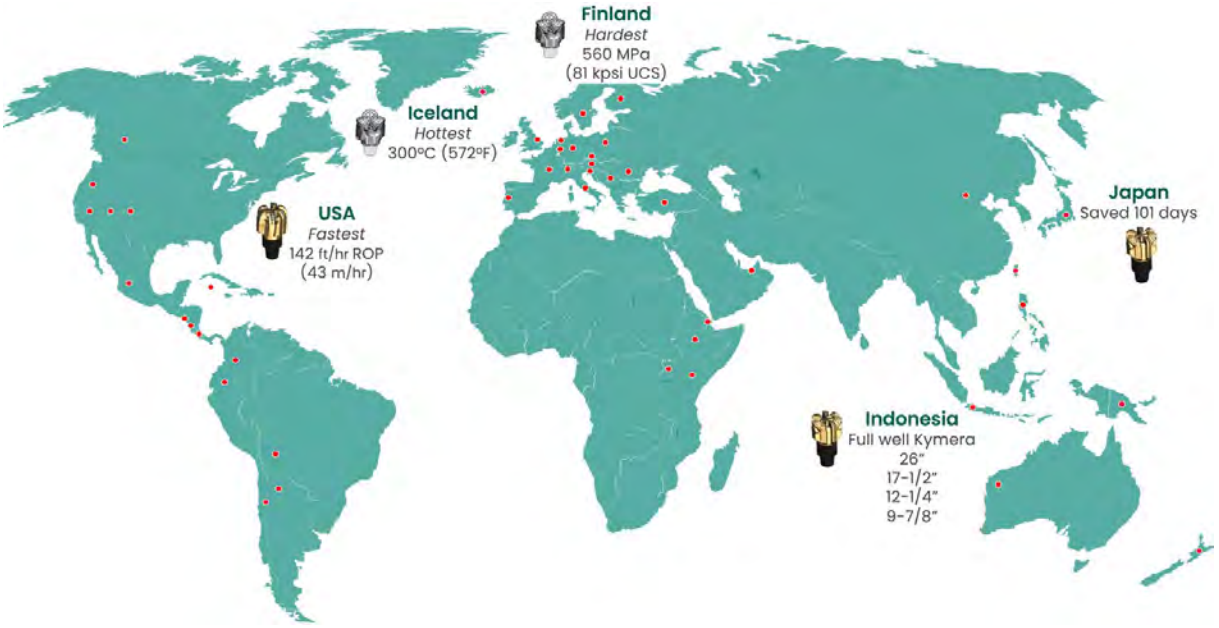

Figure 1 – Geothermal Drill Bit Solutions for diverse applications.
Red dots designate the Service Company's successful experiences in geothermal wells.

2. Learnings from Utah FORGE

Drilling efficiency was the key in the Utah FORGE project. Two important drill bit design learnings from the testing are 1) frame integrity to withstand extreme loading, and 2) efficient cutting structure to achieving faster ROP. The granite and gneiss in the Utah application are relatively homogenous and lends itself to be drilled with PDC, however the high rock strength

posed the main challenge. Simply put, a great deal of power is needed to drill hard rock, and the drill bit must stay sharp to drill faster and further.

Figure 2 – Utah FORGE core samples. Granite at left with rock strength 33-40k psi, gneiss at right. The granite formation top begins around 3,000 – 4,500 ft TVD.

In FORGE, 9.5-in PDC bits were tested on a mud motor bottomhole assembly (BHA) in a vertical and tangent well using upwards of 67k lbs of WOB and 235 rpm at the bit. By comparison, drilling a shale gas well with a similar sized PDC bit would require only half the WOB. A 3D drilling simulation software was used to optimize a cutting structure profile with strategic placement of multidimensional cutters. The 6-blades drill bit achieved a record ROP of 142 feet per hour (ft/hr). Offset runs using different drill bits yielded only 90 ft/hr – 36% slower. The reservoir static temperature of 440^{o} F (225^{o} C) at 8,000 – 9,000 feet total vertical depth (TVD) was not an issue for the PDC bit which has no moving parts. In addition the actual circulating temperature was significantly lower.

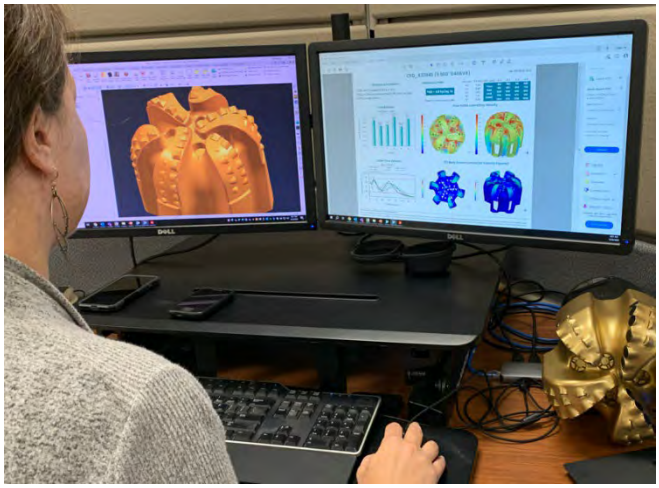

Figure 3 – Field-Based Design Engineers work closely with Operators in developing solutions. Shown on the computer screen is the original 9.5-in design from the Utah FORGE project.

Drilling Simulation Software

The 3D bit drilling simulation software is the first step to creating a robust and durable cutting structure for geothermal applications in igneous and metamorphic lithologies. A primary feature of the design methodology, the software creates advanced simulations that guide the selection, manufacture, and deployment of the optimal drill bit for specific hard and abrasive well conditions. The value proposition for the drilling simulation software are further documented by Duffy et al, 2022 and Russell et al, 2022.

The software models drill bit-rock interactions using a polygonal surface mesh that consists of connected faces to form 3D representations of the bit and rock. The polygonal mesh brings greater versatility to complex models by simulating how different bit designs and cutter layouts respond to changes in complex bit and bent motor motions, formation variations, PDC geometry, cutter size and shape, bit body changes, and diamond table thickness. The software also simulates bit performance in a range of different BHAs and drilling environments. The simulations consider drilling loads on cutters, depth-of-cut control elements, the bit body, and gauge pads. These loads are added to predict weight on bit, torque, ROP, steering force, and other operational parameters.

The full bit drilling model also incorporates a cutter overload integrity response surface model, which relies on applied pressure at the bit and cut area values to predict cutter stresses. Overload integrity risks are plotted on 3D color plots that display the predicted stresses for each cutter along the bit profile. In addition, a cutting aggressivity model characterizes the aggressiveness of different shaped cutter designs as they shear through the rock face. The software includes several grid model drilling simulations that assess how changes to cutter geometry impact drilling performance. These grid model simulations lend themselves to an iterative process that validates small changes to cutter design and layout—without the added time and cost of manufacturing and field-testing each design. By characterizing overload integrity and aggressivity—and then performing design iterations to optimize these values—the software helps pinpoint a bit design that offers improved stability and higher ROP at a lower cost per foot.

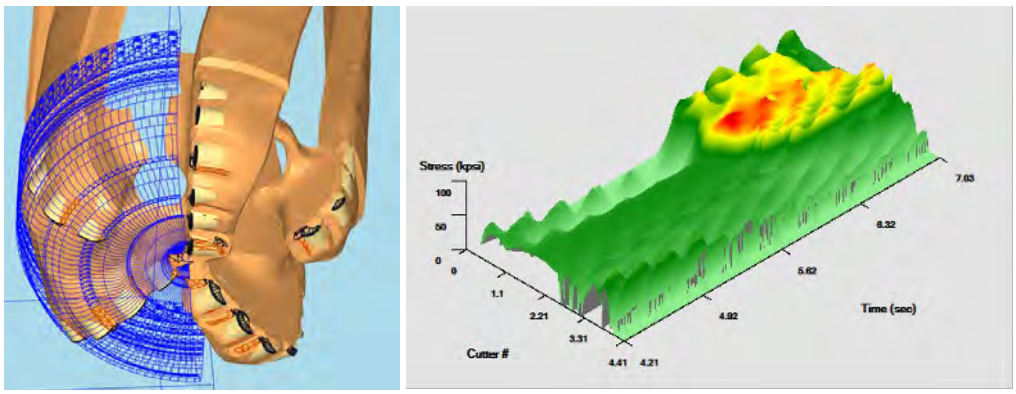

Figure 4 - Modeling drill bit-rock interactions using a polygonal surface mesh (left). A 3D cutter overload integrity risk plot highlights areas of highest cutter stress while drilling (right). With this information, the bit design team adjusts the model to minimize cutter stresses to acceptable risk levels.

Cutting Structure Profile

Stability and preventing cutter wear are primary focus for PDC bits. In high UCS applications, diamond bits can be prone to lateral or torsional instability leading to accelerated cutter wear. If the PDC cutters can remain sharp, then it will continue to achieve acceptable drilling rates of penetration whereas a dull bit will become slow and inefficient. Cutting structure profiles with a parabolic cone are preferred to distribute the high WOB forces across the inner cone and nose cutters. Longer shoulder profiles are also best suited for hardrock applications for increased durability and to prevent initial cutter wear from instability. (Hanafy et al, 2024).

Hydraulics

The higher temperatures generated when drilling hard and abrasive lithologies coupled with the inherent downhole temperatures of the formation can accelerate cutter wear. Open layout designs with maximized junkslot area and face volume improves flow while multiple nozzles maintain cooling on the outer portions of the bit.

Cutters

Strategic placement of multidimensional shaped cutters across the profile have many advantages. A durable edge cutter in the cone of the bit absorbs loading and resists breakage when high weight-on-bit is applied to drill hard formations. A chisel shaped edge placed on the nose profile improves drilling efficiency. Shaped cutters apply point loading to increase drilling rates of penetration. The shoulder of the bit which sees the largest amount of wear benefits from a cutter that is both durable and efficient.

The chisel cutters also contain a unique nonplanar diamond table geometry which reduces friction and heat generation at the rock interface which improves overall drilling efficiency. The nonplanar geometry generates 25% less heat than conventional planar cutters. This heat reduction translates to a more durable cutting edge, less cracking and spalling, and a longer drilling run life. (Russell et al, 2022).

3. Develop 1 GW of Geothermal Power by 2030

Fervo Energy began a robust drilling campaign to bring one gigawatt (GW) of power online. To achieve this, investments are directed in the categories of Drilling, Completions and Surface Facilities with 40% of the spend on Drilling. The campaign calls for steady drilling of production wells in 2024 with significant ramp up by 2026 to meet market demand. (Source: www.fervoenergy.com)

The Utah FORGE test wells were drilled as vertical and tangent ending in 9.5-in hole size. By contrast these wells are planned as vertical, tangent, curve and lateral designs with the vertical and tangent sections drilled in 12.25-in and the curve and lateral sections drilled in 8.75-in. This directional well plan along with more common 8.75-in hole size relates well with standard oil & gas applications.

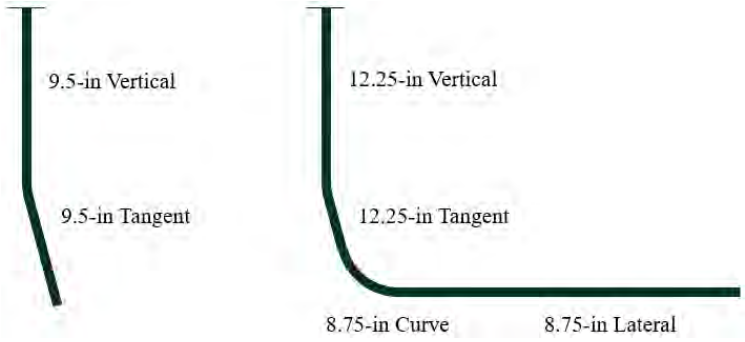

Figure 7 – Comparison of well profiles: test well at left; production well at right

4. Vertical 12.25-in Section

The performance in the 12.25-in vertical section is split into two sections based on UCS with an Upper section of low UCS, and a Lower section containing high UCS granite. PDC development was focused on the Lower granite section where drilling performance is critical for the operator's metrics. Some wells in this area had a shorter section of granite and could use aggressive bit designs while other wells needed more robust bit designs to drill over one thousand feet of granite. Based on this knowledge, three 12.25-in bit designs were selected to test using lessons learned from the Utah FORGE project. The first digit of the designation is the cutter size in fractions of an inch, and the last two digits are blade count:

- 6-blades/16mm (5/8-in) cutters – designated as 506
- 6-blades/13mm (1/2-in) cutters – designated as 406
- 7-blades/16mm (5/8-in) cutters – designated as 507

.

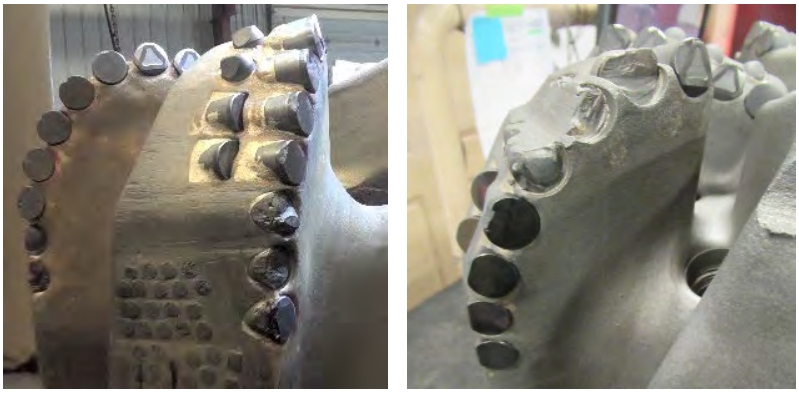

Figure 8 – Run 1 on 506 with gage cutter damage (left).
Run 2 on 506 with severe shoulder cutter damage (right).

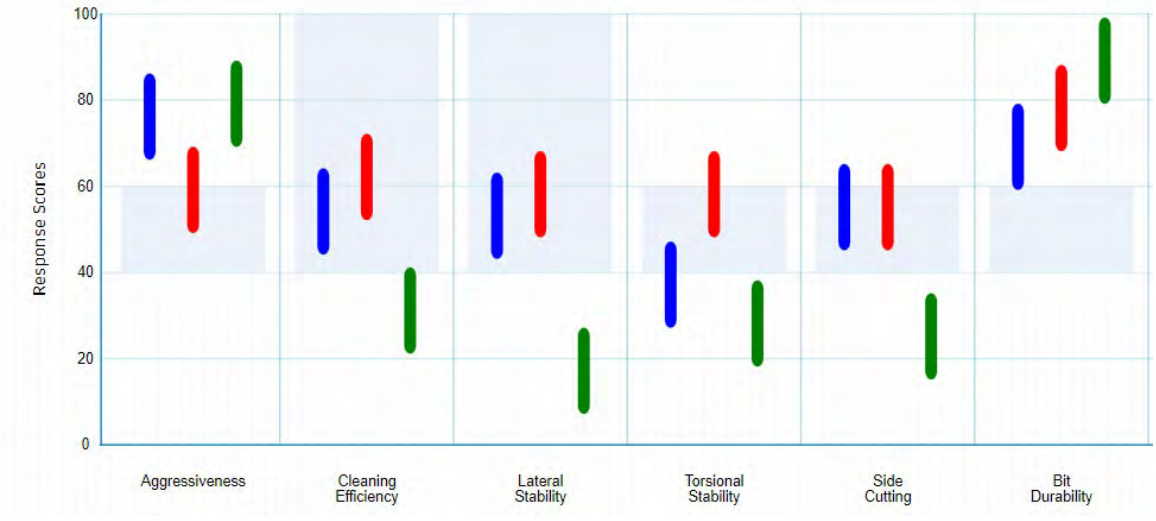

Figure 9 – Bit behavior comparison of the three 12.25-in bit designs:
506 (Blue), 406 (Red), 507 (Green)

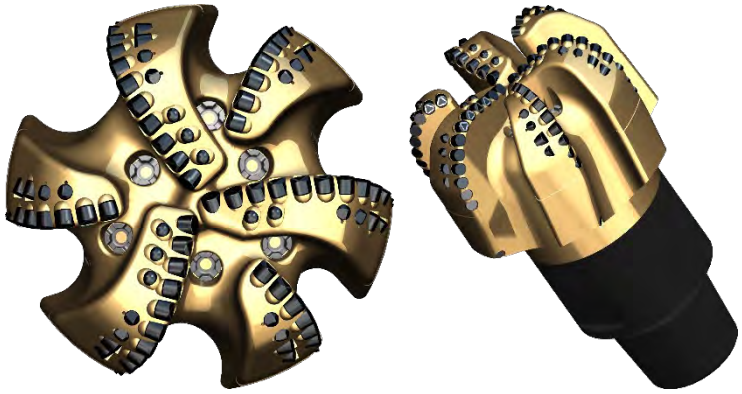

Figure 10 – 12.25-in 506 PDC Drill Bit with 6-Blades, 16mm (5/8-in) cutters, Depth-of-Cut Control for overload protection, and secondary cutting elements for durability and wear resistance

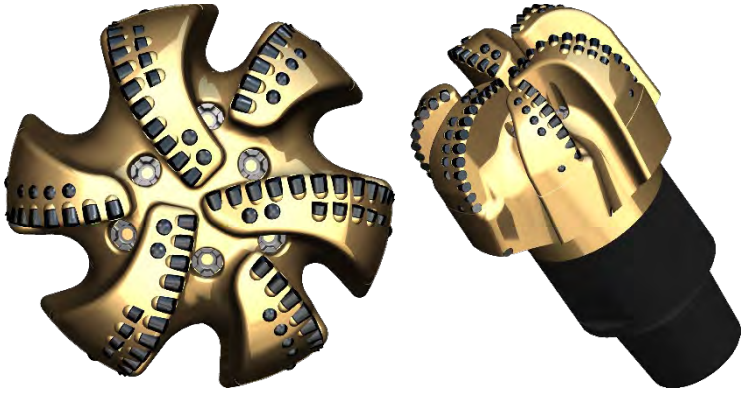

Figure 11 – 12.25-in 406 PDC Drill Bit with 6-Blades, 13mm (1/2-in) cutters, Depth-of-Cut Control for overload protection, and secondary cutting elements for durability and wear resistance

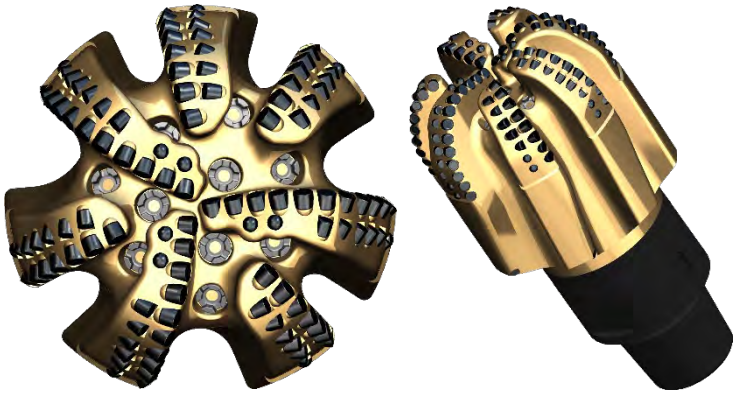

Figure 12 – 12.25-in 507 PDC Drill Bit with 7-Blades, 16mm (5/8-in) cutters, Multi-Port Hydraulics for cooling, Depth-of-Cut Control for overload protection, and secondary cutting elements for durability and wear resistance

The 506 was first to be tested with two runs in the Lower vertical. Dull analysis showed the design was not stable nor durable enough for this application. The first run drilled 1,281 feet to casing point and showed signs of lateral vibration with chipping on the gage cutters. The second run drilled 2,628 feet with surface data and dull confirming occurrence of stick-slip, leading to overloaded and broken cutters in the shoulder. See above Figure 8.

Due to future wells in this program requiring more distance to be drilled in the Lower granite section, two new designs were created to address the challenges of shoulder durability and overall bit stability that were seen on the 506. The next iteration, a 406, switched to 13mm cutters on the shoulder which increased cutter count by 15% to improve durability. It also introduced more depth of cut control for torsional stability. In addition a 507 was created to address the shoulder durability through an increase in diamond volume by adding an additional blade. Overall diamond volume increased 15% from the extra blade. A profile change increased the diamond volume in the shoulder by 52% compared to the 506 design. Figure 9 below shows the Bit Durability comparison for the three designs.

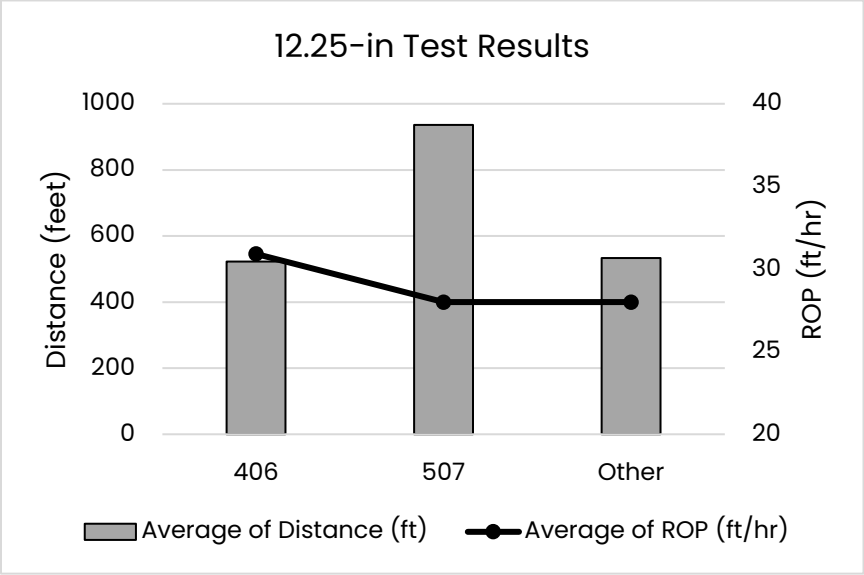

Figure 13 – Distance drilled and ROP metrics from tests on new PDC designs

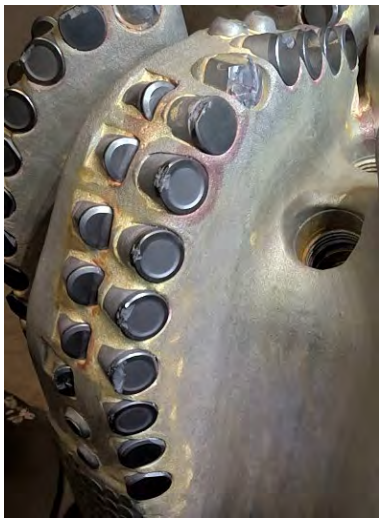
Evaluation of the 406 and 507 were done in a head-to-head test against a 6-blades/13mm cutters design from another provider. The 507 produced superior performance when compared to the other two runs by increasing the distance drilled by 79% from an average of 523 feet to 936 feet.

Dull condition also showed a large improvement with the 507 when compared to the 406. The 406 was pulled for poor penetration rate with a deep ringout in the shoulder. By contrast, the more durable 507 had a few broken cutters in the nose, and minor chipping in the shoulder.

.



After this initial testing, seven more wells were drilled with six additional tests of the 507 along with four tests of a 7-blade/13mm cutters design from another provider. The 507 showed a 43% increase in distance drilled, and a 4% increase in rate of penetration when compared to the design from another provider.

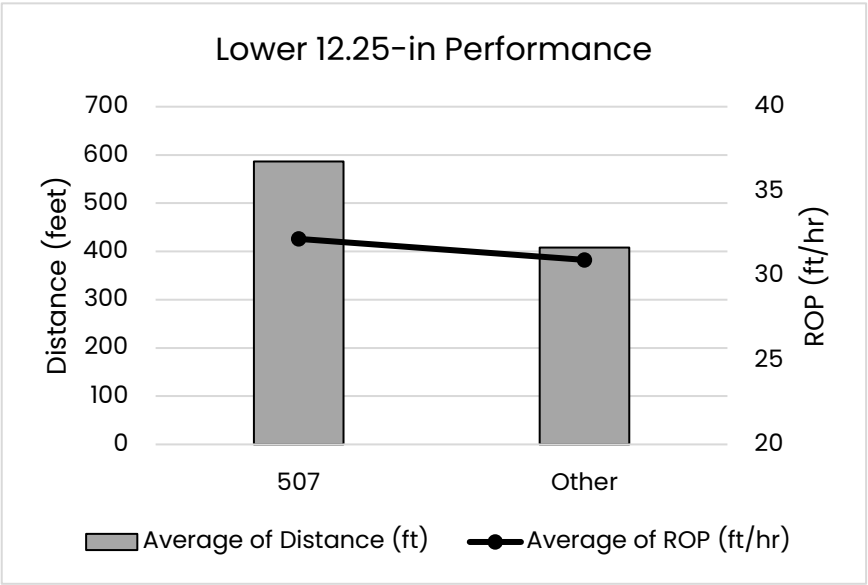


Figure 15 – Distance drilled and ROP metrics for Lower 12.25-in section

5. Curve 8.75-in Section

This drilling program was unique to this area with the goal to drill a horizontal well profile compared to the high inclination vertical wells that were drilled by Utah FORGE. The primary goal for the 8.75-in section was to drill the 1,000 feet curve in one run. The drill bit would need to build angle in the hard formation and precisely land the curve on target. Operational information for the horizontal drilling performance are documented by El-Sadi et al, 2024.

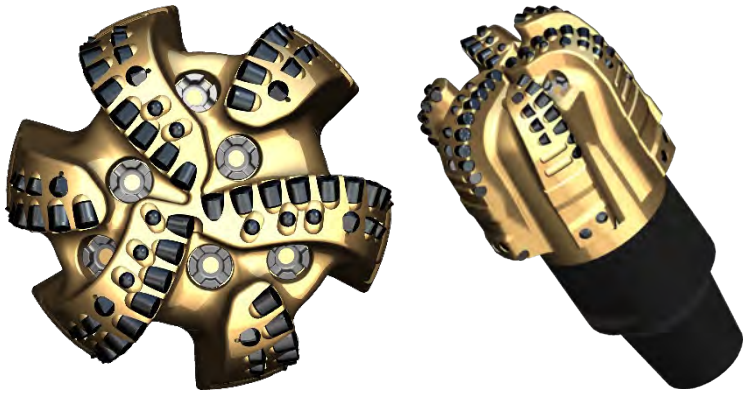

Figure 16 – 8.75-in 406 PDC Drill Bit with 6-Blades, 13mm (1/2-in) cutters, 3-in gauge pad with AntiWalk Technology for directional control, Depth-of-Cut Control for steerability, and secondary cutting elements for durability and wear resistance

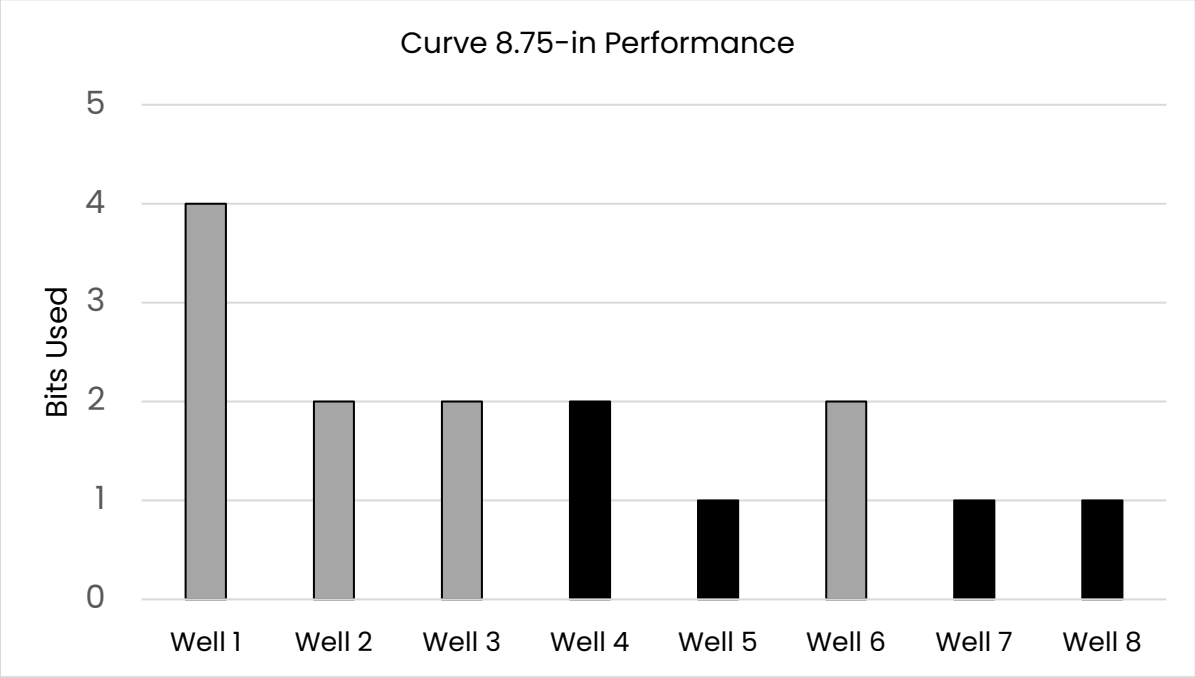

Figure 17 – Quantity of bits used in 8.75-in curve section.
The successful 406 was used on Wells 4, 5, 7 and 8 (black bars).

The first three wells in this program used PDC bits from another provider. Consequently, the first well required four bits – two PDCs and two roller cones – to complete the curve. The PDC bits from another provider were unable to properly drill the curve, resulting in low penetration rates. The PDCs were pull out of hole and roller cones were run in hole to steer the curve back on target. It was observed this highly technical section would be challenging to complete in one PDC run.

From a drill bit perspective lessons learned from oil & gas applications were applied to recommend a PDC design for this application. A successful 406 from the Permian and Anadarko Basins was chosen based on durability for drilling granite, and depth-of-cut control capability for directional toolface control. This design included a special gage configuration making it easier to steer on the directional motor assembly (Spencer et al, 2019). After the above design was introduced on well 4 a consistent one-run curve was achieved on wells 5, 7 and 8, see Figure 17. A 60% reduction in drilling days and larger scope drilling costs savings are also documented by El-Sadi et al, 2024.

6. Conclusions

By collaborating with operators and other service providers, we have optimized drilling performance in geothermal applications through advanced PDC drill bit designs. Our findings demonstrate a continuous improvement in performance, significantly reducing well costs and enhancing the economic viability of geothermal wells. Specifically, we have increased the distances drilled with PDC bits in the 12.25-in vertical and 8.75-in curve sections through software modeling and the optimization of cutting structure profiles, hydraulics, and cutters. As stated by Oueslati et al in 2019, the transfer of innovation and best practices from the established oil & gas industry is key to reducing the risk and cost of geothermal projects. This is critical to support the robust drilling campaign to bring one gigawatt of power online by 2030.

Historically, legacy roller cone drill bits have been used to drill geothermal wells at slow penetration rates. The insights gained from this Utah application are paving the way for exceptional drilling performance and establishing a foundation for the broader adoption of PDC drill bits. This engineering and technology application is making geothermal wells more economical and successful.

ABSTRACT

Japan ranks in third globally in terms of the potential of geothermal power resources with 23.47 GW; in fact, it ranks in 10th with regard to installed capacity in the world. Among many bottlenecks which hinder the domestic development of geothermal power plants, oppositions from local hot spa owners have been a primary problem. Therefore, successful consensus building with them will be of vital importance to be achieved so as to make full use of geothermal resources throughout Japan. In light of this situation, with the aim to promote successful consensus building on geothermal development, this study first developed an agent-based simulation illustrating opinion formation processes among hot-spa owners toward geothermal development. Afterwards, this study conducted questionnaire survey for hot-spa owners in Oguni town to collect data on their opinions and behaviors. Then, this study carried out the agent-based simulation with the collected data in order to check out the validity of the simulation. Finally, discussion was done as to the applicability of the invented simulation. Further research should be continued to investigate the method to validate the simulation.

1. Introduction

Japan is blessed with third-largest amounts of geothermal resources in the world, while the installed capacity of geothermal power generation is no more than 603 MW, making Japan located in 10th globally. Although Japanese government aims to increase the installed capacity to 1.6 GW by 2030, domestic geothermal development is not speedy enough to achieve that goal for now. One of the primary reasons why the geothermal development in Japan has been stagnant is intensive oppositions from local hot spa owners. They suspect that geothermal power plants reduce the output of their hot springs since they use a lot of hot vapor and water in the underground to

generate electricity. Although little data has revealed the inverse effect of geothermal power generations on the outputs of nearby hot springs in Japan, the scientific evidence alone are not effective enough to let down guards of hot-spa owners. Therefore, consensus building with hot spa owners is one of the key elements in order to just accelerate the domestic geothermal development.

2. Previous Research and Purpose of This Research

Social acceptance is a concept which describes what conditions are required for some technology to be accepted by society (Maruyama, 2014). Previous research on consensus building of geothermal development was conducted based on this concept and aimed at finding out elements contributing to successful consensus. While it provided us with helpful findings for successful consensus building with qualitative approaches, there has been little research based on quantitative approaches. Studies with quantitative approaches are highly expected not only to help verify the findings from the qualitative research to date numerically, but also to contribute to giving new perspectives to this geothermal challenge. In addition, as a concept of evidence-based policy making, or EBPM indicates, quantitative approaches and methods are effective tools to transform existing policies to solve social challenges. This is also considered true of geothermal development, and the demands for them have been increased more than ever (Yasukawa et al., 2018).

Komori et al. (2023) is one example of a few of earlier studies applying a quantitative approach to an analysis of geothermal consensus building. The study developed a compartment model to simulate an elapsed change of the number of supporters and opponents for a geothermal project over several decades. A novel characteristic of the study is an introduction of effective susceptibility number Re, a time-varying index inspired by an effective reproduction number from an epidemiologic study. They concluded through their parametric studies the Re number could represent well the level of opinion exchanges or the frequency of dialogue and interactions in their research area. While the study exhibited one possible way to numerically model consensus building of geothermal development, as they mentioned in their paper as well, the model is lack of individual diversity, that is, it does not explain the processes of interactions among individuals with different attitudes. Moreover, it seems that the effective susceptibility number suggested in the paper requires considerable efforts and careful settings of the relating parameters for the appropriate interpretation. Although they explained the relationship of the parameter change with the social trends of the research area in their paper, the parameter alteration itself was based on their arbitrary assumptions, resulting in a sort of tautological rationale and unconvincing explanation. In order to come up with effective solutions of social acceptance of geothermal energy, it is vitally required to take diversity of each individual into consideration as well as time-varying dynamics. Therefore, this study aims to construct a simulator prototype for geothermal consensus building which can illustrate diverse behaviors of individual.

3. Research Method

3.1 Agent-based Simulation

Agent-based simulation (ABS) is a bottom-up type of simulation based on the behaviors of agents, which are defined as autonomous subjects. They follow certain rules of their behaviors and act accordingly through their interactions with the others. This simulation can visualize an overall result of them and help us understand complicated dynamics of interactions among diverse agents.

An ABS of this research was developed using Artisoc ver. 4.2.1 standard, an agent-based simulator founded by Kozo Keikaku Engineering Inc.

3.2 Simulation Setting

The ABS of this research aimed to model opinion formation processes among hot spa owners and their subsequent results of the community as a whole. It was based on Axelrod's iterated prisoners' dilemma game, where players repeated prisoners' dilemma game for a certain number of times. The ABS of this study modified a number and varieties of strategies of the Axelrod's and added opinion formation processes. It was composed of agents, strategies, and payoff matrices. The agents were defined as hot spa owners, and three different types of agents were set as neutralists, supporters, and opponents. The strategies were expressed in the form of four different integers as shown in Table 1 below.

Table 1 Value – strategy correspondence

Value	Strategy
0	Random
1	All Corporation (AllC)
2	All Defection (AllD)
3	Opportunism

Each strategy defines how agents assigned to it choose cooperation or non-cooperation in interactions with other agents. Agents with random strategy decide their actions at random: cooperation at 50% and non-cooperation at 50%. Those who follow AllC strategy always cooperate, whilst those with AllD strategy never cooperate. Opportunism agents determine their actions based on the atmosphere among overall agents. When the simulation starts, all agents are assigned to one of the three types, which is to say, neutralists, supporters, and opponents. The strategies of neutralists are determined randomly while supporters and opponents take AllC and AllD strategy respectively. Table 2 and 3 below shows the payoff matrices of cooperative (Random and AllC) and risk-aversive (AllD and opportunism) agents respectively. The agents refer to these payoff matrices according to their types and the results of their interactions in order to calculate their payoff. The left and right-side number expresses the payoff for hot spa owner 1and 2 respectively, and the numbers bolded in the tables indicate the payoff given as a result of best-response strategy to the other's one.

This simulation includes two processes agents go through, which are, an opinion formation process and a learning process. A flowchart of the opinion formation process of them is shown in Figure 1. In a timestep, each agent randomly moves around a simulation field to find another agent to interact with. When the agent bumps into another agent, they interact with each other based on their strategies, which gives each agent opinion and score values, output parameters of this simulation. The opinion parameter increases when the result (Coop, Coop) is selected, and the score parameter represents the sum of payoff. The value of the score parameter can be seen as an agent's confidence, given that it reflects successful experiences of consensus building. Their values are 0 at an initial condition, and as the agents interact, they change their values as shown in Figure 1. Repeating this process 10,000 times, this simulation can illustrate how overall opinions can be formed based on interactions among the agents. In addition to the opinion formation

process, agents have their chances to conduct their learning processes, where they transform their strategies in a trial-and-error way at every 100 timesteps to review their best strategies. The flowchart of the learning process is shown in Figure 2 below. In the learning process, an agent randomly chooses another agent to compare its score to decide whether or not it changes its strategy. In this way, agents learn to find out their best strategy in the course of time. These whole processes are repeatedly conducted 100 times in order to eliminate the influence of randomness.

Table 2 Payoff matrix of cooperative agents

Hot spa owner 1 \ Hot spa owner 2	Cooperate	Not cooperate
Cooperate	(**2**, **2**)	(-1, 0)
Not cooperate	(0, -1)	(**0**, **0**)

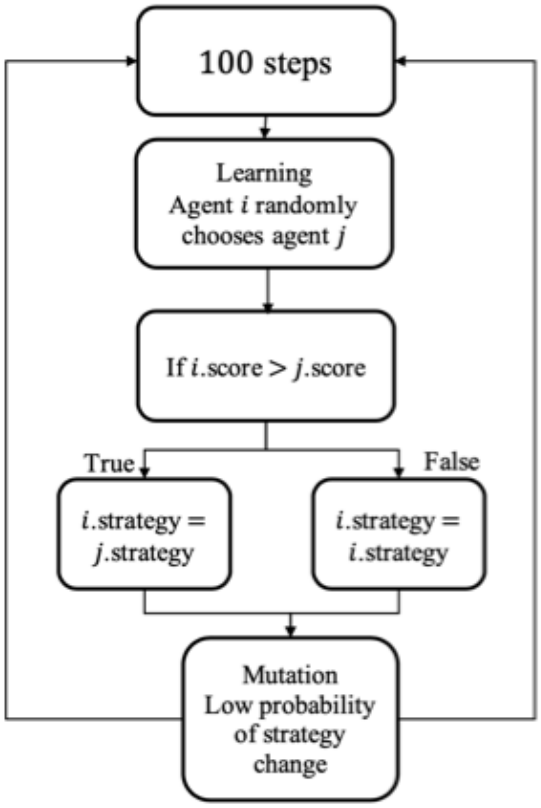

Figure 2 Flowchart of the learning process

An ABS for an analysis of an actual geothermal case has yet to be done. It is essential to put actual data into this simulation as input parameters and examine whether or not this ABS can coherently illustrate the corresponding outcome. Therefore, this study conducted questionnaire survey in Oguni town, Kumamoto Prefecture so as to collect actual data on attitudes of hot spa owners toward geothermal development and to examine the validity of the invented simulation.

4. Questionnaire Survey

The questionnaire consists of two fundamental questions which specify a respondent's residential area and its style of hot spa business, and the following fifteen questions on its basic knowledge about geothermal energy and its attitudes toward geothermal development in the research area. This survey was conducted for twenty-six hot spa owners in Oguni town between October 2nd and 13th, 2023. The questionnaire was distributed in the form of paper to each respondent and collected in person in order to increase the response rate as much as possible. As a result, 23 responses out of 26 were successfully collected and were considered enough rates to represent overall attitudes on geothermal development among hot spa owners. Questions directly related with ABS parameters settings in the questionnaire are shown in Table 4 below.

Table 4 Primary questions asked in the Oguni Town survey

Q1. What do you think about geothermal development for power generation in Oguni town in the future? 1. Strongly advance 2. Partially advance 3. Not advance very much 4. No advance at all 5. No idea Q2. As to geothermal development plans in Oguni town so far, how did you decide your attitudes toward them? Select the answer which best matches your decision-making process. 1. Never changed your opinion 2. Followed others 3. Communicated your opinion with others and did not change it in the end. 4. Communicated your opinion with others and changed it in the end. 5. Other ( ) Q3. How often do you talk about power-generation-related topics such as geothermal power generations and binary power generations with neighborhood people? 1. Seven or more times out of ten chances 2. About five times out of ten chances 3. About three times out of ten chances 4. About one time out of ten chances 5. Seldom talk about them

5. Result

Figure 3 below shows the questionnaire results with regard to questions in Table 4.

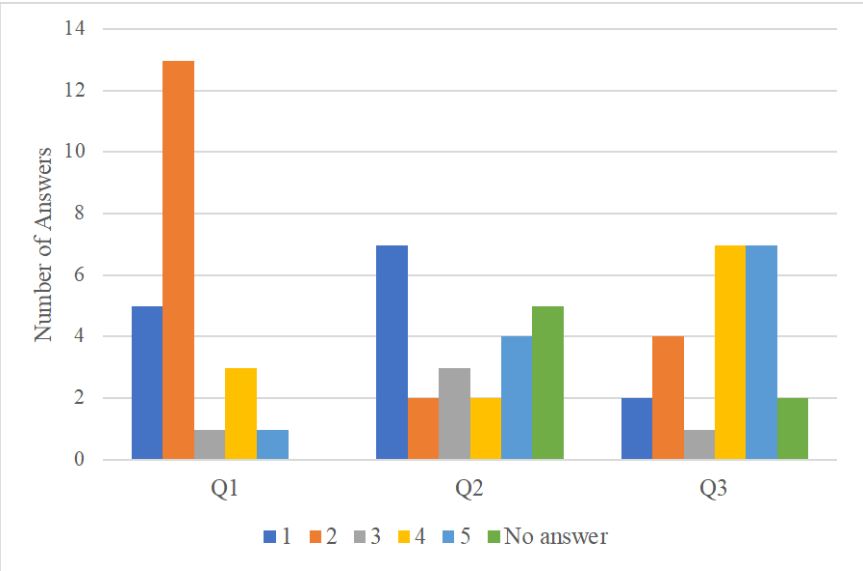

Figure 3 Questionnaire results

The ABS was modified based on this questionnaire results. There were two crucial changes made to reflect the questionnaire results to the prototype of the ABS. The first change was to modify the encounter rate of the simulation. The rate was set as about 21% based on the Q3 answer result of the questionnaire. The encounter rate was changed by coordinating the size of a simulation field as 40 × 40. The second one was about the change of agent type distribution at initial condition. This change was made so that the distribution was coherent with the Q2 result. The number of respondents who selected answer one was considered an agent without the learning processes throughout the simulation. They were allocated to either supporters or opponents based on their Q1 and Q2 answers. Those with other answers were seen as the neutralists, which follow the learning process. By customizing the behaviors of the agents this way, the simulation result is likely to reflect the geothermal development for power generation in Oguni town.

Figure 4 below displays the average strategy distribution of the agents at the end of the simulation. AllC and AllD agents are dominant strategies among the four, and AllD strategy marked the highest number of agents with 11.68, followed by AllC with 10.57. Figure 5 below shows elapsed change of average opinion and payoff value through the simulation. The average opinion value is equal to the summation of the number of agents' cooperation divided by the number of agents multiplied by timesteps. The same equation is applied to average payoff value. The average opinion value plunges down at the very early time and then remains constant at around -0.05, while the average payoff value gradually increases over time to converge to 0.59

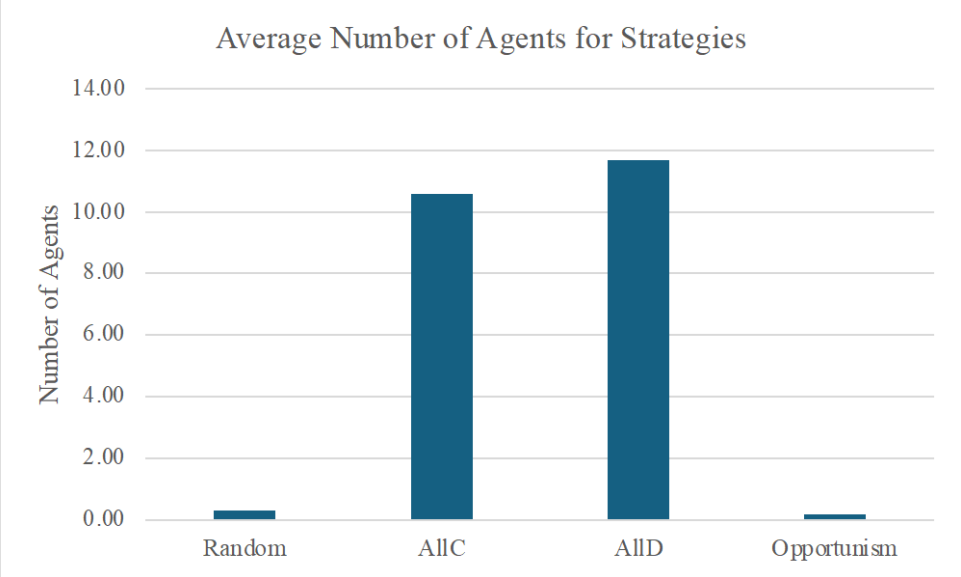

Figure 4 Simulation results about average strategy distribution of agents at the end of simulation

.

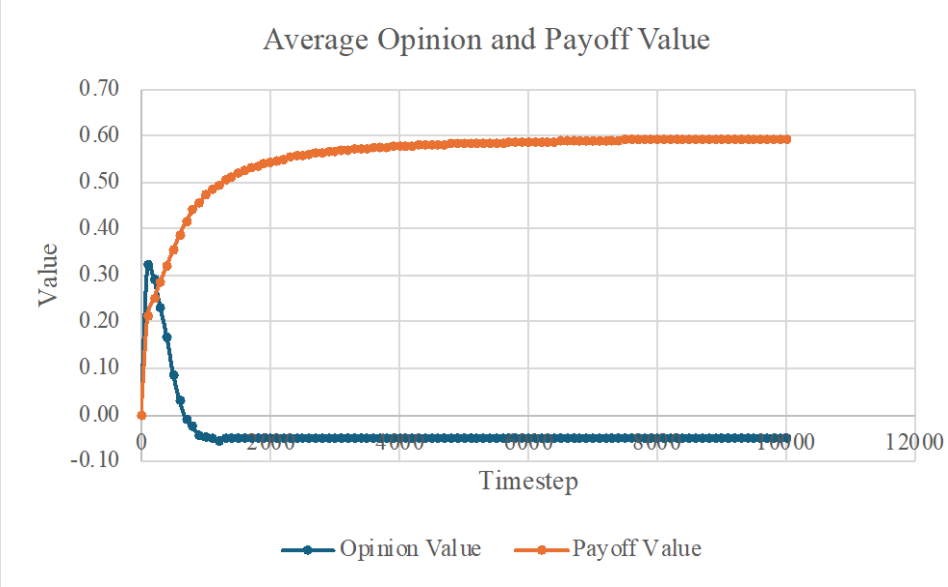

Figure 5 Simulation result on elapsed change of average opinion value and payoff value

6. Discussion

From the results in Figure 4 and 5, the invented ABS could not reproduce the opinions of hot spa owners toward geothermal development in Oguni town, given that the hot spa owners in the town are for the geothermal development as a whole. It is because the payoff matrix of risk-aversive agents, referred to by those with AllD and opportunism strategies, gives them higher payoffs than the one of cooperative agents, used by those with random and AllC strategies. As shown Table 2 and 3, cooperative payoff matrix gives the agents $2 - 1 = 1$ payoff on average while risk-aversive matrix does $2 + 0 = 2$. This difference might cause the risk-aversive agents to gain higher payoffs, which makes more agents choose not to cooperate. Another possible reason for this misfit could be an algorithm of the learning process. The learning process forces agents to suddenly change their strategies just because their payoffs are inferior to the ones of comparing agents, which might not well illustrate actual opinion formation process.

As to checking the validity of this simulation, this study found out that it was not appropriate to utilize questionnaire survey results in Oguni town. It is because the simulation result in this study shows the possible future transition of overall opinion based on the current opinion and behavior of the hot spa owners in the area, and thus there are no valid counterparts to make a comparison with now. Therefore, it is necessary to find out common facts observed in consensus building of past geothermal development for checking the validity of the simulation. The validity of the simulation can be checked out whether or not it successfully reproduces the common facts.

Although it is considered that this agent-based simulation is still halfway through to its actual application, at the same time it achieved illustration of diverse ways of thinking and behaviors among individual, which was one of the goals this study aimed at. The introduction of various types, strategies, and payoff matrices of agents enabled this simulation to illustrate diverse opinions and their complicated interactions among agents. This simulation also included time-

varying dynamics of their opinions by bringing in the opinion learning process, which could trace the change of opinions. Furthermore, there is an interesting finding to take into consideration. It is that the overall opinion might be mostly determined at very early time. The elapsed change of average opinion value in Figure 5 shows a sudden change from about 0.3 to -0.05 before 1000 timesteps, and then remains almost constant throughout the simulation. This pattern of transition may indicate the importance for geothermal developer to closely and continuously contact with hot spa owners at an early stage. In fact, the guideline for conservation of hot spring resources published by Ministry of the Environment (2024) strongly recommends that geothermal developers create a place for opinion interactions with local hot spa owners such as a council at the earliest stage of geothermal development in order to facilitate consensus building with them.

7. Conclusion

This study set out for constructing an agent-based simulation illustrating consensus building situation of geothermal development, where hot spa owners with diverse opinions and behaviors interact with one another. In order to achieve that goal, this study developed an agent-based simulation based on game theory, into which opinion formation and learning process were integrated. Diversity of the individual, which had not been realized in previous research, was introduced by setting different agent types, strategies, and payoff matrices. The combination of these elements enabled the simulation to illustrate complicated opinion formation process of consensus building on geothermal development. Adding to that, this study conducted questionnaire survey in Oguni town, Japan to utilize for validation of the invented simulation. Although the survey successfully collected actual data as to opinions and attitudes of hot spa owners toward geothermal development in the area, it was found out that it was not suitable to make use of the questionnaire results for validating the simulation. While the simulation development is not enough for application, it still indicated supportive results of activities recommended by the government for successful consensus building. Further research should focus on finding out how to check the validity of the invented simulation so that it can work as guidance for action in the future consensus building.

Probability of Discovery as a Useful Concept for Communicating Exploration Drilling Uncertainty

Greg Ussher[1], Aimee Calibugan[1] and Julian McDowell[2]

Keywords

UNFC, resource classification, exploration, drilling risk, success

ABSTRACT

The United Nations Framework Classification for Resources (UNFC) is a globally recognized system for classifying projects and the resources they produce and has an accompanying Geothermal Specification that has been developed by a working group of the International Geothermal Association (IGA). This is gaining traction as the only currently valid system for classifying geothermal projects and was recently applied to most of the New Zealand geothermal resource. Within the Geothermal Specification is a provision for reporting the Probability of Discovery (PoD) for a project before deep drilling. The PoD is the chance that a reasonable (or planned) exploration drilling program will succeed in finding a useful geothermal source.

PoD is similar in concept to Probability of Success (PoS) as applied in oil and gas exploration but allows for a more generalized evaluation without a defined drilling program. Increasing use of the PoS and PoD concept in geothermal recently is due to its promotion by leading practitioners but is yet to be universally accepted or understood. However, it is increasingly accepted as an important tool for conveying the uncertainty inherent in exploration drilling.

Recent adoption of the PoD concept as a tool to assist approvals for state and World Bank funded drilling in Indonesia has driven a need to better define PoD and how it is estimated. A methodology and calculation tool has been developed and is presented for further consideration by the industry.

1. Introduction

UNFC provides a globally consistent framework for assessing geothermal projects. It is a shift from the conventional geothermal characterization to a more holistic approach providing indications on the technical feasibility, economic viability, risks, and sustainability of the project.

Readers are directed to Beardsmore et al., (2021), UNECE (2022), Falcone and Beardsmore (2015), Grant and Ussher (2015) and Ussher et al., (2023) for comprehensive descriptions of the UNFC principles and its application to geothermal energy resources. In this paper, we focus on the application of the UNFC to an exploration project, in which the PoD is an important feature. Inherent in this stage of a project it is worth noting the key concepts of the UNFC as they apply.

Firstly, a '**Geothermal Energy Source'** is the energy contained in rocks, sediments and/or soils, including any fluid contained underground or naturally discharging at the ground surface, which is available for extraction and/or conversion into energy products.

Secondly is the difference between '**Known vs. Potential'.** A Known Source is classified where one or more wells/hot springs are established and a significant quantity of recoverable thermal energy established through testing/sampling logging. A Potential Source is one where there is no direct evidence (from drilling) establishing the existence of a significant quantity of recoverable thermal energy. The existence of energy is inferred from geoscientific data only.

2. Probability of Discovery (PoD)

The UNFC scheme has included the concept of probability of discovery (PoD). It refers to the probability that further exploration, drilling and well testing will result in the confirmation of a Known Geothermal Energy Source. It is required to be reported for the Potential Geothermal Energy Sources under the UNFC system.

Generally, PoD is similar in concept to Probability of Success (PoS) as applied in oil and gas exploration but allows for a more generalized evaluation of early-stage (pre-drilling) exploration projects. Beardsmore et al. (2021) highlighted the importance of clarity around whether shallow productive wells could be considered within the PoD concept to demonstrate existence of a deeper, yet to be drilled, resource. They comment that the deeper resource should still be considered unknown in the UNFC sense and highlighted that importance of acknowledging inconclusive results when considering ultimate classifications.

Recently, the PoD concept has been adopted as a tool to assist approvals for state and World Bank funded geothermal drilling projects in Indonesia. This has subsequently triggered the need to better define PoD and how it is estimated.

3. Probability of Success (PoS)

In oil and gas exploration, the total geological PoS is calculated by multiplying PoS values for segment elements (geological risk factors). The application of the PoS concept varies considerably through the oil and gas industry, with the number of factors used ranging from 4 to 19 depending on the company (Milkov, 2015, 2021). Milkov (2015) notes the risk of encountering bias and subjective judgments within the PoS concept leading to inconsistency across companies and wide range of factors. They proposed an algorithm in the form of systematic risk tables for probabilities for only six factors, with the intent of improving drilling decision and reducing bias.

In a study of 375 conventional petroleum exploration prospects/wells and 80 drilled wells, Milkov (2022) noted that the actual geological success rate (58%) was much higher than the average pre-drill probability of geological success, PoS (37%). Explorers, in general and on average, significantly overestimated geological risks before drilling and made many more discoveries than

expected. This may be because the estimation of risk factors was too conservative, or that the way they are combined was causing PoS to be too low.

We observe that an approach adopted by some geothermal teams with backgrounds in the oil and gas industry is to evaluate the probability of finding several key factors (suitable temperature, permeability and chemistry are often used) and then multiplying these together. It is possible that these may not all be entirely mutually independent and hence simple multiplication is overly conservative. It is also true that if one added more factors such as pressure (water depth), ability to drill wells or a minimum size, then this would add additional factors and inevitably reduce the PoS. So, a different approach is possibly worth considering.

4. Jacobs Probability of Discovery Tool

In an effort to enable a consistent and systematic approach for determining PoD, Jacobs has developed an excel-based tool which calculates the PoD of a given geothermal project. The concept is to break the review of factors down to manageable elements and give guidance to their evaluation to drive consistency of application. The calculation then works in a way that weights most strongly those elements which are most reliably assessed and can influence the PoD either positively or negatively.

The PoD tool considers the critical elements (Figure 1) required for a successful project which include the a) reservoir temperature, b) benign fluid chemistry, c) the physical ability of expected reservoir to produce (i.e., can wells be productive given favorable temperature and permeability, and considers the depth of water table), and d) the ability to complete wells in the desired area of the reservoir. The calculated PoD essentially represents the chance that after drilling the planned wells that a useful geothermal reservoir can be discovered.

Figure 1: Critical Elements for the PoD Calculation

5. PoD Calculations and Key Elements

The temperature expectation parameter is assessed firstly to indicate if production is realistic at all for a given prospect based on reservoir temperature and water level. The probability for temperature, permeability and chemistry and drilling are then determined.

A selection of 0 to 3 rating is provided for each sub-factor (i.e. for temperature the sub-categories relate to presence and character of springs, fumaroles, temperature gradient wells and heat source) with the logarithmic average of the sub-category ratings used to determine the probability for each category (where 0 = 1, 1 =10, 2=100 and 3=1000).

The overall project PoD is calculated using the minimum probability of the 5 categories multiplied by the average of all the sub-categories. The assumption here is that the PoD must be lower than the minimum of any main parameter, but these parameters are not all mutually independent so a simple multiplication of all the categories biases too low. The multiplication with the average of the parameters is used as an alternative to multiplying all the parameters together.

5.1 Temperature Expectation

Basically, this is a check on whether the expected reservoir temperature is adequate for the depth of reservoir "water level". If the temperature is too low and water level deep, wells cannot flow. This is further illustrated in the simple schematic in Figure 2. In the example, well A (high T, deep WL), well B (high T, shallow WL) and well D (med T, shallow WL) all sustain flow but on the other hand, well C (med T, deep WL) cannot be flowed realistically. Figure 3 shows the rating selection for temperature expectation sub-categories on reservoir temperature and depth to water level. Resources which do not have 'self-flowing' wells can still be developed with pumping, but water depth also strongly influences the viability of pumping, as parasitic power increases greatly as water depth increases. This correlation for pumped wells needs further consideration, but conceptually can, and should, be applied similarly.

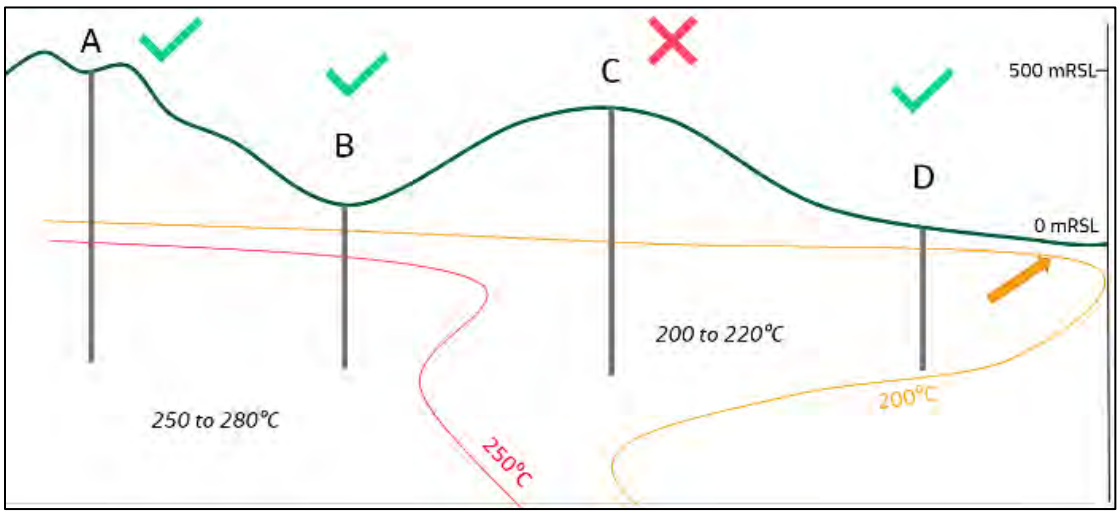

Figure 2: A simple schematic illustrating the influence of reservoir temperature and water level on the success of the well. See texts for explanation.

	0	1	2	3
Temperature expectation				
Expected reservoir temperature	Less than 210 C	210 to 230 C	230 to 260 C	More than 260 C or vapour-dominated reservoir
Water level	Near surface or overpressured or steam-dominated	150 m	300 m	deeper

Figure 3: Selection parameters for temperature expectation.

5.2 Temperature Probability

Considerations for temperature probability include the following: a) presence of high flowrate chloride springs indicated to be coming direct from reservoir which typically provide best geothermometry, b) presence of fumarole activity which is a strong indicator of an active systems and can provide good isotope geothermometry, c) shallow temperature wells that demonstrate temperature gradients within the cap of the system and are consistent with expected gradients within the clay cap and d) age of volcanics/heat source or deep structures and indicators of high heat flow. Figure 4 shows the selection parameters for temperature.

Note that these are not necessarily determining presence of a high temperature, rather the confidence that the temperature that *you expect and need for useful production* will be found. This is apparent in the selection and weighting of the sub-factors we have defined, which are all about the *confidence* that we have about the temperature indications.

Temperature probability	0	1	2	3
High flowrate springs	No springs discharging primary reservoir water	Weak, distant or dilute springs	One or two low flow springs (<1 l/s) with geothermal water content	Several low flow or one high flow springs with clear geothermal content
Presence of fumaroles	No fumaroles or steaming ground	Steaming ground	Weak fumarole activity, probably depositing sulphur	Strong fumaroles with pressurised steam - steamflows noisy
Temperature gradient wells	No TG wells	TG wells with inconslusive results or not deep enough	TG wells that support inferred temperature gradients and at least 70% of target reservoir temperature (in deg C)	TG wells achive closer to reservoir temperature or at least top of reservoir temperature
Heat source indicators	Volcanics older than Quarternary or no indicators of high heat flow region	Volcanics 0.5 to 2 Ma or indicators of deep faulted system	Volcanics 0.2 to 0.5 Ma or strong indicators of deep structural system	Younger volcanism nearby or majjor structure system, with springs on structure

Figure 4: Selection parameters for temperature.

5.3 Permeability Probability

Permeability takes into consideration the lateral outflows, fault permeability and nature of the clay cap in the system (Figure 5). Major lateral outflows indicate good permeability in liquid-dominated systems. These may be indicated by spring flows combined with geophysics. Steam-dominated systems or steam caps may have bicarbonate waters indicating boiling and high heat flow. Fault permeability is also evaluated including whether faulting is clearly providing permeability in the system, with indicators like springs or fumaroles along well-defined structures. Clay cap up-doming and thickness is another indicator for permeability. Systems with good permeability tend

to have good buoyancy above the upflow area and hence have an up-domed base of the clay cap (typically defined by geophysics; magneto-telluric signatures). The clay cap (< 10 ohm.m) also tends to be thinnest where isotherms in reservoir dome upwards. There should be caution though with up-doming of the MT conductor within a volcanic system as these may be volcanic-induced alteration. Figure 5 shows the selection parameters for permeability.

Permeability probability	0	1	2	3
Lateral Outflows from system	Limited or no outflows	Some outflows indicated with primary fluids, distal springs with small flows	Moderate outflows, distal or near springs with significant flows of primary water or bicrbonate fluids from above a boiling or steam dominated system	Strong indications of major outflows, high volume springs of primary water, bicarbonate flows off a steam dominated reservoir, or strong indicators of being a steam dominated system.
Fault permeability	There is no clearly defined faulting and no evidence that faulting is providing permeability	Some faulting is present but no evidence it is likely controlling permeability	Faulting is clearly defined and of a type that could provide permeability	Faulting is clearly defined and thermal discharges are associated with the faulting
Clay cap : up-doming and thickness	Clay cap is not well defined, is generally > 10 Ohm.m, or is very thick (> 1.5 thick in area to be drilled)	Clay cap is 0.7 to 1.5 km thick	Clay cap is less than 700 m thick with limited updoming	Clay cap is less than 700m thick and showing some updoming

Figure 5: Selection parameters permeability.

5.4 Chemistry Probability

The key considerations for chemistry assessment include a) presence of neutral, alkali chloride fluids as evidenced by spring flows is a positive indicator of having reasonably benign fluids in reservoir, b) presence of magmatic gases, highly acid-chloride springs or isotopes indicating magmatic origins raises risk that fluids may be acidic at least in places in the system and c) gas content of the fluids can cause a system to be uneconomic to develop. Figure 6 shows the selection parameters for chemistry.

Chemistry probability	0	1	2	3
Neutral reservoir fluids	There are no springs from the system to indicate reservoir chemistry	Springs indicate possible presence of acidic fluids, such as high sulphate, low pH	Springs indicate minor risk of acidic fluids	High flow springs probably of primary waters have neutral pH and no indicators of sulpate or other risk parameters.
Presence of magmatic fluids	Strong indicators of magmatic fluids (e.g., HCl, HF or SO2), or acid chloride springs and no indicatons of neutral fluids in system	Strong indicators of magmatic fluids but also evidence of neutral fluids in same system	Minor indications of magmatic fluids near system, but other indications of nuetral fluids	No magmatic indications and postive indications of neutral fluids as evidence by high flow springs
Gas content	High gas content in fumaroles > 15%	Medium content of gas in fumaroles or steaming ground (5-15%), or abundant bicarbonate ground water flows from system	Small gas content (2-5%) from fumaroles. or limited bicarbonate groundwater flows	Low has content on fumaroles or steaming ground (<2%) or not other indicators of significant gas content

Figure 6: Selection parameters for chemistry.

5.5 Drilling Probability

The drilling category focuses on the targeting of favourable area, technical risks and capability, and the organization capability (Figure 7). The overall success of the project will depend heavily on the ability to drill in the favourable part of the system as represented by the temperature, permeability conditions referenced in the earlier discussions, and that the planned well depth is sufficient to test the expected reservoir. In terms of technical risks, the target depth is at limits of rig capability, geological risks such as difficult formations, shallow thermal activity, and significant depth to the top of reservoir can all increase the risk that target depth is not reached and contribute to inconclusive drilling results. Lastly is the capability of the developer/owners' technical team, drilling contractor, contract arrangements and service company with drilling in similar conditions, which will also impact drilling success. **Error! Reference source not found.** illustrates the key characteristics of systems with favourable PoD in contrast to low PoD systems.

Drilling probability	0	1	2	3
Targeting of favourable area	Wells cannot be located in the main high probability or P50 area or not deep enough to confidently test the reservoir	Some wells are located outside the P50 area and none in high probability area or are only marginally deep enough to test the expected reservoir	All wells are located in the P50 area and wells are deep enough to test the expected reservoir	Wells are all located in high probability area and deep enough to definitively test the expected reservoir
Technical risks and capability	There are multiple concerns on geology, thermal activity, depth to top of reservoir or limits of planned well depth	Some identified concern about 2 or more factors	Minor concerns about one of the risk factors	There are no particular risk concerns identified
Organisational capability	Owner's team and drilling contractors have NO relevant experience on geothermal drilling	Owner's team and drilling contractors have worked on at least 1 geothermal well drilling.	At least key individuals in owner's team have relevent experience completing geothermal drilling and drilling contractor has relevent experience with planned drilling rig.	Owner's team (as a team) and main contractors have prior experience completing drilling on similar geothermal campaigns

Figure 7: Selection parameters for drilling.

Probability of Discovery (PoD)	Productivity check	Pre-Exploration Drilling Indicators			
	Temperature and Water Level	Temperature	Permeability	Chemistry	Drilling
Favourable PoD	Temperature high Shallow water level	Presence of fumaroles, High temperature, high flow hot springs Good quality geothermometry temperatures Younger volcanism nearby as possible heat source Presence of major structure system, with spring on structures TG wells indicating hot temperatures	Presence of several faults (extensional faults) Alignment of thermal features with the identified faults Lateral outflows Domed clay cap and thinning cap over the up-dome	Presence of alkali chloride springs No volcanic gases Stable isotope indicating predominantly heated meteoric water origin No indications of high gas content	Exploration wells are located in high probability area and deep enough to definitively test the reservoir No risk concerns identified Owner's team and drilling contractors have relevant geothermal drilling experience
Limited / low PoD	Lower temperature Deep water level	Absence of fumaroles or hot springs Low geothermometry temperatures Mixed or partially equilibrated waters Absence of alkali chloride springs (for geothermometry analysis) TG wells indicating low temperatures or no TG wells	Associated with tight structures Minimal geologic structures identified Limited outflows if a liquid system	Absence of neutral-pH alkali chloride waters Presence of volcanic gases Stable isotope indicating magmatic origin	Exploration wells cannot be located in P50 or high probability area and/or not deep enough to test the reservoir Multiple risk concerns identified Owner's team and drilling contractors have no relevant geothermal drilling experience

Figure 8: A summary of key characteristics of geothermal systems with favorable PoD vs low PoD.

6. Case Study Applications

To test if the PoD tool works with actual geothermal projects, we have applied it retrospectively on ten projects across Indonesia which have all moved to at least the exploration drilling phase. Care was taken to use the information that was available pre-drilling to calculate each PoD. Table 1 summarizes the results of the case studies which shows a good correlation between the calculated pre-drilling PoD and the post-drilling results. In this study, PoD results of <50% correlated with projects which failed to demonstrate useful geothermal resource, while all projects with >50% succeeded with the realization of installed power capacity. This demonstrates that the PoD tool, in its current state, can be effectively utilized to assess the possible outcome of a geothermal project.

Table 1: A comparison of pre-drilling PoD and the post drilling results of actual geothermal projects in Indonesia.

Project	PoD (Pre-Drilling)	Post-Drilling Results
A	89%	Success – 271 MW installed capacity
B	78%	Success – 220 MW installed capacity
C	83%	Success – 330 MW installed capacity
D	80%	Success – 140 MW installed capacity
E	59%	Success – 170 MW installed capacity
F	32%	Fail – poor permeability, 200 ºC at 2800 m
G	47%	Fail – Poor permeability, Tmax of 156 ºC at 920 m; may not have been deep enough
H	18%	Fail – 4 deep wells drilled with depths of 1800-1900 m; 2 of the wells had poor permeability; 2 wells had 140 ºC and 213 ºC discharge fluids, respectively.
I	44%	Fail – 71 ºC at 605 m; thermal gradient at 7ºC/100 m; good permeability
J	15%	Fail - Deep well had no productivity and modest temperatures

7. Conclusions

The PoD is the chance that a reasonable (or planned) exploration drilling program will succeed in finding a useful geothermal source. This represents an important concept to qualify and quantify in a systematic way such that the allocation of funds for geothermal project exploration can be considered using with a suitable and justifiable screening tool.

Recent adoption of the PoD concept as a tool to assist approvals for state and World Bank funded drilling in Indonesia has driven a need to better define PoD and how it is estimated. A methodology and calculation tool has been developed and is presented for further consideration by the industry.

A study of 10 geothermal project in Indonesia has demonstrated that the PoD tool, in its current state, can be effectively utilized to assess the possible outcome of a geothermal project. We encourage the industry to use this approach, to facilitate further development of this type of tool and refine it over time. We also encourage consideration the application of the broader UNFC system for classifying geothermal projects and fairly representing their development status.

Acknowledgements

Jacobs thanks those at UNECE, IGA, and the dedicated professionals in the wider industry who continue to support the development and use of the UNFC for geothermal resources.

Keywords

Geothermal ORC Power Plant, Green Hydrogen, Hydrogen Liquefaction, Electrolyzer, Proton Exchange Membrane

ABSTRACT

Investment in and development of geothermal power projects have been going through feast and famine cycles during the last few decades. Capital expenditure, private or institutional, are rushed into geothermal power plant development as soon as governments enact some form of incentive for renewable energy and there are no activities as soon as the incentive terms expires.

The worldwide campaign for reduction and elimination of environmental pollution and using hydrogen as the preferred fuel is well underway and being sponsored by almost all countries. Hydrogen production in general and green hydrogen in particular is rapidly increasing. Total investment in net zero emission projects that was projected at $3,000 billion for 2021-2025 will exceed $4,300 billion by 2030.

Green hydrogen is defined as the hydrogen that is produced by splitting water by electrolysis. Electrolyzers that are powered by electricity from a geothermal power plant produce green hydrogen. Utilizing a renewable source energy that generates no polluting emissions into the atmosphere produces the most sustainable and cleanest hydrogen.

The fast growth of demand for green hydrogen is an excellent opportunity for investment and development of geothermal power plants. In this paper, the authors present a brief description of green hydrogen production and liquefaction facilities. There is also a short reference to oxygen liquefaction as a byproduct of an electrolyzer. The paper continues with a simulated evaluation of green hydrogen production and liquefaction from a 15 MW geothermal ORC power plant. The simulation is configured to demonstrate green hydrogen production as an energy storage option for the period of low demand for electrical power.

1. Introduction

Geothermal power plants cost more than other thermal power plants in the regions where geothermal resources are available. In most cases the return on investment for a geothermal power

plant is longer than other types and hence there is less tendency in development and investment in geothermal power plant. The inherent uncertainties about the geothermal resource quality and quantity complicate the decision-making process.

On the other hand, the electricity produced by a geothermal power plant is in the category of renewable energy and considered as the base load. The latter characteristics are the motivations for a few countries on the ring of fire to introduce some form of short-term incentives for electricity produced by the geothermal power plants. The incentives come as tax credit, guaranteed power purchase agreement at a rate higher than conventional electricity, government sponsored interest free loans and the like.

The above referenced government-initiated incentives are normally for a limited term, i.e., 20 years. The geothermal power plant revenue drops after the sunset of the incentives and the power plants management should resort to some measures to optimize their income by reducing their losses. Capacity reduction during off peak demand, selling steam as a commodity during low demand periods and energy storage during low price power sale are some options available to the power producers.

2. Green Hydrogen Production

The worldwide campaign for reduction and elimination of environmental pollution and using hydrogen as the preferred fuel is well underway and being sponsored by almost all countries. Hydrogen production in general and green hydrogen in particular is rapidly increasing. More than seventy countries have already developed or are preparing hydrogen strategies. There are more than twenty giga-scale green hydrogen projects in progress worldwide. Total investment in net zero emission projects that was projected at $3,000 billion for 2021-2025 will exceed $4,300 billion by 2030.

There are several hydrogen production processes and with the ongoing research that list is growing. The latter expanding range of processes and technologies are color coded depending on its carbon dioxide footprint. The color code green hydrogen is produced by electrolysis using electricity from renewable sources to split water into hydrogen and oxygen without emitting carbon dioxide.

3. Geothermal Power for Green Hydrogen Production

Unprecedented demand for green hydrogen is providing another option to sell renewable power in general and geothermal power in particular for the geothermal power plant owners/investors. Figure 1 shows the green hydrogen production process. Geothermal power is an ideal power source for production of green hydrogen. The green hydrogen production process receiving power from a geothermal power plant could operate continuously and there is not much production fluctuation due to fluctuation in the electricity availability. The electricity from all other renewable sources fluctuates between 0-100% depending on the availability of the source of renewable energy. The latter fluctuation impacts the hydrogen production and provides challenges for turndown capability of the downstream processes such as hydrogen liquefaction.

In the following sections, we present a study for utilizing electricity from a geothermal Organic Rankine Cycle (ORC) to produce high purity hydrogen and liquefy hydrogen for refueling usage

or export. A brief discussion about utilization of the side product such as liquid Oxygen is also presented.

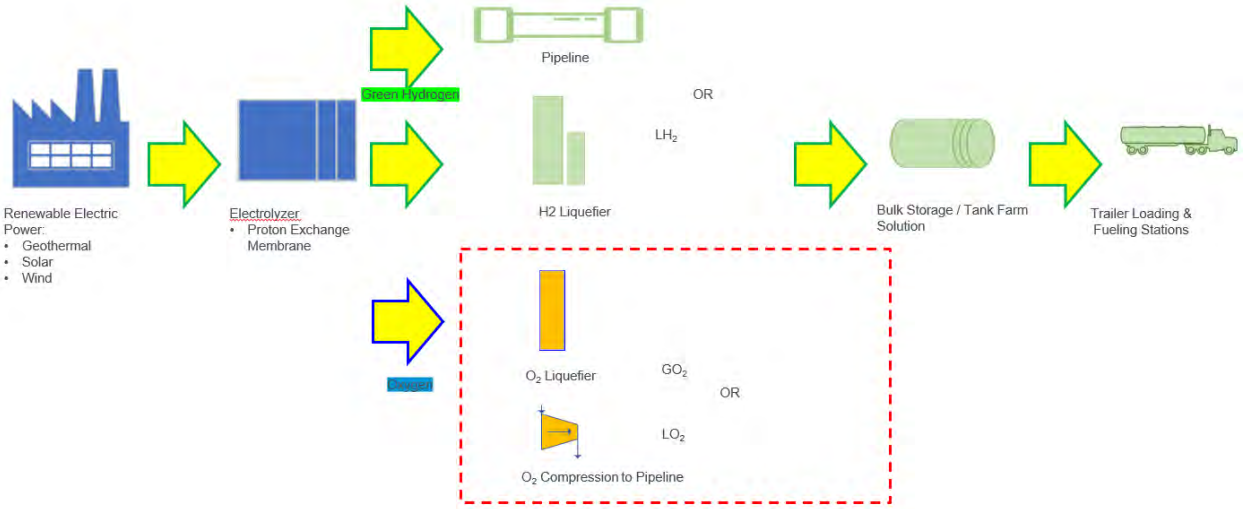

Figure 1. Green Hydrogen Production and Distribution Process

4. **Green Hydrogen Production and Liquefaction using Electricity from a Geothermal Organic Rankine Cycle (ORC) Power Plant**

The first step in green hydrogen production is electrolyzer. There are several processes to electrolyze water and each one has its own advantages and disadvantages. In this presentation we assume Proton Exchange Membrane (PEM) system, Figure 2.

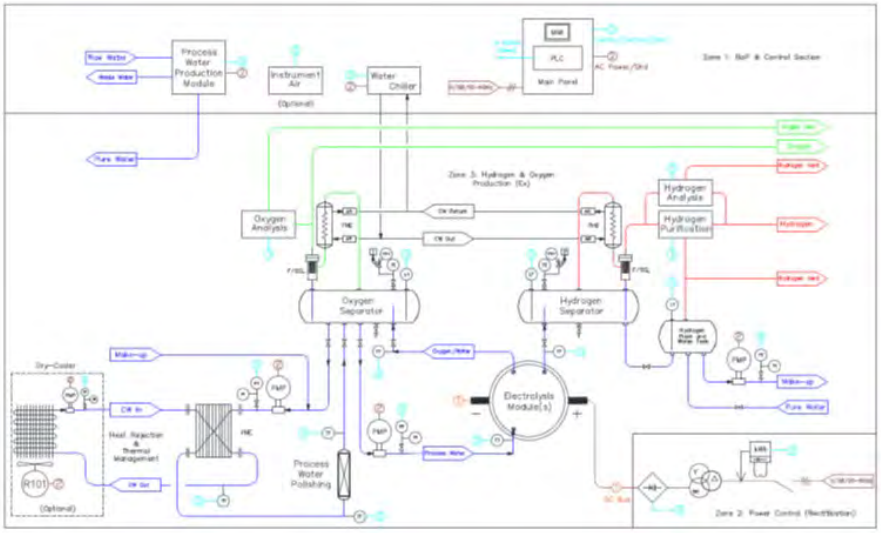

Figure 2. Proton Exchange Membrane (PEM) Electrolyzer

Figure 3. shows input to and output from the electrolyzer. It requires 340 tons per day of fresh water and 14 MW of electricity. The electrolyzer uses 46 t/d of water to produce 5 t/d of hydrogen at 10-40 bar pressure and 41 t/d of oxygen at 4 bar pressure. The balance of water, 294 t/d is discharged back into the water supply.

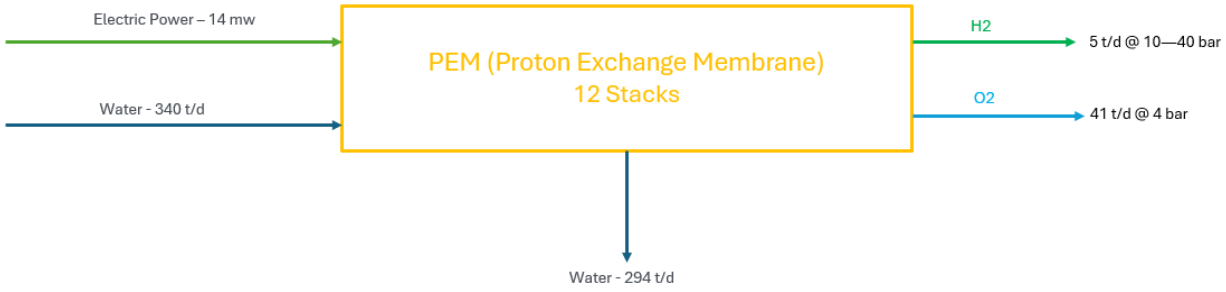

Figure 3. Electrolyzer Performance Data

There are two entirely different strategies for transportation of hydrogen for short distance, high pressure gas and low-pressure liquid. Both methods of transportation have its own advantages and disadvantages. In this study we assume that both hydrogen and oxygen products are needed, and liquefaction processes are required for transportation

Unprecedented demand for green hydrogen is providing another option to sell renewable power in general and geothermal power in particular for the geothermal power plant owners/investors. Figure 1 shows the green hydrogen production process. Geothermal power is an ideal power source for production of green hydrogen. The green hydrogen production process receiving power from a geothermal

5. Hydrogen Liquefaction

Hydrogen liquefaction requires deep cryogenic temperature and normally consists of two-step refrigeration. The preliminary refrigeration of the compressed hydrogen is normally achieved by a nitrogen cycle and the final refrigeration and liquefaction requires a deep cryogenic cycle utilizing cycle either helium or hydrogen. In this study we assume the final refrigeration cycle is a hydrogen cycle. Figure 4. Shows the hydrogen liquefaction process.

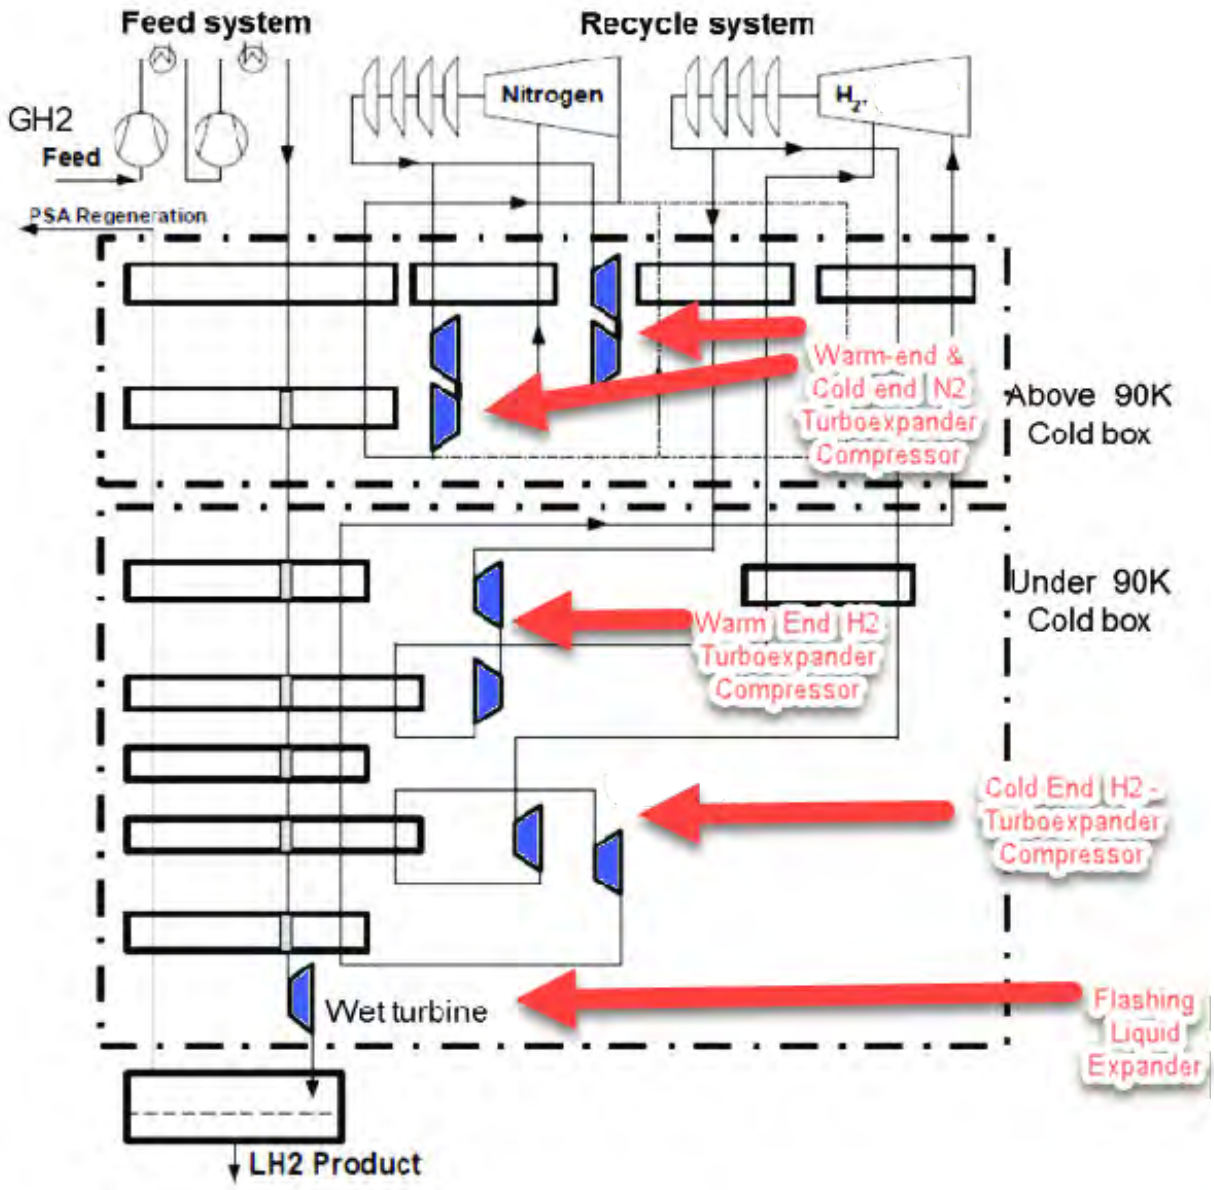

Figure 4. Hydrogen Liquefaction Schematic

Figure 5 shows the required electric power to liquefy 5 t/d of gaseous hydrogen into liquid.

Figure 5. Hydrogen liquefaction power requirements.

In this study we consider that the oxygen product will also be transported to an industrial complex by tanker truck. Figure 6 depicts the power requirements for the oxygen liquefying plant.

Figure 6. Oxygen Liquefier Data

Table 1. summarizes the performance of 5 t/d green hydrogen liquefaction plant utilizing 20 MW electricity from a geothermal ORC plant.

	PEM	LH2	LO2	Total
Electricity, MW	14	4	2	20
Fresh Water, t/d	340			
Returned Water, t/d	294			
Production, t/d		5	41

Enhanced geothermal system (EGS), Organic Rankine Cycle (ORC), ORC turbogenerator, dispatchability, modularity, power generation

ABSTRACT

The combined utilization of Organic Rankine Cycle (ORC) technology and advancements in Enhanced Geothermal Systems (EGS) hold significant promise for unlocking the full potential of geothermal resources for dispatchable power generation. Geothermal energy, with its inherent reliability and minimal carbon footprint, is the solution for sustainable electricity production. Modern drilling techniques and subsurface analytics complement ORC systems, creating a synergistic partnership that addresses key challenges in future grid management.

Future grids require firm, clean, dispatchable power to ensure reliability and sustainability. To examine this need, we took data from NREL's Cambium mid-case scenario, identified the highest emission hours per month in 2035, and then averaged net load and emissions by hour for that month. This approach allows us to pinpoint the periods within the year when emissions are at their peak, offering insights into the correlation between net load and emissions during these critical hours. The results highlight the necessity for energy resources that can ramp up production quickly and efficiently, particularly during non-solar hours. We then discuss how EGS and ORC systems enable the extraction of continuous, dispatchable, carbon-free power from geothermal resources, contributing to a more sustainable and resilient energy mix. The combination of the huge resource potential of EGS coupled with the production flexibility of ORC systems make is the key to decarbonizing future grids.

1. Introduction

Geothermal energy, with its ability to provide continuous baseload power and minimal carbon footprint, is poised to play a critical role in the global energy transition. This paper explores how Enhanced Geothermal Systems (EGS) and advanced Organic Rankine Cycle (ORC) technology combined with innovative contracting can meet the needs of future grids. Previous examples of the combination of the two technologies have been implemented by geothermal companies. At

Soultz-sous-Forêts, France, an EGS system was developed by creating artificial reservoirs in hot rock formations. Water was injected into deep wells to create fractures, allowing heat extraction. The hot water was then used to generate electricity using ORC technology. The Soultz Project demonstrated the viability of combining EGS and ORC, expanding geothermal energy's potential in non-traditional areas. Despite technical challenges, it showed how EGS can harness geothermal energy in regions without natural hydrothermal resources (Ravier et al. 2019). During the production testing of Project Red, a full-scale commercial EGS pilot, system flow rates reached up to 63 liters per second (L/s) (Norbeck and Latimer 2023). For comparison, the Soultz Project achieved a flow rate of 30 L/s (Schill et al. 2017).

1.1 Background on Fervo Energy

Fervo is a next-generation geothermal developer founded in 2017 with the mission to provide 24/7/365 firm, clean energy from geothermal resources previously considered uneconomic for geothermal power generation. Producing geothermal power requires heat, permeability, and fluid. Heat from the earth's core acts as an energy source, elevating temperatures beneath the surface. Fissures in subsurface rock provide paths for water to travel and conduct heat. As water flows through these fractures, it heats up, ultimately producing hot pressurized water that can power a thermodynamic cycle to generate electricity.

1.2. Traditional Geothermal

Traditional geothermal development targets naturally occurring fracture systems using vertical drilling. This approach presents a few significant problems. First, vertical wells intersect only a small portion of geothermal reservoirs, (Mackenzie et al. 2023). Second, in reservoirs with abundant natural fractures, drilling fluid may be lost to pores in the rock, increasing well costs (Vollmar et al. 2013). Given these challenges, roughly twenty percent of traditional geothermal wells cannot on their own support commercially viable flow rates (ESMAP 2013).

There are two primary reasons why traditional geothermal cannot meet the demands of future grids. The first is that the resource is geographically limited. Enhanced Geothermal Systems (EGS) can help expand geothermal power by more than a factor of 20, for up to 90 GW to 5 TW of clean firm power by 2050 in the U.S. (Blankenship et al. 2024) (Ricks et al. 2024). The second reason is that, as opposed to conventional geothermal, EGS can dictate its resource conditions and target specific subsurface temperatures more precisely with potentially higher values, and specify as much geothermal water flowrate as needed (and drill accordingly). Hot dry rock reservoirs, combined with horizontal drilling are order of magnitudes larger than conventional ones. This capability allows EGS to be more adaptable and scalable, addressing the temperature and resource limitations that traditional geothermal faces.

While the basic physics are comparable between traditional geothermal and EGS systems, the scalability, flexibility, and customizability of EGS systems radically change their potential contribution to future grids.

1.3 Innovative Enhanced Geothermal System

Innovative EGS uses three methods to address traditional geothermal issues: horizontal drilling, multi-zonal completion, and distributed fiber optic sensing. Precision directional drilling enables increased access to more subsurface surface area per well, cutting project costs. Multi-zone completion techniques evenly distribute the flow of injection fluids across the entire geothermal reservoir. Enhancing flow distribution dramatically extends the lifespans of enhanced geothermal systems. Finally, robust measurement and diagnostics via distributed fiber optic sensing allows thorough assessments of subsurface temperatures, pressures, and permeability with greater precision than traditional geothermal.

1.4 Background on ORC technology

ORC technology converts low to high enthalpy heat sources into electricity. ORC systems are known for their high utilization range, modular design, low maintenance needs, and minimal environmental footprint, making them ideal for geothermal applications. Organic Rankine Cycle (ORC) technology has been increasingly implemented in geothermal power generation, especially for low-to-medium enthalpy resources (100-180°C). As of recent years, ORC technology is widely used in over 20 countries, contributing significantly to geothermal capacity worldwide. The ORC process is particularly suited to locations where traditional steam turbines are not viable. It uses organic fluids with lower boiling points than water to efficiently convert geothermal heat into electricity, even at lower temperatures.

The United States, Turkey, New Zealand, Germany, the Philippines and other traditional geothermal countries are leaders in deploying ORC for geothermal applications. In the United States, ORC is extensively used in Nevada and California. New Zealand and Turkey, with its rapidly growing geothermal sector, have also adopted ORC in many of their new plants. In low enthalpy and deep geothermal basins such as Molasse Becken in Germany, ORC is the only viable option for power production.

Globally, ORC technology contributes to about 4 GWs of installed geothermal capacity (Market study by Turboden), making it a key component in the broader adoption of geothermal energy. The continued expansion of ORC technology is expected, driven by its adaptability to a wide range of geothermal conditions. Thanks to this, in the last 5 years the ORC technology has doubled its shares among other competing technologies such as single and double flash, dry steam turbines (Thinkgeoenergy 2022).

1.5 Collaboration between ORC and EGS technologies at Cape Station

Fervo Energy is developing the multi-phase Cape Station geothermal development located in Beaver County, Utah, northeast of Milford. Turboden was selected to design, procure and commission the complete ORC unit for Phase 1 of Cape Station geothermal project. This 1st phase will begin delivering around-the-clock, clean power to the grid in 2026. The turbines feature axial flow, multistage and run at 1800 rpm. The turbines are directly coupled to the electric generator and the design inlet pressure is about 29 bar and 11 bar for the high pressure and low pressure cycles respectively. The expected turbine isentropic efficiency is higher than 90% (total to static,

including all the stage losses). The axial geometry is the most suitable to achieve high efficiency in the widest range of operation; it is expected in fact a derating of the efficiency of only -3% during summer operation, and -5% during winter operation. The turbines are designed to maximize energy production according to the Cape Station site ambient conditions.

2. Overview of Future Grids

Dispatchable, air-cooled geothermal technology is essential for balancing future energy grids amid increasing fluctuations from intermittent renewable energy integration. Future grids require firm, clean, dispatchable power to ensure reliability and sustainability. To examine this need, we took data from NREL's Cambium mid-case scenario, identified the highest emission hours per month in 2035, and then averaged net load and emissions by hour for that month. This approach allows us to pinpoint the periods within the year when emissions are at their peak, offering insights into the correlation between net load and emissions during these critical hours. The results, shown in Figure 3, highlight the necessity for energy resources that can ramp up production quickly and efficiently, particularly during non-solar hours (Gagnon et al. 2023).

2.1 Grids in 2035

Projected average emission rate for in-region generation, or carbon dioxide from direct combustion in kg/MWh varies significantly across regions of the western U.S. Northern Grid West has the lowest average emission at 8 kg/MWh, while Northern Grid South has the highest average emission at 91.7 kg/MWh (Gagnon et al. 2023).

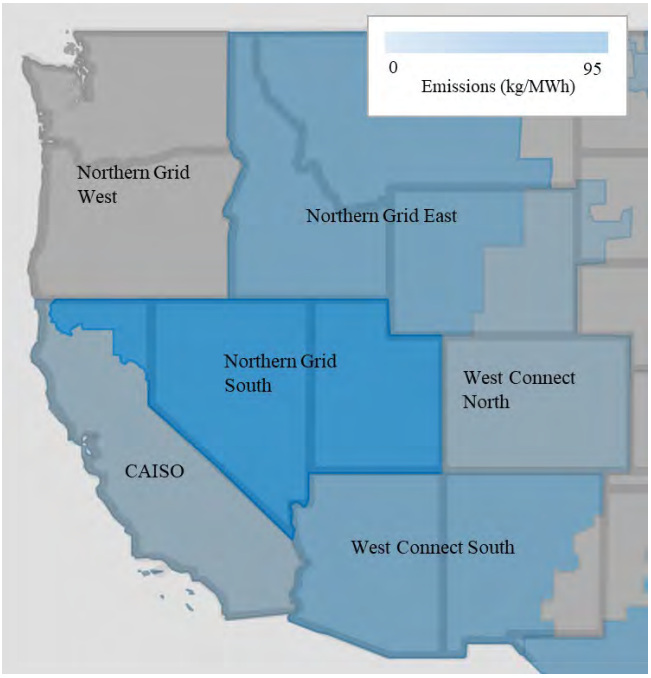

Figure 1. Heatmap of projected average emissions in 2035 in the western U.S.

In September of 2035 in the CAISO region, the load ranges from 30 GW in the morning to around 25 GW in the afternoon, and back to 55 GW in the evening, showing a ramp of 35 GW. The Northern Grid South region has a similar trend, with a net load of about 11 GW in the morning,

dropping to –2.5 GW in the afternoon, and rising to a peak of 13 GW in the evening, resulting in a ramp of 29 GW. The West Connect South shows an average net load of around 11 GW in the morning, decreasing to –0.7 GW in the midday hours, and increasing to 18 GW in the evening, resulting in a ramp of 30.4 GW.

During the month of September, all grids except for those in the Pacific Northwest and CAISO show an excess of generation during daytime hours and high emissions in the evening and morning hours. The duck curve seen so prominently in California today expands to every region across the West.

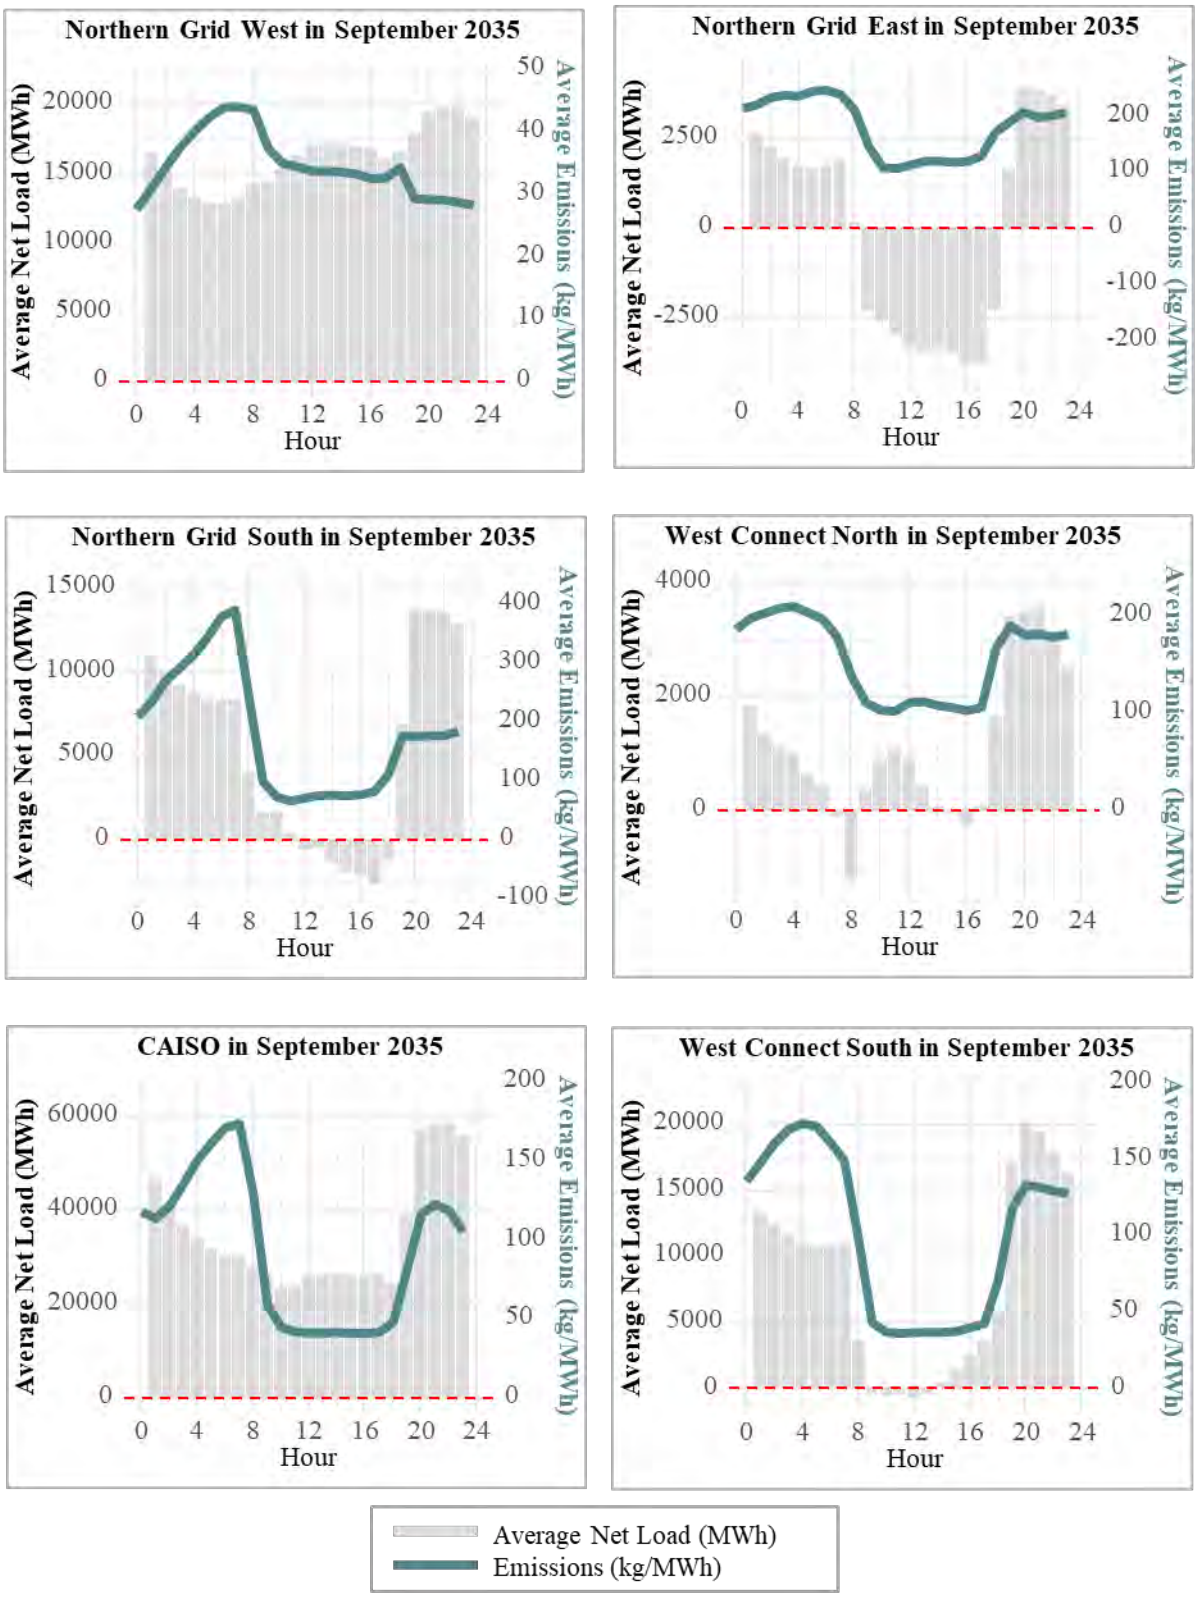

Figure 2. Emissions Versus Net Load Source: Fervo Analysis, NREL Cambium

Despite differences, all grids would be aided by a resource that is clean, flexible, and anti-correlated with solar. It must produce minimal to no greenhouse gas emissions, ramp up or down quickly to match demand fluctuations, and generate power when solar power is less available, such as during the evening or night. Dispatchable, air-cooled, geothermal is this resource.

3. Why Geothermal Works: Innovative Drilling Techniques and Coupled with ORC

Firm, clean power is not only essential for balancing future energy grids, but innovative drilling techniques and ORC technology also demonstrate technical viability for large-scale implementation.

3.1 Overview of modern drilling techniques employed by Fervo Energy

Modern drilling techniques have revolutionized geothermal well field development. These techniques, including directional drilling, hydraulic stimulation, and advanced subsurface analytics, enhance the efficiency and effectiveness of geothermal resource extraction.

Directional drilling allows for precise targeting of geothermal reservoirs, maximizing the extraction of heat from the subsurface. This technique involves drilling wells at various angles rather than just vertically, which increases the contact area with the geothermal resource and improves the overall energy yield. Hydraulic stimulation involves injecting high-pressure fluid into the well to create fractures in the rock formations. This enhances the permeability of the reservoir, allowing for greater flow of geothermal fluids and increased heat extraction. Advanced subsurface analytics, including 3D seismic imaging and real-time data monitoring, optimizes field development. These technologies provide detailed insights into subsurface geology, enabling precise well placement and efficient resource management.

These innovative drilling techniques and subsurface analytics maximize the efficiency of geothermal energy extraction, reducing costs and improving the overall performance of geothermal projects. These techniques have been applied at Cape Station and major improvements in drilling performance have been observed throughout its development (Fervo Energy 2024).

3.2 Turboden's ORC Technology

The well-known Rankine Cycle is a thermodynamic process that converts heat into work. This cycle typically employs steam as the working fluid to spin a turbine and generate power, accounting for approximately 85% of global total electricity production. In contrast, the Organic Rankine Cycle (ORC) uses an organic fluid with a lower boiling point and higher molecular mass than water, enabling it to effectively utilize lower temperature heat sources.

The ORC turbogenerator operates at slower peripheral speed and without eroding metal parts and blades. It uses low-to-high-enthalpy geothermal fluid to preheat and vaporize an organic working fluid in the evaporator. The vaporized fluid then drives a turbine directly coupled with an electric generator, producing clean and reliable electric power.

The organic exhaust vapor passes through a recuperator, heating the organic liquid upstream to the preheater, before being condensed in the condenser. The organic working fluid is then pumped back into the recuperator, preheaters and evaporator, completing the closed-cycle operation. This process is particularly well-suited for geothermal applications due to several advantages:

1. **High Utilization:** The ORC technology can effectively convert low to high-temperature heat sources into electricity (as opposed to steam plants).
2. **Modular Design:** The scalable design allows for easy integration with existing geothermal infrastructure.
3. **Low Maintenance:** ORC systems have relatively low maintenance costs and high operational reliability.
4. **Environmental Benefits:** The ORC process produces no emissions and has a minimal environmental footprint.
5. **Dispatchability:** It can provide a consistent and reliable source of electricity that can be adjusted to meet demand fluctuations.

The use of an automatic control system for the ORC turbogenerator minimizes the need for continuous monitoring. The ORC turbogenerator can operate at partial loads, self-adapting to the available thermal power or following a grid operator's load profile. This flexibility enables ORC power plants to adjust their output to match grid demand, thereby enhancing the reliability of geothermal energy as both a base load and peak load power source. As a base load source, geothermal energy provides a stable electricity supply to meet minimum demand. As a peak load source, ORC plants can, given resource conditions (available via EGS) quickly ramp up output to meet higher demand during peak hours (Turboden 2016).

4. Innovating Technology along with Contracting

While EGS and ORC power plants are technically viable for adjusting to grid demand, current contracting structures lack the flexibility needed to provide economic incentives for operators to adjust to energy market fluctuations. This section discusses current and future contracting structures.

4.1 Traditional PPAs

Traditional Power Purchase Agreements (PPAs) offer fixed pricing, quantity, and terms for electricity, ensuring financial stability and predictable revenue for a developer. They benefit EGS by providing a guaranteed level of revenue but do not adapt to real-time energy demand fluctuations. Consequently, the traditional PPA’s fixed prices offer minimal environmental benefits as they do not incentivize EGS to align production with demand variations.

4.2 Capacity Agreements

Capacity agreements involve setting a fee for available capacity, ensuring operators get paid for maintaining readiness to generate electricity, regardless of actual production. This structure provides financial stability while allowing production flexibility to meet market demands. However, the facility is not incentivized to produce Renewable Energy Credits (RECs) nor load follow.

4.3 Merchant Sales

Merchant sales electricity at fluctuating market-based prices, allowing operators to respond dynamically to real-time demand. This setup maximizes environmental benefits by incentivizing operators to supply energy during high-demand periods, reducing grid reliance on carbon-intensive

sources. Merchant agreements introduce significant financial uncertainty due to price fluctuations, making it challenging to secure financing.

While traditional contracting structures do not meet the mark, innovative contracting can combine successful aspects from different structures.

4.4 Clean Transmission Tariff

Fervo worked with Google and NV Energy in a Clean Transition Tariff (CTT) which creates long-term agreements for utilities and customers to invest in clean firm capacity, like enhanced geothermal energy, ensuring 24/7 clean energy supply. NV Energy, through a unique energy supply agreement with Google, partnered with Fervo Energy to add 115 MW of geothermal power. This collaboration offers a customizable framework for varying state regulations, enhancing clean and reliable power delivery (Corio and Kober 2024).

4.5 Hybrid Contracting Structures

Geothermal developers are also exploring hybrid contracting structures, combining merchant contracting during the day and set prices during the night to meet the grid's needs. Merchant contracting disincentivizes producing energy during hours when solar and storage capabilities meet or exceed energy demands since prices during these hours are typically low or negative. This hybrid ensures pricing certainty by contracting set prices outside hours of solar energy and storage capabilities. It also provides a degree of flexibility to meet demands during the day if prices reflect significant need for renewable energy, while also providing additional incentives to supply energy at night when carbon intensive resources are likely to be called upon.

4.6 Tolling with Time Based Brine

Another viable contracting structure is a PPA with prices shaped to market demand. During hours when renewable energy supply is high relative to demand, prices would be set low if an operator supplied electricity. During hours when renewable energy supply falls below demand, prices would be set higher to account for limited hours that the resource is called upon. This structure provides financial certainty for an operator while allowing a limited degree of flexibility to respond to energy demands.

4.7 Looking Ahead

To address the limitations of traditional contracting structures, Fervo Energy is exploring innovative and hybrid contracting concepts that combine successful aspects from different structures. These include merchant contracting for real-time demand responsiveness, capacity agreements for financial stability, and tailored pricing to reflect market demands. Collaborations like the Clean Transition Tariff (CTT) with Google and NV Energy, adding 115 MW of geothermal power, demonstrate the potential for flexible, long-term agreements to support 24/7 clean energy supply while meeting future grid demands (Corio and Kobor 2024).

5. Challenges and Development Risks

Geothermal energy development faces some challenges and risks. Drilling and stimulation involve geological uncertainties that can lead to cost overruns and delays, necessitating advanced

techniques and real-time monitoring. Induced seismicity, caused by high-pressure fluid injection, is another concern. Fervo mitigates induced seismicity risk through comprehensive seismic monitoring and an Induced Seismicity Mitigation Plan (ISMP). Reservoir maintenance and depletion also pose challenges, particularly with flexible and dispatchable operations that require careful management of pressure and temperature.

ORC is a proven and mature technology with millions of cumulative operational hours worldwide. The critical components such as the Turbines are not in contact with geothermal fluids (such as traditional flash steam Turbines), ensuring long life of the components with minimal maintenance activities. Most of the equipment is available “off-the shelf” and can be procured in a short time in case of need. In a traditional hydrothermal project, the main risk during operation is represented by the potential fouling, scaling or corrosion inside the tubes and pipes of the plant. At Cape Station it is expected minimum scaling and corrosion potential at the design temperatures of production and reinjection, with the expected levels of minerals dissolved in the water being low, due to the fact they stem from ground water and not deep mineral-rich faults.

6. Future Prospects

Flexible Enhanced Geothermal Systems hold significant potential for load-following generation and long-duration energy storage, making them a critical asset in decarbonized electricity systems. This paper evaluates the impact of operational flexibility on the long-term value and deployment potential of EGS power in the western U.S., finding that flexible EGS substantially increases optimal geothermal penetration and reduces bulk electricity supply costs compared to inflexible systems. With a potential 5 TW electric generation capacity in the U.S., EGS can complement large-scale deployment of variable renewable energy resources (Ricks et al. 2024).

6.1 Modularization

The ORC plant is designed with modular components. Turbines, generators, pumps, heat exchangers, and air-cooled condenser are based on identical modules that can be replicated to scale up with capacity. Modularity is helpful for maintainability as well, as the same spare parts can be shared for different ORC units. For Phase 1, Turboden has split the overall capacity in three generators, 62.5 MVA each, which is currently at the higher end of four-poles synchronous generators available on the market. The other components such as turbines, ORC pumps and heat exchangers, are designed to accommodate for higher flowrates and inlet temperatures, together with the minimum ambient temperatures at site, to overcome any “bottleneck” for the energy generation at off-design conditions. Other components such as the air-cooled condenser are made by modular items (bundles and fans), replicated in a number suitable for ensuring optimal condensing pressure at all times of operation.

The same modularization will be implemented at Phase 2, where it is anticipated to reach higher temperatures and capacity for each ORC module. This will further allow a decrease in capex per MW installed, thanks to the higher scale and higher efficiency effect.

6.2 Geothermal Anywhere

While this paper analyzes the Western U.S. emissions and net load in 2035, other power markets will face similar challenges due to the increasing integration of intermittent resources like solar and wind. Firm, clean energy that can function as both a baseload and peak energy source is

necessary in every market to balance and decarbonize the grid. Geothermal energy, with its capability for stable and dispatchable power, stands out as a versatile solution that can be implemented in various geographical regions.

7. Conclusion

This paper has outlined the critical advancements and collaborative efforts between EGS and ORCs in the geothermal energy sector. Innovative drilling techniques, such as horizontal drilling, multi-zonal completion, and distributed fiber optic sensing, address traditional geothermal challenges by enhancing reservoir access, improving fluid distribution, and providing precise subsurface diagnostics. These advancements significantly increase the efficiency and reliability of geothermal energy extraction. Complementing this, ORC technology efficiently converts low to high-temperature heat sources into electricity, offering high efficiency, modular design, low maintenance, environmental benefits, and dispatchability. The synergy between EGS drilling innovations and ORC systems ensures optimized energy production and operational flexibility. Together, they pioneer a new model of clean, sustainable, and reliable power generation. Their innovative contracting strategies, including carbon-based and hybrid models, further enhance the financial viability and environmental impact of geothermal projects. This collaboration exemplifies how advanced technology and strategic contracting can drive the future of geothermal energy, providing a robust solution to meet the demands of evolving energy grids.

Keywords

Pelton turbine, mechanical energy storage, geothermal, high pressure, high efficiency, geopressured geothermal systems

ABSTRACT

This paper presents a technological advancement in energy storage and geothermal technology with the development of a high-pressure Pelton turbine designed for deployment on the flowback cycle of deep well operations. Conventionally used at high-head hydroelectric sites, the Pelton turbine has been reimagined to harness high-pressure held in deep wells, offering a new pumped storage approach in the form of mechanical energy.

The custom-designed Pelton turbine features a 3.2MW rating across a range of pressures from 3,500 to 5,000 psi, making it a unique but robust solution for extracting energy from high-pressure energy storage or geothermal reservoirs. With efficiency on par with pumped hydro storage facilities, this turbine introduces a scalable and cost-effective solution to geothermal energy extraction. This turbine technology will increase the mechanical efficiency and decrease the cost of energy storage and geothermal facilities, making them a more likely solution for a source of energy storage or geothermal power generation.

The use of this technology in the subsurface energy storage industries marks a significant departure from traditional geothermal practices, as it now captures the abundant pressure available from pumping and flowing back water in deep wells, providing a simple yet highly efficient means of energy extraction. This has allowed companies to develop new means of energy storage technologies, lower the cost and increase the efficiency of geothermal applications, which harvests both pressure and heat, and become cost-competitive with other forms of energy storage and baseload power.

The simplicity of the high-pressure Pelton turbine offers an affordable and scalable solution, paving the way for the widespread deployment in geothermal and energy storage wells. This paper discusses the design, performance expectations, and transformative potential of this technology, positioning it as a key player in the sustainable energy landscape.

1. Introduction

The search for more sustainable and efficient energy sources has led to significant advancements in renewable energy technologies. Among these, geothermal energy stands out as a promising and consistent source of power. Most typical geothermal systems currently only harvest the heat in a geothermal reservoir, and do not consider the pressure that could be harvested, inherently increasing the efficiency of a system, which opens the geothermal industry to a new type of geothermal, called Geopressured Geothermal Systems (GGS). Unlike traditional Enhanced Geothermal Systems (EGS) or Advanced Geothermal Systems (AGS), GGS harvests not only the heat but also the inherent pressure (mechanical energy) within geothermal wells, effectively doubling the net power output of these wells.

A suite of technologies has been developed to harness geothermal energy at various heat grades and applications. The first is a mechanical subsurface storage technology, a deep but low-grade geothermal energy storage system, which utilizes the high-pressure Pelton turbine to convert mechanical energy (pressure) to electricity. This system is similar to traditional pumped storage hydro (PSH) but operates under higher pressures due to the natural geostatic forces acting upon the artificially created fractures. These fractures, created through gravity fracking, act as subterranean balloons that are filled with water. The Earth's tendency to close these fractures results in the water being expelled with significant force to the surface, which is then converted into energy using the Pelton turbine. Additionally, the previously mentioned GGS technology is similar to the mechanical subsurface energy storage technology, but at greater depths utilizes both the pressure and heat of the produced water. See Figure 1 for a typical pumped storage hydro (PSH) system.

The Pelton turbine, traditionally employed in lower-pressure PSH facilities, has been re-engineered to leverage the high pressures encountered in GGSsystems. This adaptation represents a leap in technology, as it combines the reliability and simplicity of established hydroelectric equipment with the novel application of high-pressure geothermal energy extraction. The custom-made high-pressure Pelton turbine is a testamentto innovation, cost reduction, and the rapid deployment of utility-scale and commercially viable renewable energy in the geothermal space.

This paper delves into the technical and practical aspects of thehigh-pressure Pelton turbine and its role in advancing the availability of geothermal systems. It explores the design considerations, engineering challenges, and the potential for this technology to help revolutionize the geothermal industry.

2. Background on Pelton Turbines

The Pelton turbine, also known as the Pelton wheel, is an impulse-type water turbine that was developed by the American inventor Lester Allan Pelton in the 1870s (see Figure 2). It marked a significant advancement in hydroelectric technology, extracting energy from the impulse of moving water (the kinetic energy) rather than the water’s dead weight, which was the common

method of the time. Pelton's design was revolutionary because it extracted almost all of the water's impulse energy, making it a highly efficient piece of technology.

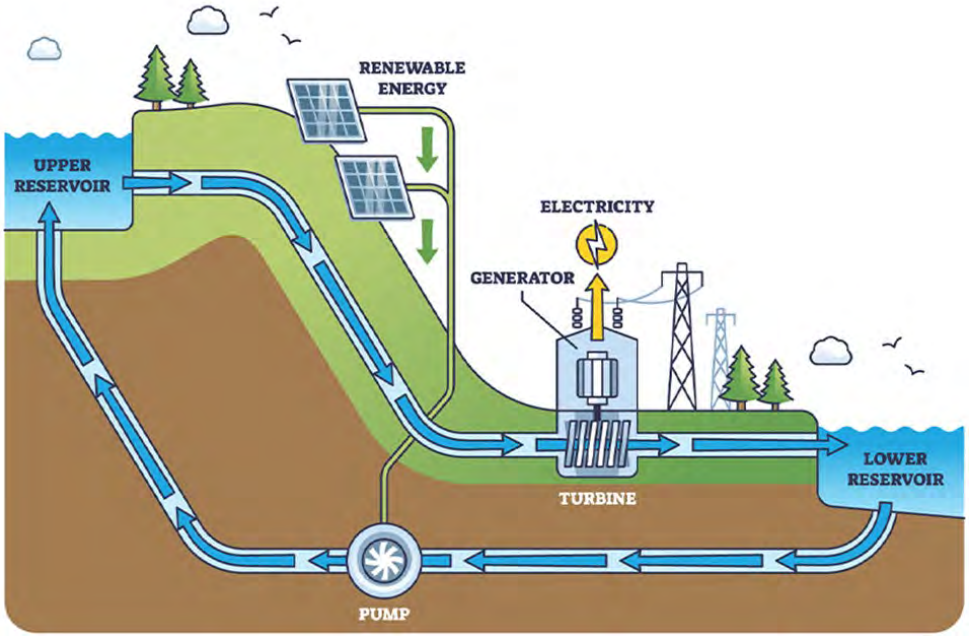

Figure 1: Setup of a closed loop pumped storage hydropower (PSH) facility (Cropley 2023).

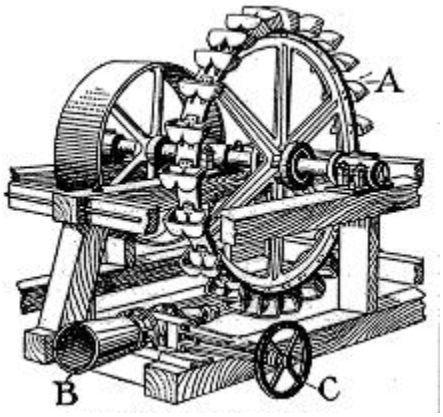

Figure 2: Pelton turbine produced by Lester A. Pelton in the 1870s from his patent, which was granted in 1889 (Vermilion History Society 2020).

Lester Allan Pelton, born in 1829, moved to California during the Gold Rush era and eventually turned his attention to the inefficiencies of water wheels used in mining operations. By the mid-1870s, Pelton had developed a wooden prototype of his new wheel, and in 1878, the first commercial model was installed at the Mayflower Mine in Nevada City, California. The efficiency advantages of Pelton's invention were quickly recognized, and it became a sought-after product for mining and later, hydroelectric power generation.

The Pelton wheel operates on the principle of capturing the kinetic energy of a high-velocity water jet. The water strikes specially designed buckets along the wheel's perimeter, which splits the

water jet and reverses its flow, effectively transferring its momentum to the wheel. This design allows for high mechanical efficiency, especially in applications where a high head of water is available, which results in more energy.

The Pelton turbine has been used in modern energy needs for PSH, which is a type of hydroelectric power generation used to balance supply and demand on the electricity grid. The system involves two reservoirs at different elevations. During periods of low electricity demand, excess electrical power is used to pump water from the lower reservoir to the upper reservoir. When there is a high demand for electricity, water is released from the upper reservoir back down to the lower reservoir, passing through turbines to generate electricity. A Pelton turbine, specifically, is used in high-head, low-flow applications within this system. The Pelton turbine operates by converting the kinetic energy of a jet of water into mechanical energy; water from the upper reservoir is directed through nozzles to strike the buckets of the Pelton wheel, causing it to spin and drive a generator. This setup is highly efficient for energy recovery in pumped storage systems due to the Pelton turbine's ability to operate efficiently at varying water flow rates and pressures.

3. Background on Long Duration Energy Storage Systems in the Subsurface

Long-duration energy storage (LDES) technologies function as underground, pumped-hydro-like mechanical energy storage systems in deep geologic structures created via a vertical fracture system in low-permeability (< 50 millidarcy) formations. The rock can be sedimentary or hard rock (igneous, granites, etc.), as long as the permeability is low. The resulting fracture system, sealed underground, acts like a reservoir for holding pressurized water.

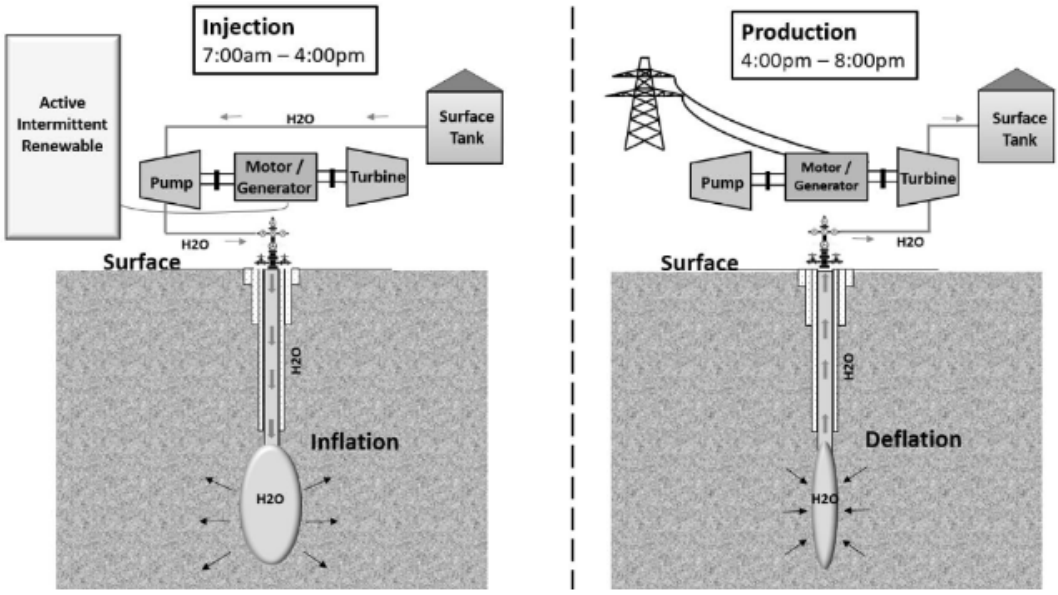

Figure 3: Schematic of a subsurface mechanical energy storage system in its two phases: the storing of energy (left) and production of energy (right) (Simpkins, et al. 2023).

For mechanical energy storage (without heat), the target geologic formations for the reservoirs are deep, typically 7,000 to 12,000 feet, where the high in-situ stresses in the rock drive the fracture closure and therefore the discharge cycle. Charging involves pumping water from a surface storage through the wellbore into the fracture network, which acts as an artificial underground reservoir,

and building pressure above hydrostatic by inflating the fracture network with a volume of water. Discharging involves turning off the pump and allowing the fracture to partially deflate and push the water back up the wellbore to the surface, where it drives a Pelton type turbine-generator. The round trip efficiency (RTE) of this system is 70-75% with a duration range of 4 to 24+ hours, and water losses less than 2% as measured during a2023 commercial pilot demonstration. These vertical fractures are operated between fracture opening and fracture extension pressure, meaning there is always a volume of water in the fracture, and only about 10% of this volume is cycled to maintain a high RTE. This technology is very flexible in that, if required, additional water can be pulled from the fracture to generate electricity with the only potential impact being lower RTE. The energy storage system produces free low-quality heat (< 100°C) that can be potentially used to power cooling and/or thermal desalination systems.

A variant of this mechanical energy storage technology involves stored subsurface water harvesting natural geothermal heat from the surrounding formation, which is used to generate electricity through a binary cycle power plant, using either a commercial Organic Rankine Cycle (ORC) or a proprietary supercritical CO2 (sCO2) power system. In this scenario, both the heat and pressure energy of the water contribute to the net electricity generation at the surface. For this geothermal energy storage technology, a formation temperature between 150 and 250°C is required.

These technologies were developed as a response to the challenges posed by intermittent renewable energy sources such as wind and solar power, which have done a great job greening the grid, but are frequently curtailed and contribute to grid instability. The variability in generation from these sources and the inability to control the time of day when the power is generated makes it difficult for electricity grids to consistently meet peak demand, particularly during periods when renewable output is low, such as nights or cloudy days. Traditional solutions like natural gas peaker plants and coal-fired power stations provide reliable energy supply but come with environmental concerns. Figure 4 shows what is called a “duck curve” that shows the electricity demand/supply throughout the day typically controlled by solar energy production between 9 AM and 6 PM.

These technologies address these challenges with a mechanical and/or thermal energy storage system designed to enhance grid stability and support renewable energy integration. These innovative technologies store energy underground in subsurface formations (see Figure 5), utilizing the natural high-pressure environment to store water under pressure and/or harvest heat. During periods of high demand or low renewable generation, the stored water is released and channeled through a Pelton turbine to convert kinetic energy into electricity. This cyclical process of water injection and extraction enables these systems to function as a sustainable energy storage solution. This energy storage can cost-effectively deliver a storage duration of 4 to 24+ hours, readily enabling time matching with any intermittent power source. Modeling of blended Levelized Cost of Energy (LCOE) for solar paired with Sage’s EarthStore is $0.05/kWh at 100+MW scale, assuming a price point of $0.02/kWh for solar. The same blended LCOE of solar paired with lithium-ion batteries is double, or $0.10/kWh.

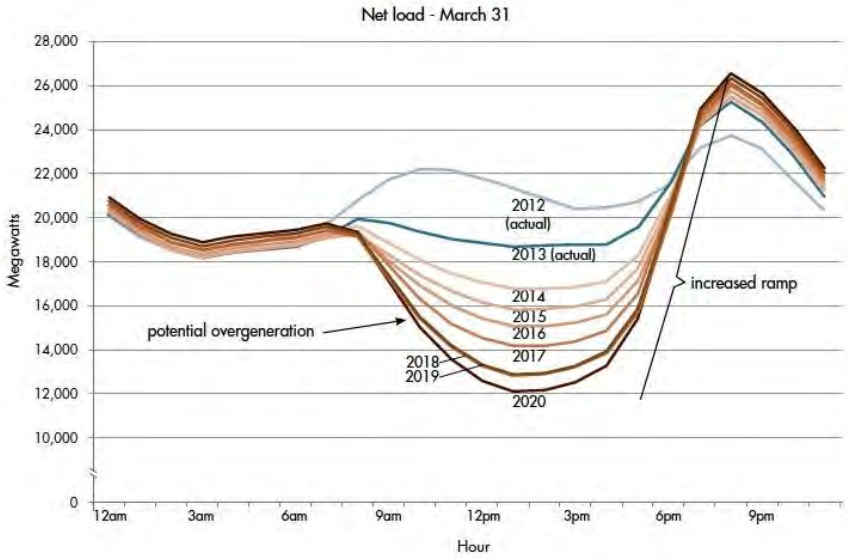

Figure 4: Energy demand "duck curve" (Jones-Albertus 2024).

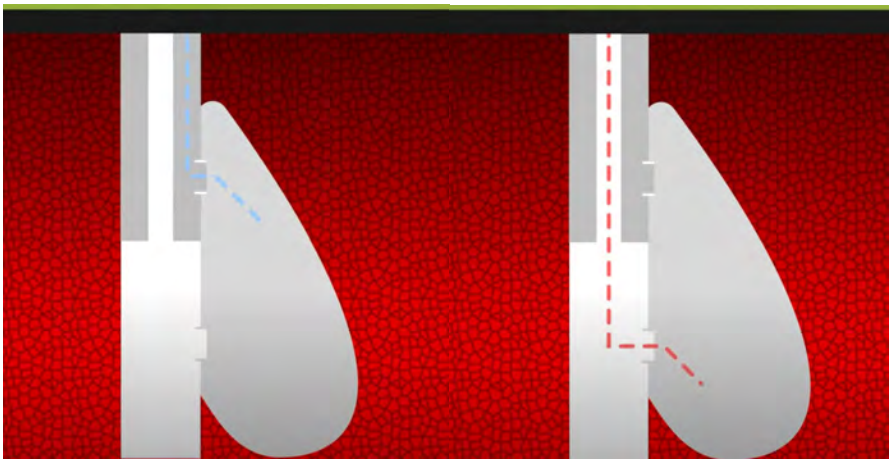

Figure 5: Sage Geosystems' pump in and flowback process (Sage Geosystems 2024).

In regions like California, where seasonal energy demands vary significantly (see Figure 6)—peaking during hot summer months—the flexibility of energy storage types like these becomes crucial. These technologies enable the energy supply to be varied throughout the year, complementing the intermittency of solar and wind power, and their own changing generation profile by season. Additionally, the capability to provide long-duration energy storage is invaluable during extreme weather events such as storms, tornadoes, hurricanes, etc. by ensuring continued energy supply to critical facilities such as hospitals, data centers, and military bases when conventional renewable sources are unavailable.

As the demand for clean energy storage solutions grows amid global efforts to reduce carbon emissions and enhance energy resilience, these technologies represent a pivotal advancement in sustainable energy technology. Their ability to integrate seamlessly with existing renewable infrastructure while mitigating the challenges of intermittency underscores their potential to support a reliable, commercially viable, and environmentally responsible energy future.

4. Experimental Data from Preliminary 1MW Study

Before developing a full-scale high-pressure Pelton turbine, a preliminary study was conducted for a smaller-scale version. The parameters for this study included pressure ratings from 1,500 to 3,500 psi (pressure per square inch), a flow rate between 1.9-4.2 CFS (cubic feet per second), a target of 1 MW (megawatt) power output, and a higher limit of 95°C for the temperature of the water coming out of the well. It is important to note that the 95°C temperature limit was to ensure the fluid stays in single-phase, as Pelton turbines are not designed to handle two-phase fluids.

The biggest challenge in this study was that this would be the highest head for a Pelton turbine in history. It would require a Variable Speed Drive with the wide pressure range as well as a high speed generator capable of 180% overspeed.

Critical engineering tasks included jet formation, runner modeling and stress analysis, the variable speed mechanism, and the generator design. A significantconcern that was considered but resolved was the stress that the runner would be experiencing, especially when encountering water with higher TDS (total dissolved solids) or when sharp-shaped solids were present in the water. These dissolved solids could wear down the “cups” or “buckets” on the runner, which is the part of the Pelton turbine that is pushed by the water in order to turn. Pelton turbines already have a very robust design, and material considerations such as the addition of coatings on the runner buckets can overcome erosion concerns.

The study found it possible to design and manufacture a Pelton turbine and control system for the presented conditions.

5. Results and Discussion

In the preliminary 1MW Pelton turbine study, several critical challenges and solutions were identified and addressed. First, adapting Pelton turbines to operate at unprecedented high heads posed significant engineering hurdles, particularly regarding runner stresses and shaft speeds. With

shaft speeds typically lower in hydroelectric turbines, the high pressure Pelton's operation at 1,800 rpm necessitated advanced Computational Fluid Dynamics (CFD) and Finite Element Analysis (FEA) for runner design to withstand centrifugal forces effectively. Addressing natural frequencies also required iterative refinements to ensure structural integrity.

Second, achieving optimal jet formation at velocities up to 262 meter/second or 860 feet/second presented another pivotal challenge that was resolved. The design intricacies of the nozzles and precise jet formation were meticulously analyzed through two-phase CFD simulations. These efforts were crucial in optimizing energy transfer efficiency from the high-pressure water jets to rotational mechanical energy.

Another issue was the need for variable speed operations, which was paramount given the wide range of pressures encountered. Traditional Pelton turbines operate most efficiently within a narrower pressure band. This prompted the adoption of a variable frequency drive (VFD) for the generator. This adaptive control system dynamically adjusts turbine speed relative to inlet pressure, thereby maximizing efficiency across varying operational conditions.

Lastly, the design of a robust generator capable of up to 180% overspeed under uncontrolled load rejection conditions was pivotal. Collaboration with a company to custom-design a generator not only addressed rotor stresses at elevated speeds but also accounted for unique rotor dynamics induced by the Pelton turbine's operational characteristics. This solution ensured reliable performance and longevity of the generator amidst demanding operational scenarios.

6. Summary and Conclusion

Energy storage and geothermal energy are critical technologies needed to deliver clean power generation amidst growing concerns over climate change and energy security. The development of Geopressured Geothermal Systems (GGS) technologies, distinct from traditional Enhanced Geothermal Systems (EGS) or Advanced Geothermal Systems (AGS), enhancing energy extraction efficiencies by leveraging both heat and pressure from geothermal wells will be pivotal to the clean energy industry. The development of long duration energy storage technologies in the subsurface, utilizing the newly developed high-pressure Pelton turbine design, exemplifies a significant technical leap in renewable energy solutions, technology, and equipment development. This paper details the engineering complexities and solutions involved in adapting Pelton turbines to operate efficiently under high pressures, optimizing jet formation dynamics, implementing variable speed operation strategies, and designing resilient generators. This high-pressure Pelton turbine is pivotal in advancing the practical viability of geothermal energy as a scalable, reliable, and environmentally responsible energy source. As research and development continue, such innovations hold promise for broader adoption and integration of geothermal technologies in the global energy mix, contributing to sustainable development goals and reducing the reliance on fossil fuels.

Keywords

Declining geothermal wells, ejectors for geothermal, geothermal experimental work

ABSTRACT

Geothermal production wells are susceptible to pressure decline over time, which could make them unusable for power generation when their pressure drops below the plant's operating conditions. This situation could decrease the power output, necessitating drilling make-up wells at a considerable capital cost. This study looks at options for using an ejector to mitigate this problem. An ejector is a static device that can potentially be used to draw fluid from a low-pressure well using a flow from a nearby high-pressure well. In ejectors, two flows are combined in a mixing chamber, and the mixture passes through a diffuser, leaving at an intermediate outlet pressure, which could be higher than the pressure of the low-pressure well.

Although ejectors are widely utilized in industries such as oil and gas and refrigeration, their application in geothermal energy has mainly been limited to gas extraction from power plant condensers. However, the literature lacks reports of successful ejector use for inducing geothermal fluid from low-pressure wells. As part of the Geoejector project, this paper focuses on the design, development, and performance analysis of a supersonic laboratory scale ejector prototype constructed at Reykjavik University. The prototype was tested using saturated steam for primary and secondary flows under different pressure conditions.

1. Introduction

An ejector is a static device that mixes a high-pressure primary flow with a low-pressure secondary flow in a customised mixing chamber. The mixture passes through a diffuser, leaving the ejector at an intermediate outlet pressure (Villa et al., 1999).

In a supersonic ejector, the high-pressure primary fluid expands and accelerates through a converging-diverging nozzle, reaching supersonic speed. This creates a low-pressure region at the

nozzle's exit, which allows the entrainment of the low-pressure secondary fluid into the mixing chamber, where both fluids start to mix until thoroughly combined inside the constant area mixing section (CAMS). A series of shock waves are produced within the CAMS, compressing and decelerating the flow to subsonic velocities before entering the diffuser. Further fluid compression and an increase in pressure are achieved as the combined streams flow through the subsonic diffuser section of the ejector (Manoj & Lijo, 2021) (Aidoun et al., 2019).

The performance of an ejector is characterized by the pressure, temperature, and velocities of primary and secondary fluids, the dimensions of the ejector, and its back pressure. Key geometrical factors influencing the performance of the ejector include the nozzle exit position (NXP)[1] and the ratio between the CAMS and the primary nozzle area (Yan et al., 2012).

A schematic view of a typical supersonic ejector is shown in Figure 1. The numbers represent flow positions used for the supersonic ejector calculations of the analytical model developed by (Andal, 2023), where 1 is the entrance of the primary flow, 2 is the nozzle's throat position, 3 is the nozzle's exit, 4 is the primary flow at the hypothetical throat[2] position, 5 is the entrance of the secondary flow, 6 is the secondary flow at the hypothetical throat position, 7 is the CAMS, 8 is the shock wave position, and 9 is the diffuser exit.

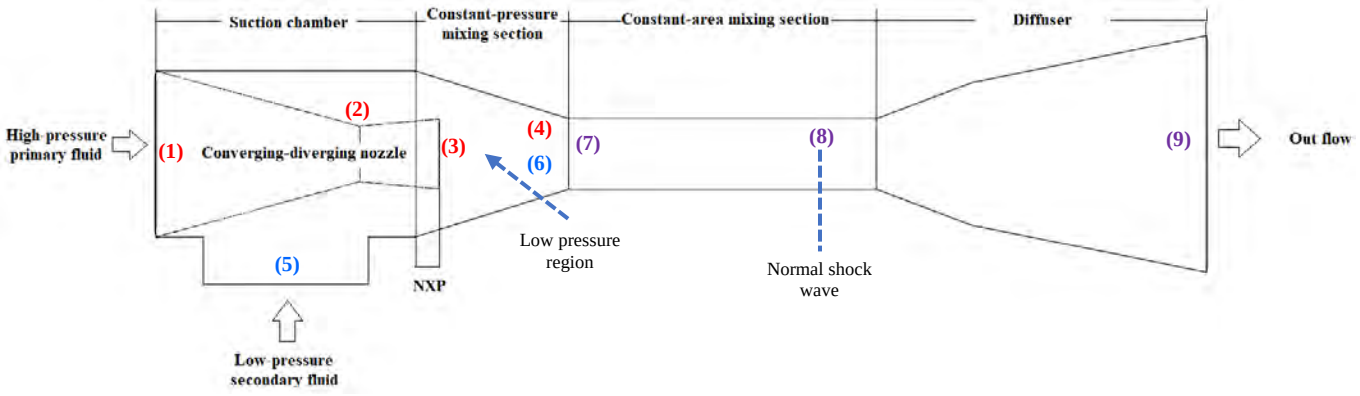

Figure 1. Schematic of a supersonic ejector adapted from (Ding et al., 2016).

In the geothermal industry, ejectors mainly extract non-condensable gases from condensers (Strušnik et al., 2016). Still, no published experimental validated information exists regarding their usage for fluid extraction from geothermal wells. A patent from 1999 (United States Patent N° 5899273, 1999) described an ejector to increase the fluid recovery from geothermal wells, but no further information on its usage was found. Also, it is known that the company Reykjavik Energy used an ejector on the Hellisheiði power plant in 2012 for managing scaling in a turbine which got high-enthalpy dry steam from a new well. The flow from that well was used in an ejector as the primary flow, and fluid from low-enthalpy two-phase wells was used as a secondary flow. This seemed to have washed the high-enthalpy steam and solved the scaling issue in the turbine (G. Kjartansson, personal communication 2023).

[1] The nozzle exit position (NXP) is defined as the distance of the primary nozzle exit from the inlet of the constant pressure mixing section (converging section) (Yan et al., 2012).
[2] The hypothetical throat is where the secondary flow is assumed to have reached sonic velocity (Huang et al., 1998).

In 2021, the power company Landsvirkjun tested a rudimentary subsonic ejector at the Theistareykir Geothermal Power Plant to use the high-pressure geothermal fluid from well ThG-11 to induce flow from the low-pressure well ThG-15. The tests showed that entrainment from the secondary flow was achieved. However, the pressure of the primary flow during the tests was kept between 12.6 and 15.4 bar-g, which is far below the nominal operating pressure of well ThG-11 (25 bar-g on average). This resulted in the pressure difference between the high- and low-pressure wells during the tests being significantly lower than in actual operation. Using an analytical model, it was estimated that an average of 20.6% pressure reduction of the primary flow occurred in the convergent nozzle used in the tests (Guardia et al., 2023). A significantly greater reduction in pressure would be needed under real operational conditions.

For that reason, the analysis developed by (Guardia et al., 2023) suggested that a supersonic ejector employing a convergent-divergent nozzle would be required to create enough under-pressure to entrain the secondary flow under normal primary pressure conditions of well ThG-11. In that sense, an analytical model was developed by (Andal, 2023), finding that a supersonic ejector could potentially increase the pressure of the fluid from well ThG-15 up to and above the working pressure of the power plant (9.5-10 bar-g), which would potentially add up to 0.8 MWe for additional power generation.

This study focuses on designing and building a laboratory-scale supersonic ejector prototype at Reykjavik University based on the analytical model developed by (Andal, 2023). The prototype was tested using saturated steam for primary and secondary flows under different pressure conditions and for different geometrical factors NXP and area ratio.

2. Methodology

2.1 Ejector design

The supersonic ejector prototype was designed for a primary flow of 0.005 kg/s entering at 7.2 bar-g and 212°C, and a secondary flow of 0.003 kg/s entering at 2.3 bar-g and 170.6°C. Table 1 shows the properties and dimensions of the ejector calculated with the analytical model (Andal, 2023) for the flow positions presented in Figure 1.

Table 1. Calculated properties and dimensions of the laboratory scale ejector

	1 **Entrance of the primary flow**	**2** **Nozzle throat**	**3** **Nozzle exit**	**4** **Primary flow at hypothetical throat**	**5** **Entrance of the secondary flow**	**6** **Secondary flow at hypothetical throat**	**7** **CAMS**	**8** **Shock wave**	**9** **Diffuser exit**
Diameter (mm)	15.7	2.4	3.4	-	20.0	3.1	4.0	4.0	20.0
Mass flow (kg/s)	0.005	0.005	0.005	0.005	0.003	0.003	0.008	0.008	0.008
Pressure (Bar-g)	7.2	3.4	0.1	0.8	2.3	0.8	0.8	1.2	2.7
Enthalpy (kJ/kg)	2866.0	2754.9	2508.2	2592.8	2803.0	2698.7	2701.6	2741.1	2841.6
Mach number	0.0	1.0	1.9	1.6	0.0	1.0	1.1	0.9	0.0

Note: The points are indicated in Figure 1.

According to the analytical model, the CAMS should have a diameter of 4.0 mm, but three additional ejectors with different CAMS diameters were made to test the performance sensitivity to this parameter: 5.0, 7.0, and 9.0 mm (see Table 2 and Figure 2).

Table 2. Dimensions of ejectors used in the laboratory experiments.

Ejector type	D1 (mm)	D2 (mm)	D3 (mm)	D4 (mm)	D5 (mm)	L1 (mm)	L2 (mm)	L3 (mm)	L4 (mm)	L5 (mm)	L6 (mm)	NXP (mm)
4.0 mm CAMS	15.7	2.4	3.4	4.0	20.0	63.0	5.6	63.2	74.9	20.9	66.5	5.4

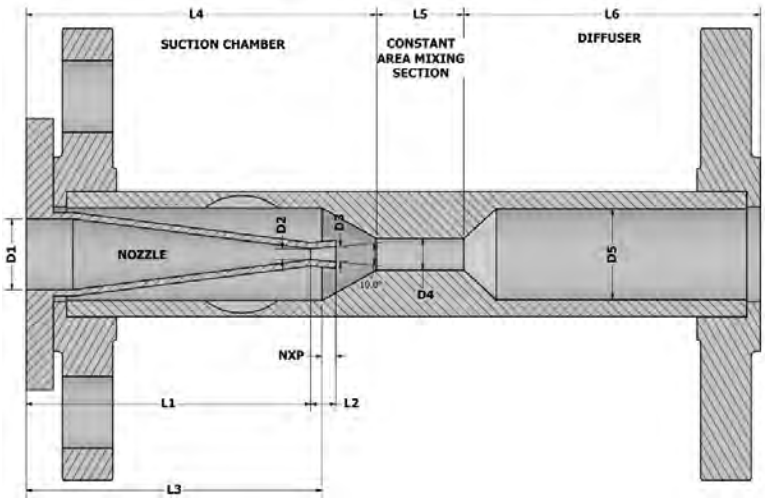

Figure 2. Drawing showing the general setup of the ejectors that were manufactured.

2.2 Ejector manufacturing

An aluminium nozzle was 3D printed to fit the dimensions in Table 2 (see Figure 3) in Tæknisetur ehf.-IceTec, using the selective laser melting printer iSLM160 (Tæknisetur ehf.-IceTec, 2024).

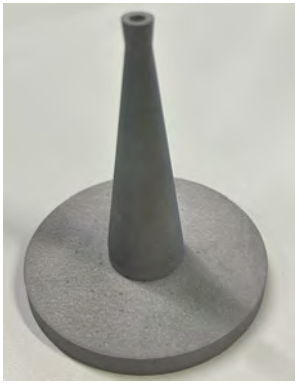

Figure 3. Aluminium nozzle printed in 3D.

The four mixing chambers were manufactured at Reykjavik University with Stainless Steel 304 using a high-precision lathe machine model TR1340VS from JESCO MACHINERY LTD. Holes of 4.3 mm were made in all mixing chambers. Then, 5 mm threads were made on them to introduce the miniature pressure sensor.

Finally, to test different NXPs, two aluminium blocks were manufactured to get 0 mm and -7.4 mm NXP, respectively (see Figure 4 and Figure 5).

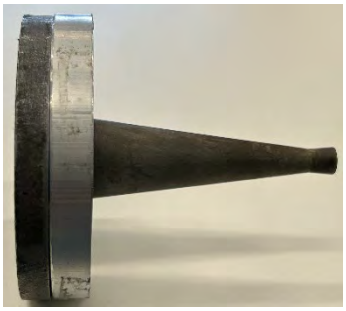

Figure 4. Nozzle with Aluminium block used for 0 mm NXP.

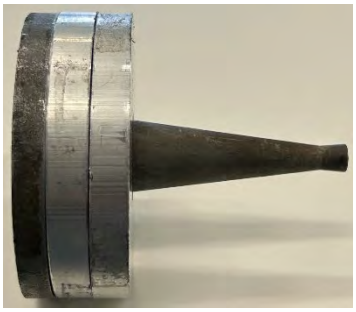

Figure 5. Nozzle with Aluminium block used for -7.4 mm NXP.

2.3 Equipment

Two boilers were used for the primary and secondary steam flow production. The boiler used for the primary flow production can produce steam at a pressure range from 7-7.2 bar-g pressure at a temperature between 212 and 215°C. In contrast, the boiler used for the secondary flow production has a pressure range from 1-10 bar-g and a working temperature from 100-185°C.

The following pressure, temperature and mass flow sensor equipment was used to obtain the data during the experiment. Their location is shown in Figure 6:

- 3 pressure sensors PCE-28/EXD type with a pressure range of 0 to 10 bar-a.
- 1 micro pressure sensor JC91 type with a pressure range of 0.7 to 10 bar-a.
- 4 temperature probes STA 206 P-type with a temperature range of -20 to 250 °C.
- 1 vortex flow meter Endress D 200 Model with a pressure range of 0 to 10 bar-a, and a temperature range of -40 to 260°C.
- 1 Pressure gauge with a pressure range of 0 to 12 bar-a.

All sensor values were recorded using a Programmable Logic Controller (PLC). Finally, two separators were used in the experiments to remove the water from the steam flow, and a heat exchanger was used to condense the total outlet flow from the system for the total mass flow measurement.

2.4 Setup

Figure 6 shows the schematic diagram of the process flow of the laboratory experiment setup, while Figure 7 shows the final setup that was implemented. The setup includes two boilers for steam generation for the primary and secondary flows and two separators to remove water residuals from the flows. Pressure sensors (PS), temperature sensors (TS), and a vortex flow meter (VFM) are used to measure pressure, temperature, and mass flow, respectively. The setup also incorporates the manufactured ejectors and a heat exchanger to condense the total mass flow, which is then measured using beakers and a scale (FM). Additionally, air pressure regulators were included to test for leakages with air before conducting the steam tests.

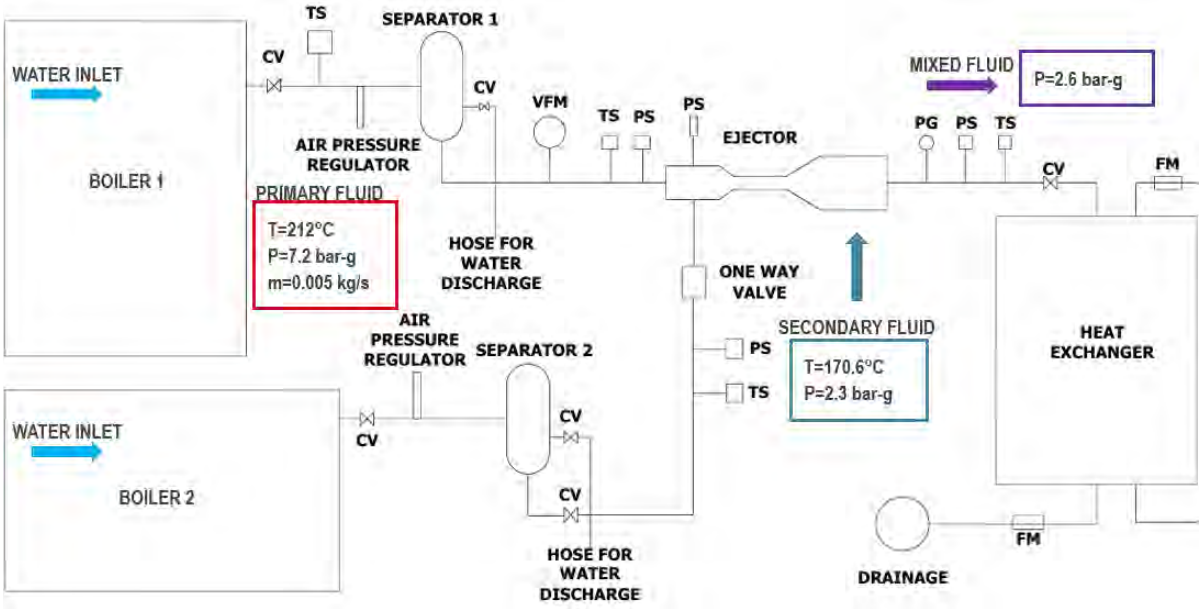

Figure 6. Schematic diagram of the laboratory experiment setup.

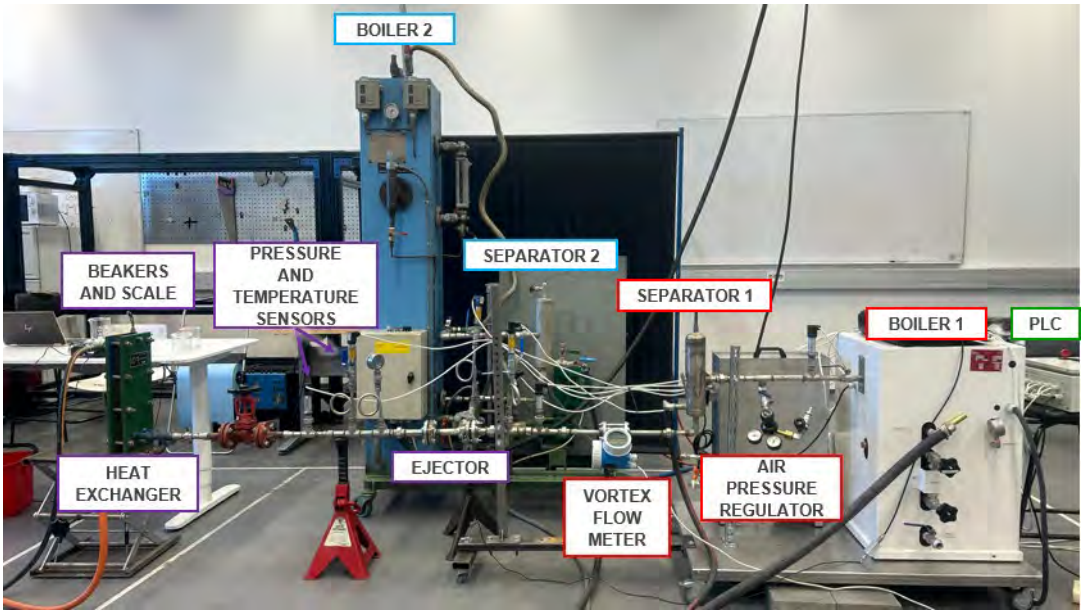

Figure 7. Final set-up laboratory experiments.

2.5 Process

The four ejectors (see Table 2) were tested using the same pressure and temperature for the primary (7.2 bar-g and 212°C) and secondary inlets (2.3 bar-g and 170.6°C), as well as the same outlet pressure or back pressure (2.6 bar-g). The analytical model suggests an outlet pressure of 2.7 bar-g; during the tests, however, a 2.6 bar-g pressure was set to have a better reading of the pressure gauge.

The outlet valve for the water separated from the primary flow was kept open until no more water was seen coming out. Then, the valve was closed and waited until a reading of 7.2 bar-g was on the primary flow boiler pressure gauge. After reaching the desired pressure in the primary flow (7.2 bar-g), we closed the outlet valve to achieve a back pressure of 2.6 bar-g.

After 2 minutes of reaching the desired outlet pressure, we started the mass flow readings at the heat exchanger outlet using a scale and three beakers until we had 12 consecutive readings (each reading after filling up one beaker of 300 mL). The primary flow was measured simultaneously with the vortex flow meter.

Boiler 2 for the secondary flow production was turned on when completing the primary flow readings. The outlet valve for the water separated from the secondary flow was kept open until no more water was seen coming out. Then, we closed the valve and waited until getting a reading of 2 bar-g on the secondary flow boiler pressure gauge. After two minutes of reaching the desired secondary flow pressure, we started the total mass flow readings at the outlet of the heat exchanger using a scale and three beakers until having 12 readings (each reading after filling up one beaker of 300 mL). The primary flow was measured simultaneously with the vortex flow meter.

3. Results

3.1 Effect of variation of area ratio

Table 3 summarizes the main results of the tests for different area ratios, which is one of the geometrical parameters that affect the ejector performance.

The area ratio here is the ratio of the CAMS area to the nozzle's throat area (see Equation 1); the gained pressure refers to the difference between the outlet pressure (or back pressure) and the secondary flow pressure (see Equation 2); and finally, the entrainment ratio is the ratio of secondary flow to the primary flow (see Equation 3).

$$Area\ ratio = \frac{CAMS\ area}{Nozzle's\ throat\ area} \tag{1}$$

$$Gained\ pressure = Back\ pressure - Secondary\ flow\ pressure \tag{2}$$

$$Entrainment\ ratio = \frac{Secondary\ flow}{Primary\ flow} \tag{3}$$

Table 3. Gained pressure, back pressure, entrainment ratio, and average pressure in the suction chamber for different area ratios.

Nozzle's throat diameter (mm)	CAMS diameter (mm)	Area ratio	Back pressure (bar-g)	Secondary flow pressure (bar-g)	Gained pressure (bar)	Entrainment ratio	Average pressure in the suction chamber (bar-g)
2.4	4.0	2.69	2.57	2.23	0.34	0.04	2.70
2.4	5.0	4.20	2.94	2.23	0.71	0.17	1.97
2.4	7.0	8.23	2.73	2.23	0.50	0.08	1.97
2.4	9.0	13.61	2.63	2.24	0.39	0.04	2.10

Figure 8 shows the pressure, temperature, and mass flow values of primary, secondary, and outlet flows during the ejector test for the 4.0 mm CAMS. The average pressure of the secondary flow (2.2 bar-g) is lower than the average pressure at the suction chamber (2.7 bar-g), preventing the entrance of the secondary flow into the system for most of the test time. This is confirmed by the low temperature recorded by the secondary flow sensor (104.4°C on average), and the total flow obtained from the test is very close to the primary flow, indicating no entrainment of the secondary flow. Therefore, the 4.0 mm CAMS ejector does not function effectively under the experimental conditions.

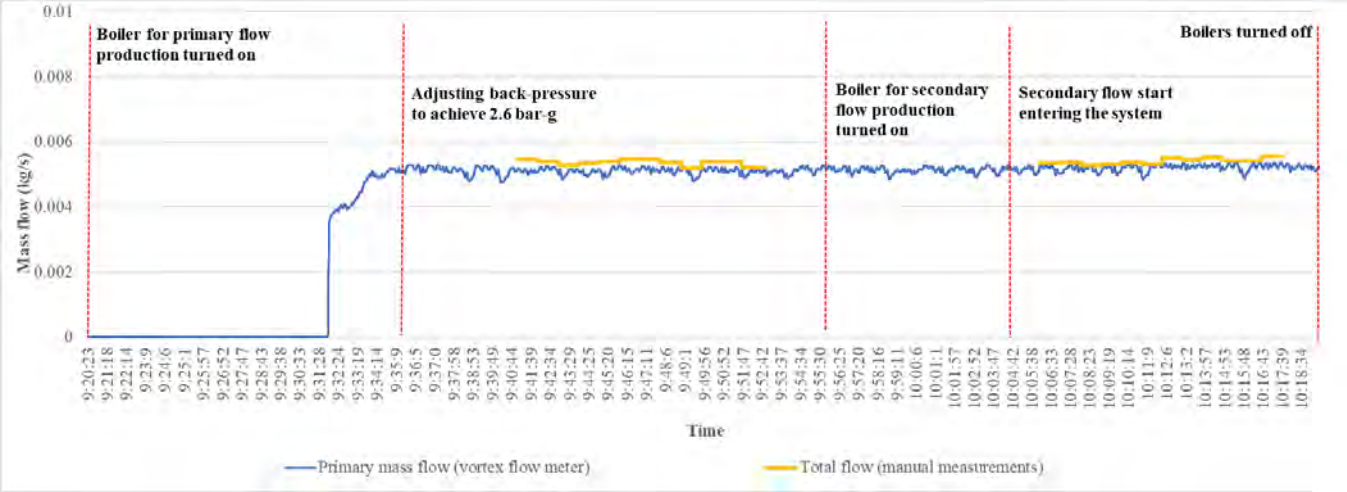

Figure 8. Results of pressure (top), temperature (middle), and mass flow (bottom) variation of primary, secondary, and outlet flows in the 4.0 mm CAMS ejector test.

In contrast, Figure 9 shows the pressure, temperature, and mass flow variation of primary, secondary, and outlet flows in the 5.0 mm CAMS ejector test. Here, the pressure of the secondary flow (2.2 bar-g) is higher on average than the pressure at the suction chamber (1.9 bar-g), allowing the entrance of the secondary flow into the system. This is confirmed by the high temperature registered in the secondary flow sensor (169.7°C on average), and the total flow obtained from the test is 16.6% higher than the primary flow, indicating the successful entrainment of the secondary flow. Therefore, the 5.0 mm CAMS ejector operates effectively under the experimental conditions.

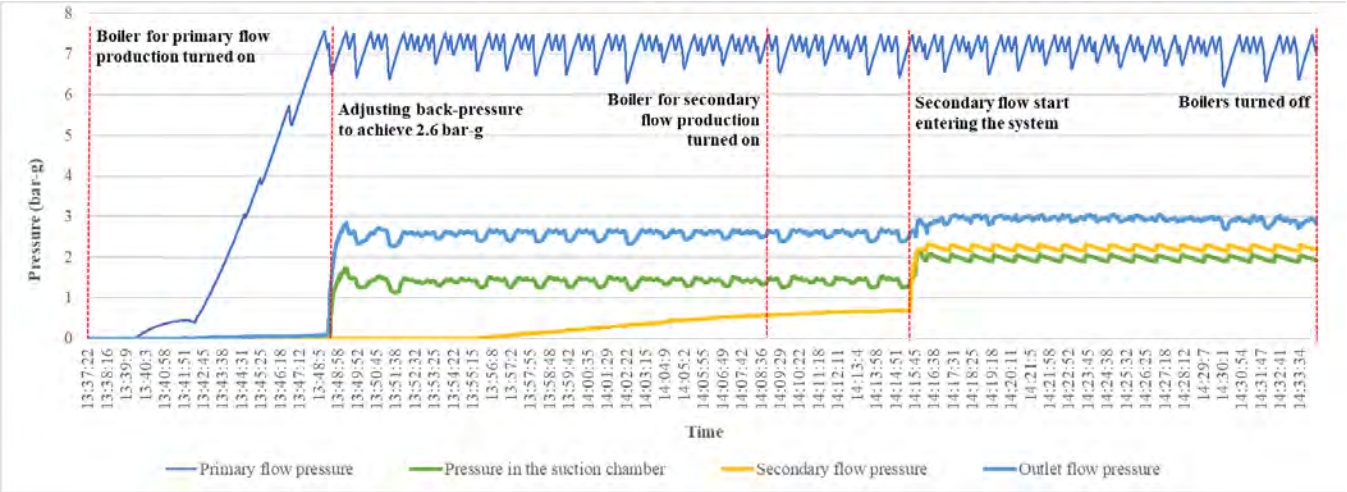

Figure 9. Results of pressure (top), temperature (middle), and mass flow (bottom) variation of primary, secondary, and outlet flows in the 5.0 mm CAMS ejector test.

Similarly, Figure 10 shows the pressure, temperature, and mass flow variation of primary, secondary, and outlet flows in the 7.0 mm CAMS ejector test. When the two flows are combined, the average pressure of the secondary flow (2.2 bar-g) is higher than the average pressure at the suction chamber (1.9 bar-g), allowing the entrance of the secondary flow into the system. This is confirmed by the high temperature recorded by the secondary flow sensor (169.8°C on average), and the total flow obtained from the test is 7.9% higher than the primary flow, indicating successful entrainment of the secondary flow. Therefore, the 7.0 mm CAMS ejector operates effectively under the experimental conditions but with less entrainment than the 5.0 mm CAMS ejector.

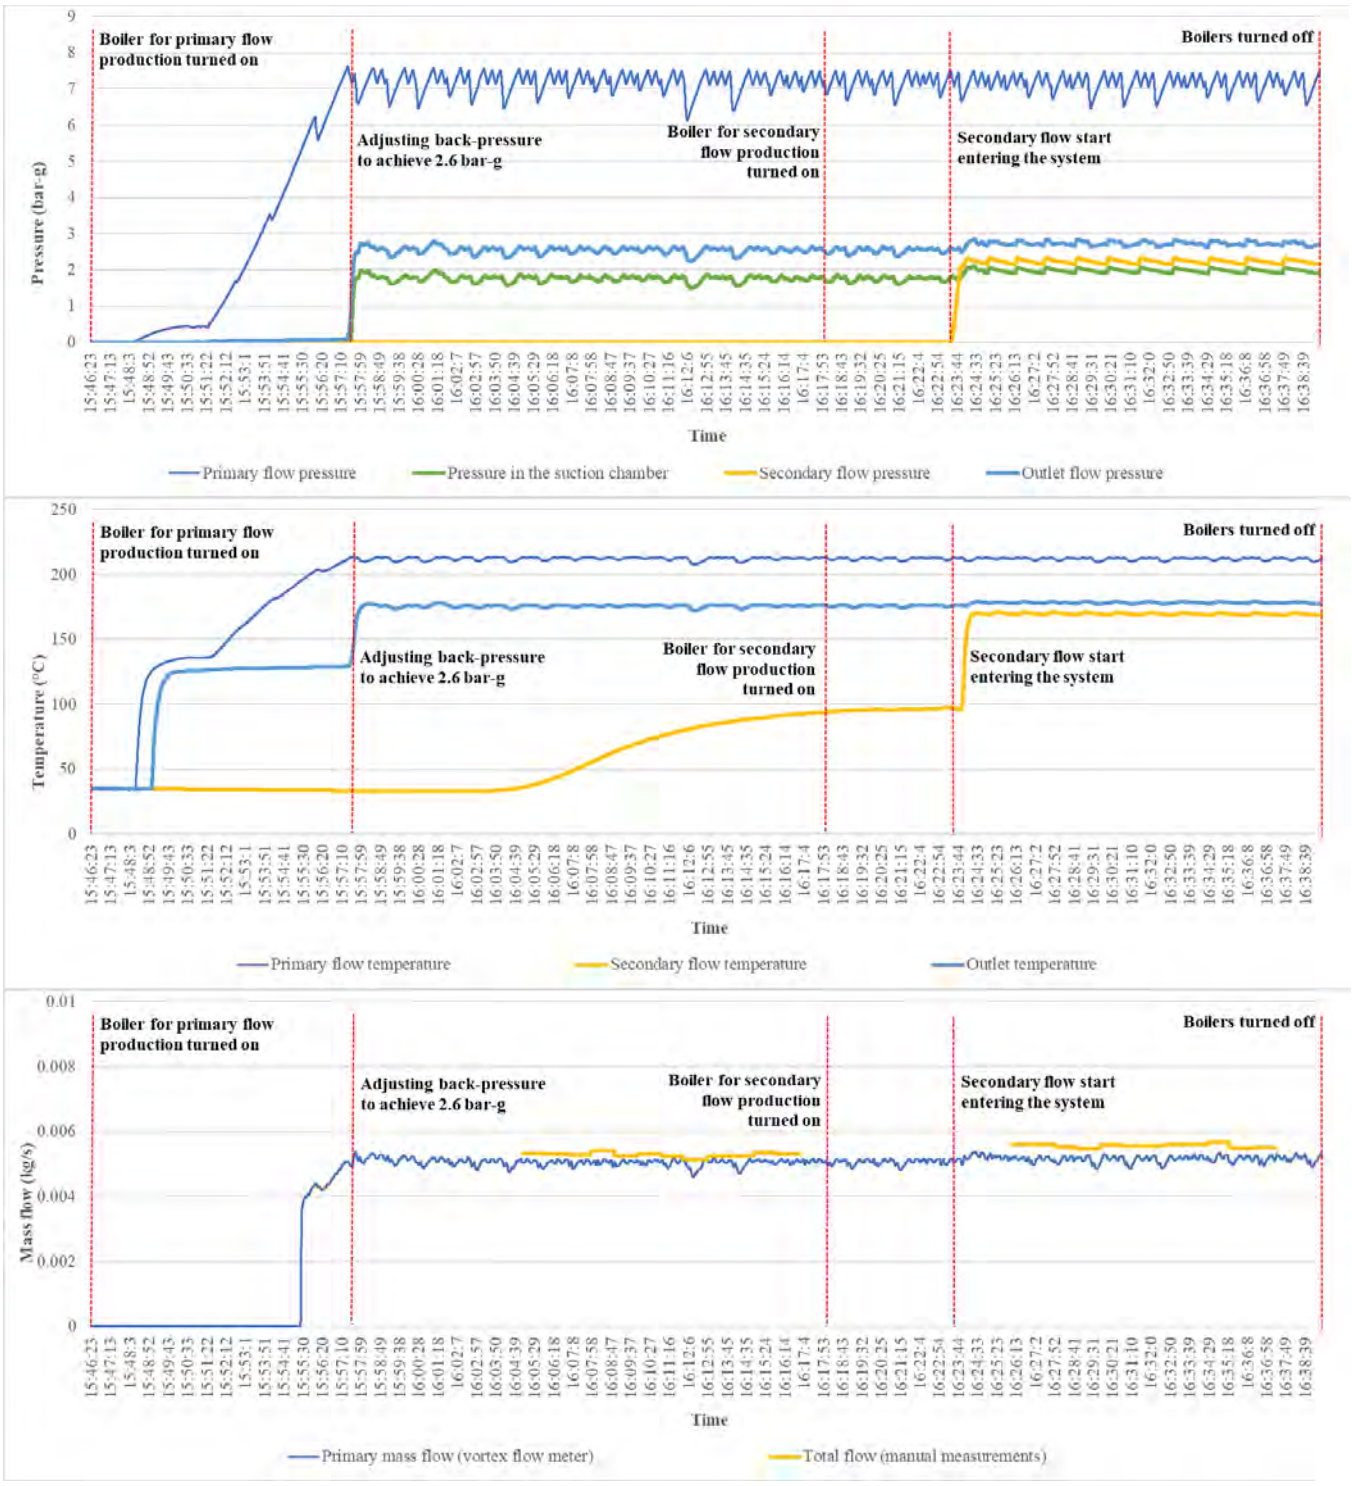

Figure 10. Results of pressure (top), temperature (middle), and mass flow (bottom) variation of primary, secondary, and outlet flows in the 7.0 mm CAMS ejector test.

Finally, Figure 11 shows the pressure, temperature, and mass flow variation of primary, secondary, and outlet flows in the 9.0 mm CAMS ejector test. The average pressure of the secondary flow (2.2 bar-g) is higher than the average pressure at the suction chamber (2.1 bar-g), allowing minimal entrance of the secondary flow into the system. This is confirmed by the high temperature recorded

by the secondary flow sensor (168.8°C on average), and the total flow obtained from the test is just 4.2% higher than the primary flow, indicating very low entrainment of the secondary flow. Therefore, the 9.0 mm CAMS ejector operates under the experimental conditions but with very low entrainment.

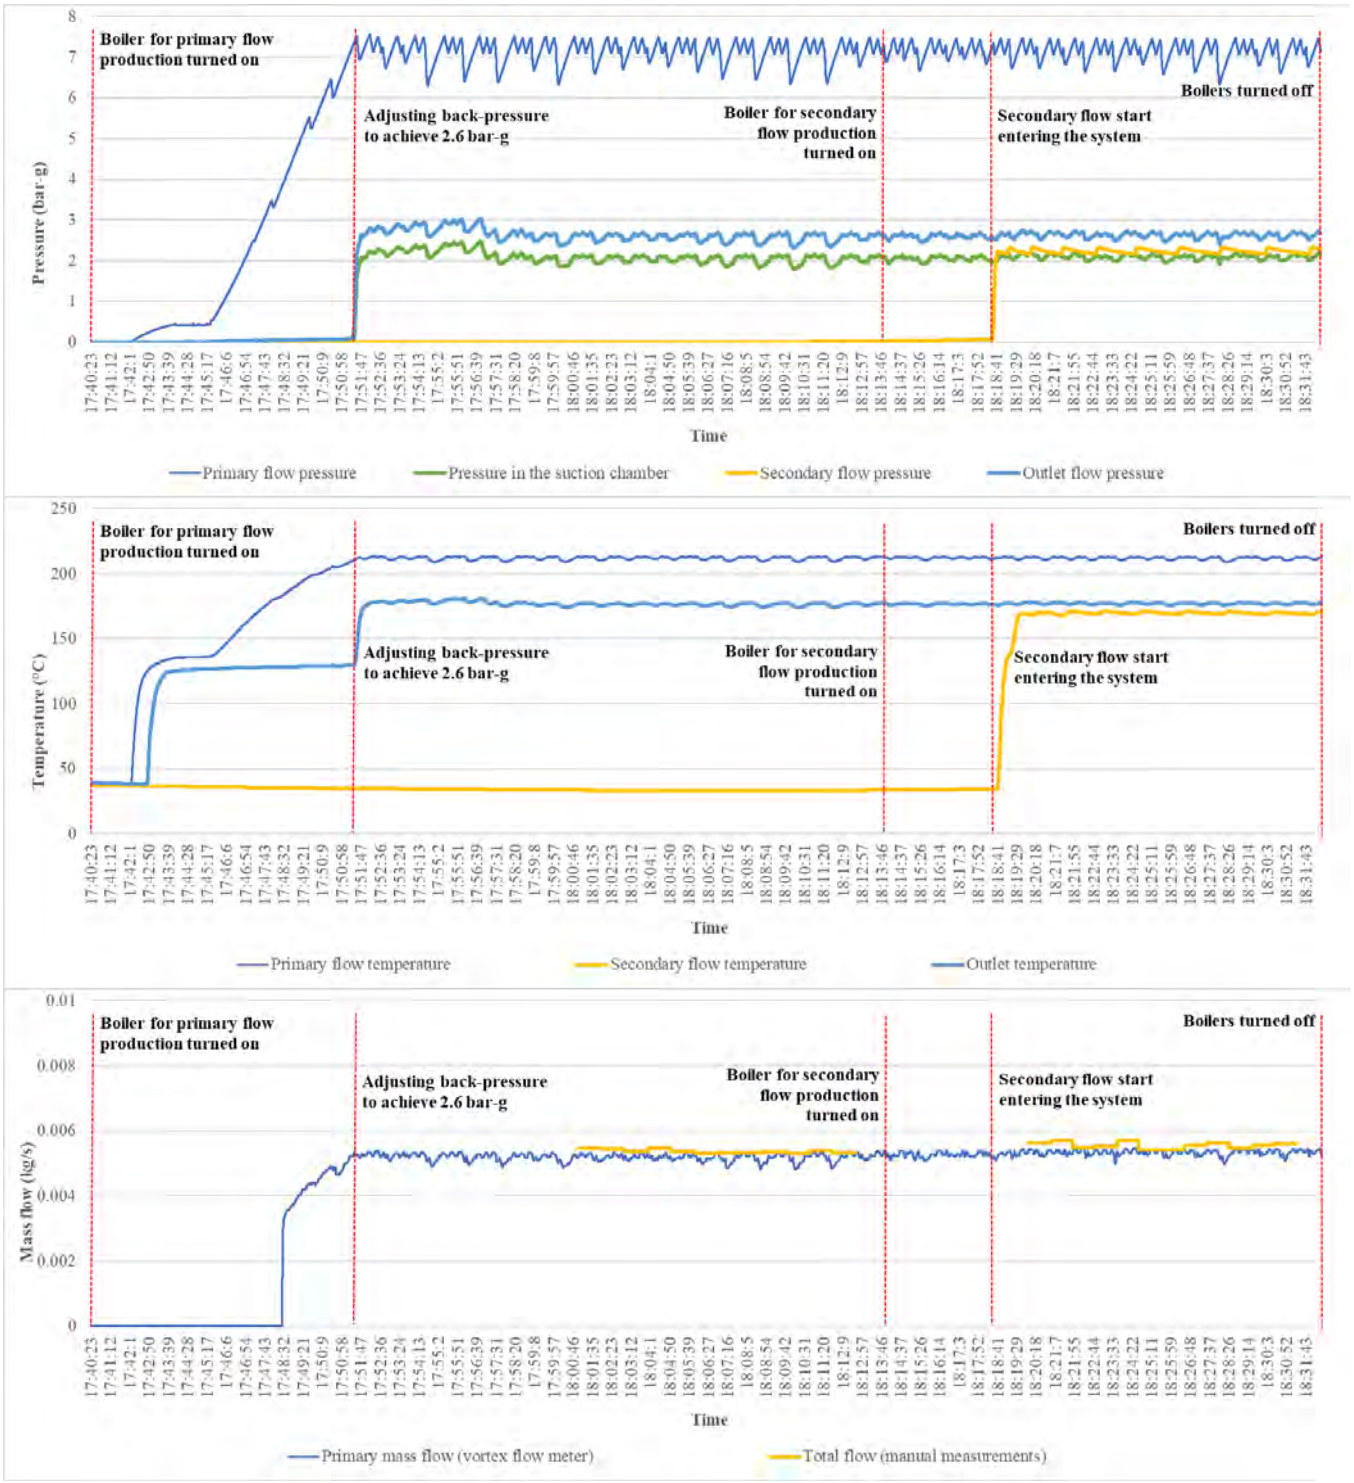

Figure 11. Results of pressure (top), temperature (middle), and mass flow (bottom) variation of primary, secondary, and outlet flows in the 9.0 mm CAMS ejector test.

Figure 12 shows the variation in the entrainment ratio for the manufactured ejectors with different area ratios. The area ratio of 4.2, corresponding to the 5.0 mm CAMS ejector, has the highest entrainment ratio, indicating the greatest entrainment of the secondary flow. This suggests that an area ratio of 4.2 is optimal for this ejector setup, as both lower and higher area ratios result in decreased entrainment.

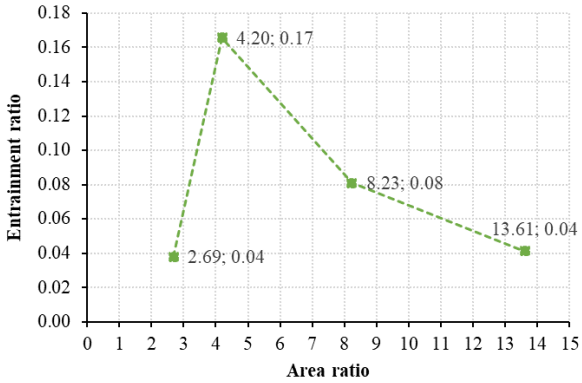

Figure 12. Entrainment ratio variation with the area ratio.

The low entrainment from the 4.0 mm CAMS ejector results from its small diameter, which prevents the combined fluid from going inside the CAMS, increasing the pressure in the suction chamber, as seen in Figure 13. On the other hand, the low entrainment in the 9.0 mm CAMS ejector results from its big diameter, which decreases the pressure in the CAMS to similar values to the secondary flow pressure, preventing a regular flow from high to low pressures.

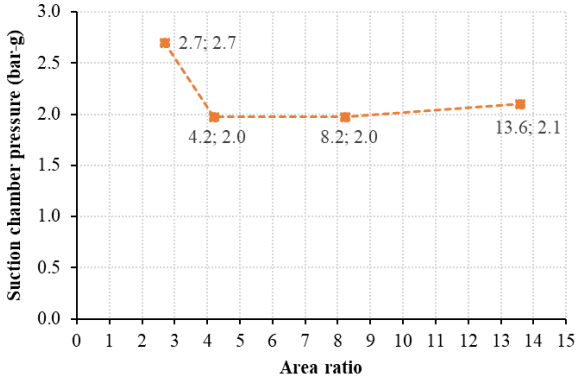

Figure 13. Suction chamber pressure variation with the area ratio.

Despite setting up the same secondary flow pressures and the same back pressure for all the tests, an increase in the final back pressure values was observed following the same behaviour as the entrainment ratio (see Figure 12), which means that the back pressure increase is a result of the entrainment of the secondary flow. The gained pressure for all the cases is presented in Figure 14.

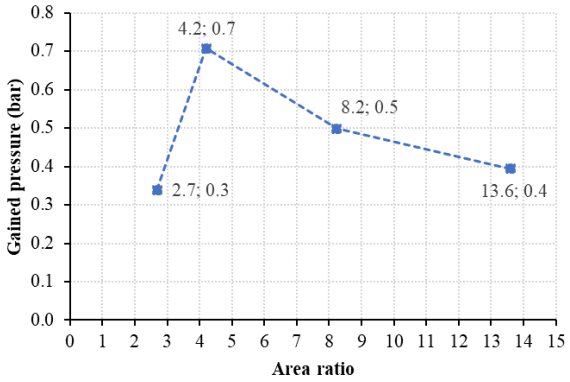

Figure 14. Gained pressure variation with the area ratio.

3.2 Effect of variation of NXP

Table 4 summarizes the main results of the NXP tests performed with the 5.0 mm CAMS ejector.

Table 4. Gained pressure, back pressure, entrainment ratio and average pressure in the suction chamber for different NXP.

NXP (mm)	Back pressure (bar-g)	Secondary flow pressure (bar-g)	Gained pressure (bar)	Entrainment ratio	Average pressure in the suction chamber (bar-g)
-7.4	2.83	2.30	0.54	0.01	2.18
-0	3.01	2.30	0.71	0.06	2.06
7.8	2.90	2.30	0.61	0.05	2.02

Table 4 and Figure 15 show that a 0 mm NXP provides the highest entrainment ratio, while the -7.4 mm NXP has the lowest, reaching even negative values (back flow). This suggests that there is more entrainment of the secondary flow when the nozzle exit goes further inside the constant pressure mixing section. Also, a slight decrease in the suction chamber pressure is seen when this happens (see Figure 16). However, when the NXP continues to increase, the entrainment ratio decreases slightly, and this could mean that part of the primary flow is lost due to the collision with the walls of the constant pressure mixing section.

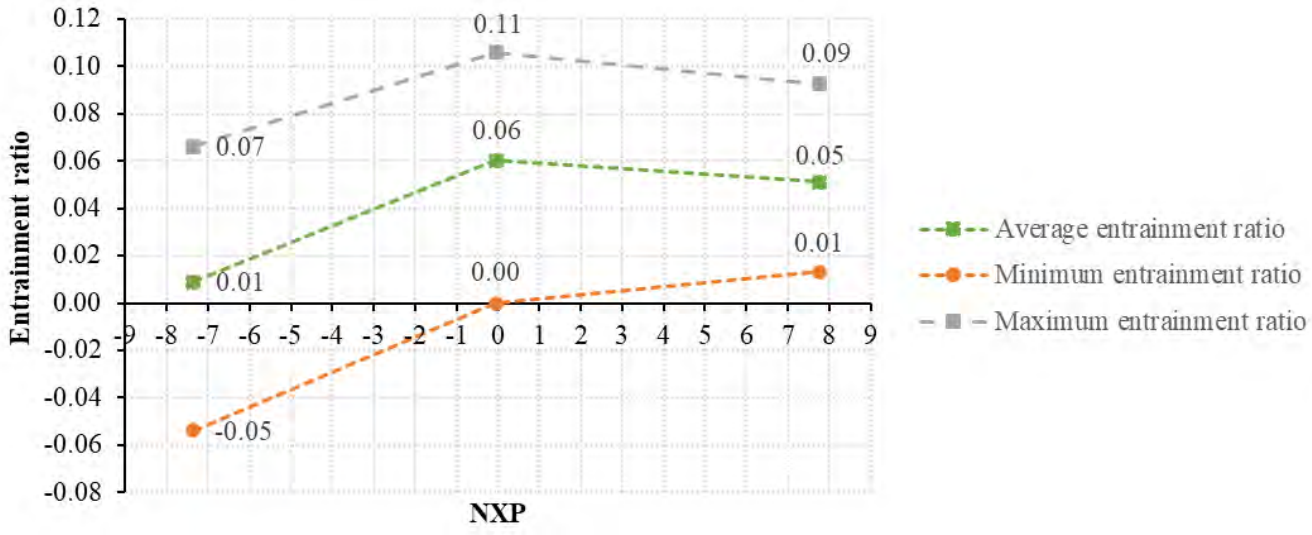

Figure 15. Entrainment ratio variation with the NXP.

For the three NXP tested, the suction chamber pressure values recorded had a standard deviation between 4.9 and 5.1% despite the greater deviation of the primary flow pressures, with standard deviations between 19.7 and 25.5%. At the same time, entrainment ratio values had a standard deviation between 2.2 and 3.3%. This means that fluctuations on the primary flow pressures have minimal effect on the values of the entrainment ratio, so the changes on the entrainment can be attributed to the variations on NXP.

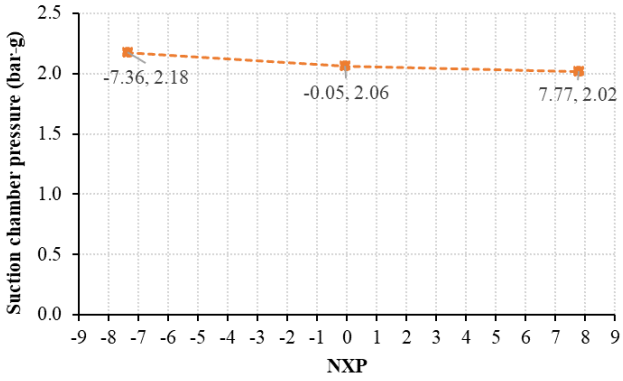

Figure 16. Average suction chamber pressure variation with the NXP.

Finally, more pressure from the secondary flow could be gained with 0 or positive NXP, as shown in Figure 17.

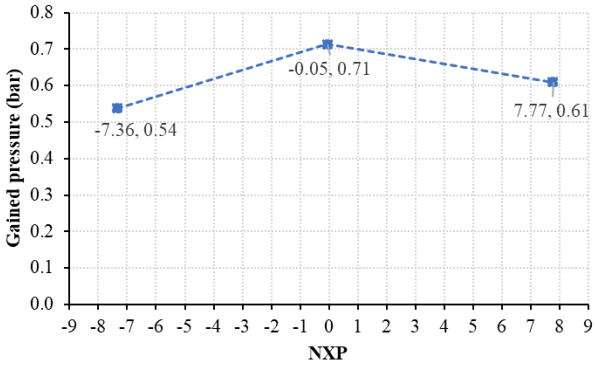

Figure 17. Average gained pressure variation with the NXP.

4. Conclusions

The supersonic ejector prototypes built at the laboratory of Reykjavik University fulfilled the ejector principle.

An area ratio of 4.20 corresponding to a 5 mm CAMS ejector was optimal for the testing conditions, showing the highest entrainment ratio and gained pressure.

An area ratio of 2.69 corresponding to a 4 mm CAMS ejector showed the worst performance due to the low CAMS diameter, which does not enable the entrance of the secondary flow and increases the pressure in the suction chamber. On the other hand, high CAMS diameters also reduce the entrainment ratio due to the decreased pressure difference between the back pressure and the secondary flow pressure.

Ejectors with zero and positive NXP provide a higher entrainment ratio and gained pressure for the ejector prototypes tested.

Further improvements in the analytical model and the development of computational fluid dynamics (CFD) models are suggested to provide a better understanding of the performance of the supersonic ejector prototypes.

An Overview of the Performance Testing of a Supercritical CO_2 Geothermal Turbine

John Klaerner and Lev Ring

Southwest Research Institute and Sage Geosystems

Keywords

Supercritical CO_2 (sCO_2), sCO_2 Turbine, sCO_2 Power Cycle, Flow Loop, Geothermal

ABSTRACT

A new supercritical carbon dioxide (sCO_2) turbine has been tested to conditions anticipated for geothermal power production. The prototype machine owned by Sage Geosystems was designed by Southwest Research Institute (SwRI) for operation in a low to mid-enthalpy geothermal field at a 3 MW scale. The closed loop CO_2 system within a geothermal power plant will allow for improved conversion of heat to power by taking full advantage of the efficiency and power density of sCO_2 turbomachinery. The megawatt-scale system offers a significant reduction in overall size and cost versus other commercial heat-to-power conversion systems.

This paper will present data from the laboratory testing of the Sage Geosystems sCO_2 turbine at SwRI to show the aerodynamic performance and power output along with how the data is used to prove the models of the 3 MW setup under field conditions. Design parameters including process temperature, pressure, and speed will all be achieved throughout the test progression. The proven mechanical integrity and rotordynamics of the modular design will be discussed, along with operating procedures of turbine subsystems used for this design.

The turbine has been successfully operated at full design temperature and over 80% of the design speed at the time of this publication. Further tests are ongoing to reach full operating conditions in Summer 2024. The paper will conclude with details on the turbine startup and shutdown process to provide a better understanding of potential use cases for a similar class turbine.

1. Introduction

Geothermal energy was originally used for various heating applications. It was not until 1904 when the renewable energy source was used to produce electricity (Lund, 2004). From then on, various configurations and systems have been designed and manufactured to convert geothermal energy (or heat) to moving electrons. These systems include various steam cycles and Organic Rankine Cycles (ORCs) which run on different refrigerants in a separate closed loop system. In recent years, the revolution of supercritical carbon dioxide (sCO_2) cycles and turbomachinery have demonstrated a successful and efficient system for turning heat into mechanical energy across a vast range of temperatures (Moore et al., 2018, Nielson et al., 2022).

sCO_2 is also considered a refrigerant in power systems (e.g., R744) and is used as a baseline for comparing the global warming potential (GWP) of other cycle refrigerants over time; many of which have or are being phased out. By having a GWP orders of magnitude below other energy cycle mediums and also acting as a fire suppressant, there are many positive environmental and safety attributes about sCO_2 when compared to other refrigerant-based systems.

With a supercritical regime above 31°C and 73.8 bar (88°F and 1,071 psi), CO_2 can remain in the same phase throughout a full cycle at common geothermal conditions in comparison to the refrigerants used in ORCs, which experience a constant temperature phase change during the heat input and rejection process. When in the supercritical phase, CO_2 fluid densities can be comparable to liquids while maintaining the viscosity of a gas, allowing for very efficient energy input. The additional benefit of an sCO_2 system is the reduction in machinery size, equating to reduced overall costs in hardware and footprint. This size reduction, for the same power level, is what CO_2 turbomachinery is known for.

Improved efficiency, smaller footprint, and lower equipment cost enables CO_2 to reduce the overall costs of geothermal energy production and are all reasons Sage Geosystems (Sage) sees the merit in this cycle (Nielson, Weiss, 2022). While many CO_2 cycle components are becoming commercially available, a mid-enthalpy turbine at 3 MW power scale remains uncustomary. Based on geothermal conditions from South Texas wells, the rotating machinery team at Southwest Research Institute (SwRI) has used previous design and test experience to develop, commission, and test a 3 MW sCO_2 geothermal turbine for Sage.

The turbine and impeller configuration under test in the laboratory are designed to operate at 150°C and 158 bar (300°F and 2,300 psi), but the modularity and interchangeability features of the design allow for easy movement between wells or quick aerodynamic changes to maximize the power output at various well conditions. Overall dimensions of the turbine are approximately 3ft diameter and 4ft in length, creating a five to ten times smaller unit than other steam turbines of similar power output. Table 1 details the operating range that the turbine is intended to function. The impeller designed and installed for the laboratory test is on the lower end of the power output range due to laboratory component limits such as the heat source and sink, piping size, and the capabilities of the compressor used to supply the flow.

Table 1. Turbine Operation Range

Condition	Range
Power Output	0.5 to 3 MWe Output
Operating Speed	22,000 RPM
Inlet Pressure	22.5 MPa max
Outlet Pressure	10 MPa max
Inlet Temperature	175°C max

To date, the turbine and subsystems needed for operation have been fully commissioned and have undergone multiple laboratory tests with CO_2. This paper discusses results and achievements while also illustrating learnings from operating a high-speed overhung turbine. Further information on the test setup and operating configuration has been previously published (Kerr et al., 2023).

2. Impeller and Machinery Design

Based on the desire to have a machine configuration that could be used in a wide array of operating conditions, the turbine was designed in an overhung configuration, shown in Figure 1, allowing for reduced effort in changing critical turbine components to accommodate different flow designs. One aspect considered in machine design that plays a large role in operation is critical speed of the rotor and impeller assembly. This is the rotational speed of the rotor that matches and excites the natural frequency of the spinning shaft, potentially causing vibration issues in a machine if not well dampened. A design effort was made to keep the nominal operating speed below the rotor critical speed to reduce complexity and avoid having exclusion ranges which affect startup and shutdown scenarios. This was made possible through the design and fabrication of a lightweight titanium impeller.

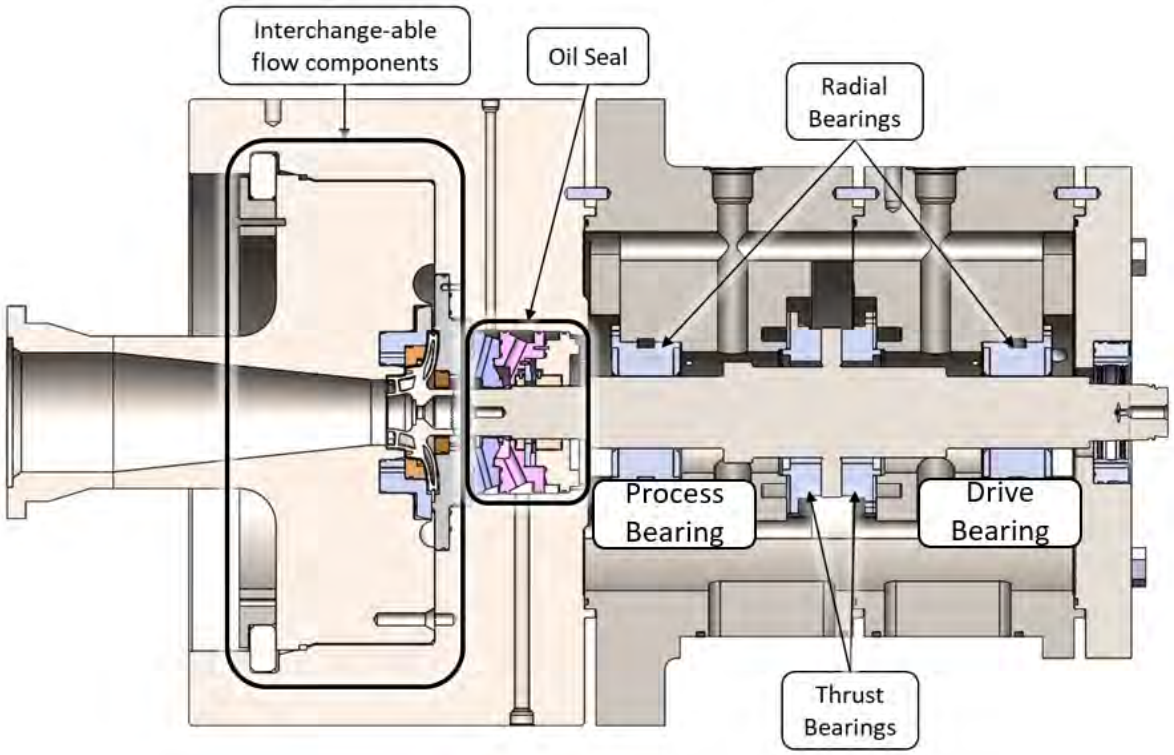

Figure 1. Turbine cross section with key components

The goal of a higher rotor critical speed also affects the design and selection process of the tilting pad radial bearings used in the turbine. Geometric parameters such as clearance ratio and preload, both illustrated in Figure 2, were set accordingly. The selected bearings had a clearance ratio of 1.5 mils per inch and a preload of 0.45, both of which are within typical manufacturer recommended bounds but also different from other tilted pad journal bearings operated at similar speeds in other SwRI designs. The selected bearings also have an integral squeeze film damper (SFD), a system that can provide increased dampening to the rotor supports at the cost of some support stiffness. This feature was intended to be locked/unused for the subcritical speed design to keep bearing stiffnesses high.

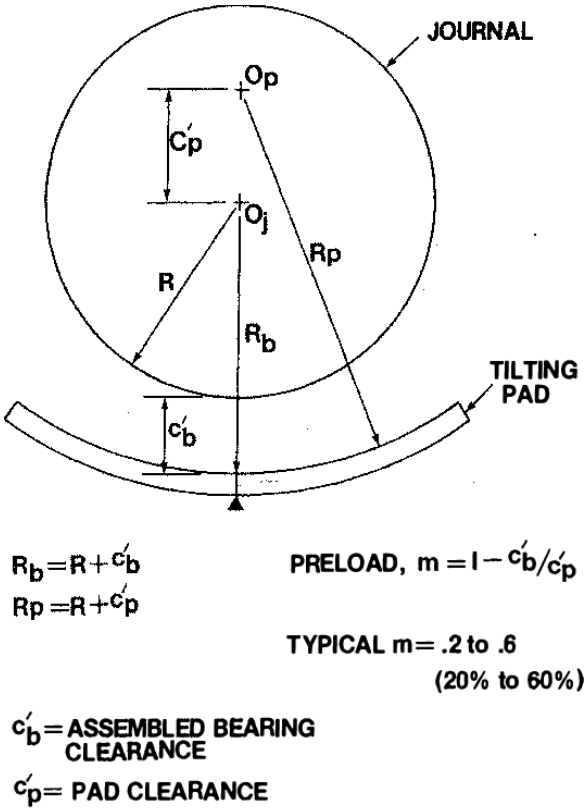

Figure 2. Tilting pad journal bearing geometry parameters (Nicholas, 1994)

The previously published spin test of the turbine using compressed air (Kerr et al., 2023) was with the titanium impeller, however, issues in the print quality and unremovable build support material in the impeller knee area compelled the team to switch to a heavier material with better printing quality experience. The new impeller, made of Inconel, provided a much cleaner finish following subsequent machining and balance efforts. In contrast, the weight increase of the overhung impeller prevented the turbine operational speed from remaining below the new rotor critical speed and required the SFDs be unlocked. This weight change altered the vibration response of the rotor and shifted the critical speed to 10,000 RPM.

Figure 3 shows the initial predictions of the shaft vibration response using the heavier Inconel impeller in conjunction with the SFD's. While the model predicted a low vibration response, the machine would need to be operated in a way to avoid the critical speed during startup and shutdown phases.

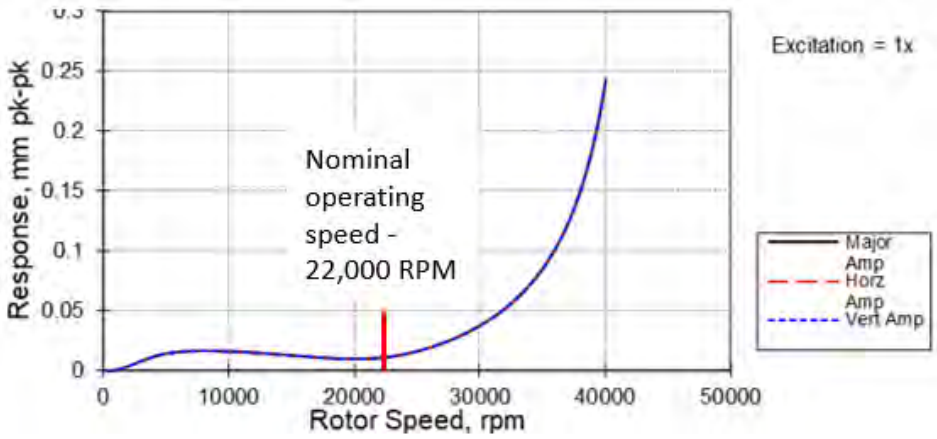

Figure 3. Model prediction of the turbine shaft vibration response

3. Test Plan

With the turbine complete and other systems ready for operation, the original test matrix was reviewed and iterated upon. While the turbine skid includes a 12.233:1 ratio gearbox and 3 MW synchronous generator for electricity production, initial uncoupled (spin) tests were needed to understand the performance of the turbine alone. This also simplified initial tests, allowing SwRI turbine operators to better understand the nuances of the turbine without the additional complexity of the full equipment train. The uncoupled test would also allow for quantifying the frictional losses in the turbine from both windage and drag forces. Following spin testing of the turbine, it will then be coupled to the gearbox and generator. Using a load bank system, the generated power output will be measured and the overall heat-to-electricity efficiency will be determined.

Milestones such as initial spin, bearing break-in, seal break-in, surpassing the critical speed, reaching full temperature, and reaching full speed all needed to be completed to validate the turbine. Each condition met on the test plan aids the SwRI turbine operators in understand how the turbine and subsystems function, and also how the compressor and turbine operate simultaneously in the test.

In the laboratory facility, a multi-stage sCO_2 compressor is used to drive the sCO_2 flow needed to operate the turbine. The SwRI-housed integrally geared compressor, fully tested in recent years (Allison et al., 2018), requires a full-time operator and takes approximately 1 hour to reach full speed from initial startup. The compressor limitations due to its dry gas seals require that compressor inlet pressures remain above 24 bar (350 psi) at full speed. This provides a minimum turbine inlet pressure of approximately 27.5 bar (400 psi) for startups. The abundance of real-time data monitored by SwRI operators, for controlling and analyzing both the compressor and turbine, is depicted in Figures 4 and 5. Over 300 data channels are being recorded in the combined operation. Additional vibration monitoring of both machines is conducted at a third control station by another SwRI test engineer.

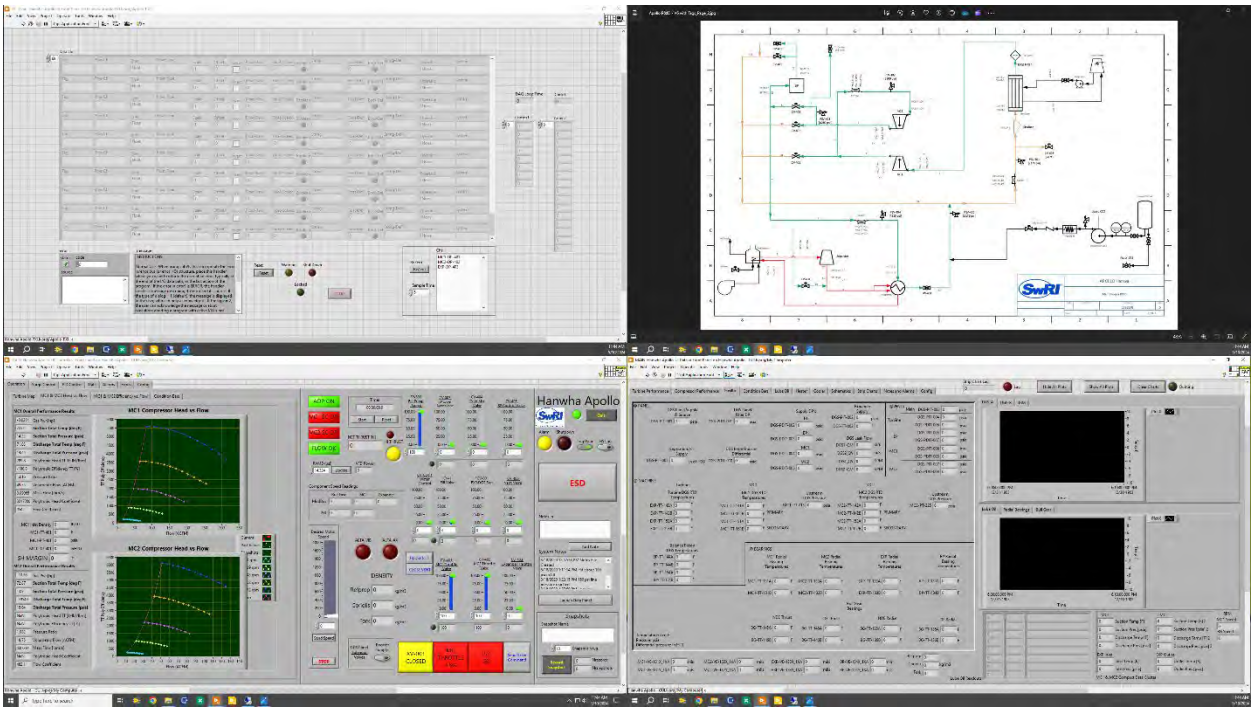

Figure 4. SwRI Operator's view of CO_2 compressor control panel and operating conditions

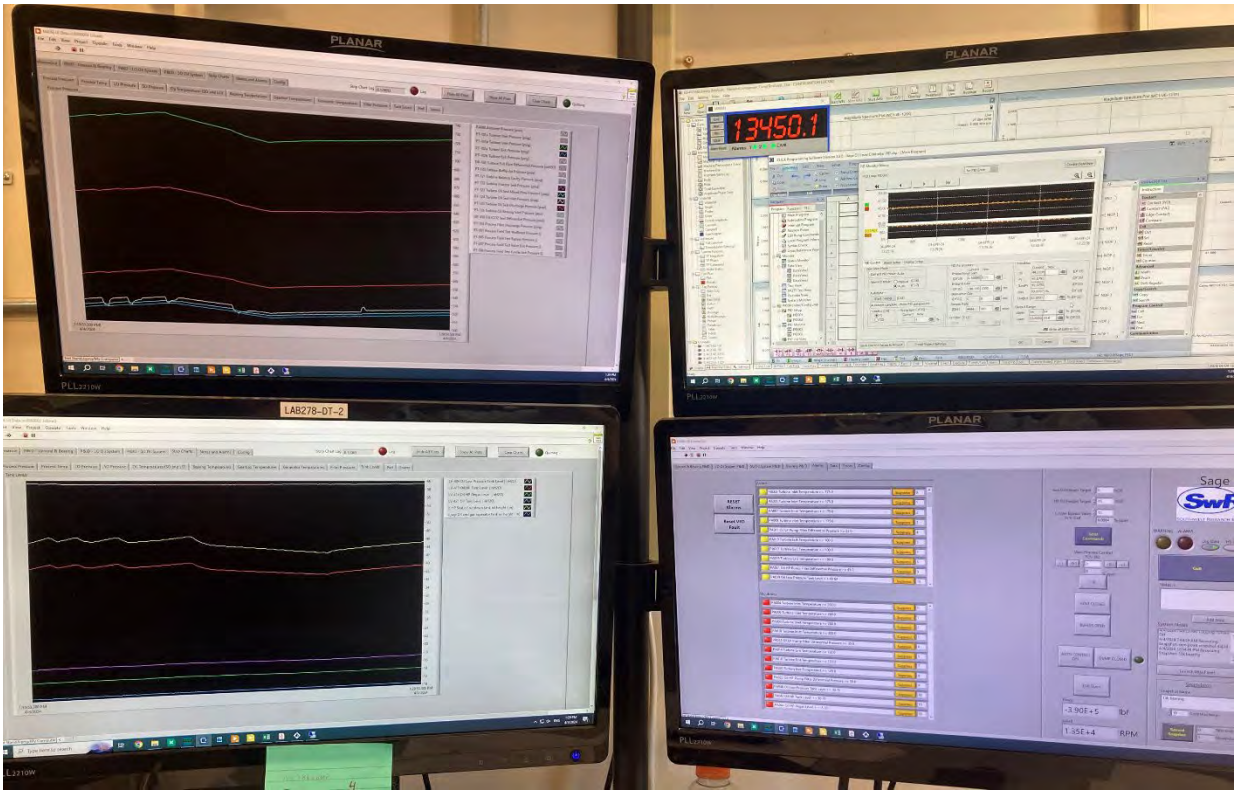

Figure 5. SwRI Operator's view of Sage Geosystems turbine control panel and operating conditions

4. First Startup

As previously published, startup procedures of purging the CO_2 loop and starting the oil seal system and lubrication system were all followed as planned. The first startup of the turbine with CO_2 went well, but operators did experience a high breakaway torque that had to be overcome. Due to the single overhung nature of the design, the pressure forces on the impeller result in a significant axial force against the opposite thrust bearing, keeping lubrication oil from getting between the surfaces. Breakaway torque requirements were estimated to be 10X that of the torque required to keep the rotor spinning after startup. These acting pressure forces can be seen in Figure 6, equating to approximately 350 lbs. per one hundred psi of pressure when stationary.

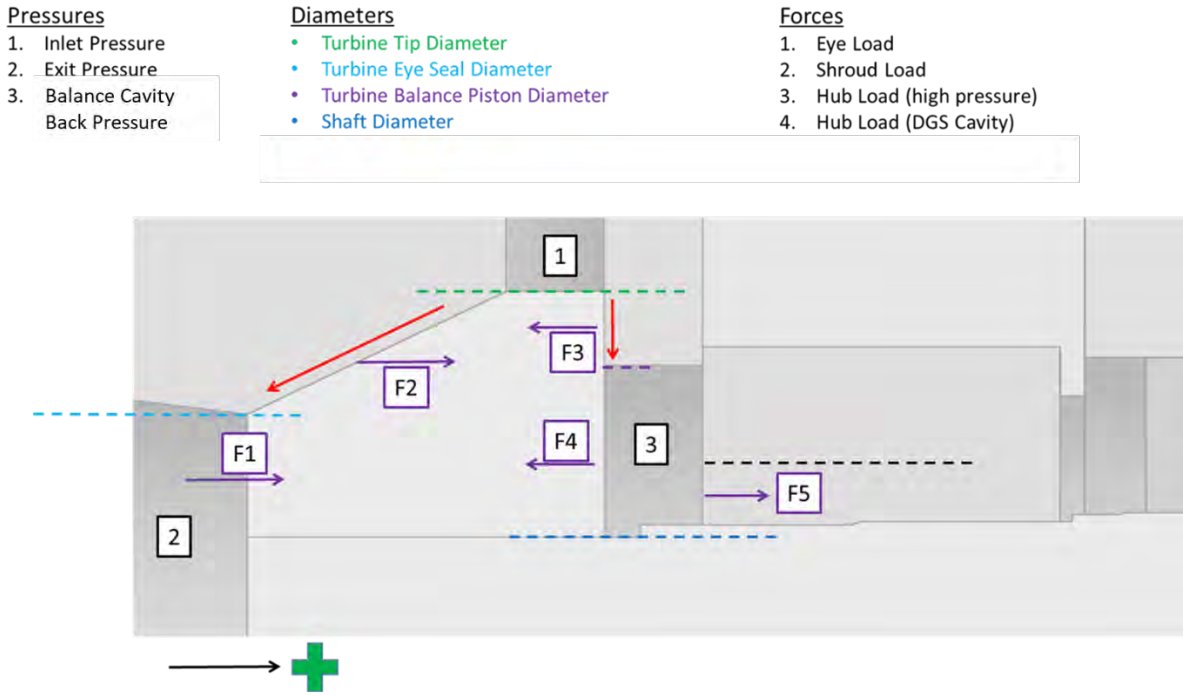

Figure 6. Map of pressure forces on the impeller adding to the thrust load at startup

To overcome the high breakaway torque, the turbine was spun by hand under no flow conditions from the disconnected shaft end. Once spinning, there was enough momentum in the machine to allow personnel to clear the area before introducing CO_2 flow to keep the machine turning.

A CO_2 flow rate of 1.5 lbm/s at 77°C and 31 bar (170°F and 450 psi) was needed to maintain a speed of 2,700 RPM as depicted in Figure 7. Due to the operating principles of hydrodynamic bearings, 2,000 RPM was selected as the lowest continuous speed. While the turbine had previously spun faster in an air spin test, the speed was not maintained long enough due to the limited air volume to achieve steady state performance of the system. The turbine was run at this low idle speed for 15 minutes to allow for bearing temperatures to stabilize while also providing time for monitoring of the oil seal and seal subsystems. Although used in various other machines for decades, this marked the first time a CO_2 machine operated with a floating ring oil seal.

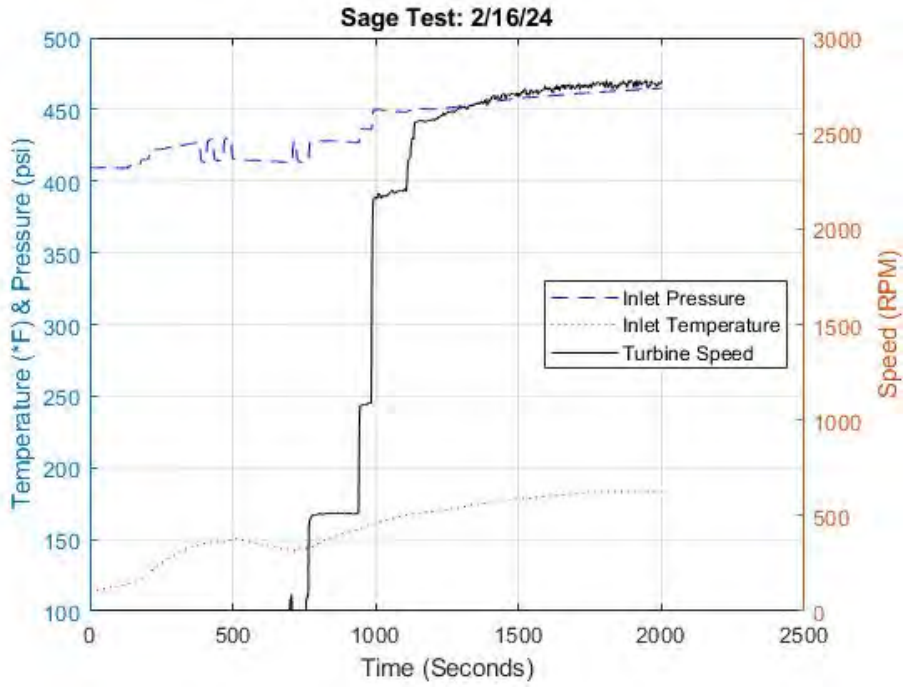

Figure 7. Graphical illustration of the turbines first spin with CO_2

Following the hold at idle speed, flow was gradually increased to speed the turbine up to 4,000 RPM, where it was again allowed to stabilize. Vibration data showed very low synchronous vibrations but did indicate the existence of a sub-synchronous vibration at approximately 40% of running speed. While not alarming at this operating condition, the vibration frequency and characteristics resembled that of floating ring oil seals in other machines (Allaire et al., 1987). Floating ring oil seal operation in other machines and rotordynamic effects have shown that there is a limit on speed at lower pressures. An example plot of this speed limit published by Dresser Rand can be seen in Figure 8.

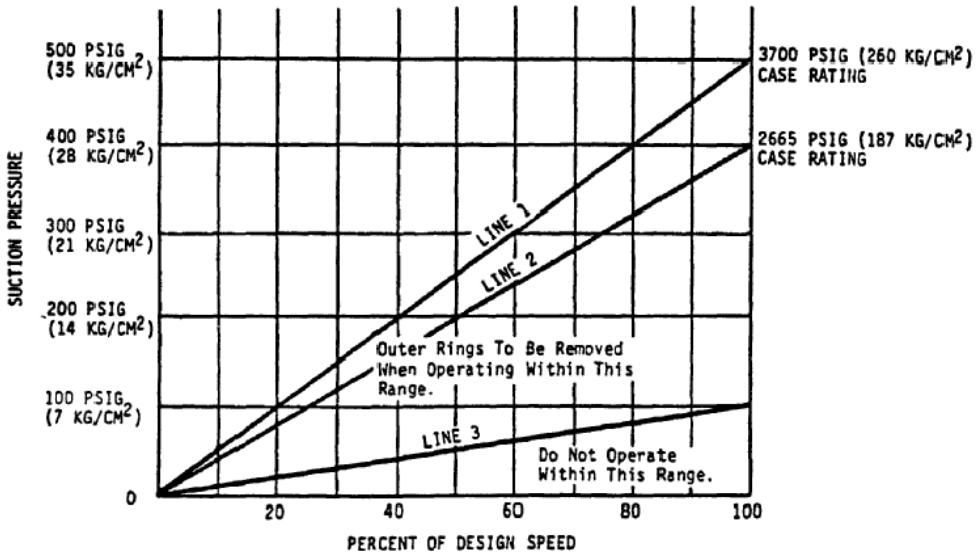

Figure 8. Minimum suggested operating speed versus pressure from literature (Wilcox, 2000)

To continue past 4,000 RPM, CO_2 was added to increase the fluid mass in the loop. This increases pressure and mass flow at a steady rate which also increases speed of the turbine. The slow acceleration (200 RPM per minute) shown in Figure 9 allowed for SwRI operators to continue monitoring of the various subsystems while managing the test.

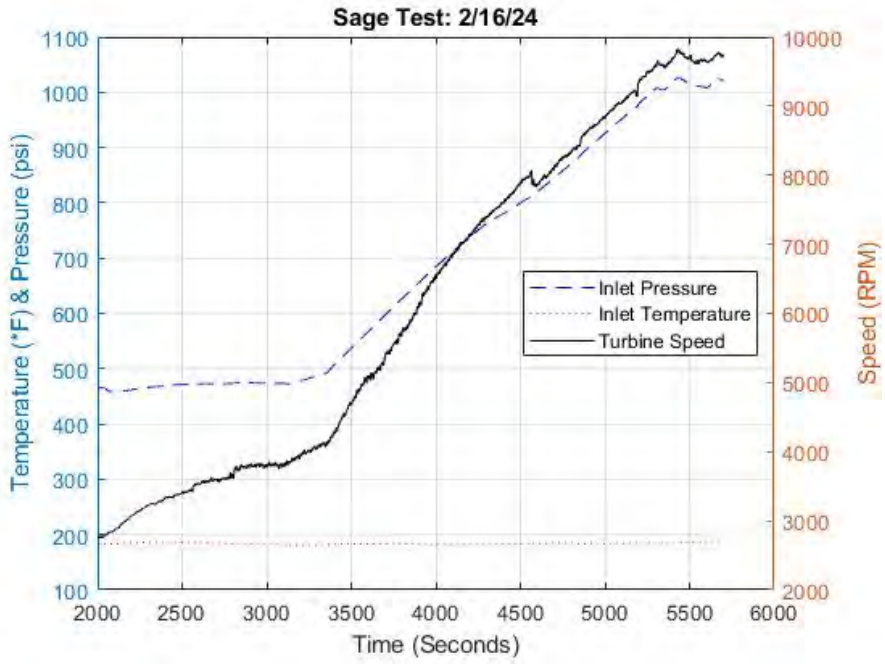

Figure 9. Adding CO_2 to the loop slowly increases pressure and turbine speed.

Upon reaching 9,500 RPM, the process side radial bearing reached a pad temperature of 107°C (225°F), a level that was not at the shutdown limit of 121°C (250°F), but still much higher than the bearings should operate; especially below half speed. To lower the bearing temperatures back to a normal operating range below 93°C (200°F), the turbine speed was reduced and held near 8,000 RPM.

As seen by the bearing temperature and speed plot in Figure 10, there were instances near 8,000 RPM when the process radial bearing temperature would fluctuate 10-15°F rapidly. These changes also correlated to speed change spikes of a few hundred RPM and the appearance and disappearance of sub-synchronous vibrations. All of these are effects of the oil seal rings shifting position which changes the load exerted on the process radial bearing. As expected, less radial load from the oil seals lowered the bearing temperature and increased the turbine speed.

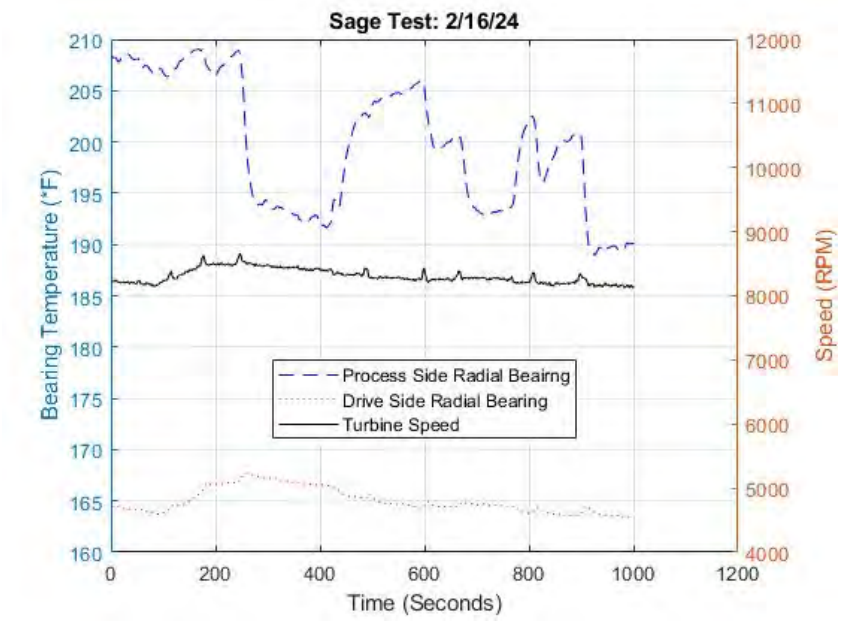

Figure 10. Plot of radial bearing temperatures and spikes in rotation speed caused by the oil seal

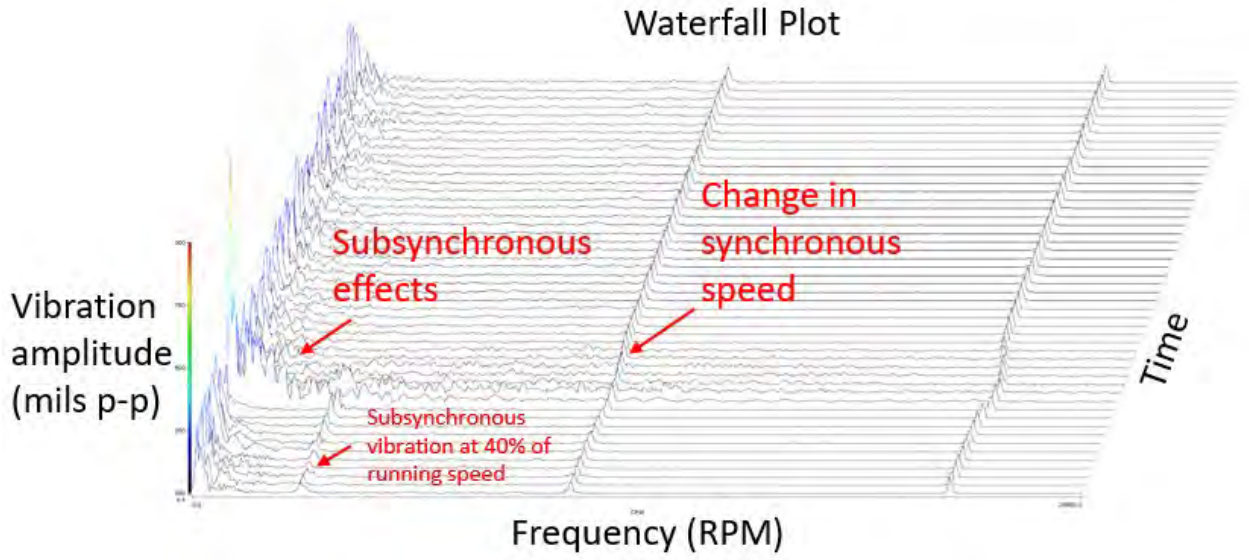

Figure 11. Waterfall plot of the various turbine vibration frequencies during operation

While the maximum speed was limited by the bearing temperatures, operation at full inlet temperature was still achieved during the test. Over a one-hour span of operation, the turbine inlet temperature was increased from 93°C to 150°C (200°F to 300°F) using the heat source, a natural gas burner blowing over an Inconel tube heat exchanger. Full temperature inlet conditions of 150°C (300°F) were maintained for a duration of the test to allow the turbine, casing, and other internal components to reach maximum equilibrium temperature. The full temperature operation also allowed for the team to ensure that the "sour" oil, a mixture of the drain from the oil seal and the process CO_2 buffer flow, was operating at a suitable temperature.

After 4 hours of turbine operation, the turbine was shut down along with the CO_2 compressor system and other subsystems. Project engineers began investigation of the root cause(s) of the high bearing temperature. Based on the data collected for the first test, the high bearing temperatures were the only abnormal condition.

5. Corrective Actions

Following a review of the test data and operating conditions, the turbine was removed from the test stand and disassembled to inspect the rotor and radial bearings. As previously mentioned, the radial bearings had a tighter clearance ratio than other SwRI designs, and while no vibration issues were noticed, the high bearing temperature pointed towards the need to increase clearance between the bearing and rotor. A check of the movement of the rotor in the journal bearing was done to confirm the as-operated clearance. This helped in finalizing further calculations to determine how much material needed to be removed from the rotor bearing journals. Figure 12 shows the directional clearances and flower-shaped support pattern expected for a tilting pad journal bearing with 4 pads.

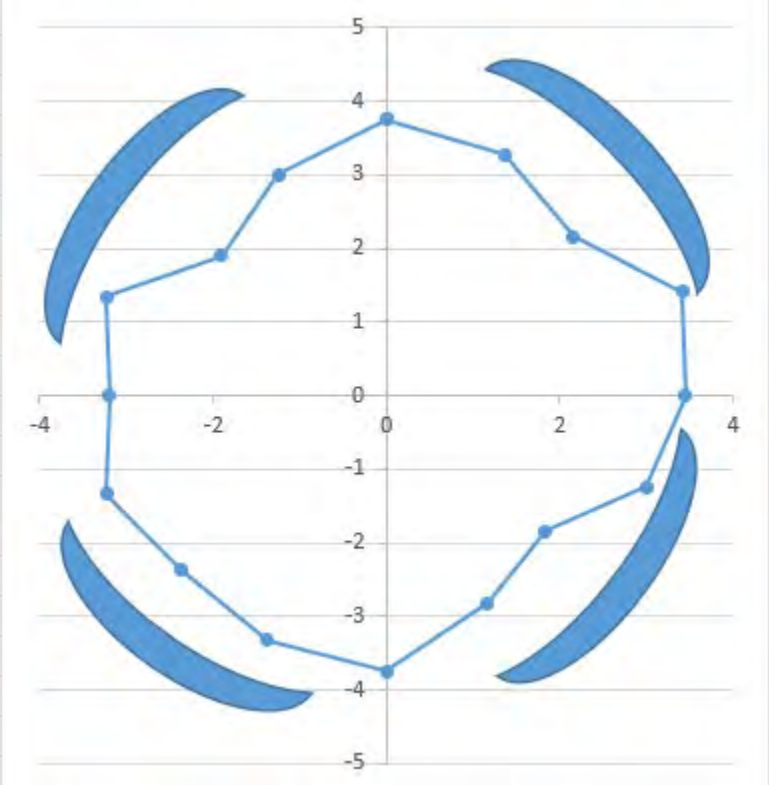

Figure 12. Depiction of process radial bearing clearance with respect to pad orientation

While the journal bearing clearances were being increased, the team evaluated other system changes that were needed. A hydrostatic oil feature was designed and added to the thrust bearing to lessen the breakaway torque mentioned. Targeted startup pressures for the turbine are desired to be above the supercritical level of 73.8 bar (1,071 psi), which would only add to the high breakaway forces from the thrust bearing. Each of the 10 pads that make up the tilting pad thrust bearing were cross-drilled and plumbed with 1/16th-inch tubing to supply high pressure oil,

creating a constant oil film between the rotor thrust disk and bearing. Figure 13 shows the distribution of the oil lines to each drilled pad.

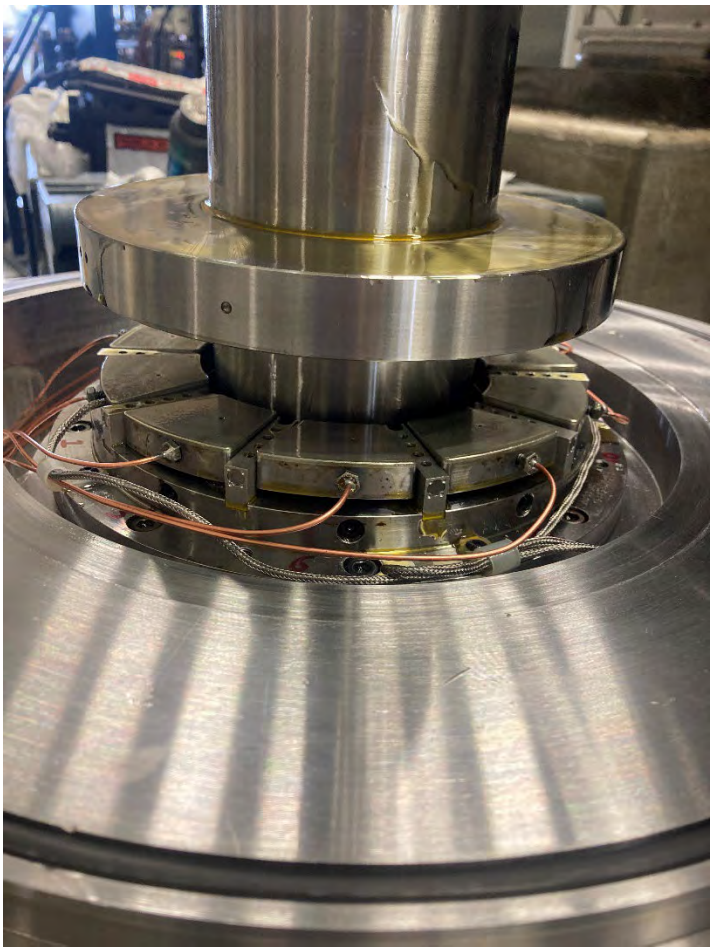

Figure 13. Lines plumbed into each thrust bearing pad to supply hydrostatic jacking oil

While working with the bearing manufacturer on rotordynamic calculations and predictions, SwRI directed the original rotor manufacturer to reduce the bearing journal diameter. This change increased the clearance ratio to 1.9 mils per inch, allowing the bearing temperatures to run at a cooler temperature while maintaining rotordynamic stability. Grinding of the rotor journals was followed by a rebalance of the shaft. The modified components were inspected upon completion, and the turbine was reassembled for further testing. Other internal components were inspected while the machine was disassembled, but no abnormalities were noted.

6. Further Testing

Startup for the second turbine test followed the process used for the first operation. The turbine oil seal system was activated prior to completing purge cycles of the loop to remove all air in the piping system. Following the third purge cycle, the system CO_2 pressure was increased to 220 psi to meet the compressor startup parameters and then further raised to 400 psi at the compressor inlet while the driver was increased to full speed.

Before the second spin of the turbine, bearing lubrication oil was confirmed to be in operational condition, followed by initiating the hydrostatic jacking oil supply to the modified thrust bearing. Figure 14 shows a before and after illustration of the rotor axial position and the approximate 2 mils in which the rotor shifted as a result of the jacking oil. This small gap filled with oil provided the decrease in resistance necessary to eliminate the high breakaway torque. Manual rotation of the turbine was performed under this condition and confirmed that the high breakaway torque was no longer an issue. By already having oil between the thrust disk and bearing pads, starting torque was now estimated at less than 2X the torque required to maintain rotation.

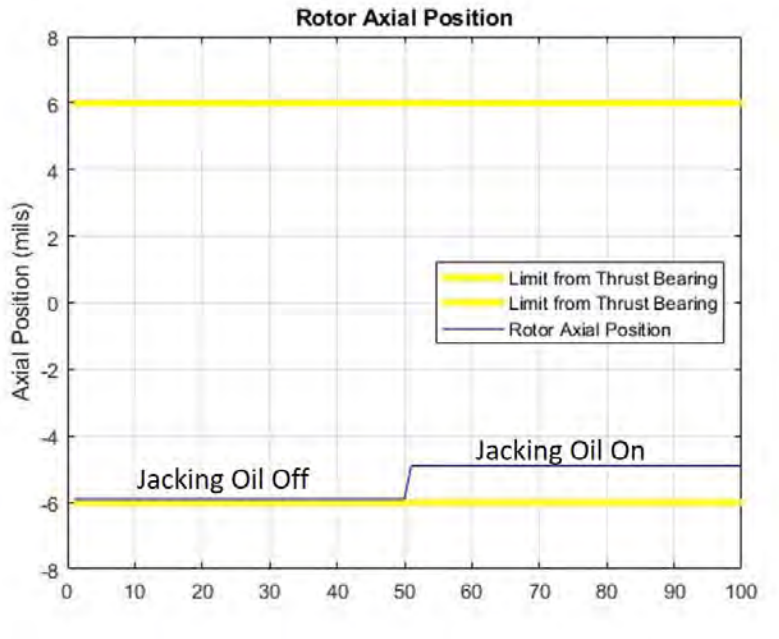

Figure 14. A blue line indicating the rotor axial position shift due to jacking oil. The yellow lines represent the nominal axial limits during operation based on the thrust bearings.

Startup of the turbine occurred at conditions similar to the previous run; turbine inlet of 77°C and 28.8 bar (170°F and 410 psi). There was no need to perform an initial spin by hand to overcome the breakaway torque for this test. Once stable rotation was established, the hydrostatic jacking oil valve was closed to prevent any undesired oil flow in either direction.

Monitoring of the turbine systems, including the bearing temperatures that limited the previous test and vibrations based on the new machine assembly, demonstrated that all operating parameters were closer to the design conditions. Upon reaching 9,500 RPM, the previous maximum speed, bearings temperatures were approximately 35-40°F lower than during previous operation. Synchronous vibrations remained extremely low, showing a good machine balance, however, the small amount of sub-synchronous movement was still present from the oil seals.

The turbine was slowed to adjust the compressor flow conditions to ensure adequate flow was available to surpass the turbine critical speed, with the intent of limiting the time in the 10,000-RPM range. Once the compressor conditions were ready, the turbine was accelerated via a position change of the turbine control valve, up to a speed of 12,000 RPM. At this point, the sub-

synchronous vibrations subsided, and the process end radial bearing temperature decreased again by 35°F as shown in Figure 15.

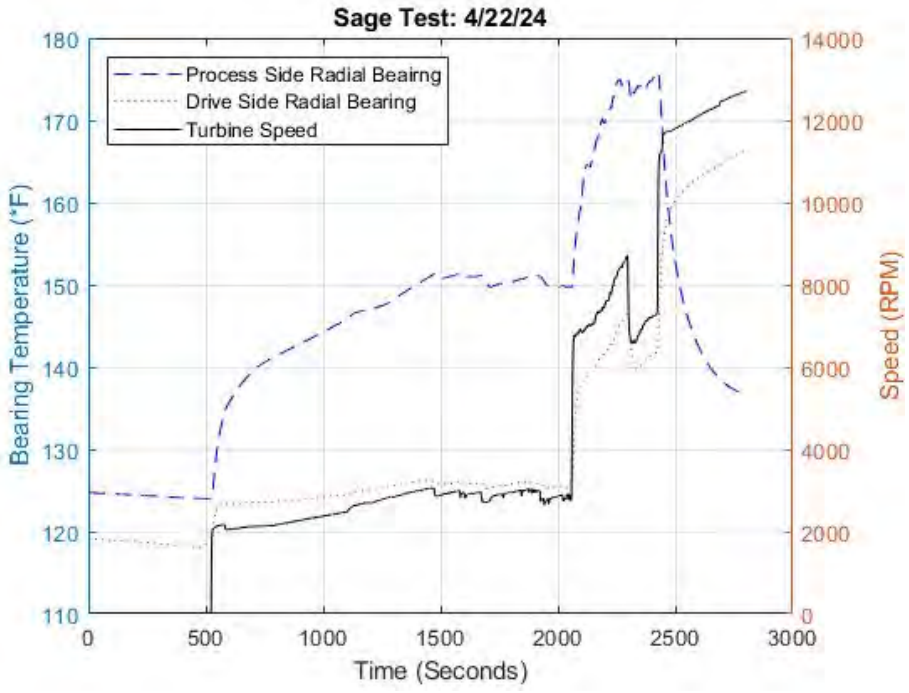

Figure 15. A significant decrease in process radial bearing temperatures occur when the oil seal rings lock in place

These effects can both be contributed to the “locking” of the oil seals in their desired location and lessening the load applied through the rotor to the nearest journal bearing. The new maximum attained speed near 12,000 RPM was held while all systems reached equilibrium. At this point in the test, the system was over half speed and reached that level in less than 40 minutes from initial turbine rotation.

A steady increase in loop pressure after this point provided a steady increase in speed. The heat source flame temperature was increased as well with the increasing flow rate to maintain a stable temperature between 135°C and 150°C (275°F and 300°F) at the turbine inlet. Turbine inlet pressures were increased to 70.7 bar (1,025 psi), resulting in a turbine speed of 18,000 RPM. Turbine discharge pressure at that time was 46.5 bar (675 psi) with all systems running steady. At that point there was a peak in sub-synchronous vibrations, again likely from the oil seal, that caused the machine to trip based on pre-programmed emergency limits set into the control and data acquisition systems.

Testing that occurred on subsequent days allowed for operations between 14,000 and 17,000 RPM but were each halted due to vibrations from the oil seal system. Based on test configurations run throughout each test, it was determined that the seals were not being supplied sufficient seal oil to stay locked at increased speeds. The subsequent achievable speed was lowered by each vibration induced shutdown, indicating that parts of the oil seal were wearing prematurely. This was also confirmed in other literature (Allaire, Kocur, 1985). Oil system modifications, exterior to the turbine, are underway at the time of this publication to ensure additional seal oil can be supplied

and better controlled based on the test learnings. The face seal of each floating ring is being re-machined to provide a better sealing surface.

The system was designed to operate with 10 psi oil pressure differential across the process oil seal. The existing oil seal rundown tank configuration limited the supply to 4.5 psi which lowered the flow through each seal, reducing the stabilizing effects. For further operations, the oil supply pressure will be based on a differential pressure measurement directly at the seal. The rundown tank will stay active for failure or emergency shutdown scenarios, but not dictate the high-pressure supply.

7. Conclusions and Next Steps

The completed operations of the Sage Turbine have been very successful from both operational and design perspectives. Each test has achieved new milestones and brings the technology closer to field-ready status. Improvements to the design include the bearing clearance adjustments as well as addition of the hydrostatic thrust bearing features. Learnings of the free-spinning characteristics and oil seal system operation aspects have been documented and small adjustments are being made to continuously improve the setup.

A final uncoupled (spin) test will be conducted to ensure the turbine is operating as intended, with the various modifications presented, to allow the turbine to reach the full design speed of 22,000 RPM. This is the final milestone before coupling the turbine to the gearbox and generator for load testing. Prior to supplying any excitation current to the generator or turning on the load banks, the full equipment train (turbine, gearbox, and generator) will be operated at full speed to observe and understand the impact of the additional load resulting from the newly-connected equipment.

The sCO_2 turbine load testing will be conducted following the most recent and proven startup procedure used during the spin testing phase. The load testing will be performed in stages to evaluate the turbine's startup performance under higher pressures and will culminate in full supercritical operations above 31°C and 73.8 bar (88°F and 1,071 psi).

Power output up to approximately 500kW is expected from the test impeller considering losses in the rotating equipment at full design conditions. This energy will be absorbed by a load bank connected to the generator and operated in load steps of 5kW. Power output will be monitored and recorded with the generator DECS-150 control system.

These tests will be used as the final data points to show the aerodynamic efficiency of the CO_2 system and how it operates under geothermal conditions. Heat-to-electricity efficiency modeling and calculations at full-scale conditions will also be performed using this data, allowing comparisons of this sCO_2 turbine system to systems in use today for geothermal power generation. Simple impeller changes based on specific well conditions remain a key feature in the modularity of Sage's efficient turbine design. These machinery design and fluid characteristics combined provide a path to lower Levelized Cost of Electricity (LCOE), making geothermal energy cost competitive with other renewable sources.

Keywords

Low-enthalpy geothermal, direct-use heat, techno-economic assessment

ABSTRACT

This study evaluates the techno-economic feasibility of two different deep geothermal system designs for direct-use heating to meet the Calgary Airport Authority's energy demands and support net-zero carbon targets. Geological targets of interest include Upper Devonian carbonates and pre-Cambrian basement rocks, assessed for their geothermal potential and reservoir characteristics. A closed-loop geothermal system in u-loop configuration and an enhanced geothermal system were simulated to compare environmental and economic performance using the GEOPHIRES-X software. Results show that systems deployed at 4 km depth with water as the working fluid have the capacity to reduce 59% of natural gas consumption and abate approximately 396,000 tCO_2-equivalent emissions for YYC over the study period. This research demonstrates the feasibility of deep geothermal systems in low-enthalpy basins within urban centres and highlights important areas for future work to support geothermal development in these basins.

1. Introduction

The Government of Canada has set ambitious net-zero targets for 2050, which have influenced similar targets across the country by provincial governments and industry. As part of an ambitious net-zero strategy, the Calgary Airport Authority (CAA) is exploring behind-the-fence renewable energy generation to integrate with or replace current energy systems at the Calgary International Airport (YYC). YYC is the fourth busiest airport in Canada and as such, operates continuously at full-scale resulting in high energy consumption, emissions, and operating costs. Reliance on the

Alberta grid for electricity and natural gas for heating introduces uncertainty when setting sustainability strategies, in addition to other challenges related to climate risk in the region on a whole.

Calgary, Alberta is situated in a “low-enthalpy” geothermal zone, characterized by a geothermal gradient of approximately 25ºC/km depth. From the Middle Paleozoic to the Precambrian basement (approximately 2.5 to 3.8 km depth), reservoir temperatures are estimated to be 60 to 100 ºC (Majorowicz and Grasby, 2021). Advances in drilling technology and geothermal system efficiencies are increasingly making these low-enthalpy zones, specifically near urban areas, more technically favourable to geothermal development for direct-use heat or electricity generation via organic Rankine cycle turbines. As a reliable, base-load energy source, deep geothermal resource development will be a key piece in driving sustainable growth and meeting commonplace net-zero targets. This study evaluates the techno-economic feasibility of deep geothermal systems for direct-use heating under the low-enthalpy reservoir conditions estimated for YYC.

2. Background

2.1 Calgary International Airport Current Emissions and Energy Demand

On average from 2018 to 2023, the Calgary Airport Authority (CAA) emitted 13,400 tCO_2e of scope 1 emissions and 65,000 tCO_2e of scope 2 emissions (Calgary Airport Authority, 2024). Scope 1 emissions are those generated on-site from activities like burning natural gas or other fuels and scope 2 are associated with using electricity from the local grid. Over the past six years, YYC’s natural gas and electricity demand has averaged about 277,000 GJ and 111,450,000 kWh annually, respectively (Komaromi, 2024).

YYC has two main terminal buildings, the International Terminal Building (ITB) and the Domestic Terminal Building (DTB). Heating for the DTB is provided by a central utilities plant that contains three natural gas power boilers. Two of the original boilers from 1976 are still in operation and a third boiler was added in 2001. There is a combined 30 MW of thermal energy provided by this plant. There is also a geothermal field for the ITB which is currently experiencing performance issues and is not used. Recent engineering assessments found that approximately 54% of natural gas is used for heating and cooling, 5% for domestic hot water, 36% for ventilation (blowers and fans), and the remaining 5% for small equipment like cooking appliances (Komaromi, 2024). Given the current system design and allocation of natural gas, 59% could be replaced with a renewable heat source such as direct-use heat from a deep geothermal system.

The global aviation sector anticipates steady passenger growth over the next decades with an estimated two-fold increase by 2043 (Transport Canada, 2022; International Air Transport Association, 2024). As the fourth largest airport in Canada, YYC expects to experience similar growth in passenger numbers and will need to accommodate this through facility expansion. Additionally, electrification of transportation is increasing demand for electric vehicle charging infrastructure (Komaromi, 2024). YYC is facing the challenge of meeting these demands while striving for more sustainable operations and meeting net-zero by 2050 targets. Deep geothermal development is being assessed as part of a broad net-zero pathway and decarbonization roadmap which looks to integrate building efficiency upgrades with renewable energy technology to provide a secure, carbon-neutral energy supply and enhanced climate-resiliency.

2.2 Geology of the Western Canada Sedimentary Basin

The Western Canada Sedimentary Basin is a massive wedge-shaped package of sedimentary deposits extending from the Rocky Mountains to the Canadian Shield. In the deepest part of the basin along the Rocky Mountain deformation belt, it is approximately 5 km thick. The sedimentary succession of the WCSB lies unconformably on the pre-Cambrian basement. The Paleozoic to Middle Jurassic interval is primarily shallow marine deposition with carbonates, evaporites, and terrigenous shales (Mossop and Shetsen, 1994) while the Devonian succession is characterized by carbonate platforms deposited during subtropical, open-marine conditions. The Devonian succession is subdivided into four groups: the Beaverhill Lake Group, the Woodbend Group, the Winterburn Group, and the Wabamun Group (Mossop and Shetsen, 1994). Due to their geothermal potential (Weydt et al., 2018; Majorowicz and Grasby, 2021) and lateral extent below Calgary, the Woodbend Group and pre-Cambrian basement are of particular interest for this study.

The Cooking Lake Formation carbonate platform and overlying Leduc Formation reefs of the Woodbend Group have well documented potential for geothermal development. The Cooking Lake Formation forms an approximately 75 m thick platform that the Leduc Formation reefs built upon, reaching thicknesses of approximately 250 m in some areas (Mossop and Shetsen, 1994). The Leduc Formation reefs are surrounded by Duvernay, Majeau Lake, and Ireton formation shales. The reefs have an average porosity of approximately 8%, reservoir permeability of 10^{-12} to 10^{-15} m^2, and thermal conductivities ranging from 3 to 5 W/m K (Weydt et al., 2018). Hydrologically, the aquifers belong to the Upper Devonian Hydrogeological Group which consists of four aquifers, separated by laterally discontinuous aquitards. The Leduc Formation is a historic hydrocarbon reservoir in the WCSB with some of the provinces' most prolific pools and production dating back to 1947 (Chow et al., 1995).

The pre-Cambrian basement is not as well studied as the overlying sedimentary units, particularly under the deepest parts of the basin in the western part of the province where the study area is. Generally, the basement is composed of crystalline igneous and metamorphic rock types that vary spatially with evidence of deformation and recrystallization (Burwash et al., 1994).

2.3 Geothermal gradient and temperature

The Precambrian basement has significant influence over the thermal conditions and heat distribution of the WCSB (Majorowicz and Grasby, 2020). In the thickest parts of the basin, temperatures are highest and range from around 110 to 120ºC. Majorowicz and Grasby (2020) estimate maximum temperatures of approximately 170ºC in the northwest part of the province. The study area at Calgary, AB has temperatures ranging from approximately 70 to 100ºC depending on the target formation.

The geothermal gradient is a function of heat flow and thermal conductivity and varies laterally across the WCSB. The highest vertical temperature gradients, approximately 40 to 55ºC/km, occur in the sparsely populated northern part of Alberta. In the southwest where the study area is, the gradient is estimated to be about 25 to 30ºC/km (Majorowicz and Grasby, 2020).

2.4 Advances in geothermal drilling

The cost of exploration and drilling in geothermal development is a major component of capital costs of projects. Drilling often occurs under challenging conditions including borehole instability,

ultra-high strength rocks (e.g. crystalline granites), and high subsurface temperatures that can exceed temperature limits of drilling and completions tools. Recently, demonstrations by the Frontier Observatory for Research in Geothermal Energy (FORGE) and Fervo showed that enhanced geothermal systems (EGS) can successfully be drilled in hot, dry granites with significant reductions in drilling time which translates to lower capital costs (Sugiura et al., 2021; El-Sadi et al., 2024).

At the Eavor-Deep project in New Mexico, insulated drill pipe technology was field tested and demonstrated the ability to use existing bottom-hole assembly tools for drilling and completions in high-temperature rocks. The ability to apply existing drilling technology to exploit geothermal resources will enable hotter, more economically feasible configurations (Brown et al., 2023; Vetsak et al., 2024).

3. Methodology

To assess the techno-economic feasibility of deep geothermal development at the Calgary International Airport (YYC), a business-as-usual scenario was modelled to compare the energy and resulting emissions performance of deep geothermal systems. To establish estimated formation depths and reservoir rock properties, a subsurface assessment was conducted and the results were used in subsequent geothermal systems modelling (Komaromi, 2024). Data sources include internal YYC reports and documents, publicly available well logs, and other literature.

GEOPHIRES-X, a techno-economic simulator developed for geothermal system application, was used to model reservoir, wellbore, and surface plant performance and costs (Beckers, 2016; Beckers & McCabe, 2019). Two designs for direct-use heating were assessed, both using water as the working fluid: an EGS and a closed-loop geothermal system (CLGS) in u-loop configuration. The estimated geologic properties for the Leduc Formation and the pre-Cambrian granite in the WCSB were incorporated into the model for simulations run at 3 km depth and 4 km depth, respectively. Appendix tables A-1 to A-4 summarize the parameters used in the geothermal systems modelling.

4. Results

4.1 Well log analysis

Based on the well log analysis of formation tops in the study area, the Leduc formation is estimated to be approximately 200 m thick and 3000 m deep below Calgary. The basal Cambrian sandstone (BCS) overlying the pre-Cambrian basement is estimated to be 3200 m deep. There were no wells in the study area that fully penetrated the BCS so thicknesses could not be determined as part of well log analysis. However, the BCS is documented throughout the WCSB as having a thickness ranging from 40 to 80 m (Alberta Geological Survey, 2024). There was only one well in the eastern portion of the assessed area that fully penetrated the Leduc Formation, and it showed a thickness of 128.4 m. This is in line with regional thinning of sedimentary successions from west to east in the WCSB (Komaromi, 2024).

All the wells in the study area had recorded bottom-hole temperatures (BHT) that were used to estimate temperatures in the subsurface. For BHTs recorded in the Leduc Formation, temperatures range from 141ºC to 61ºC and with an average of 84.6ºC. BHTs recorded in the BCS ranged from

86ºC to 52ºC and had an average of 74.3ºC (Komaromi, 2024). It should be noted that all wells used in this study were drilled for oil and gas exploration with some dating as far back as 1951. Therefore, BHT recordings may not accurately reflect the geothermal conditions in the reservoir.

Only one well in the study area had recorded gas analysis data. Analysis was done higher up in the succession in the Wabamun Formation at an interval from 2500 m to 2520 m and shows 0.1227 ppm of hydrogen sulphide gas (Komaromi, 2024).

4.2 GEOPHIRES simulation results

Two geothermal systems were simulated at two target depths using GEOPHIRES-X based on the estimated subsurface parameters and rock properties. All systems were simulated using water as the working fluid, with a geothermal gradient of 25°C/km, and with an injection temperature of 40°C. At 3 km depth, geology-specific parameters used were based on lithological properties of dolomite: reservoir heat capacity of 920 J/kg/K, reservoir density of 2900 kg/m3, and reservoir thermal conductivity of 5.3 W/m/K. At 4 km depth, geology specific parameters were set based on lithological properties of granite: reservoir heat capacity of 790 J/kg/K, reservoir density of 2650 km/m^3, and reservoir thermal conductivity of 3.5 W/m/K. For the EGS, reservoir porosity and permeability were set at 20% and 1e-15 m^3, respectively, and with one production and one injection open hole wellbores. The CLGS was configured with two, 1 km multilaterals for a total of 2000 m of non-vertical length.

4.2.1 Enhanced geothermal system results

The EGS modelled at 3 km depth has an average heat production of 8.57 MW_{th} and an average production temperature of 76.6 °C. This is equivalent to approximately 285,000 GJ of heat provided annually. Figure 1 shows the production temperature and heat production over time for the EGS system at 3 km depth. Based on default GEOPHIRES-X parameters, the total capital cost is estimated to be $22.18M and operating costs are $1.01M annually. The results of the simulated EGS at 3 km depth are presented in Table 1.

When modelled for 4 km depth and the lithologic properties of granite, the EGS system has an average heat production of 11.78 MW_{th} and an average production temperature of 91.7 ºC, or approximately 376,000 GJ of heat annually, on average. Figure 2 shows the results of the simulated EGS over time at 4 km depth. The capital cost of this system is estimated at $31.32M with an annual operating cost of $1.4M. Table 1 provides a summary of the results for the simulated EGS at 4 km depth.

4.2.2 Closed-loop geothermal system results

The CLGS modelled at 3 km depth has an average heat production of 7.18 MW_{th} and an average production temperature of 68.0 °C. Figure 3 shows these results. The total capital cost is estimated to be $28.93M and operating costs are $0.6M/year, based on the GEOPHIRES default parameters. The results for the CLGS at 3 km depth can be found in Table 2.

At 4km depth, the CLGS has an average heat production of 7.83 MW_{th} and average production temperature of 70.7 ºC, giving approximately 224,000 GJ/ year in produced heat. Figure 4 shows these results. The estimated capital cost of this system is $40.72M while the operating cost is $0.99M/year. Table 2 summarizes the results of the CLGS at 4 km depth.

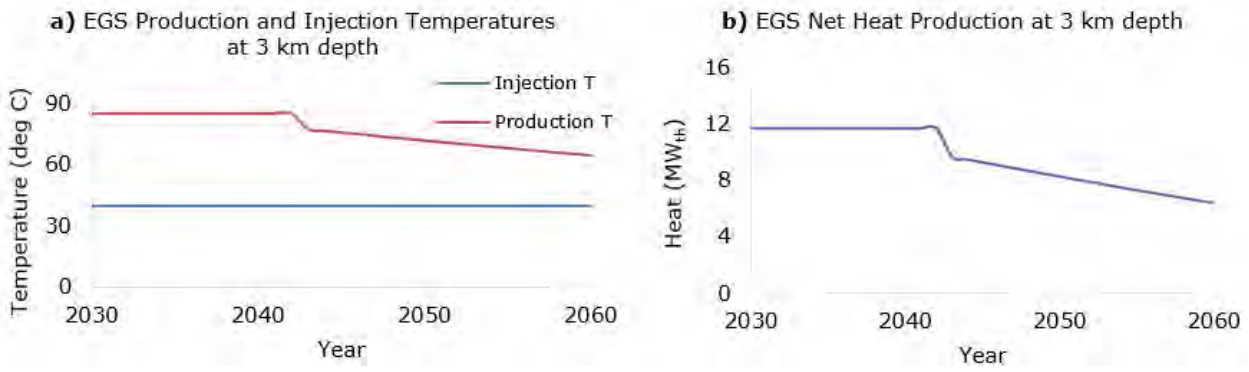

Figure 11: Simulation results for enhanced geothermal system at 3 km depth with one injection and one production wellbore. a) Production and Injection temperature results; b) Net heat production results.

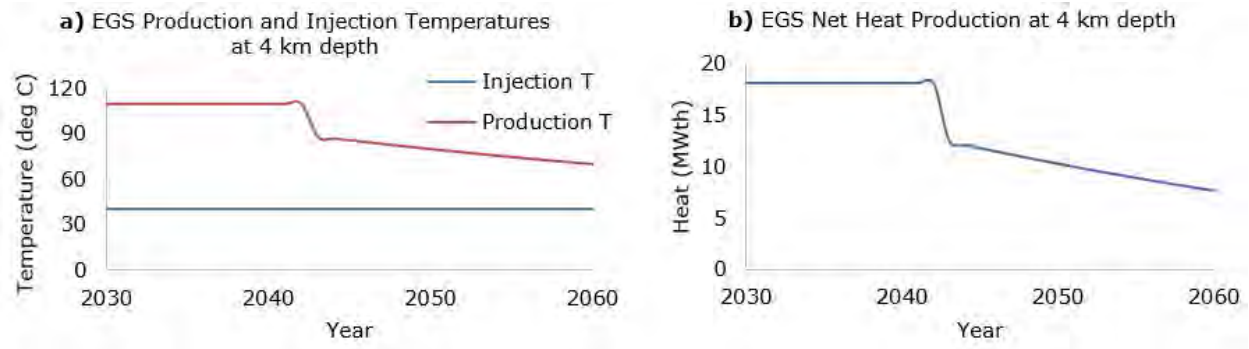

Figure 22: Simulation results for enhanced geothermal system at 4 km depth with one injection and one production wellbore. a) Production and injection temperature results; b) Net heat production results.

Table 1: Simulation results for enhanced geothermal systems at 3 km and 4 km depths.

Enhanced Geothermal System for Direct-use Heating (3 km depth)	
Average net heat production	8.57 MW_{th}
Average net annual heat provided	74.5 GWh/year
Average geofluid production temperature	76.6 ºC
Total capital costs	$22.18/M
Total annual operating costs	$1.01M/year
Levelized cost of heat	$9.91/MMBTU
Enhanced Geothermal System for Direct-use Heating (4 km depth)	
Average net heat production	11.78 MW_{th}
Average net annual heat provided	74.5 GWh/year
Average geofluid production temperature	91.6 ºC
Total capital costs	$31.32/M
Total annual operating costs	$1.4M/year
Levelized cost of heat	$9.57/MMBTU

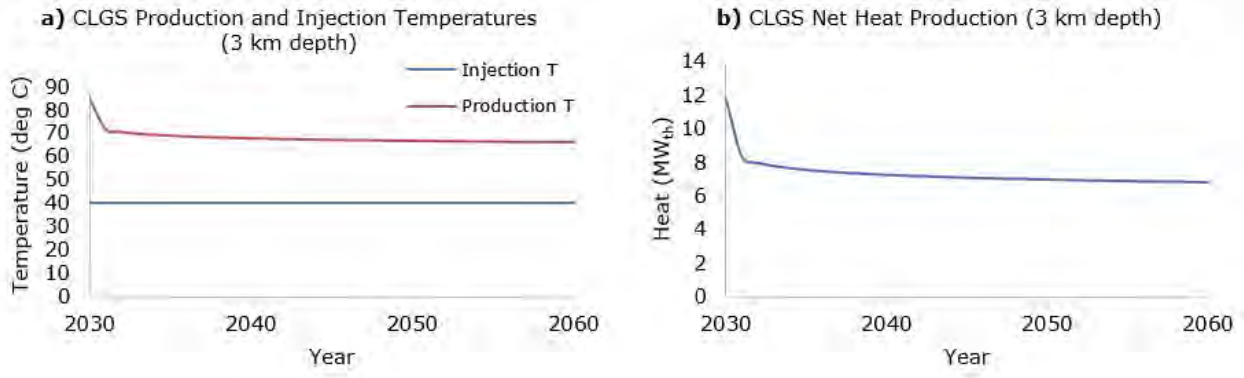

Figure 3: Simulation results for closed-loop geothermal system in u-loop configuration at 3 km depth with two, 1 km multilaterals. a) Production and Injection temperature results; b) Net heat production results.

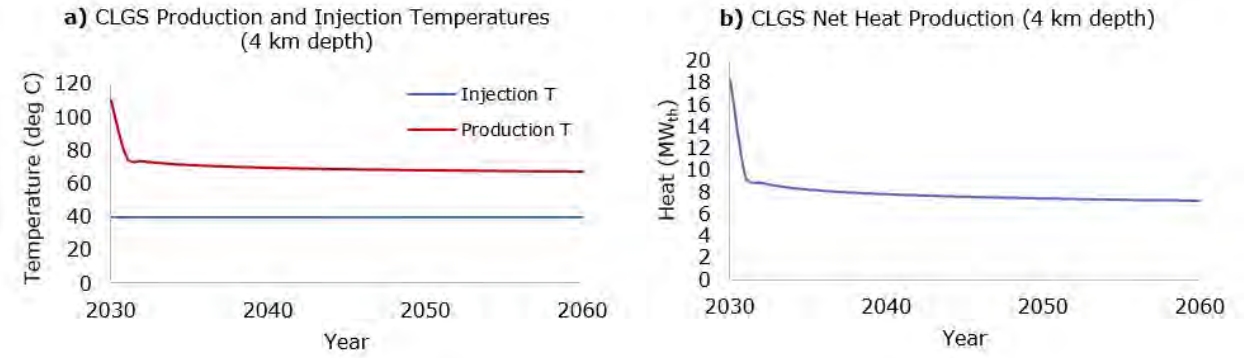

Figure 4: Simulation results for closed-loop geothermal system in u-loop configuration at 4 km depth with two, 1 km multilaterals. a) Production and Injection temperature results; b) Net heat production results.

Table 2: Simulation results for closed-loop geothermal system designs at 3 km and 4 km depths.

Closed-loop Geothermal System for Direct-use Heating (3 km depth)	
Average net heat production	7.18 MW_{th}
Average net annual heat provided	57.0 GWh/year
Average geofluid production temperature	68.0 ºC
Total capital costs	$28.93M
Total annual operating costs	$0.6M/year
Levelized cost of heat	$13.98/MMBTU
Closed-loop Geothermal System for Direct-use Heating (4 km depth)	
Average net heat production	7.83 MW_{th}
Average net annual heat provided	61.97 GWh/year
Average geofluid production temperature	70.1 ºC
Total capital costs	$40.72M
Total annual operating costs	$0.99M/year
Levelized cost of heat	$15.51/MMBTU

4.3 Energy and environmental performance

For either a CLGS or EGS at 4 km depth, the entire 59% of business-as-usual natural gas consumption for heating and domestic hot water can be replaced with direct-use heat from geothermal resources. This is equivalent to a reduction in approximately 7.8M GJ of natural gas over the entire study period from 2030 to 2060 and results in approximately 396,000 tCO_2e emissions abated.

At 3 km depth, the forecasted natural gas demand will exceed the annual heat production of the EGS around 2056 and the CLGS around 2053, by a very small margin.

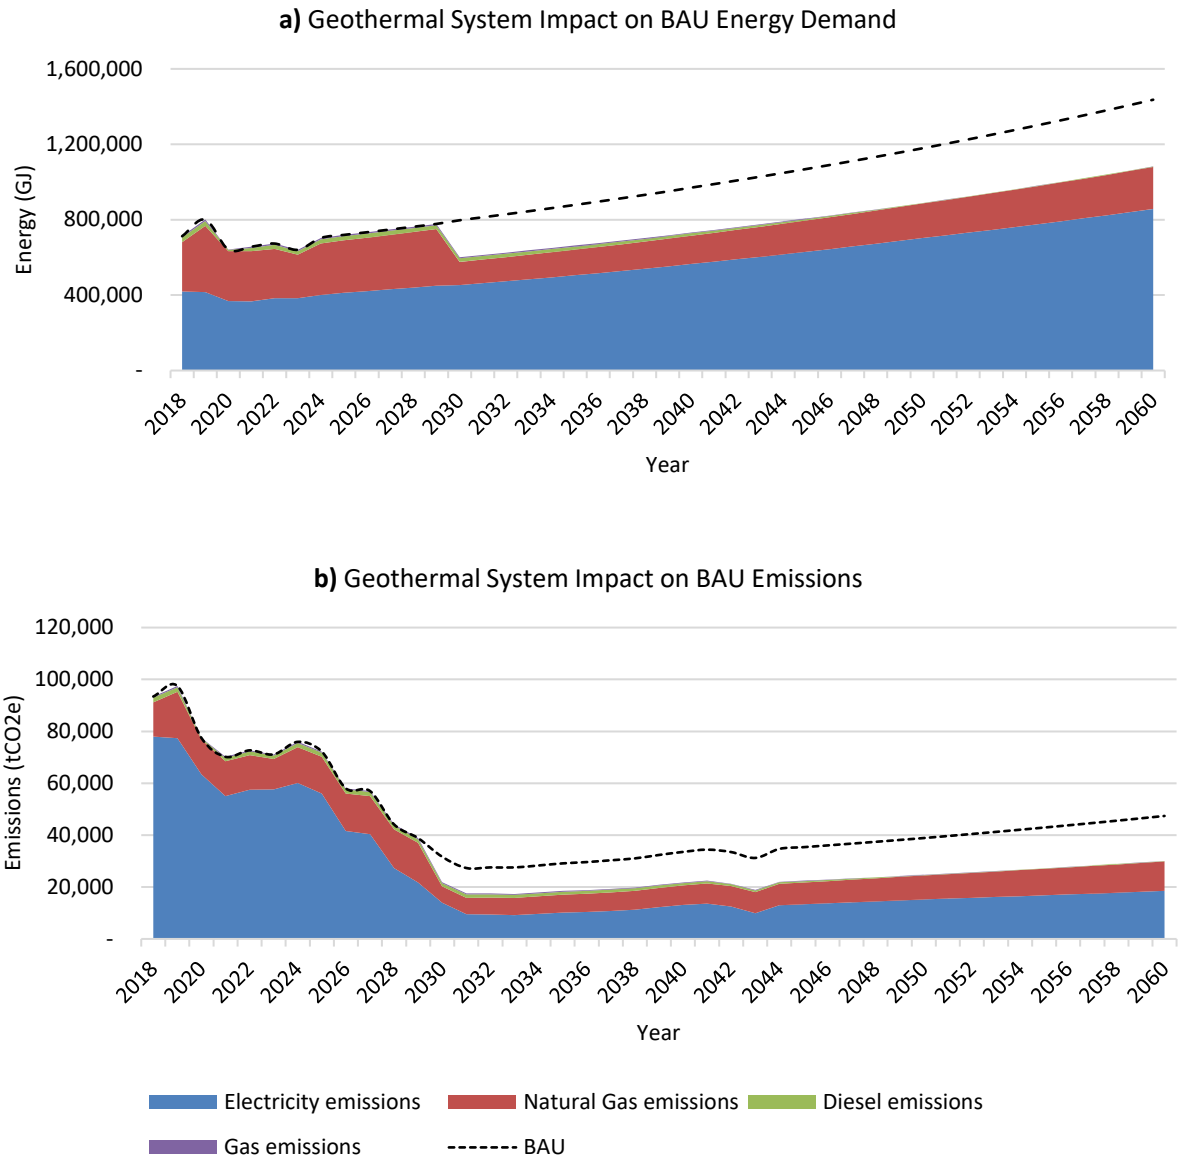

Figure 55: Energy and emissions reduction from business-as-usual forecast for either EGS or CLGS at 4 km depth. a) Reduction in natural gas consumption off business-as-usual forecasted values; b) Emissions abatement from geothermal system off business-as-usual forecast (adapted from Komaromi, 2024).

5. Discussion

Exploitation of low-enthalpy geothermal resources near urban centres could be critical for supporting net-zero carbon targets due to geothermal energy's ability to provide baseload, reliable power and replace high emitting fuels like natural gas for heating. This study assessed the techno-economic feasibility of either an enhanced geothermal system or a closed-loop geothermal system at two different target depths under the estimated reservoir conditions in Calgary, Alberta to support the net-zero targets of the Calgary International Airport (YYC). Results show that at 3 km depth, either an EGS or CLGS can meet the energy demand of YYC for the beginning of the study period, however, after about 25 years of production, thermal draw down along with increasing demand due to business growth led to a deficit in heat production.

At 3 km depth, the target sedimentary unit would be the Leduc Formation. This is a well-documented oil and gas reservoir that has been producing in the region since the late 1940s. However, spatial distribution of these hydrocarbon reservoirs is complex and there are also documented brine and water reservoirs. While co-production of geothermal fluids and hydrocarbons is technically feasible and demonstrated as commercially viable, for YYC the goal is simply decarbonization via deep geothermal system development and co-production of hydrocarbons lies outside of their interests. Additionally, the Leduc Formation and overlying sediments are known to contain hydrogen sulfide gas. Since YYC is situated within an urban area, hydrogen sulfide release would be dangerous, costly, and could have far reaching impacts beyond just the operation of the airport. Therefore, an EGS system in the Leduc Formation dolomites carries higher risk of encountering hydrocarbons or H_2S than a CLGS due to the necessary production of subsurface brines in an EGS system. These risks emphasize the importance of further exploration and research into the subsurface conditions at YYC to better characterize reservoir conditions.

By drilling to 4 km depth into the pre-Cambrian crystalline basement rocks, the risk of hydrocarbon co-production is much lower than in the Leduc Formation, however drilling becomes more challenging and costly. Additionally, stimulation at these depths for an EGS development is more technically challenging than would be in the sedimentary overlying rocks. However, heat production from either an EGS or CLGS in the pre-Cambrian basement would be more than sufficient to meet current and future energy demand of YYC.

The levelized costs of heat (LCOH) were calculated using default parameters in GEOPHIRES-X. This allows comparison on a relative scale only where the EGS systems at both 3 and 4 km depths have lower LCOH due to lower capital costs and higher heat production. However, if an EGS system were to be drilled within the Leduc Formation, additional infrastructure for mitigating co-produced gas risk would likely be required and was not accounted for here. For all systems, the cost of weatherization to protect surface equipment from the very cold winter temperatures also would need to be assessed. Additionally, further assessment of existing infrastructure at YYC and the viability of integrating with a deep geothermal system will need to be analyzed in detail to establish more certain cost figures.

Ultimately, there are risks and rewards for each chosen subsurface depth and for each design of geothermal system. Given the risk of hydrocarbon and H_2S gas in the Leduc Formation, an EGS at this interval may be the least feasible option for YYC despite sufficient heat production for at least the next 25 years, based on the models. A CLGS in the Leduc Formation would carry less

operational risk of co-produced gases but the additional cost for lower heat production, makes this a less attractive option. If capital allows, a CLGS at 4 km depth carries the lowest operational risk and will provide enough heat to meet the growing needs of YYC until at least 2060 with abated emissions significantly helping YYC to achieve their net-zero targets.

6. Conclusions

The techno-economic feasibility of deep geothermal systems at the Calgary International Airport were assessed based on the estimated subsurface conditions. Results show that economically, an EGS system at 3km depth could sufficiently meet the energy needs of YYC for the next 25 years based on business-as-usual forecasting and simulations run in GEOPHIRES-X. However, in considering operational risk due to hydrocarbons in the sedimentary units, an EGS or CLGS at 4 km depth is favourable. Subsurface conditions below YYC are not well known and this study demonstrates the need for additional research with the end-goal being a science well drilled on YYC property. Overall, a deep geothermal system to support the net-zero targets of YYC is shown to be both technically and economically feasible.

ABSTRACT

This study builds on the existing techno economic and environmental life cycle assessments performed for a geothermal district heating and cooling system implementation in Tuttle Oklahoma with four existing oil and gas wells. Its resilience in meeting the peak annual heating and cooling loads of the district assuming a temporary disconnection from the electrical grid is assessed both qualitatively and quantitatively. Attributes of resilience and qualitative criteria established by Kolker et al. (2022) for geothermal district heating systems are applied to the proposed case to highlight its vulnerabilities. Results indicate that increasing the redundancy and diversity in the physical configuration of the distributional piping can considerably increase the system's resilience. A quantitative assessment executed via the REopt tool predicts that the ancillary electricity required to power the geothermal system's heating and cooling can be met by an onsite emergency diesel generator during times of grid outages for over 28 days.

1. Introduction

The resilience of an energy system describes its ability to sustain normal operation and meet typical loads during and around times of disruptions induced by various forces. Disruptions are a result of system component fatigue and end of life, natural disasters, extreme weather, human error, and upstream supply chain issues. As highlighted by Kolker et al. (2022), resilience is defined differently across stakeholders such that attributes of resilience (i.e. reliability, redundancy, resourcefulness, responsiveness) are discussed to compare the resilience across energy systems that differ in primary source (e.g. natural gas, photovoltaic, wind) and physical configuration/scale (e.g. distributed energy resources, district energy system).

The potential disruptions that an energy system risks and its suitability to be resilient in a given application are geographically dependent as the environmental, political, social, and economic

context changes. For example, it is not logically sensible to compare the resilience of a concentrated solar microgrid operating in Texas, United States versus southern Chile due to the stark difference in the annual distribution of incoming solar irradiance, policy around energy (resources) and security, end-use applications and social patterns of energy consumption, and the cost to deliver energy from various primary sources. The most resilient energy system for each location would look very different because their unique risks yield an optimal solution that is impactful under the local conditions of the site.

Additionally, there is no uniformly established method of quantifying the resilience of an energy system. This makes the comparison of resilience between two different energy systems a rather qualitative exercise subject to criteria established by the analyst. The existing literature on energy system resilience is sparse, conceptual, and high level. It mainly discusses concepts and definitions related to energy resilience and proposes relevant metrics that can be analyzed and/or quantified for a comparative assessment of energy resilience. Additionally, studies on energy resilience tend to be focused on grid electricity generation rather than district heating and cooling for which geothermal as an energy source is least considered.

However, the topic of energy resilience is becoming an emerging area of study in regard to meeting energy demands in a time of increasing natural disasters and extreme weather events. Namely, heating and cooling which contributes to 35% of total end use building energy consumption is a crucial service to consistently uphold. Global average surface temperatures continue to increase at an alarming rate such that natural phenomena such as droughts and hurricanes have become stronger and witnessed more frequently. Their effects have been proven to devastate energy infrastructure, including the lives and services that are dependent on such. At the same time, energy consumption has increased due to climate change and population growth such that resilient energy systems are essential to minimize the disrupting effects of energy supply shortages to society and the economy during times of critical loads. Renewable energy presents itself as a promising solution to address one key driver (e.g. carbon emissions) of warming temperatures which in turn affects energy system functionality and energy consumption patterns. Specifically, geothermal energy is a resilient alternative to heating and cooling when compared to conventional systems due to low transportation needs in its upstream supply chain, a high capacity factor, long operational lifetimes, low operational costs, and subsurface equipment which is shielded from ambient conditions.

To address the lack in literature assessing the system resilience of geothermal energy, we consider the use of four abandoned oil and gas wells in Tuttle Oklahoma for a direct use geothermal district heating and cooling system implementation. Its resilience is evaluated relative to the existing decentralized natural gas system of boilers and furnaces in a district of 250 homes, a primary school, and a secondary school. Details on the technoeconomic feasibility and environmental life cycle impacts of such energy system transition are detailed in Oh et al. (2024) and Marroquin et al. (expected), respectively. We leverage the criteria proposed by Kolker et al (2022) as a “variety of relative resilience criteria that can be evaluated to allow more structured analysis of resilience improvements associated with a particular resilience mitigation strategy” for qualitatively measuring the resilience of geothermal district heating systems. Additionally, we configure the National Renewable Energy Laboratory’s (NREL’s) local-scale renewable energy dispatch model named REopt for a quantitative resilience analysis of the proposed geothermal system to answer two key questions. First, what is the maximum grid outage duration that the geothermal system

can withstand while meeting 100% of the heating and cooling demand of the district at a probability of at least 50% during times of peak electricity consumption by the geothermal system (i.e. during peak heating and cooling loads). Second, what is the probability distribution that the geothermal system will survive the outage while meeting its heat load as a function of outage duration? The model considers the existing natural gas fired heating system of the district such that results highlight the net energy resilience benefits of a geothermal energy system implementation.

2. Methods

Kolker et al. (2020) summarizes current energy use in Arctic countries and dives into the opportunities for increased geothermal energy as a renewable resource for electric and thermal energy supply, including cascaded use. In doing so, resilience attributes of integrated geothermal energy systems are highlighted to determine whether techno economically feasible geothermal systems would be resilient relative to the current energy practices in the Arctic. The high-level resiliency attributes of geothermal energy are leveraged to formulate a list of questions which are each attributable to one of the four pillars of resiliency (i.e. reliability, redundancy, resourcefulness, and recovery). Unique sets of resilience attributes, components, and criteria are presented for geothermal power and thermal systems, respectively. In this study, we adopt the key resilience attributes and components of thermal systems (i.e. Table 3) from Kolker et al. (2022) to qualitatively measure the resilience of the proposed geothermal district heating and cooling system for the Tuttle district.

REopt is a web-based tool that evaluates the technoeconomic feasibility of integrating renewable energy resources and more energy efficient methods into the existing power grid of a residential, commercial, or small industrial stock of buildings. The model can consider resources such as photovoltaics and geothermal heat pumps including systems with combined heat and power and battery storage. User defined inputs consist of energy goals (e.g. cost savings, clean energy), energy system technologies (e.g. wind, battery), site & utility information (e.g. site location, building floor area, heating fuel cost, utility provider), and energy load profiles (e.g. annual hourly electricity consumption, heating fuel consumption, and cooling load profiles). The model optimizes the capacity sizes and dispatch strategies of the integrated electric and thermal technologies such that the electric, heating, and cooling demands of the building stock are supplied at the site's lowest life cycle cost of energy.

For the case of this study, grid electricity, central plant water-to-water ground source heat pumps, and a diesel generator were selected in REopt as source technologies to supply the energy profiles of a primary school, secondary school, and 250 single family homes located in Tuttle Oklahoma. In the previous work of Oh et al. (2024), the representative building types of the district were modelled in EnergyPlus to simulate their energy flows and heat transfers. Outputs served as input into GeoPHIRES to estimate the potential geothermal energy that can be extracted from a nearby abandoned oil and gas well site to supply heat to the district. With an economic life cycle assessment executed in parallel, the technoeconomic feasibility of a direct-use geothermal district heating and cooling system integration in the aforementioned Tuttle district was established. From the previous work in EnergyPlus, the output heating fuel consumption and cooling load of the buildings (Figure 1) was inputted into REopt.

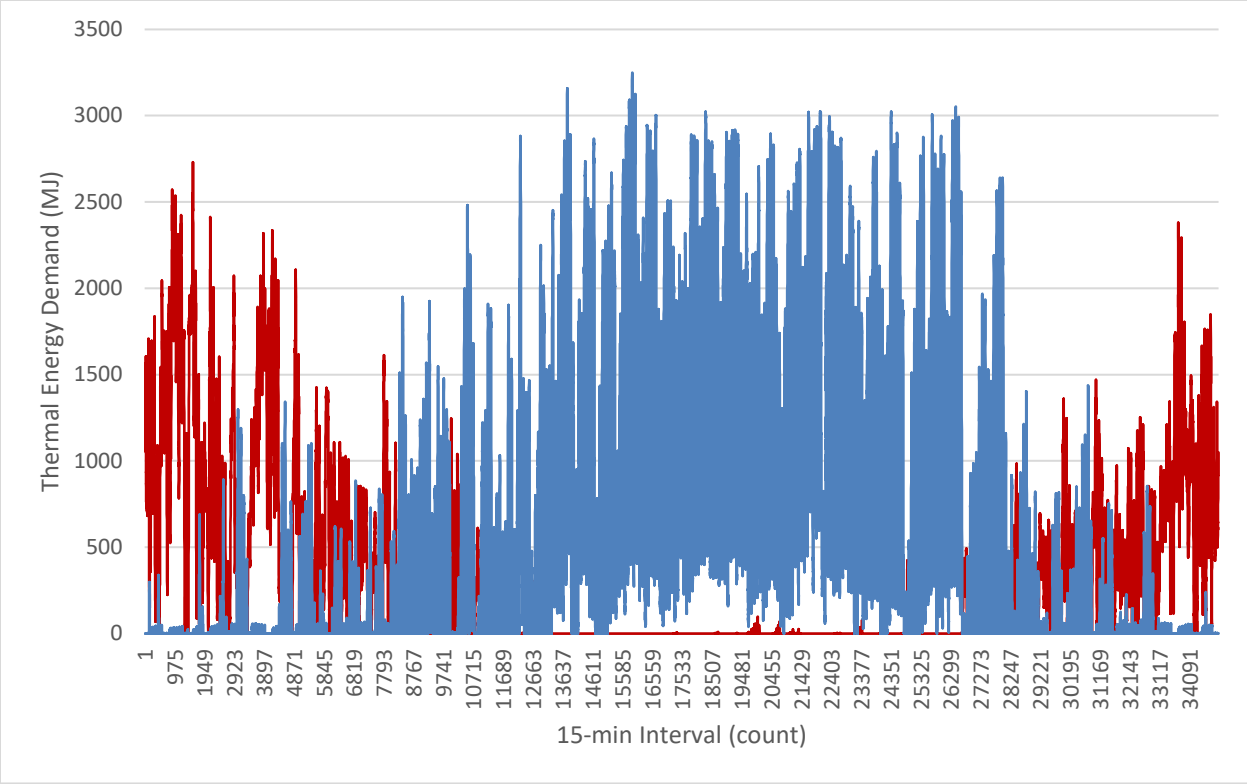

Figure 1: Heating and cooling demand of the Tuttle district as outputted by EnergyPlus based on the local weather and relevant energy performance parameters of the building stock

Although the direct-use geothermal system considers a central plate heat exchanger rather than central ground source heat pumps, a tool-based quantitative analysis of energy resilience is largely constrained to the limitations of the REopt tool. This is because no other tool with the same objective functionality exists to the knowledge of the authors at the time of this study. Geothermal capabilities within REopt are relatively new and currently have ongoing efforts to improve and expand such that the most representative energy system module within REopt to the proposed case of this study is central water-water ground source heat pumps. However, it is important to note that relevant metrics can be calculated following various approaches and equations as outlined in Das et al. (2020) whose applications are independent of the system design.

Additionally, results of Oh et al. (2024) indicated that the high electricity consumption required to power the cooling supply of the district relative to the heating supply via direct geothermal use deem the system techno economically infeasible for cooling. This is because a direct-use geothermal system must be coupled with an absorption chiller to provide cooling in addition to heating. At the same time, a chiller requires electricity as its primary source of energy to extract heat from water while a central plate heat exchanger requires electricity as ancillary energy to extract and inject subsurface geothermal fluid. The electricity consumption of the chiller is about 80% of the cooling demand while the electricity consumption of the well pumps is orders of magnitude less than the heat demand. The annual cooling demand is also greater than heating by a factor of 1.32 and a 1:1 heat exchange is assumed at the central plate heat exchanger. As a result, significantly more electricity is consumed for cooling versus heating. More electricity consumption than a conventional air-conditioning system was concluded for the direct use

geothermal system in cooling mode such that geothermal cooling is not techno economically feasible via direct use. However, the central ground source heat pump system chosen in REopt to represent the proposed case study exhibits a higher annual average coefficient of performance (COP) for cooling relative to heating. It is determined by REopt as a function of inlet and outlet temperature. Therefore, the central plant water-to-water heat pumps within REopt are selected to serve as proxy for a geothermal system implementation that is techno economically feasible of meeting the heating and cooling demand of the Tuttle district.

Furthermore, existing energy resilience analyses optimize electricity supply rather than heating and cooling. As an example, critical load within REopt is defined as the electricity demand that must be met during an outage (i.e. temporary disconnection from the electric grid) such that the probability of an off-grid energy system to meet the electric loads of a community is the metric to quantify the resilience of the system. However, a geothermal heating and cooling system is inherently tied to the electric grid. This is because delivering geothermal energy requires an ancillary electrical input to circulate fluid and upgrade the exergy of extracted geothermal energy as needed to meet a given demand. This means that during times of a grid outage, a geothermal heating and cooling system will lose functionality in addition to all other electrical appliances in a building. This also indicates that by specifying the electrical load of the district to be the total consumption at the meter as outputted by EnergyPlus (Figure 2), results of energy resilience from REopt would be optimized to meet the loads of existing electronic appliances rather than heating and cooling from geothermal energy.

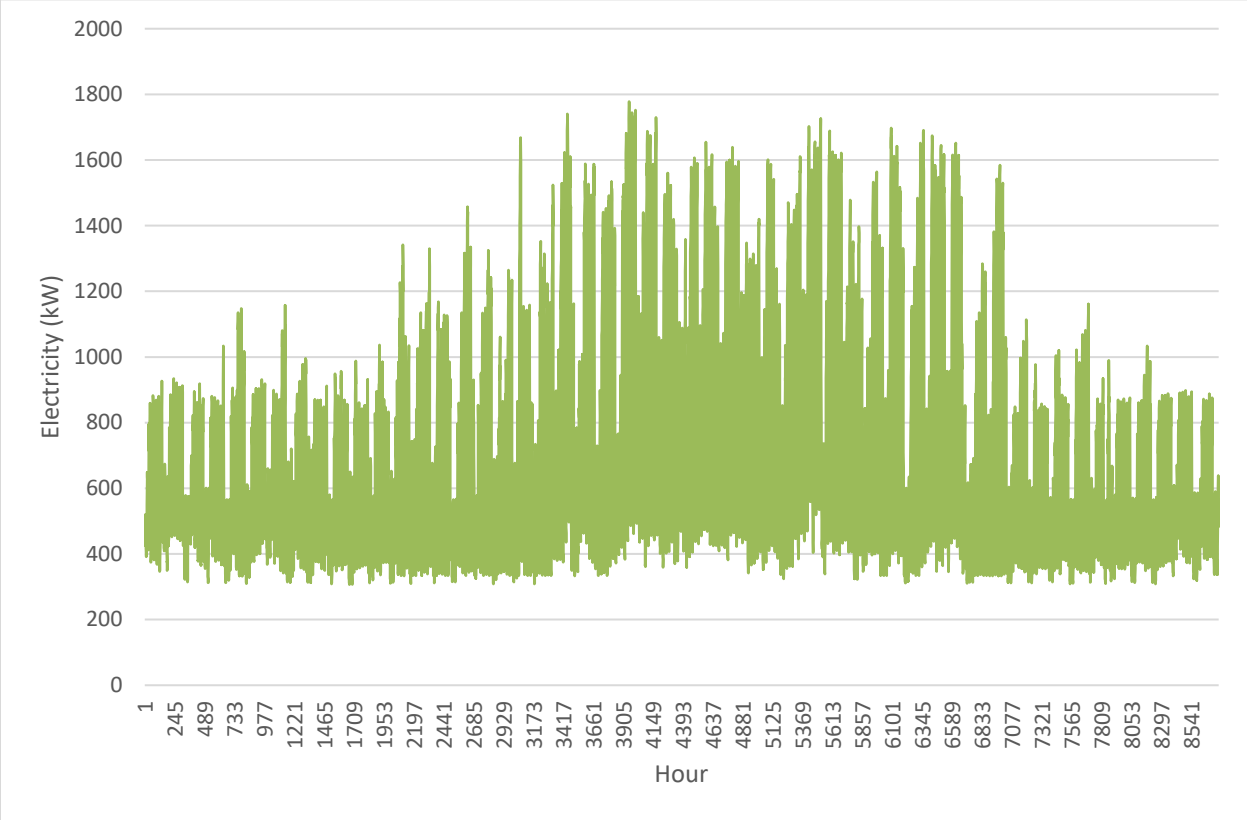

Figure 2: Electricity consumed by the district as outputted by EnergyPlus based on the local weather and relevant energy performance parameters of the building stock

Given that the objective of this study is to evaluate the resilience of a geothermal district heating and cooling system, the application of the REopt tool to assess energy resilience was strategically modified from current practice. To overcome its limitation of considering only the effect of an outage on electricity supply, REopt was executed in two sequentially dependent runs. The initial execution of REopt involved selecting only cost savings as the energy goal in order to generate and leverage cost optimal system performance dispatch information (i.e. REopt's main functionality). The energy system dispatch represents a single-year of data at the hourly level of electricity generation and/or consumption by the technologies considered in the model's optimization. Non-zero electric loads are outputted for the relevant technologies if they are deemed cost effective for installation and operation against the continuing operation of the existing grid and heating and cooling system to meet building loads. However, new technologies can be forced into the solution of the objection function which is set to minimize the life cycle cost of energy even if operating the existing system is the cost optimal solution.

The adoption of a geothermal district heating and cooling system to displace the existing natural gas boilers and electric chillers of the Tuttle district results in a negative net present value such that by default, REopt outputs zero dispatch of the geothermal system. It also indicates that loads are met entirely by the grid and existing heating and cooling systems. This is due to the high upfront cost of manufacturing and installing the various geothermal energy system components which would not be required for the existing system. The integration of the diesel generator is also neglected due to the cost of delivering diesel as a fuel for on-site electricity generation rather than purchasing from the grid. Therefore, the geothermal heat pump was manually forced to be integrated into the solution by specifying in the inputs that its purchase and installation to displace the existing heating and cooling system is a constraint that must be met. The model now considers the input heating and cooling loads to be entirely met by the new geothermal technology. As a result, dispatch results contain the required annual electrical consumption profile of the ground source heat and circulation pumps to meet the specified heating and cooling demand of the district (Figure 1).

The hourly system performance dispatch results of the pumps for heating and cooling as outputted by REopt served as the input electrical load for the second simulation. GSHP as an energy source was unselected such that the electric grid and emergency diesel generator are the two options the model must now choose from to meet the electrical demand of the district. In this run, electrical demand represents the electricity required to deliver the heating and cooling demand of the district via a central plant geothermal heat pump system. At the same time, electricity is the constraining factor to a continuous supply of heating and cooling by the geothermal system during times of grid outages such that the resilience outputs of the new REopt run can be used to infer the resiliency of the geothermal system in supplying heating and cooling. In fact, one can expect the ancillary electrical energy needed by the geothermal system to be supplied by the off-grid emergency generator during times of grid outages.

The last input parameters to be specified in REopt before initiating the second run were specific to the assessment of resilience. The "multiple outage" model was selected to consider four 2-hour outages over the course of a year whose outage periods (i.e. start date and time) are by default determined by the model to occur at seasonal energy demand peaks based on the input electricity load profile and its maximum values per season (i.e. winter, spring, summer, autumn). Mixed integer linear programming optimizes the objective function with respect to life cycle cost of

energy such that demand is supplied at the lowest cost from various sources. This applies to times of critical and non-critical load. The sizing and dispatching of energy is constrained to the technologies specified by the analyst and their limitations (e.g. operational and maintenance cost). Therefore, loads met during times of grid outages by technologies with ancillary input electricity requirements (e.g. geothermal) must rely on a generator.

3. Results

Kolker et al. (2022) expands on the four qualitative attributes of energy system resilience by developing a list of criteria to assess large scale grid connected geothermal power systems, geothermal microgrids, and geothermal district heating systems (section 6). The criteria are presented as generic then further applied to a set of case studies representing existing systems in Artic countries. In this study, we adopt the established qualitative criteria to assess the resilience of the proposed geothermal district heating and cooling system of the Tuttle district in meeting the peak thermal loads of the district at times of electric grid disruptions. As formatted in Table 9 and 10 of Kolker et al. (2022), we present the results below.

Table 1. Qualitative criteria of resilience for a geothermal district energy system as established by Kolker et al. (2022) and applied to the proposed case of Tuttle Oklahoma

Attribute	**District Energy Components**
Reliability **(How does the system perform under typical conditions?)**	**Maintenance plans** Monitor heat carrier working fluid and refrigerant levels in the heat pump-based system and water in the distributional side of the direct use geothermal system. Replenish fluids to levels required for typical operating conditions as needed. Ensure geothermal heat extraction does not exceed regulation and reinjection of fluid follows protocol.
	Performance monitoring Continuously record the production and injection temperatures of the wells including production flow and geothermal exchange rates. Monitor inputs and outputs of system components during peak thermal loads.
	Age of system/components As part of the maintenance, track the length of service each system component has acquired since the commencement of its operation. Different units have varying design lifetimes.
	Maintain outage stats Document the energy flows of the system during times of grid outages. Statistically analyze historical data to predict the

	probability distribution of future outages. Leverage results to reinforce the system to better withstand such events.
	Leakage detection system As part of the maintenance, periodic checking of pipes for deterioration and signs of potential failure. Installation of continuous pressure monitoring system to detect fluctuations that occur at pipe failure.
Redundancy **(What single points of failure does the system exhibit?)**	**Multiple heat plants** Multiple water-to-water ground source heat pumps at central plant in the geothermal heat pump-based system. A heat exchanger of multiple brazed steel plates at the central plant and a natural gas boiler in the direct use geothermal system.
	Multiple heat sources Four inactive oil and gas wells 2 km south of the district with a borehole depth of 2.1 to 3.3 km and geothermal resource temperatures of 65 to 90 deg C. Geometry of wells offer a doublet or quartet configuration with variable flow rate and heat extraction.
	Redundant workforce Electric utility would ensure a secure grid connection of the geothermal system during normal operating conditions. An on-site team dedicated to maintaining the physical components of the district heating system would involve geothermal heat pump or plate heat exchange and water pump design experts.
	Redundant pumps Submersible water pumps sit inside the boreholes, circulation pumps between the wells and the central plant, and circulation pumps between the central plant and district. To prevent system malfunction due to pump failure, auxiliary backup pumps should be installed.
Resourcefulness **(Are there diverse and flexible options to bounce back from disruption?)**	**Building level thermal resilience** Thermal performance of buildings affects the loads imposed on energy systems and therefore indirectly influences the planning strategies for system resilience. Assuming thermal loads predicted by REopt will be consistent during anticipated grid outages, the thermal performance of buildings is not further considered as a factor affecting the resilience of the proposed geothermal district heating system in this study.

	Meshed distribution systems One production and one injection pipe form a closed geothermal loop at the wellfield side of the system. The distributional side consists of a central, bi-directional, hot/cold supply/return loop that connects to the piping networks of the individual buildings. Further efforts to design a more resilient pipe network is required to ensure the delivery of thermal energy in the case of a main line failure.
	Ability to exceed design capacity in extreme hot or cold events Thermal energy equipment sizing such as central heat pumps or absorption chiller are based on the annual peak heating and cooling demands of the district. A factor of safety in the design of each system component would be required to accommodate for extreme hot or cold events that exceed the current design capacity of the proposed geothermal system.
	Thermal storage capacity The central heat pump-based system can fully meet thermal requirements without any thermal storage, given sufficient electricity to fill the exergy gap between geothermal supply and thermal demand. The central plate-based system can also fully meet thermal requirements given sufficient natural gas for peak heat and an absorption chiller for cooling. In any case, thermal storage can be utilized to store energy when geothermal supply is greater than demand and used during peak thermal loads. This would decrease the dependency on imported electricity and natural gas.
	Ability to meet multiple temperature delivery needs Delivery of thermal energy is in the form of water. Existing buildings have temperature mixing valves such that they are repurposed for the proposed geothermal system to deliver water at desired and variable end use temperatures.
	Time to recover – thermal resilience of buildings Thermal performance of buildings affects the loads imposed on energy systems and therefore indirectly influences the planning strategies for system resilience. Assuming thermal loads predicted by REopt will be consistent during anticipated grid outages, the thermal performance of buildings is not further considered as a factor affecting the resilience of the proposed geothermal district heating system in this study.
	Ease of recovery – supply chain flexibility

	Supply chain issues during critical loads are not expected as the primary source of geothermal energy is undisrupted and diesel for electricity is stored on-site.
Recovery **(Will the system return to normal operation after undergoing a disruption?)**	**Standardized parts and supplies** For all major and minor physical system components, an up-to-date list of the most readily available vendors and manufactures must be maintained. Contact information and relevant products must be documented in the database.
	Plan for recovery Replace damaged components (if any) and redirect electrical input to geothermal system from grid to emergency generator. Monitor on-site supply of diesel. Ensure diesel shortages do not occur via communication with the electric utility regarding their recovery and informing the district of excessive thermal loads.
	Spare parts inventory Each main physical system component (e.g. heat pump) with an expected lifetime of less than 30 years must have a spare stored on-site. Ancillary components such as wirings and insulation can be ordered accordingly after unforeseen events occur.
	Workforce for recovery A specialized force would be kept on standby and deployed by the central, on-site maintenance team during grid outages to ensure expected functionality of the emergency generator in replacing the grid's service at critical loads.

As expected, the electricity required to supply the heating and cooling demand of the district during grid outages (i.e. critical load) is met entirely by the emergency diesel generator. It is expected to meet 100% of the critical loads at an average probability of 98.4% for an outage duration of two hours. This corresponds to an annual total of 5162 kWh of electricity generated on site for which 1206 (i.e. 23.4%) is attributable to the winter outage, 1311 (i.e. 25.4%) to spring, 1376 (i.e. 26.7%) to summer, and 1269 kWh (i.e. 24.6%) to autumn (Figure 3). Their corresponding times of occurrences which are consistent with the seasonal thermal demand peaks are February 17 at 3pm, May 24 at 2pm, June 14 at 2pm, and September 11 at 2pm.With an assumed fuel higher heating value (HHV) of 40.7 kWh/gallon and a thermal-to-electric conversion efficiency (% HHV-basis) of 32.2%, at least 394 gallons of diesel are expected to be stored on site per year to drive the critical heating and cooling load supply. Additionally, the maximum grid outage duration that REopt's Energy Resilience Performance (ERP) post-processing tool can consider is 672 hours (i.e. 28 days). For 28 days of dysconnectivity from the grid, the geothermal system has a 53.5% chance of meeting 100% of the heating and cooling demand during those times.

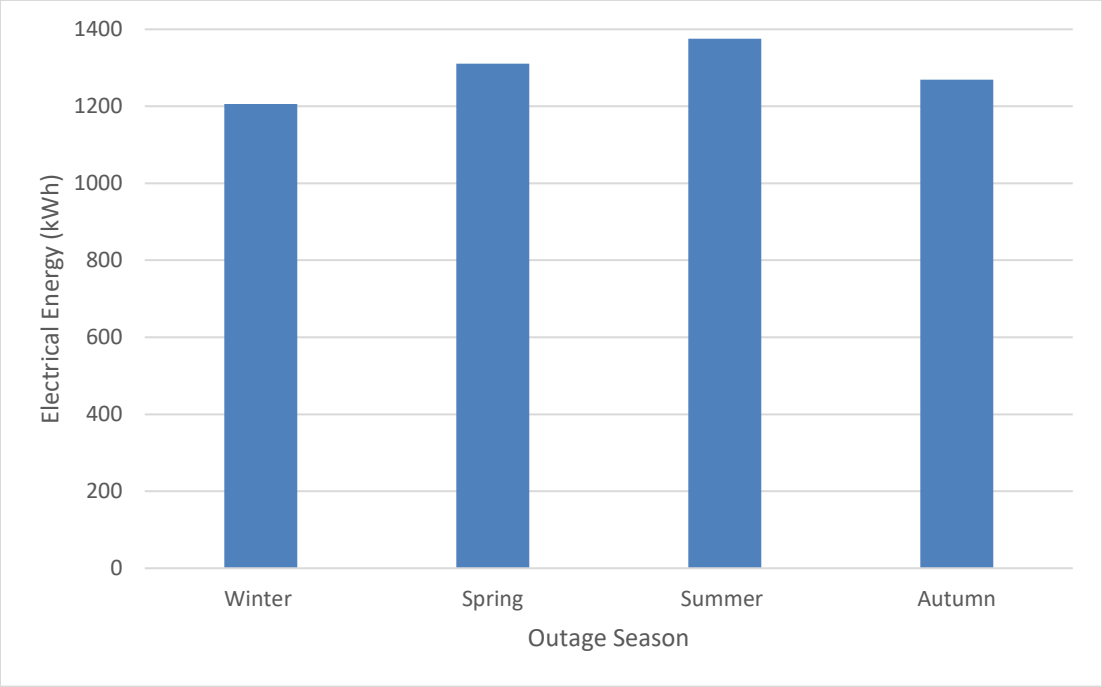

Figure 3: Electrical power supply of emergency diesel generator to geothermal heat pump system for heating and cooling during the Winter, Spring, Summer, and Autumn 2-hour grid outages occurring on February 17 at 3pm, May 24 at 2 pm, June 14 at 2pm, and September 11 at 2 pm, respectively

As the modelled outage duration increases from 1 to 672 hours, the average probability of surviving an outage starting at any time during the year steadily decreases (Figure 4). Although difficult to infer from the graph, the rate of change in probability decreases with respect to increasing outage duration. In other words, the difference in probability between surviving a 24- (i.e. 96.4%) versus 48-hour (i.e. 94.4%) outage is greater than the difference in probability between surviving a 624- (i.e. 55.9%) versus 648-hour (i.e. 54.7%) outage. This equates to a difference in probability of 2.08 versus 1.21%, respectively. The greatest rate of decrease in survival probability (i.e. 1.52%) is observed between a 0- (i.e. 100%) and a 1-hour (i.e. 98.5%) outage.

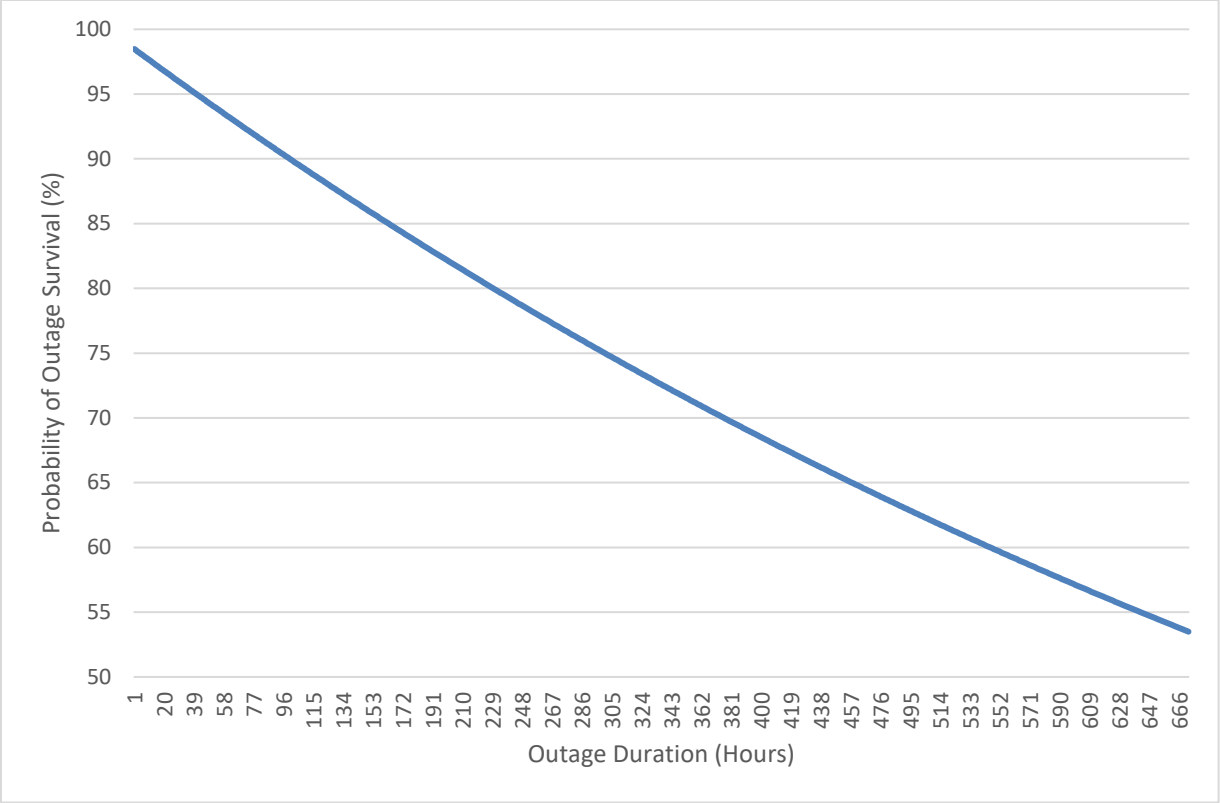

Figure 4: Probability distribution function of outage survival with respect to outage duration for the emergency diesel generator in meeting the electrical load of the geothermal district heating and cooling system

Conclusions

Literature and tools that assess the energy resilience of a geothermal district heating and cooling system are sparse in the existing domain. Additionally, the repurposing of inactive oil and gas wells for direct geothermal use is a renewable energy option that can meet the thermal loads of communities. This study adopts the qualitative framework from Kolker et al. (2022) and the quantitative assessment tool (i.e. REopt) from the National Renewable Energy Laboratory to establish the resilience of a direct-use geothermal district energy system in meeting the thermal loads of an existing community in Tuttle Oklahoma. The previous works of Oh et al. (2024) determined the technoeconomic feasibility of such an energy system implementation via life cycle cost estimations, geologic modelling, and building energy simulations for which the results served as input to this study.

The qualitative assessment performed highlights critical properties of the proposed geothermal energy system which influence its reliability, redundancy, resourcefulness, and recoverability. While it also serves as a blueprint of best practices to maximize the system's resilience in meeting the typical thermal loads of the community, the quantitative assessment estimates the system's capability in meeting the four seasonal peak thermal loads with an assumed grid outage. Although the results of this study are high level, the methods described can serve as a foundational building block to increase the available literature on the intersection of energy resilience and geothermal district systems. Additionally, results can support others' analyses.

ABSTRACT

High Temperature Reservoir Thermal Energy Storage (HT-RTES) is a promising solution for large-scale energy storage that can stabilize the electric grid, increase its flexibility, and provide energy on demand. Despite its advantages, the HT-RTES wells require a higher standard for cement integrity due to higher temperatures and thermo-mechanical stresses during injection and production. In this study, we provided a thorough mechanical investigation on the hydrophobic fly ash cenospheres (FCS) incorporated calcium aluminate cement, which exhibits a lower thermal conductivity compared to conventional oil and gas well cement to prevent heat losses. The cement was treated with superhydrophobic polymethylhydrosiloxane (PMHS). The compression tests were conducted under in situ high pressure high temperatures, with pressure reaching up to 10 MPa and temperature up to 180 °C. The findings revealed that the PMHS-treated specimens, after undergoing simulated thermo-mechanical stresses, showed an increase in cement compressive strength from 4.6-30 MPa to 6.1-33 MPa, an improvement in elastic modulus from 0.34-1.37 GPa to 1.1-3.3 GPa, and an enhancement in Poisson's ratio from 0.07-0.15 to 0.1-0.33. Therefore, lightweight calcium-aluminate cement formulations with PMHS treated FCS could preserve its mechanical performance after subjecting to thermal shock. We further incorporated the measured properties into a fully coupled thermoporoelastic model for wellbore integrity analysis. Results show that the novel PMHS treated FCS could resist large range of pressure and temperature perturbations during heat injection and production. Overall, this novel formulation could be a promising solution to the durability of the HT-RTES wells.

1. Introduction

In a thermal storage site, hot fluid is injected into a subsurface reservoir, where the formation rock absorbs and retains the heat energy from the injected fluid. When the heat energy is needed, those hot liquid will be produced to the surface. The cyclic injection and production occur daily, seasonally, or even longer durations based on specific applications. To achieve the long-term

effective thermal storage, safe wellbores are essential, and cement integrity is one of the primary concerns for the wellbore durability. A proper cement system needs to have the following characteristics: (1) good resistance to thermal shock and thermal cycling over large temperature ranges; (2) low thermal conductivity to minimize the thermal loss during the repeating injection and production across the wellbore; (3) low modulus to withstand severe pressure and temperature perturbations caused by injection and production; and (4) low density to avoid fracturing the weak, unconsolidated, or naturally fractured rock formations.

Ordinary Portland cement (OPC) is known for its poor performance in thermal shock resistance. Temperatures between 200-300 ℃ could cause micro-cracking propagation (Boquera et al., 2021). The dihydroxylation of portlandite happens in OPC at temperatures ≥ 500 ℃, leading to free lime formation that converts to highly expansive hydration products (Sugama et al., 2018). In contrast, Calcium aluminate cement (CAC) is capable to withstand thermal shock at temperatures over 500-600 ℃ (Sugama et al., 2018; Boquera et al., 2021). The usage of fly ash and silica flour improved cement performance at elevated temperatures.

The thermal conductivity of OPC depends on the water saturation content, density and porosity. It varies between 0.3 and 1.3 $Wm^{-1}K^{-1}$ (Wolterbeek et al., 2023). According to Fourier's law of heat conduction, the heat loss due to conduction is linearly related to material thermal conductivity. Zhou et al. (2023) developed a chemical-induced nitrogen-filled foam cement with low thermal conductivity of 0.3 $Wm^{-1}K^{-1}$ that achieved a 11.77 °C higher temperature at the wellhead compared to adjacent wells using fly-ash low density cement.

The elastic modulus of OPC can go up to over 40 GPa, and the oilwell cement has an elastic modulus between 1 and 10 GPa (Nelson, 2006). The geothermal cement has been found with similar elastic modulus as oil well cement (Philippacopoulos and Berndt, 2001; Pyatina, 2018). Higher elastic modulus up to 15 GPa has been reported under specific testing conditions and formulations (Pang et al., 2021; Meng et al., 2023). Well integrity modeling analysis have shown that elastic modulus is more important than compressive strength in maintaining well safety (Lavrov and Torsæter, 2016; Meng et al., 2021).

Cement density ranges from 1400 kg/m^3 to 2400 kg/m^3 depending on specific applications. Density can be adjusted by using heavyweight additives (Barite, Hematite, Ilmenite) or lightweight additives (gas, bentonite, microspheres). For the geothermal well, the formation might be naturally fractured, and a lightweight cement is beneficial to avoid fracturing the formation.

To achieve the preferred properties of geothermal cement, one type of PMHS treated FCS incorporated calcium aluminate cement has been created (Simerjeet, 2012; Sugama et al., 2018; Sugama and Pyatina, 2021). Its mechanical properties under uniaxial compression conditions, thermal conductivity, water-repellent property, phase identification, and microstructures have been quantified (Sugama and Pyatina, 2021). However, the mechanical properties under triaxial conditions have not been evaluated. In this paper, we have conducted triaxial compression tests under high temperature high pressure conditions, with pressures up to 10 MPa and temperatures up to 180 °C. Our results have demonstrated the good performance of PMHS-treated cement in thermal resistance under simulated wellbore conditions.

2. Methods

2.1 Experiments

The materials used to prepare the PMHS-treated alkali-activated calcium aluminate cement with Class F fly ash have been described in detail by Sugama and Pyatina (2018) and their description will not be repeated here. The preparation procedures, however, are as follows.

1) Pouring cement slurry into the test mold, followed by 24 hours curing at room temperature;
2) Removing the mold and curing the samples at 99±1% relative humidity for 24 hours at 85 ˚C;
3) Autoclaving the samples for 24 hours at 250 ˚C.

For each formulation, we evaluated their mechanical performance before and after undergoing thermal shock. The thermal shock is performed by three-cycle of 200 °C heating for 24h, followed by old water quenching for 30 minutes. The detailed experimental matrix is shown in Table 1.

Table 1 Experimental matrix

Specimens	Thermal Shock	Testing Conditions
1	No	Uniaxial compression test
2		Uniaxial compression test
3		Uniaxial compression test
4		10 MPa confining pressure
5		180 °C, no confining pressure
6		180 °C, 10 MPa confining pressure
7	Yes	Uniaxial compression test
8		Uniaxial compression test
9		Uniaxial compression test
10		10 MPa confining pressure
11		180 °C, no confining pressure
12		180 °C, 10 MPa confining pressure

We utilized our high-temperature and high-pressure triaxial compression equipment (Figure 1) to measure the mechanical properties of cement. The equipment can withstand temperatures up to 200 °C and provides a confining pressure range from 0 to 70 MPa. The load capacity of the equipment is 1000 kN. Axial and radial deformations were monitored using high temperature linear variable differential transformer rated up to 200 °C. Throughout the compression tests, we maintained the strain rate at approximately 10^{-6} /s. For high temperature high pressure experiments, a customized rubber is required to tolerate the harsh environment and avoid fluid communication between the sample and the silicone confining oil.

This facility shown in Figure 1 is capable to control and monitor pore pressure as well. However, the pore pressure was not applied in our experiments because cement typically has low permeability, and it takes a long time for pore pressure to stabilize. Thies PMHS treated cement has a low permeability of 0.1-0.15 micro-Darcy (Bauer et al., 2020). During the high temperature test without confining pressure, we left the pore pressure line open to the atmosphere to allow free water evaporation. This was necessary to prevent thermal induced pore pressure from building up and potentially breaking the rubber in the absence of confining pressure. As to the high temperature high pressure tests, it is recommended to increase the confining pressure to at least 2 MPa before raising the temperature. The water boiling point at 2 MPa is over 212.5 °C, which avoids

significant thermal induced pore pressure. If the sample is brittle, the confining pressure can go directly to the designed value. Since the cement samples seem to be ductile, it is better to elevate the pressure to 10 MPa after temperature reached 180 °C. During the heating stage, a continuously constant confining pressure control was maintained with self-designed software.

Figure 1: Triaxial compression equipment with sample setup

2.2 Modeling

The measured parameters have been implemented into one thermoporoelastic analytical model. The model development and details have been described in our previous publications (Meng et al., 2021, 2023; Zhang et al., 2022). The model demonstrates how the cement performs under pressure and temperature perturbations during fluid injection and production.

3. Results

3.1 Mechanical properties of cement before thermal shock

Three uniaxial compression tests have been conducted, and their mechanical properties are close to each other with small variance (Figures 2 to 4). The compressive strengths are 4.7 MPa, 4.6 MPa, and 5.1 MPa, respectively. The elastic modulus is (1.15 ± 0.05) GPa, (1 ± 0.03) GPa, and (1.2 ± 0.1) GPa. Poisson's ratios were recorded at 0.14 ± 0.1 for the first two tests, and 0.10 ± 0.1 for the third test. The stress strain curves in Figures 2 to 4 indicate plastic deformation near the peak strength values. For instance, in Figure 3, axial strain increases from 0.4% to 0.6% as axial stress approaches the maximum value of 4.6 MPa, and continues to increase to 1.2% as axial stress drops to 2 MPa. This demonstrates the strong ductility of the cement, which is not typical for brittle Class G cement. In our previous experiments, the axial deformation for Class G cement with silica flour is around 0.4% at the maximum axial stress point and the stress dropped quickly after that (Meng et al., 2023). Additional evidence of ductility was observed in the triaxial compression test under 10 MPa confining pressure, where axial strain exceeded 10% as the axial stress continued to rise (Figure 5).

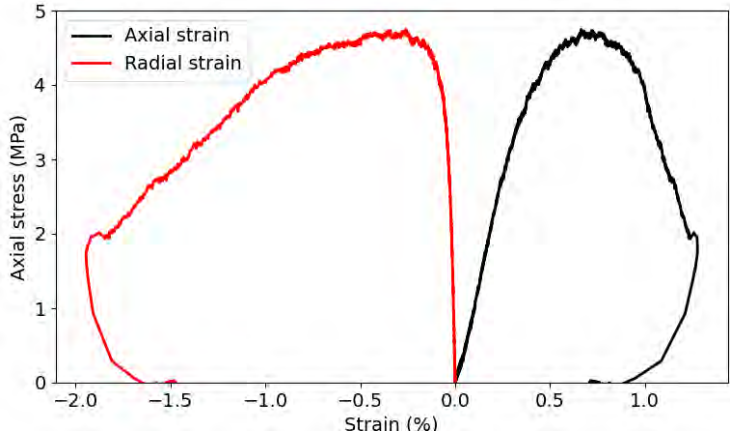

Figure 2: Stress - strain curve of the first uniaxial compression testing before thermal shock

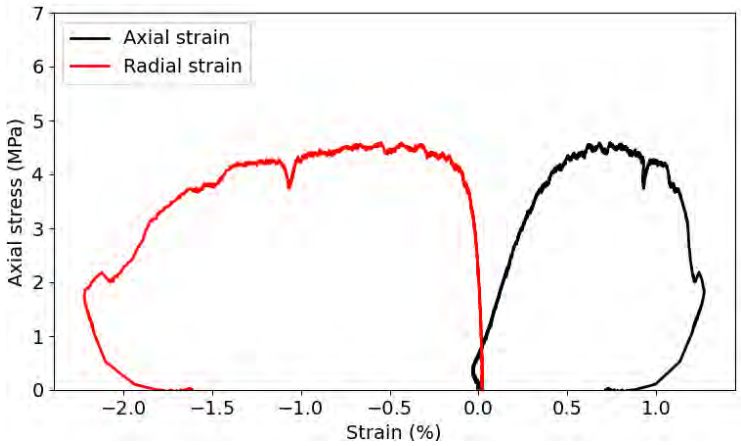

Figure 3: Stress-strain curve of the second uniaxial compression testing before thermal shock

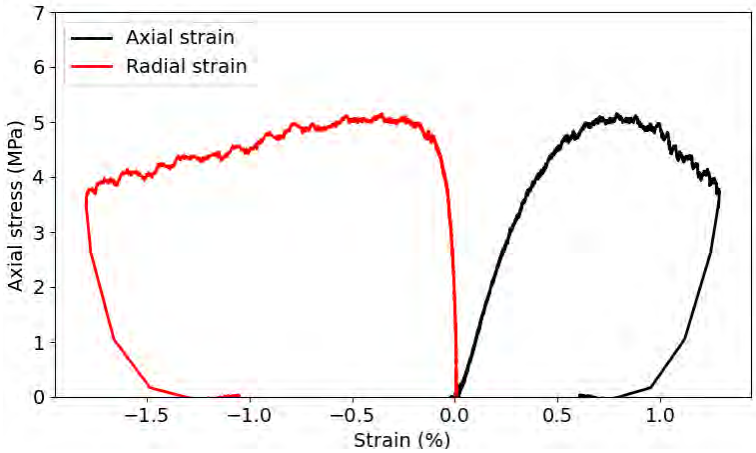

Figure 4: Stress-strain curve of third uniaxial compression testing before thermal shock

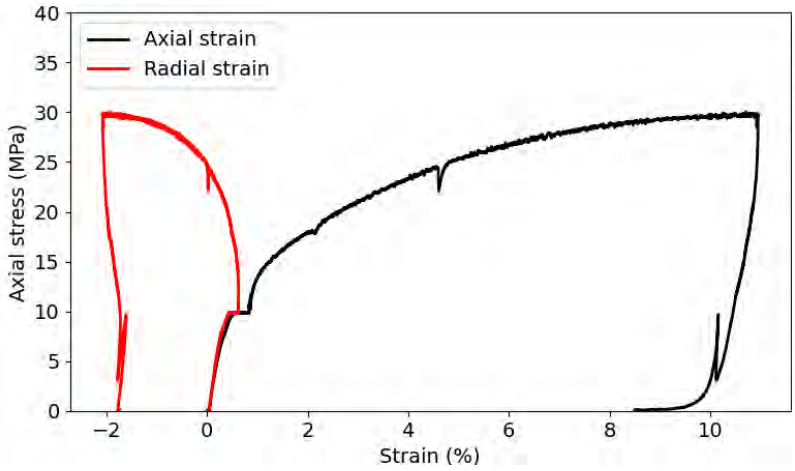

Figure 5: Stress-strain curve under 10 MPa confining pressure before thermal shock

In the following 10 MPa, 180 °C triaxial test, the stress-strain curve shows more complex behavior compared to the test conducted under high confining pressure alone (compare Figure 6 with Figure 5). Figure 7 shows the process of the progressively increasing pressure, temperature, and compression stress. Initially, the confining stress was raised to 10 MPa, during which the axial strain increased from 0 to 2%, and radial strain from 0 to 0.7%. With the confining pressure held constant at 10 MPa, the temperature was then raised to 180 °C. During this stage, the axial strain further increased to 6%, while the radial strain sensor failed. After temperature reached to 180 °C, the axial strain was still increasing under a slower rate. To save time and avoid axial strain sensor out of range, the specimen started to be compressed. This strong ductile performance creates challenges to our measurement.

There are two ways to improve the future testing performance. Firstly, as mentioned in the Experiments section, initially setting the confining pressure to a lower value of 2 MPa before elevating the temperature might help mitigate deformation during the temperature elevation, though it would not prevent the deformation after 10 MPa is applied. Secondly, curing the specimen under 10 MPa and 180 °C during the specimen preparation stage might prove beneficial. The cement sample was prepared under ambient pressure conditions, which is expected to be less consolidated than high pressure curing. If the curing conditions were maintained the same to the testing conditions, the specimen might show less plastic deformation.

For uniaxial compression test under 180 °C, the specimen shows stronger deformation compared to uniaxial compression tests under room temperature. Axial strain is 1.4% when reaching the peak value for the 180 °C, while the ambient tests showed only ~0.6% axial deformation at the peak stress point.

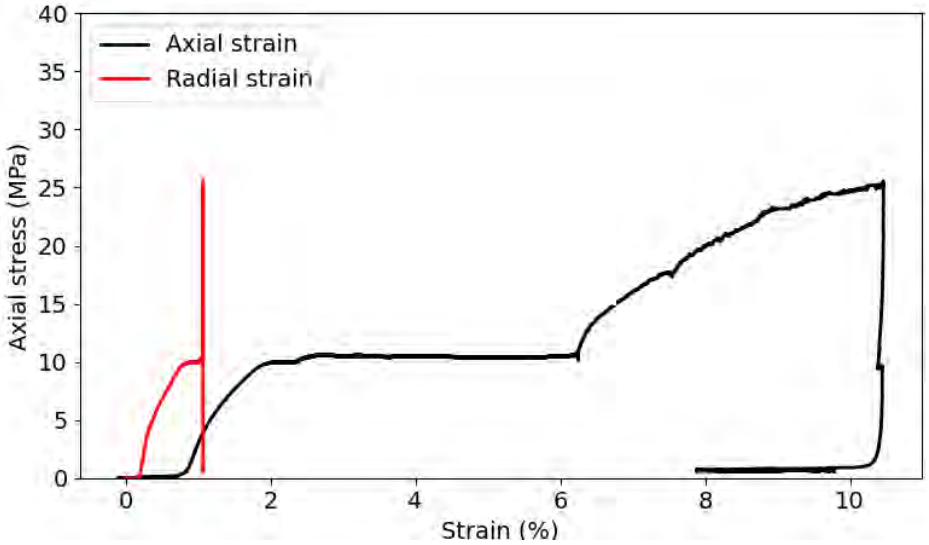

Figure 6: Stress-strain curve under 10 MPa confining pressure and 180 °C before thermal shock

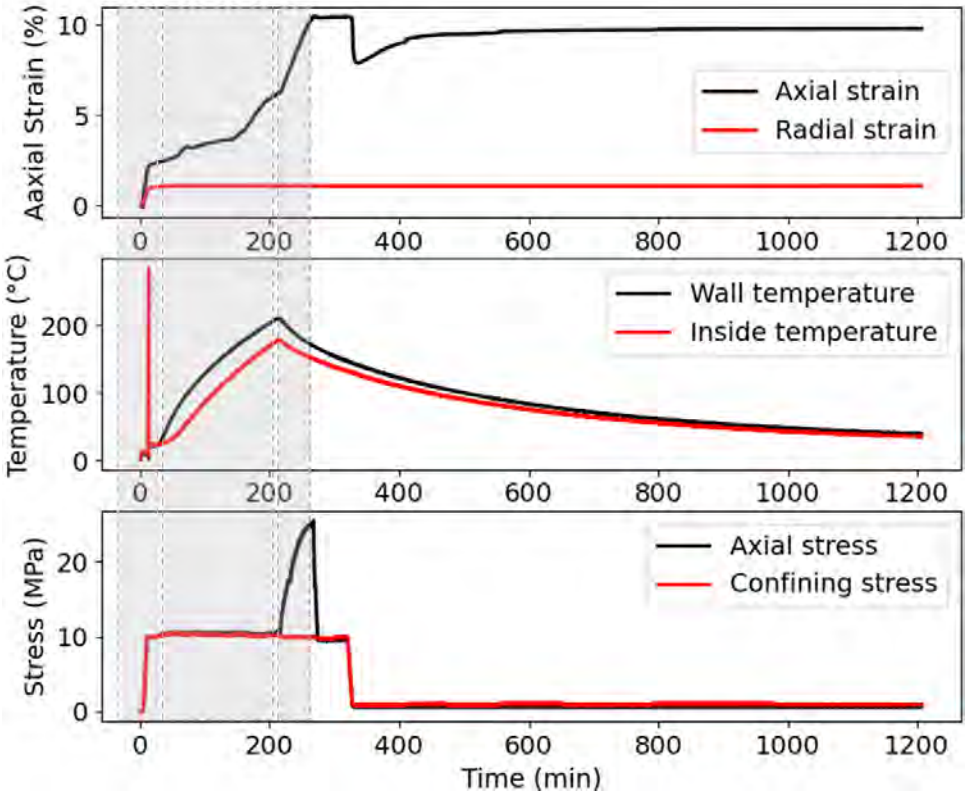

Figure 7: Triaxial compression testing under 10 MPa confining pressure and 180 °C. The first grey area shows that this cement has strong deformation during confining pressure application. The second grey area shows that the deformation continues during the heating stage. The third grey area shows the compression stage.

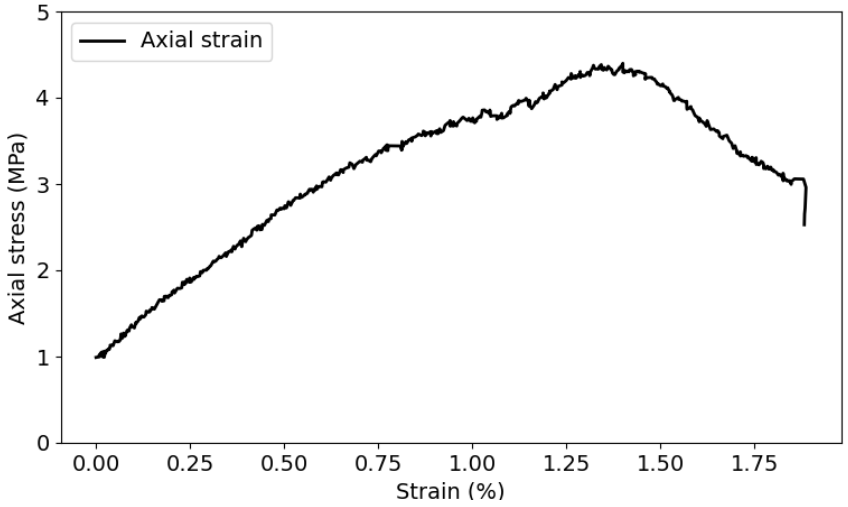

Figure 8: Stress-strain curve under 180 °C before thermal shock

3.1 Mechanical properties of cement after thermal shock

The same types of experiments were conducted on the specimens after undergoing thermal shock. The detailed stress-strain curves are shown from Figures 9 to 14, and the mechanical properties are summarized in Table 2. After experiencing thermal shock, the compressive strength of the specimens increased to 7.6 MPa, 6.14 MPa, and 6.7 MPa, representing a 42% increase compared to the samples without thermal shock. The elastic modulus also increased to (1.75 ± 0.15) GPa, (1.15 ± 0.05) GPa, and (1.6 ± 0.1) GPa, demonstrating an increase of 34%.

In the 10 MPa confining pressure compression test, the compressive strength increased slightly from 30 MPa to 32 MPa, while modulus increased from (1.7 ± 0.2) GPa to (2.5 ± 0.4) GPa. Comparing the shapes of the stress-strain curves in Figures 5 and 12, the specimen subjected to thermal shock reached near peak strength at just 4% axial strain, whereas the stress for the non-thermal shock specimen continued to climb until reaching 10% axial strain. This behavior indicates that the thermal shock reduces the ductility of the cement.

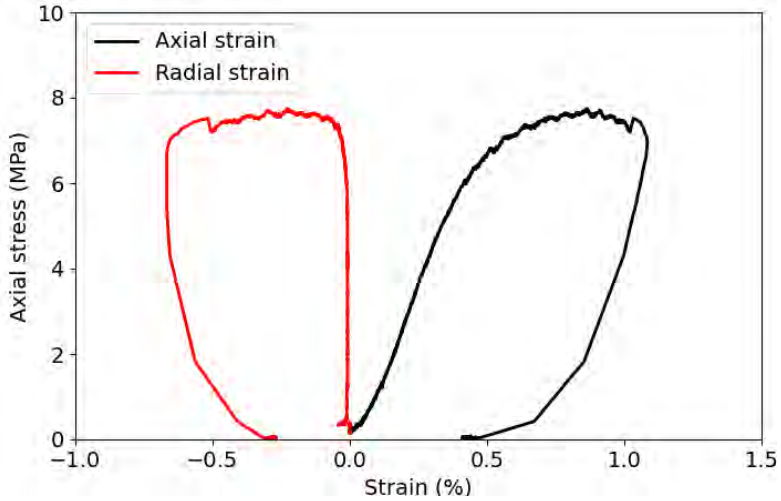

Figure 9: Stress-strain curve of the first uniaxial compression testing before thermal shock

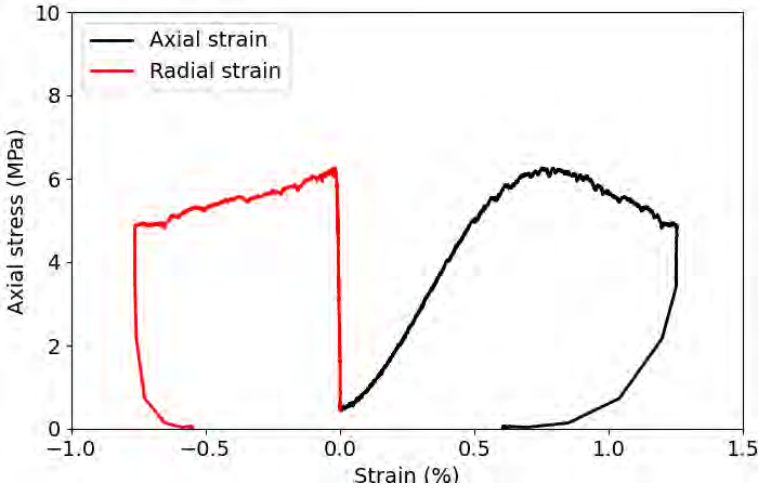

Figure 10: Stress-strain curve of the second uniaxial compression test after thermal shock

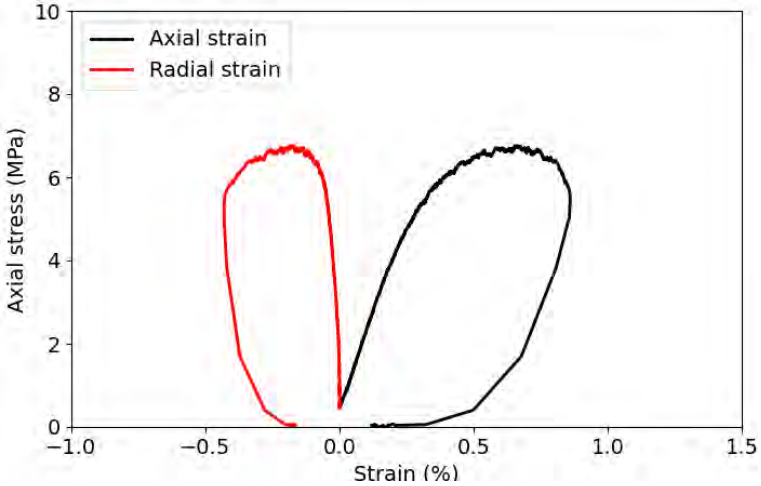

Figure 11: Stress-strain curve of the third uniaxial compression test after thermal shock

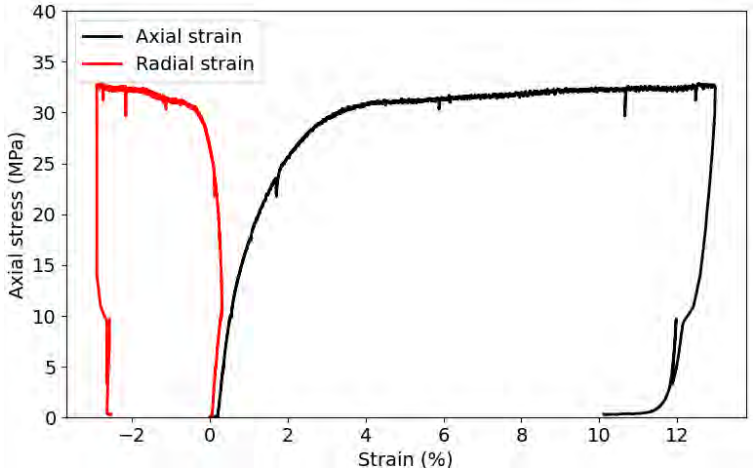

Figure 12: Stress-strain curve under 10 MPa confining pressure after thermal shock

Similar behavior was observed in the compression tests conducted under 180 °C and 10 MPa confining pressure, as shown in Figures 6 and 13. After undergoing thermal shock, the compressive strength increased from 25 MPa to 32.3 MPa, and the elastic modulus increased from (1.33 ± 0.05) GPa to (3.15 ± 0.15) GPa. At near maximum axial stress, the axial strain recorded was only 3% for the specimen that had undergone thermal shock, in contrast to the continuing increase in stress beyond 10% axial strain observed in the specimen without thermal shock.

The results of uniaxial compression tests under 180 °C further confirmed this pattern of increased compressive strength coupled with reduced ductility, as shown by comparisons between Figure 14 and Figure 8.

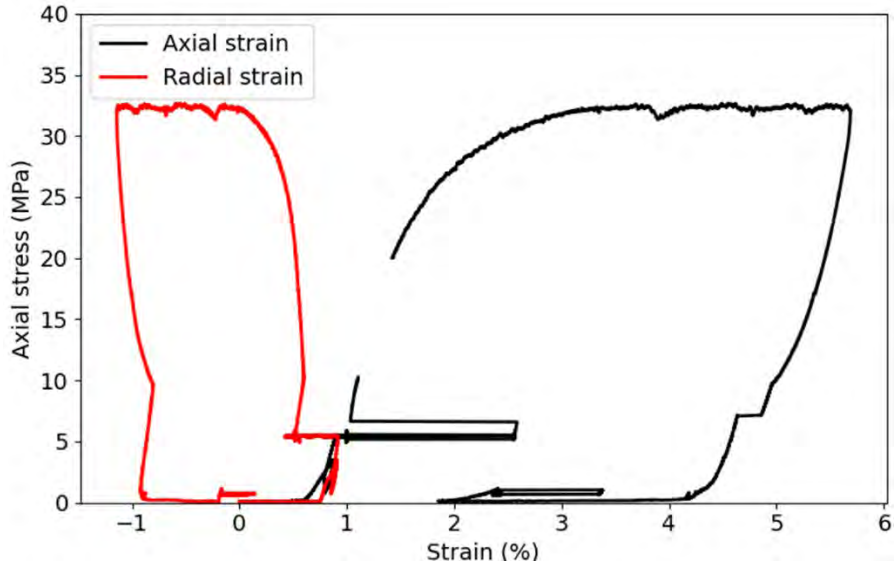

Figure 13: Stress-strain curve under 10 MPa confining pressure and 180 °C before thermal shock. Axial strain data was lost in the middle of the test, resulting in the disconnection of the black curve.

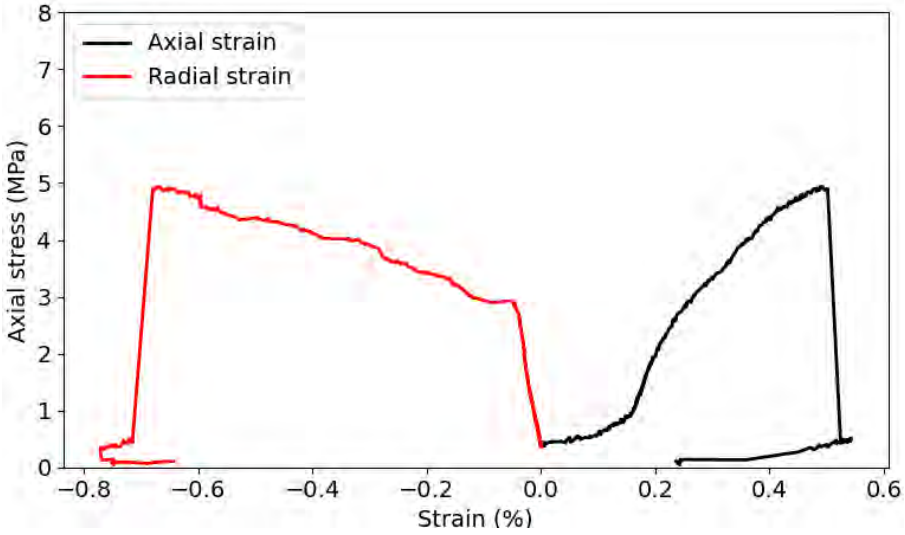

Figure 14: Stress-strain curve under 180 °C after thermal shock

Table 2 Mechanical properties of the PMHS treated cement before and after undergoing thermal shock.

PMHS treated Cement	Before Thermal Shock			After thermal shock		
	Strength (MPa)	Modulus (GPa)	Poisson's ratio	Strength (MPa)	Modulus (GPa)	Poisson's ratio
UCS 1	4.7	1.15 ± 0.05	0.14 ± 0.01	7.6	1.75 ± 0.15	--
UCS 2	4.6	1 ± 0.03	0.14 ± 0.01	6.14	1.15 ± 0.05	--
UCS 3	5.1	1.2 ± 0.1	0.1 ± 0.01	6.7	1.6 ± 0.1	--
UCS average	4.8	1.12 ± 0.06	0.08 ± 0.01	6.8	1.5 ± 0.1	0.04 ± 0.01
10 MPa	30	1.7 ± 0.2	0.09± 0.02	32	2.5 ± 0.4	0.13 ± 0.02
180 C	4.34	0.35 ± 0.01	--	4.9	1.9 ± 0.3	0.3 ± 0.02
10 MPa 180 C	25	1.33 ± 0.05	--	32.3	3.15 ± 0.15	0.17 ± 0.02

The above experimental results show the promising performance of this PMHS treated FCS incorporated calcium aluminate cement after undergoing thermal shock. The fundamental mechanisms have been explained by Sugama and Pyatina (2008), which were summarized here:

(1) Cenospheres + sodium metasilicate → silanol and sluminol groups on the surface

(2) Silanol and sluminol groups + PMHS → siloxane oxygen-linked M-FCS

(3) At high temperatures of 175 °C or 250 °C → depolymerization at the FCS surface

(4) Siloxane → low crosslinked silicon-like polymer after repolymerization

(5) The repolymerization-induced product protects FCS from pozzolanic reactions

3.2 Modeling results

Using the data obtained from our triaxial compression tests, we applied a thermoporoelasitc model to determine the safe operating envelope for this cement. Figure 15 shows that this cement has a wide range of safe applications. No failures were observed in the normal range of pressure and temperature perturbations. The temperature drawing down by 50 °C is an aggressive change that typically challenges regular brittle cement. The main reason for this wide envelope is due to low modulus of this cement.

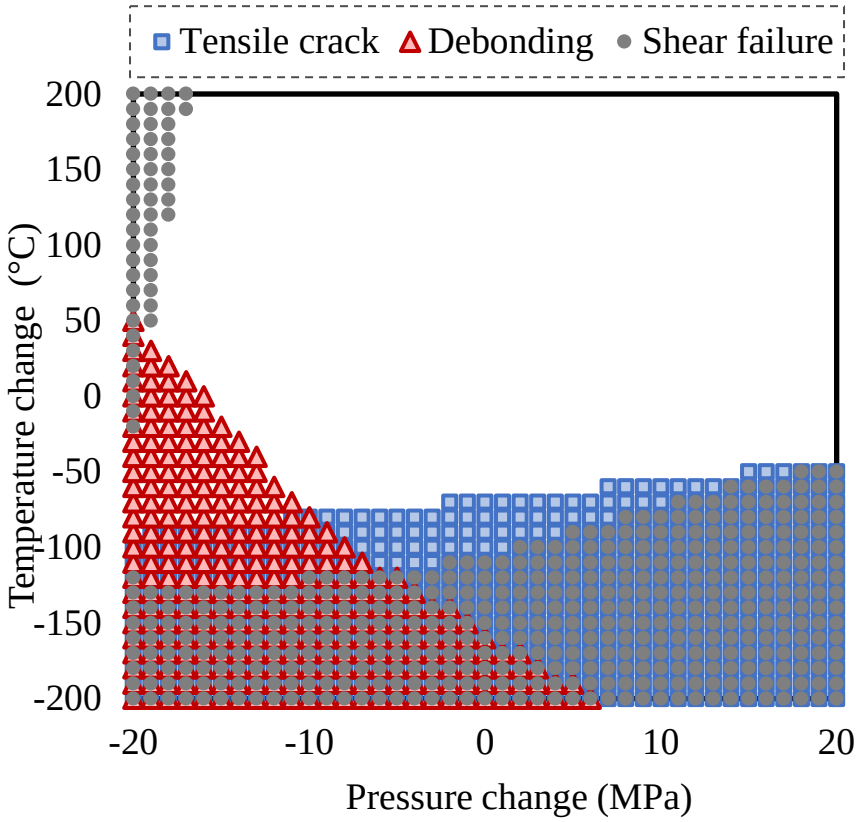

Figure 15: Safe operating envelope for the PMHS treated cement

4. Conclusions

Our study focused on PMHS-treated alkali-activated calcium aluminate cement with Class F fly ash, subjecting it to thermal cycling and measuring their mechanical properties through triaxial compression tests under high pressure and high temperatures. The key insights are summarized as follows:

1. This novel cement formulation demonstrates robust performance in resisting thermal shock. Instead of mechanical degradation, both the strength and modulus of the cement increased after exposure to thermal shock.

2. PMHS induced the dehydrogenation, depolymerization, and repolymerization processes, resulting in the formation of polymers that protects the FCS from pozzolanic reactions. This explains the cement's capability to maintain its mechanical performance under thermal shock.

3. The low modulus of this cement contributes to a broad safe operating envelope, as shown by modeling analysis. This highlights the cement's capability to effectively handle variations in pressure and temperature, offering significant advantages for its use in harsh environments.

The Third Electric Energy Transition Calls for Geothermal Energy Assurance

John R. Muir, Andrew J. Van Horn

GreenFire Energy, Inc., Walnut Creek, California

Keywords

The third electric energy transition, energy security, electric power, thermal energy, the U.S. electricity grid, geothermal energy, resilience, reliability, baseload power, resilient continuous power, closed-loop geothermal energy systems (CLG), enhanced geothermal systems (EGS), advanced geothermal systems (AGS), the "heat beneath our feet," green energy, clean energy microgrids, resilient community energy systems, climate change, global energy transition.

ABSTRACT

The third electric energy transition in the last one-hundred years is now underway in the United States. This major transition is challenging the "centralized grid" model of power generation and distribution, especially for large, energy intensive end-users. These consumers include manufacturing plants, data centers, metal smelters, refineries, chemical plants, military bases and emergency services that now consume about a third of all electric power.[1]

The third transition has not been a planned evolution, but instead emerged from the disruptive combination of rapidly escalating energy demand, climate change concerns, increasing volatile energy prices, and recurring U.S. regional power outages. Consequently, traditional suppliers, typified by today's electric and gas utilities, load serving entities (LSEs) and energy service providers (ESPs), are being supplemented and supplanted by new types of energy suppliers including Distributed Energy Resources (DERs), aggregators of demand responsive customers, microgrids, resilient community grids, Battery Energy Storage Systems (BESS), "prosumers," and Community Choice Aggregators (CCAs). The key driver for this transition is the need for "energy assurance" – a multi-factor concept that includes the continuous availability, reliability, resilience, scalability and price stability of energy while still meeting goals for decarbonization.

Energy assurance has also become a primary concern of large organizations that consume enormous supplies of electricity and thermal energy. These organizations realize that electric energy demand is outstripping supply and that the regulated "commodity" energy market model is incapable of responding adequately. Availability is now a top priority. But even if the regulated market could generate sufficient energy to meet market demand, the ability to deliver that energy reliably is highly suspect due to aging transmission lines, line congestion, and the prevailing vulnerability to weather related events, fire, and cyber-attacks. As a result, energy-intensive

organizations are actively seeking “behind the meter” energy solutions that enable them to assure and control their energy supply.

This “behind the meter” strategy has obvious advantages, first because it avoids some costs and risks of transmission, distribution, regulatory oversight, and wholesale market coordination, and second because self or co-located generation allows energy-intensive organizations to pay for the energy attributes that most closely correspond to their needs.

The quest for energy assurance has spurred intense interest in geothermal energy. In addition to its enormous potential magnitude, geothermal energy offers a unique combination of energy assurance attributes. Geothermal energy can provide both firm, baseload electric power and direct thermal energy that is critical in many manufacturing operations. “Behind the meter” geothermal power also offers price stability and insulation from grid outages and regulatory mandates. In short, geothermal energy is moving from being an attractive energy alternative to an indispensable component of the third electric energy transition.

Introduction

In the United States a highly regulated electricity market has evolved for over 100 years as electricity consumption became ubiquitous, transmission networks proliferated, and different fuels for power generation came into use. Because the geothermal industry has failed to actively participate in drafting and influencing the laws and regulations that have structured U.S. energy markets until very recently, funding for and investment in geothermal energy has been orders of magnitude lower than that for other energy technologies.

In order to enable geothermal energy to gain essential funding and to reduce the time for projects to come online and generate revenues, it is important for industry participants to have a better understanding of the actions, events and mandates that have enabled oil, coal, natural gas, nuclear and hydro energy supplies to dominate energy markets and more recently for solar, wind, hydrogen and batteries to compete for market share.

The following sections describe the first two U.S. electric energy transitions and discuss elements of the third energy transition now in progress. The first energy transition of the electricity grid was defined by the regional electrification architecture of large-scale projects such as the Grand Coulee and Boulder dams and the Tennessee Valley Authority that made electricity available to large numbers of homes and businesses for the first time during in the 1930s. That first model comprised capital intensive infrastructure, including generating plants powered by coal and hydro-electric dams, high-capacity regional transmission lines to transport power, and local distribution systems owned and operated by utility companies.

Figure 1 below illustrates some of the major events in U.S. electricity and natural gas markets between 1875 and 1970. Significant technological advances and infrastructure development were accompanied by the creation of large companies to supply equipment, the Bonneville Power Administration and major utility companies, the initiation of state regulation, the formation of the Federal Power Commission, the National Electric Reliability Council, and the U.S. Environmental Protection Agency (EPA.) The era was characterized by ongoing significant year-over-year electric load growth and the expansion of U.S. energy systems.

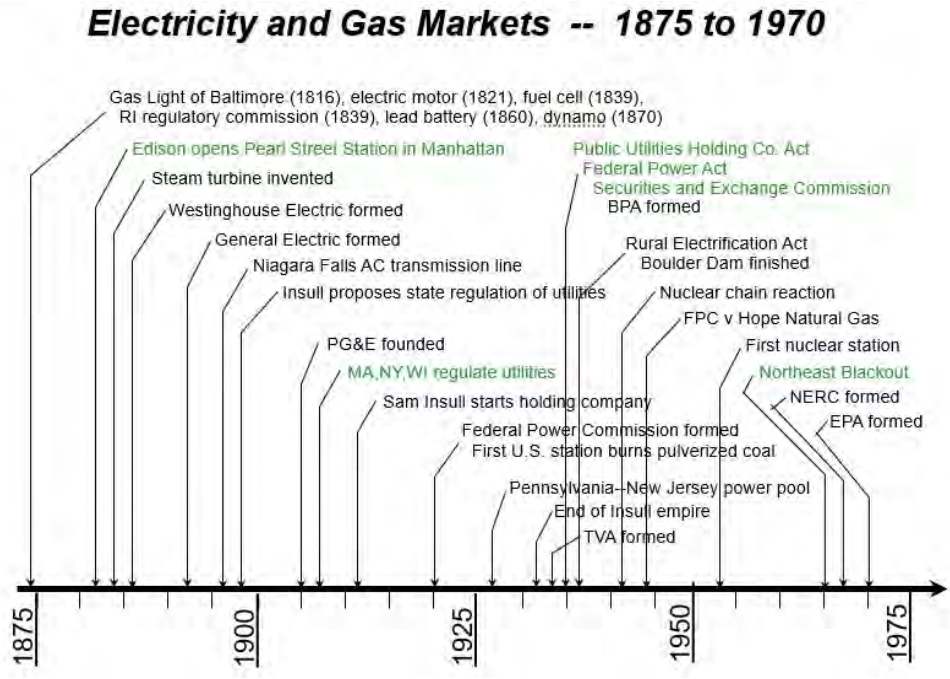

Figure 1. Key Events in U.S. Electricity and Natural Gas Markets – 1875 TO 1970

The Second Major U.S. Electric Energy Transition Began in the 1970s

The transition away from the utility-owned infrastructure model in the U.S. began in the late 1970's as governments and utilities responded to environmental and natural gas supply availability concerns by enabling power purchases at system "avoided costs," and by mandating minimum thermal efficiencies and prohibiting new natural gas-fueled plants. One result was that independent or merchant power producers could compete on price with utility-owned generators.

Figure 2 illustrates key U.S. events between 1970 and 1990, during the "Second Electric Energy Transition," which initiated many elements of the current market structure. Events included the formation of the U.S. Environmental Protection Agency (EPA) with accompanying clean air and clean water legislation and regulations, the founding of the Electric Power Research Institute, the OPEC oil embargo with impacts felt around the globe; PURPA, PIFUA and the NGPA legislation, and Federal Energy Regulatory Commission Orders affecting electricity, natural gas, oil and hydropower transactions, reliability standards, and the rates charged in interstate commerce.

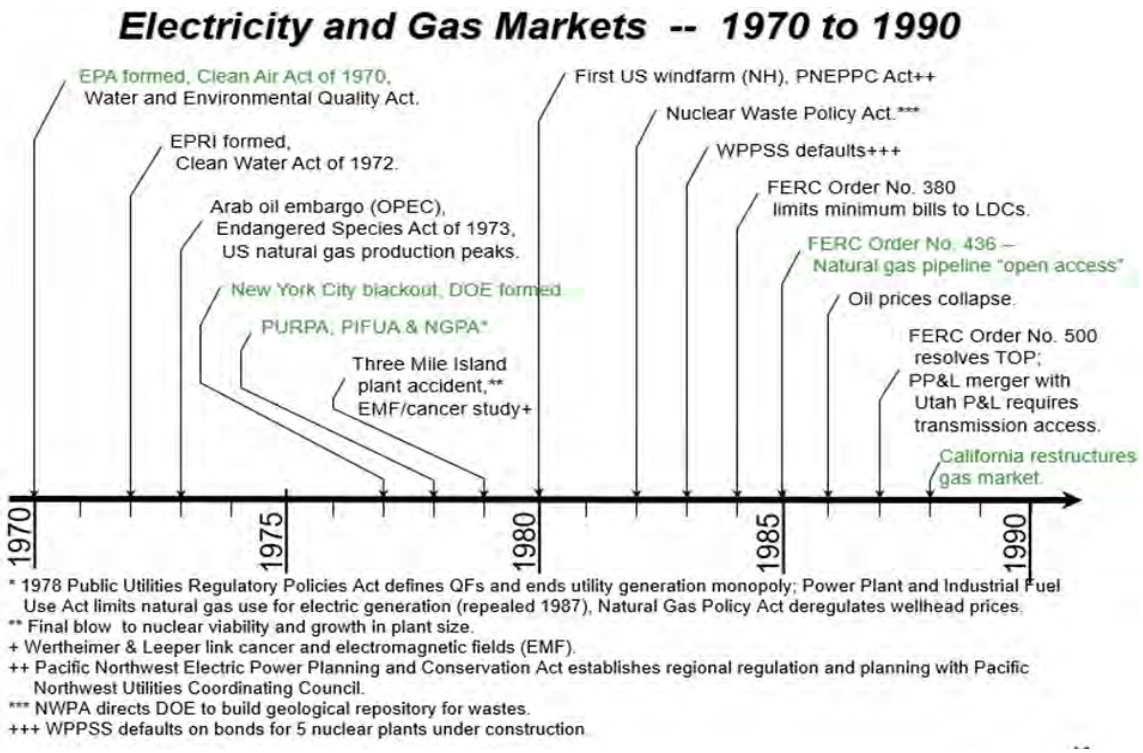

Figure 2. Key Events in U.S. Electricity and Natural Gas Markets Initiating the Second Electric Energy Transition, 1970 to 1990.

Legislation allowed more efficient energy resources, such as cogeneration, wind farms and biomass plants to be built and to create their own "learning curves." Learning curves for advanced technologies demonstrated cost reductions and performance improvements resulting from more deployment and "learning-by-doing." Independent System Operators (ISOs) and Regional Transmission Operators (RTOs) dispatched power plants on the basis of bids into hourly day-ahead and real-time wholesale electricity markets, paying market-clearing prices rather than costs-of-service.

During the 1990s grid operations became progressively more centralized by region. Natural gas combined cycle units became the preferred choice for capacity additions in many states. Open transmission access allowed wholesale markets to be designed and operated, and the electric utility industry was restructured.

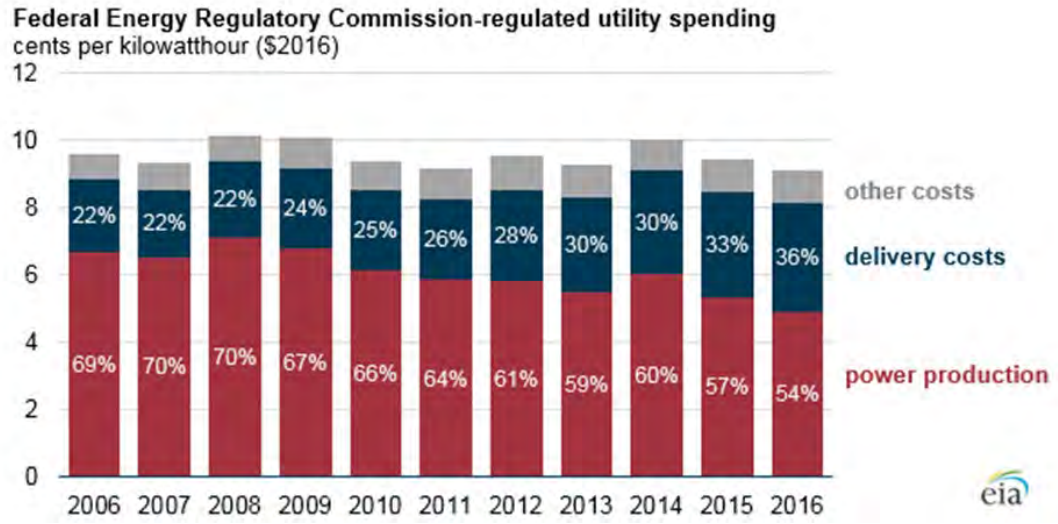
Three major regional electricity grids now operate in the U.S. and Canada. The Western Interconnect extends from the Pacific Ocean to the Rocky Mountains; the Eastern Interconnect operates east of the Rocky Mountains, and the independent Texas Interconnected system is essentially only in Texas. Interstate wholesale power transactions are regulated by the Federal Energy Regulatory Commission (FERC) and retail transactions are regulated within most states by state Public Utility Commissions.

In 2024 the core architecture for regional power systems remains in place, as utilities, merchant generators, grid operators, Electric Service Providers (ESPs) and balancing authorities dominate the generation, dispatch and distribution of electricity. There are sixty-six U.S, one Mexican and

eight Canadian control areas that maintain the reliability of the major North American interconnected grids.

In the past, new technologies took decades to be developed, penetrate, and eventually dominate electricity capacity additions. These technological advances led oil, coal, natural gas and nuclear to become the primary fuels and also spawned immense supporting infrastructure and regulatory bodies that make transitions difficult. Nevertheless, the quest to reduce costs and decarbonize the U.S. economy has resulted in the significant expansion of low-cost, just-in-time natural gas production and pipeline transport methods to fuel gas-fired applications. Together with additions of renewable, intermittent solar and wind plants, the U.S. electricity industry has been able to achieve a reduction in annual CO_2 emissions of about 28% between 1995 and 2023. Today, the combustion of natural gas for power and heating buildings produces only about 40% of the greenhouse gas emissions (GHG) that burning coal would produce to provide an equivalent amount of combustion energy. Despite these improvements, natural gas cannot enable the US to achieve its "zero carbon" goals

The cumulative result of legislative and regulatory mandates has changed cost structures and created regional grids. Today's commodity power rates contain multiple and significant unbundled costs. Since the 1980s, electricity rates paid by end-use customers that are set by public utility commissions like the California Public Utilities Commission (CPUC) contain not only the costs of building, operating and maintaining power plants, transmission and distribution systems, but also include costs for ISO ancillary services, above-market costs of Qualifying Facilities and stranded assets, reliability must-run contracts, nuclear decommissioning and public benefits charges, among others. As a result, the relationship between the actual cost of generation and the price paid by the end-user has become increasingly decoupled. Figure 3 shows the results of this trend between 2006 and 2016, as the delivered cost of electricity rose continuously when compared to the cost of generating electricity.



Source: US Energy Information Administration, FERC Financial Reports, September 2017

Figure 3. Electricity Prices Reflect Rising Delivery Costs and Declining Production Costs

The Third Electric Energy Transition

The Third Electric Energy Transition can be described as a move toward the general de-commodification of energy and, most specifically, electricity. A Megawatt-hour (MWh) is no longer just a unit of energy, but instead is energy generated and delivered with specific attributes such as price, price stability, scalability, reliability, environmental impacts, and resilience. Because participants in the energy market value these attributes differently, there is no longer one standard commodity value proposition.

Various attributes comprise the concept of energy assurance, even though each customer seeks its own balance of features. Attributes that were formerly understood as part of a standard offering of capacity and energy can now be differentiated and given separate valuations. Consequently, the Third Electric Energy Transition is spawning multiple types of solutions that enable organizations to contract for the bundle of energy attributes that best matches their specific priorities. Examples of this trend include energy efficiency, demand-side responses, distributed energy resources, microgrids, Community Choice Aggregators, resilient community grids, and self-generators.

In 2018 Sheldon Peterson, the former CEO of the National Rural Utilities Cooperative Finance Corporation, characterized the tasks facing the energy industry as Decentralization, Digitalization, Decarbonization, and Disintermediation (the 4-Ds).[2,3] Rapid electrification and volatile markets make accomplishing the 4-Ds complex and challenging. Traditional utilities and ESPs need to raise their rates high enough to cover increasing costs but keep rates low enough to retain enough customers to provide sufficient revenues to pay for the new obligations now part of the third energy transition. However, if too many customers depart as disintermediation occurs, then the risks of a potential Death Spiral are magnified, adding instability to our interrelated energy systems.

Although solar, wind and battery technologies have become essential contributors to increased electrification and decarbonization, they are not fully capable of addressing our 4-D challenges. The risk of greater reliance on inherently intermittent solar and wind grows proportionately with its prevalence in grid-delivered electricity. Worse, we cannot eliminate all the risks that impact wind and solar energy systems including powerful storms, wildfires, widespread episodes of extreme heat, coastal flooding, and rising sea levels. For example, past volcanic and weather events like the eruption of Mt. Tambora in 1815 would, if repeated, bring about a “year-without-sun,” causing global crop failures and rendering electric grids dependent on solar and wind largely inoperable. Other risks with very high consequences, such as war or sabotage, are largely ignored but could be mitigated by having a more diverse and robust set of energy supplies.

As a result, the widely used LCOE calculation (Levelized Cost of Energy) is no longer an accurate metric for comparing the true cost of generation technologies because it does not take into account intermittency and reliability. Hence, although wind and solar appear to have a cost advantage relative to other energy sources using standard LCOE calculations, when the cost of providing necessary “firming” power is included, the actual cost is much higher. Figure 5 below demonstrates that the estimated cost of “firming” the grid to overcome the intermittency of wind and solar now costs more than the wind or solar power itself in California.

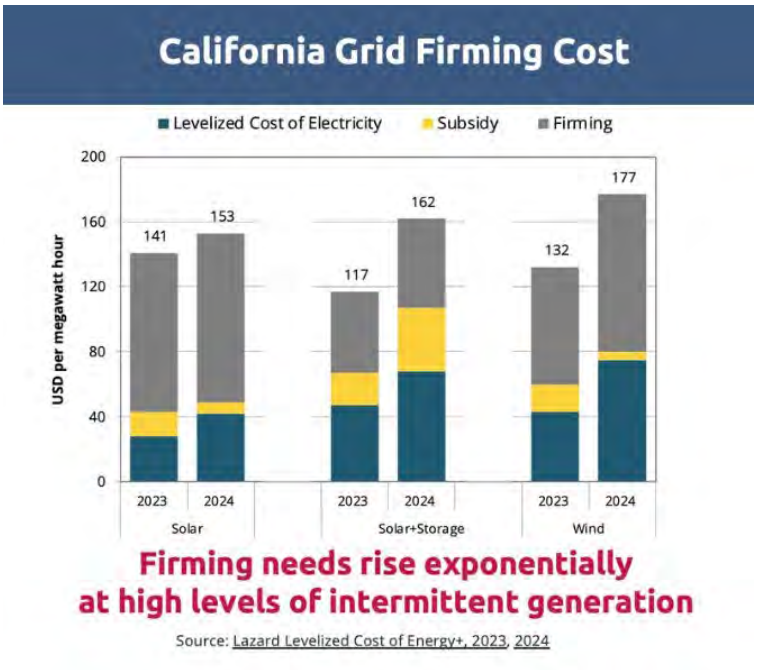


Figure 5 California Grid Firming Cost[4]

Multiple Factors Are Driving the Third Electric Energy Transition

The factors driving the Third Electric Energy Transition are fundamental, long-term, and structural.

Accelerating demand for clean energy sources

- The global demand for power has accelerated much faster than predicted, leading to shortages in many markets. For example in the United States "projections of electricity demand growth have doubled. The nationwide forecast of electricity demand growth by 2028 increased from a projection of 3.8% in 2022 to 7.8% in 2023".[5]
- National and regional climate policies, combined with low current natural gas prices, have substantially curtailed or eliminated the use of traditional baseload energy sources, such as coal and oil.
- Availability of energy has become a potentially significant constraint on growth.
- Manufacturing, in particular, needs thermal energy in addition to reliable, clean electric power.

Price Increases and Price Instability

- After decades of relative price stability, electric power consumers are confronted with the rapid escalation of power prices along with increased price volatility

Grid Instability

- As intermittent resources, such as wind and solar power generation, comprise a greater percentage of total grid capacity, the volatility of the energy supply increases.
- Prolonged power failures (sometimes with devastating impacts, as occurred in Texas in February 2021, during a winter storm), more frequent outages, brownouts, and power rationing have become increasingly common in both developed and emerging economies.
- Much of the electric grid is comprised of aging infrastructure and has shown its vulnerability to weather, fires and other disruptions.
- Power generation has become less predictable, because baseload coal and nuclear plants are being retired and non-geothermal renewables, including hydro power to a certain extent, are weather-dependent.

Regulatory and Legal Inertia

- Utilities are burdened by a complicated regime of regulations and restrictions that make it difficult to meet rapidly mounting demands for power.
- Existing powerlines are congested and building new transmission lines can require decades of contracting with multiple parties to permit, finance, and build.
- Intermittent power sources are inherently inefficient for large capacity power lines.

Energy Assurance and Other Key Attributes Are Required by Energy Intensive Organizations

To large energy-intensive organizations, “energy assurance” comprises multiple attributes in the right combination:

- **Availability**: sufficient energy must be available to accommodate expansion and growth. For example, some major textile plants in northeastern Spain have curtailed needed plant expansions, due to draught and regulatory controls that inhibit them from obtaining additional needed power.

- **Flexibility**: because using electric power to heat materials can be prohibitively expensive, the energy mix may require both heat and electric power,

- **Reliability and Resilience:** Reliability means a high level of uptime, and Resilience means resistance to and recovery from unforeseen events, such as major weather events or purposeful attacks. To energy intensive organizations, the consequences of power shortages and power instability have been nearly existential. Disrupted operations, damage to continuous process plants, and wasted materials have become a serious business risk. Predictably, vulnerable organizations no longer view energy as a commodity with assured availability. Instead, large power consumers consider their future power needs with respect to both reliability and resilience.

- **Stable affordability**: the energy supplied must be stable and cost-effective for the intended application. Today, geothermal power purchase agreements are being signed from

$70/MWh to $100/MWh for greenfield projects[6] and for $20 to $35/MWh for additional output from retrofits utilizing existing infrastructure.

- **Ancillary attributes:** Energy assurance alone is not sufficient. Other critical attributes sought by companies considering procuring their own energy supplies are:
  - Source: clean (ethical sourcing, reduced or no greenhouse gas emissions, limited water use & wastes),
  - Land: economical use of land and public acceptability,
  - Safety: low risks to employee and public welfare, health and safety,
  - Lifecycle costs and impacts: costs and impacts evaluated across the entire supply chain, including end-use and disposal over the project/product and its replacement's lifetimes.

Geothermal Energy Is A Key Element of the Third Energy Transition

As discussed in prior GRC papers,[7,8,9] geothermal energy could provide clean, carbon-free, around-the-clock, weather independent, energy secure, dispatchable, reliable, scalable and resilient power and heat in many more locations than it is used today, but only if interdisciplinary geothermal research, innovations and advances continue to achieve cost reductions and performance improvements like those occurring in recent months during 2023 and 2024.[10,11,12,13,14]

Figure 4 shows the value proposition and attributes provided by next-generation geothermal energy systems.

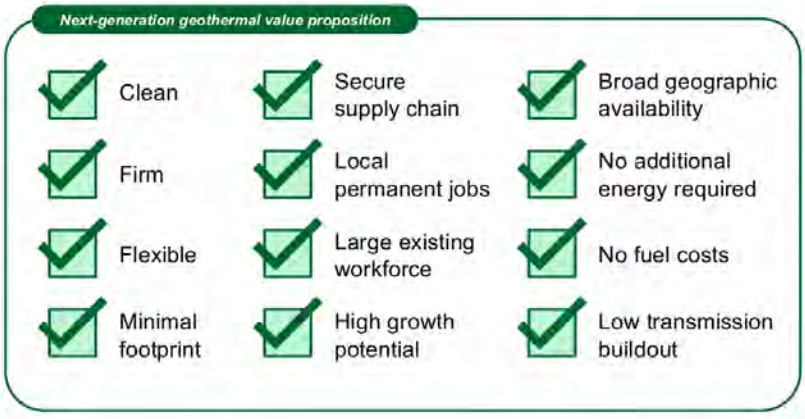

Figure 4 Features and Attributes of Next-generation geothermal projects[15]

Because the list of energy assurances required by consumers is comprehensive, it becomes obvious that geothermal energy is the ideal source to enable and accelerate the Third Energy Transition. No other renewable energy source provides clean energy in two forms (electrical and thermal) with high availability, reliability and resilience. Further, geothermal energy has far more global energy potential than coal, oil and gas combined, so it is inexhaustible in practical terms. In short, geothermal energy is uniquely suited to the requirements of the third energy transition.

Benefits of Co-location

These advantages can be made even more valuable by co-locating energy-intensive operations on top of or adjacent to geothermal resources. The clean, continuous, and reliable power generation from a "behind the meter" installation provides the energy assurance that energy-intensive organizations seek. They can:

- Avoid or mitigate utility price and rate increases,
- Eliminate grid vulnerabilities,
- Obtain both thermal energy and electric power,
- Meet clean energy and environmental stewardship goals,
- Reduce their energy footprint with land requirements 1/10 of solar and wind farms.

Having become aware of the significant benefits of geothermal energy, a number of industrial projects around the world are currently considering co-locating new facilities with geothermal energy operations. Such projects demonstrate the potential for geothermal to be a significant contributor to the third energy transition. Examples of such projects include:

- Data center companies that, due to the additional computing demands of artificial intelligence (A.I.) need to multiply the number of data centers by 4-fold, but can't get the added electric power, don't trust the grid, and want to control future prices,
- A carbon capture company that needs thermal energy to extract carbon, but knows heat is expensive and fossil energy is not low-emitting,
- Military bases that require absolute power assurance, hardened infrastructure, and resilience,
- A government-controlled power company that is directed to develop geothermal resources,
- Large textile companies that need to expand operations but cannot get additional power and are water constrained,
- Large chemical companies that need to expand operations but cannot get additional power, are water constrained and must meet GHG emission reduction goals.
- Steel manufacturing plants, which must have continuous power.
- Oil companies that need power for field operations and seek to convert depleted oil wells into geothermal power wells, thus displacing diesel generators.
- Companies mining bitcoins. It has been estimated that crypto currency operations consume 0.6% to 2.3% of all U.S. electricity demand in 2023. Of course, this electricity usage consumes resources and produces pollutants, while producing no realizable products.[16]

Advanced Geothermal Energy Systems Are Evolving to Match Customer Priorities

In order to realize its full energy assurance potential, geothermal power must be made more geographically available and scalable. While progress is being made across the entire spectrum of geothermal energy systems, Advanced Geothermal Systems (AGS) based on closed-loop architectures are particularly promising for third generation applications.

Closed-loop geothermal (CLG) energy systems make geothermal projects feasible in a much broader spectrum of resources than conventional hydrothermal systems and, in principle, more than Enhanced Geothermal Systems (EGS). This is because closed loops don't require the combination of large volumes of water and high subsurface permeability needed for conventional systems or the need for large-scale fracking, provided there is sufficient heat to extract. Closed-loop systems are much easier to permit because nothing is injected into the subsurface or extracted other than heat. A wide variety of CLG designs are now being developed and deployed that will provide the flexibility to use a variety of working fluids to enhance power output.

Two types of geothermal settings for "behind the meter" power projects

Organizations seeking energy assurance must evaluate many factors when deciding to co-locate a facility near a geothermal resource. However, the choice of geothermal resource will fundamentally determine the time, expense and control of the project. The key difference is whether the geothermal resource has already been at least partially developed or whether it is a "greenfield" project.

The fastest, least complicated way of providing additional geothermal energy is to work with existing projects. Such projects are in operation in many parts of the world with a combined capacity of about 16 GW. By applying closed-loop technology many of these projects can significantly expand production at an existing geothermal site. Choosing to co-locate with an existing geothermal operator has significant benefits:

- Most required permits have already been issued and additional permits should be relatively easy to acquire.
- The geothermal resource is proven, so project risk is small.
- Key infrastructure is already in place.
- Most projects have inactive wells and/or depleted permeability in fields that might be restored using closed-loop technology. Some projects also have idle electric generators that could be used.
- A contract can be executed to produce and deliver power from existing facilities or to finance and drill new wells and install additional generation.

Greenfield projects take longer to complete, but offer some advantages in terms of ownership, control, and flexibility.

- Industrial companies can do joint development of a given site to create a geothermal energy park, which is controlled by the participants.

- New projects should be able to take advantage of new forms of government subsidies and tax credits.

Increased Funding and Other Reforms Are Necessary to Continue the Third Energy Transition

The tasks required to implement the Third Energy Transition in the U.S and elsewhere are daunting and will require concerted, long-term investment by both the private and public sector.. According to the U.S. White House:

> "$3 trillion in private investments will be made over the next decade to address climate change, with 70% of these investments required to originate from utility and energy companies, clean energy developers, and financing institutions. While that may seem like a big number, it falls far short of the projections that indicate the need for annual investments to be nearly double that forecast, ranging from $4 trillion to $6.9 trillion just to meet the emissions reduction targets outlined in the Paris Agreement. This underscores the urgency and scale of finding clean ways to produce baseload power, and the need for substantial commitments from both the public and private sectors to drive meaningful change."[17]

For decades geothermal energy has been significantly underfunded by DOE and private investors compared to other energy systems. Even in 2022, the "Inflation Reduction Act and the Bipartisan Infrastructure Law concentrated clean energy investments in solar and wind, which are great near-term solutions for decarbonization, but neglected to invest sufficiently in continuous energy solutions like geothermal energy, which are necessary to reach full decarbonization in the long term." As also pointed out, "the increasing mix of intermittent renewable energy sources like solar and wind must be balanced by sources of clean firm power that are available around the clock in order to ensure grid reliability and reduce the need to overbuild solar, wind, and battery capacity. Geothermal power is a leading contender for addressing this issue."[18]

A January 2024 Federation of American Scientists report describes how increased government support could help commercialize clean energy, including geothermal power and heat technologies.

> "Next-generation geothermal technologies, such as enhanced geothermal systems (EGS), closed-loop [CLG] or advanced geothermal systems (AGS), and other novel designs, promise to allow access to a wider range of geothermal resources. Some designs can potentially also serve double duty as long-duration energy storage. Rather than tapping into existing hydrothermal reservoirs underground, these technologies drill into hot dry rock, engineer independent reservoirs using either hydraulic stimulation or extensive horizontal drilling, and then introduce new fluids to bring geothermal energy to the surface. These new technologies have benefited from advances in the oil and gas industry, resulting in lower drilling costs and higher success rates. Furthermore, some companies have been developing designs for retrofitting abandoned oil and gas wells to convert them into geothermal power plants. The commonalities between these two sectors present an opportunity not only to leverage the existing workforce, engineering expertise, and supply chain from the oil and gas industry to grow the geothermal industry but also to support a

> just transition such that current workers employed by the oil and gas industry have an opportunity to help build our clean energy future."[19]

> "The expansion of the [worldwide] geothermal industry presents considerable employment opportunities as well, with more than 196,000 individuals employed in 2021 according to the International Renewable Energy Agency's 2021 Annual Review. Many of these workers bring transferable skills and expertise from the oil and gas sector, facilitating a smooth transition."[20]

As proposed in May 2024, the 2025 federal budget promises to be instrumental in training and employing our vital future science and energy workforce.

A March 2024, New York Times article stated,

> "the growth of artificial intelligence requires huge data centers to train the evolving large-language models, making proximity to users less necessary…But as more of these sites start to pop up across the United States, there are new questions on whether they can meet the demand while still operating sustainably. The carbon footprint from the construction of the centers and the racks of expensive computer equipment is substantial in itself, and their power needs have grown considerably…Just a decade ago, data centers drew 10 megawatts of power, but 100 megawatts is common today."… "The Uptime Institute, an industry advisory group, has identified 10 supersize cloud computing campuses across North America with an average size of 621 megawatts…This growth in electricity demand comes as manufacturing in the United States is the highest in the past half-century, and the power grid is becoming increasingly strained."[21]

> "A.I. is only a small percentage of the global data center footprint. The Uptime Institute predicts A.I. will skyrocket to 10 percent of the sector's global power use by 2025, from 2 percent today"[22]

The May 5, 2024, Economist magazine cited the latest quarterly reports from Alphabet (Google's corporate parent), Amazon and Microsoft, stating that

> "the world's cloud-computing giants—collectively invested $40bn between January and March, most of it in data centres equipped to deal with growing artificial-intelligence (ai) workloads. Last month Meta, which does not have a cloud business but does run a data-hungry social-media empire, said its capital expenditure could reach $40bn this year as a result of AI-related projects. That is not far off the $50bn that Saudi Aramco, an oil colossus, is planning to splurge. Microsoft is likely to spend more."

Artificial Intelligence (A.I.) is poised to revolutionize the energy sector, mirroring the transformative effects of the Internet and mobile communications on global economic growth, according to a recent article by Wood Mackenzie.[23] A.I. promises to raise demand for energy, drive efficiencies, support low-carbon technologies, and address climate change while boosting the global economy. A.I.'s reliance on power-intensive data centers will necessitate massive investments in geothermal power generation to deliver power "behind the meter." As proof, tech companies are signing new power purchase agreements with early-stage geothermal companies.

And independent power producers are considering building data centers at existing generation facilities.[24]

In November 2023, Google announced that its data center project powered by geothermal energy is now operational:

> "To make the rapid progress needed to address climate change, we must accelerate a clean energy transition on a planetary scale. That's why we set an ambitious goal to operate our data centers and office campuses on 24/7 carbon-free energy (CFE) on every grid where we operate by 2030, with the ultimate aim of accelerating the decarbonization of the world's electricity systems.

Many industrial and commercial facilities around the world are seriously examining the feasibility of applying geothermal energy, particularly for plants operating in power systems where the costs of firm power have increased with higher penetrations of intermittent solar and wind generation. For example, Lazard's 2023 and 2024 Cost of Energy Studies[25] estimate how grid firming costs increase as the levels of intermittent generation go up in California. As illustrated previously in Figure 5, firming costs in California now exceed traditional LCOE values.

The Advantages of Geothermal Energy Today

Today, geothermal energy systems offer the most reliable, resilient, 24/7, continuous power and heat with the smallest footprint and lowest lifecycle costs of all renewable resources.

Geothermal projects add more jobs, have more secure domestic supply chains, and create more environmental benefits than solar or wind. Geothermal is largely carbon free and can also displace natural gas for heating. It can help balance the grid and provide baseload power and system diversity, as well as enhancing international energy security by reducing the risks of sabotage and deliberate disruptions in energy trade across borders.

Geothermal energy is weather independent and will still be operating when events like the explosion of Mt. Tambora in 1815 obscure the sun globally for months, and solar power systems cease to function.

What do we need to do?

Reductions in permitting time for projects, increased exploration and increased RD&D will make geothermal learning curves more robust and bring down costs. Geothermal technologies can provide energy assurance to individual companies, district heating projects and to regional electricity grids.

If we are serious about global decarbonization and electrification, we need to recognize that geothermal energy is now an essential energy resource.

Conclusions

Electricity continues to expand its share of the global energy market, as the need for energy in all forms surges beyond even optimistic estimates. At the same time, recent events have impacted

energy availability and electric grid reliability and stability, underscoring the essential importance of energy assurance. Consequently, energy intensive companies are prioritizing energy assurance and paying premium prices to obtain the mix of reliability, resilience, and stability they need. Among all clean energy sources, renewable geothermal energy offers a compelling value proposition that is driving intense interest in co-locating energy intensive companies near geothermal resources.

Thus, over the next several decades we must develop and deploy diverse clean technologies both upstream and behind-the-meter with essential reliability and resilience attributes. At the same time, we need to implement more workable markets, revise outdated government and regulatory policies, adapt the utility and energy supply business models, and encourage international cooperation.

To properly maintain and expand our complex electricity and energy systems, we need to evaluate the benefits of increased diversity and the role that continuous investments in RD&D must play to innovate, develop and build the future technologies we need to supply and deliver decarbonized heat and electricity in the U.S. and around the world.

ABSTRACT

Otutu is part of the larger Kenya Central Rift and lies in between the Eburru and Elmenteita volcanic field, within the larger Kenya Rift Valley. The area covers a longer portion of the rift floor thus becomes a good representative of the active rift segment. Geological and geochemical surface exploration studies were undertaken in the area, an area outside the normal central volcanoes so as to understand the areas' geothermal relevance: volcanology, surface mineralogical and chemical characteristics of the volcanic lavas within the study area. This study gives us a better understanding of the behaviour of a rift segment. During fieldwork, several geological structures were mapped and several samples collected for further analysis. A wide variety of lava rocks were identified and these included alkali olivine basalts, trachytes and abundant. The petrochemical results from both ICP-MS and ICP-AES included the rock composition in terms of major oxides, trace and rare earth elements. These results were used to plot various diagrams that included the variation diagrams (for both major oxides, trace elements), Total Alkali-Silica diagram, the AFM diagram, CIPW Norm Classification and also normalized Rare Earth Elements plots. These results provided a complete view of the various kind of liquids emitted during the last million years along this active segment of the rift. It can, therefore, be concluded that the Otutu rift is an important heat release area. It possibly has a shallow underlying anomalous mantle along the rift axis, where successive magma rejuvenations have taken place. This is supported by the steam vents that are aligned along open fissures and faults synchronous and post-dating the volcanic events. These results are of interest for the future geothermal development of the area. However, further studies are recommended on the area in order to complete the surface study of this geothermal site.

1. Introduction

Otutu rift is part of a rift segment that is located on the floor of the KRV between the Eburru and Lake Elmenteita areas. It is approximately 140 km northwest of Nairobi, 11 km northwest of Lake

Naivasha. KRV is made of a succession of central volcanoes alternating with single rift segments. Otutu is one of the rifts spreading segments (characterized by fissure eruptions) located between the two central volcanoes of Eburru and Menengai (Figure 1).

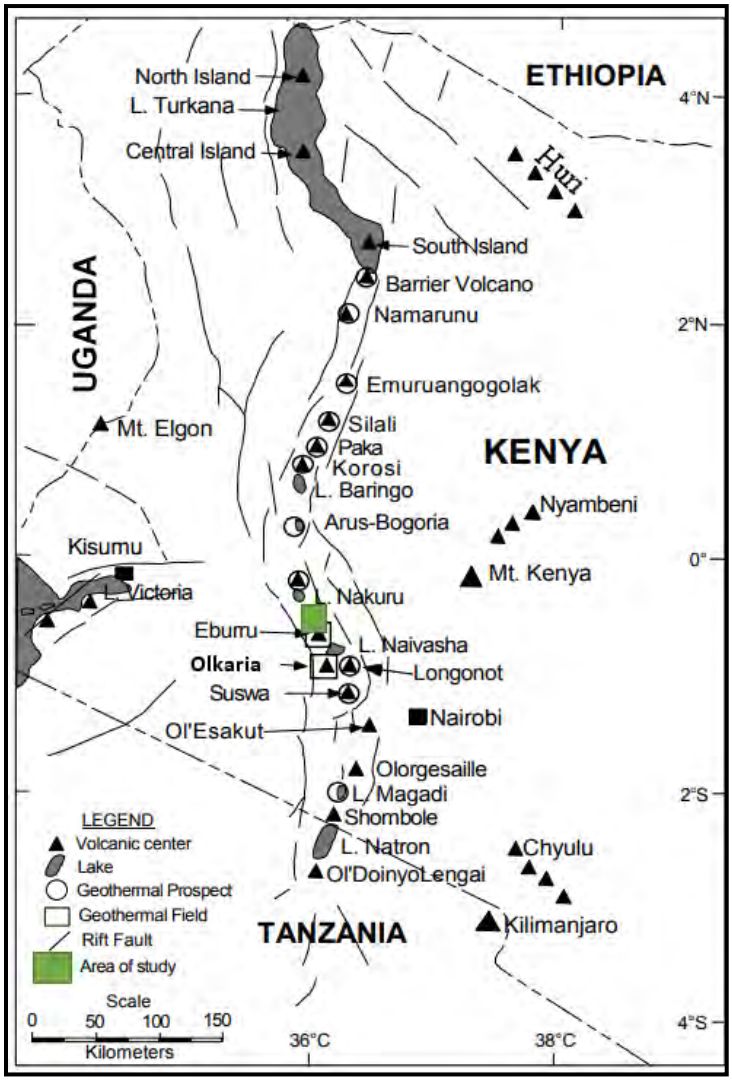

Figure 1: Map of the Kenya Rift showing the location of the Quaternary volcanoes (in black triangles) along the rift axis and the study area (in the green rectangle). Open circles are geothermal prospects in Kenya (Lagat, 2004).

The floor of the central KRV is characterized by two geologic settings: central volcanoes and flat-lying fissural volcanic fields. The central volcanoes have massifs of the order of 10 to 20 km wide with average reliefs of 100 to 500m above the rift floor. These central volcanoes are averagely-spaced 50 to 70 km from each other and alternate with flat-lying fissural volcanic fields occupying the low lands. The fissural fields are dominated by basaltic and intermediate lavas and interlayered by peralkaline silicic pyroclastic fall deposits that came from the surrounding central volcanoes and lacustrine sediments that originated from periods of high rift lake levels.

There are several grabens in the Kenya rift formed as a result of rifting. These fault troughs include the Elmenteita volcanic area, the area around Solai and Lake Nakuru. These areas are characterized

by widespread open fissures and normal faults showing long lasting crustal instability. These were formed during the Lower Pleistocene or Lower-Middle Pleistocene epoch, McCall (1957). McCall (1957) notes that the graben in Elmenteita experiences numerous volcanic activities as it is one of the least unstable troughs in the rift.

The noted line of instability, where thermal conditions are also noted, appears as the current axis of the rift spreading. This line extends southwards towards Eburru shoulders and further south passing through the western shores of Lake Naivasha towards Ol'Njorowa Gorge within the Hell's Gate National Park.

By looking at the bigger picture of the central segment of the KRV, it is observed that there is a succession of basaltic rift segments (B) that alternate with silicic central volcanoes (C). This can be seen by the following studied areas: Suswa is made of trachytic and phonolitic lavas (C), and thereafter we have the Akira plains with basaltic lavas (B); Olkaria and Longonot-Trachyte and rhyolites (C), then we have the Ndabibi-basalts (B), northwards occur Eburru trachytes and rhyolites (C), then Elmenteita Basaltic lavas (B); then Menengai – trachytes (C), (Clarke et al., 1990).

In terms of geothermal development, it is only in Eburru, Menengai, Olkaria and recently Paka and Korosi geothermal fields where deep drilling activities have taken place until now. Currently, appraisal and exploratory drilling is on-going at Paka and Korosi respectively. These two fields are far north of the earlier-mentioned three geothermal fields with more than 15 deep wells have been drilled so far between them. Geographically, the study area is bound between 0°27'S to 0°38'S and 36°11' to 36°21'.

The Kenya Electricity Generating Company, PLC (KenGen) together with Geothermal Development Company (GDC) have been exploring the KRV for its geothermal energy resources in the country so as to provide environmentally clean and low-cost energy for the country. KenGen is currently producing electricity from geothermal resources at Olkaria and Eburru while GDC has undertaken production drilling in Menengai and is currently carrying out exploratory drilling further north, in Paka volcano and Korosi areas.

Additionally, the Government of Kenya has licensed several other geothermal areas to private investors to explore and develop the resources for power generation and direct use. These includes Akiira and AGIL geothermal companies.

2. Results

2.1 Geology

Otutu rift was affected by rhythmic phases of spreading, during which dramatic volcano-tectonic events occurred, including both extensional tectonics and magmatic eruptions along the same active N-S trending faults and fissures of the rift axis. These volcanic activities in the rift axis are clearly linked with successive tectonic events characterizing the rift opening. During the fieldwork, it was noted that the whole volcanic activity in the study area is essentially characterized by lava flows, scoria cones and domes, without marked pyroclastic eruptions. The exception was noted in the areas influenced by the shallow water, thus producing hyaloclastites, which are generally easily altered and therefore difficult and unreliable to use for chemical analysis.

Quite a wide variety of differentiated products were observed in the study area, which is essentially a fissural area. It was also observed that shield structures tended to form, built on initial basaltic flows and intermediate terms (hawaiites, mugearites and trachyte flows). But these were cut by successive spreading events (normal faulting), allowing for a new magmatic cycle to occur (including basalts and highly differentiated products like rhyolites). It is worth noting that each of these eruption phases produced a variety of magma types that ranged from basaltic (basalts, basaltic trachy-andesites and trachy-andesites) lavas to trachytes and peralkaline rhyolites. The trachytes mainly occur on the slopes of the Eburru volcano both as shield building lavas and Late-phase flows, and this explains the close affinity with the Eburru Late-phase rhyolites with which they are associated in space. The basaltic lavas which occur at the foot of the Eburru volcano have been found not to co-genetic with the rhyolites and trachytes, which occur at the study area, along the same volcano-tectonic axis known as the Otutu rift. Whereas the evolution of the Eburru lavas was made possible by the thick overburden that allowed for the magma to differentiate at low pressures to form the trachytes and rhyolites, the Elmenteita lava evolved from small size magma chambers at mid-crustal depths. The results further demonstrate that even though the basaltic lavas occur in the same area, they were produced from different mantle sources. Below (from Plates 1 to 8) are some of the images taken of the study area and its surroundings.

Generally, normal faulting is in the same direction, N-S, and is well expressed in this study area with slight variations towards E-W. The exception is in areas that are covered by the most recent – sub-historic – Aa basaltic lava flow in Badlands. In the north-eastern part of the area, they tend to be visibly younger from east to west (that is, towards the rift axis) where they also affect more recent lava flows. The recent “Aa” basaltic flow (Plate 1) characterising the Badlands appears to extend mainly in a transverse, E-W direction. The SW limit of the flow is rectilinear and strikingly trending E-W. Due to its low viscosity, the basaltic flow flowed laterally towards the west, forming deep caves.

Plate 1: The researcher standing at the boundary of the Elmenteita volcanic basaltic flow, which is in the background, appearing as a highly vegetative field. In the far background are some of the structures that are aligned along the N-S Rift Axis.

Numerous cones are also observed, which correspond to former emission centres. Two variety of cones are clearly distinguished: hyaloclastite rings of large diameter, which pre-date the last sub-aerial basaltic lava flows, and subaerial scoria cones contemporaneous with this latest volcanic event, showing the emissive source of these Aa basalt flows. The largest and the most probably spectacular faulted hyaloclastite ring, is Losiriwe or “the Sleeping Warrior”. This spectacular structure is well seen from the Naivasha-Nakuru road crossing the active rift south of Lake

Elmenteita (Plate 2). It has a regular circular shape, with a basal diameter of 1.4 km and a maximum height of 120 m along part of the rim of this 900 m wide cone. This ratio of 1/10 between height and diameter is typical for such subaqueous hyaloclastite rings. As observed above, it is affected by normal faults on both sides and a small graben resulting from an open fissure along its axis, showing that this cone was at some stage in time the spreading axis of the rift. At present, the active axis of the rift is shifted 3 km east, at the level of the two other coalescent hyaloclastite cones elongated along the N-S trending rift axis with a sub-aerial eruptive phase having produced both subaerial scoria cone (Plate 3) and a lava lake of basaltic composition.

Plate 1: One of the distinct structures, Sleeping Warrior, a highly faulted dome that is located between the Elmenteita volcanic area and Lake Elmenteita.

Plate 3: View of the most recent scoria cone in the southern part of the Badlands.

Further south, these normal faults appear quite spectacular with important throws. Some of them clearly show that the tectonics affected the axis of an elongated shield volcano trending in the same meridian direction. Towards the active rift axis, normal faulting also affects very recent volcanic centres, such as a doubled rimmed scoria cone or an obsidian dome further south (Plate 4). On the western side of the rift axis, normal faulting is less visible, but open faults are still frequent, and attentive observations show that the tectonics was also quite violent there. Several hyaloclastite and scoria cones are cut by the N-S normal faults, which dip west, and some are left with only the western rim, with the central and eastern side having been down faulted and covered by more recent lava flows emitted along the rift axis as seen in Plate 5.

Plate 4: One of the Recent obsidian domes along the active rift axis cut by open and normal faults.

Plate 5: Cedar Hill, a recent rhyolitic dome made of anorthoclase porphyritic obsidian located to the SE of the Badlands area on the northern slope of Eburru volcano (photo by Varet, 2017).

2.2 Petrography

All the collected, over 120, rock samples were subjected to initial petrographic analysis in the field before taking samples to the laboratory for more analysis. Petrographic analysis was used to study the mineralogical evolution, confirm the rock type(s), the alteration minerals, and any other additional minerals not observed by the binocular microscope or the hand lens. Petrographic analysis assisted in;

i. Identification of the rock-forming minerals

ii. Characterization of the rock porosity

iii. Modal analysis (mineralogical composition)

iv. Analysis of the rock sample texture

Identifying the mineral phases and sequencing (phenocrysts were used as representatives of magmatic reservoir while groundmass used to depict the mode of eruption).

Rock types present in the study area range from alkali basalts to trachytes and peralkaline rhyolites. Both rhyolites and alkali basalts were found in areas around the Eburru volcano and also in the

volcanic field south of Lake Elmenteita. The collected samples were analyzed petrographically, and thereafter, 21 samples were picked based on their location, physical state and rock type for whole-rock analyses.

For petrographic microscope analysis, thin sections were prepared at KenGen's Geology lapidary laboratory in Olkaria, Kenya. The process included sawing of the rock samples, polishing, preparation and characterization in order to determine the samples' mineralogy. The thin sections were thereafter mounted on a petrographic microscope for analysis. For this project, thin sections were analysed in both KenGen' s Geology Laboratory in Kenya and the BRGM laboratory in France using Optika B-353POL and the LEICA DM 4500P Microscope, respectively.

2.3 Petrochemistry

Twenty-one (21) samples from the over 120 rock samples collected were subjected to whole-rock analysis (analysed for Major, Trace and Rare Earth Elements) using ICP-AES and ICP-MS in University of Occidental Britany (UBO), Brest, France. The samples were picked based on the surface outcrops and structures observed, in view of establishing a representative picture of the magmatic variations within Otutu rift, across and along the rift segment in particular. Therefore, aphyric or sub-aphyric samples were selected, as they directly allow to trace the evolution of the magmatic liquids. Of course, attention was also paid to the phenocrysts and their composition in the same magma types. It is noted that porphyritic samples were discarded during the critical selection of samples for petrochemical analysis as this study centred on the evolution of the liquid composition. This choice also explains some of the gaps observed in this sequence i.e. trachytes and rhyolites. Whole-rock analysis involved both major and trace/rare elements analysis. Major and trace elements are widely used to test petrogenetic models (Barberi et al. 1975; Reynolds et al., 1992; Bach et al., 1994; Perfit et al., 1994, 1996, 2001; Wendt et al., 1999; Sims et al., 2002).

2.3.1 Major Oxides

Lower Elmenteita basalts have SiO2 ranging from 48.26 to 55.46%. However, typical basalts would be in the range of 45 to 52%. This wide range of silica content can be attributed to fractional melting. The MgO and CaO values also range from 3.7 to 6.5% and 6.3 to 11.0%, respectively. These high MgO and CaO are typical major oxide trends of basalts. Upper Elmenteita Basalts have SiO2 ranging from 48.32 to 55.4%. They also have MgO and CaO values ranging from 3.8 to 6.0% and 6.5 to 10.4%, respectively. Generally, basalts are rich in MgO and Cao but low in silica.

The trachytes consist of Pliocene Gilgil Trachytes and Eburru shield-building trachytes. The early trachyte has 68.21% silica, 0.15% MgO, 0.56% CaO. This is relatively higher than what is noted in the shield building trachytes. The shield-building trachyte has SiO2 ranging from 63.28 to 67.37% with MgO and CaO being 0.01 to 0.17% and 0.61 to 1.38%, respectively.

The rocks occur on the Eburru volcano, and are dominantly on the northern slopes. The lavas have high SiO2 contents of 69.2-71.4%. The Fe2O3 (t) content are high as they range from 7.33 to 10.1%. The rocks have very low MgO contents of 0.01-0.14%. Their Na2O and K2O content ranges between 5.1-7.7% and 4.2-5.0%, respectively. The rhyolites at Eburru have been classified as pantellerites due to their low alumina content as compared to the alkalis (combination of K2O and Na2O). In this case, the alumina ranges between 7.11 and 8.8% while the alkali ranges from 9.40 to 11.16%.

a) Total Alkali-Silica classification

From Figure 2, the TAS Diagram shows a regular trend for all samples, slightly above the alkaline / sub-alkaline dividing line (dotted red on the diagram below), which is typical for all transitional series found elsewhere in the EARV, including Afar (Barberi et al., 1975). The rock sampled ranged from mafic through intermediate to silicic rocks (basalts, trachy-basalts, basaltic trachy-andesites, trachy-andesites, trachytes and rhyolites).

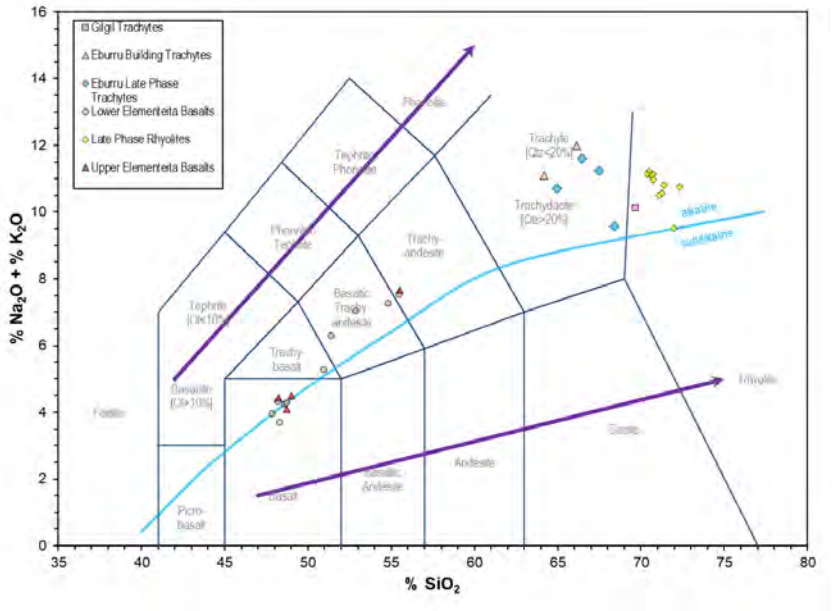

Figure 2: Total Alkali vs Silica Diagram for the study area.

Lower Elmenteita basalts vary in composition from basalt through trachy-basalt to basaltic trachy-andesite. Their alkali content varies from 3.69 to 7.51%, while their silica content varies from 48.31 to 55.46%. All the upper Elmenteita basalts samples except sample EN/EBLE 25A fall under the basalt category. Their normalized silica content varies from 48-49%, with the alkalis part ranging from 4.09-4.49%. Sample EN/EBLE 25A has a relatively high silica content (55.1%) and relatively high alkalis (7.66%).

Generally, the Upper Elmenteita basalts are low in both silica and alkali compared to the Lower Elmenteita basalts. They have a general composition of 45-52% SiO2 and 2 to 5% alkalis. This is noted in the upper Elmenteita suite but apparently the lower Elmenteita suite seems to be higher in their silica and alkali content. This varying composition noted in these basaltic suite (lower Elmenteita) could be as a result of fractional melting.

The one sample of Gilgil trachyte has high SiO2 (69.67%), which make it fall within the rhyolite field. However, the petrographic analysis clearly indicates that the lava is trachyte. The lava has an alkali content of 10.12%. Eburru shield trachytes all fell under the trachytes. They had alkali concentrations of 9.3-11.2%, with silica content ranging from 64.2 to 67.4%.

Generally, trachytes are feldspar-rich and thus have 60-65% silica content and an average of 7% alkali. Most of the samples had high silica and alkalic content and were plotted towards the tail end of the trachyte portion in the TAS diagram.

Rhyolite plot with an alkali content of 9.4 to 11.2% while the silica content was 70.4-71.4%. This is expected of rhyolites as they are the most silica-rich igneous rocks. They usually have higher SiO2 (69-77%) and alkali (>7%).

All the trachyte and rhyolite suites are all silica saturated with concentrations ranging between 64.18 and 71.4% by weight. The suites also have relatively high alkali contents that range between 9.3 to 11.2% and 9.4 to 11.2% by weight, respectively.

Therefore, all the samples plotting above or around the line that separates the alkaline and sub-alkaline rocks (Figure 2). This means that all the rocks sampled were alkaline/calc-alkaline rocks. Alkaline magmas are known to be derived from mantle-derived basaltic melts. These melts usually have had a residence in the crust and thereafter evolve through the assimilation and fractional crystallization (AFC) processes.

Sub-alkaline rocks can occur due to a variety of factors, including fractionation process affecting tholeiitic basaltic series, the influence of enriched mantle sources, crustal contamination, or the mixing of different magma types. In these instances, basaltic magmas derived from mantle melting can interact with continental crustal rocks or undergo assimilation and fractional crystallization processes, leading to the development of more evolved magmas with intermediate to felsic compositions. These evolved magmas may exhibit sub-alkaline or even calc-alkaline characteristics, similar to those found in convergent plate boundary settings.

b) AFM classification

AFM Diagrams, in their classification, distinguishes between the two usual types of parental magmas; alkali and tholeiitic (Figure 3).

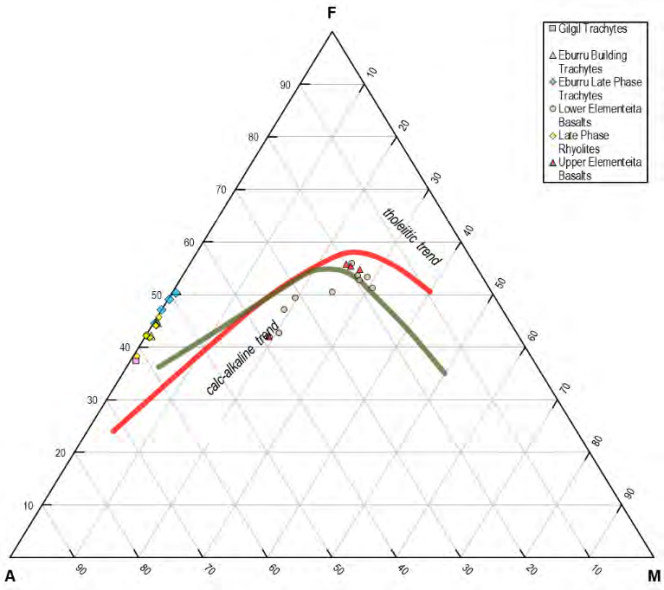

Figure 3: AFM Diagram for the Otutu study area.

It is noted that the lavas evolved through depletion of Fe and Mg and enrichment of alkalis. All the samples were plotted below the tholeiitic (sub-alkaline) series. It is noted that tholeiitic magmas

usually form at relatively shallow depths compared to alkalic magmas and differentiate into the SiO2 oversaturated rhyolites.

Figure 3 shows both trachytic and rhyolitic lavas plotting on the zero MgO axis due to their very low MgO contents while having high contents of alkali and Fe. The evolution of the Elmenteita and Eburru lavas can be described by the fractional crystallization process involving crystallization of ferromagnesian minerals (olivine, pyroxenes and plagioclases) as shown by decreasing Mg and Fe with an evolution from basalt through trachyte to rhyolite. The evolution is characterized by the enrichment of alkalis in the liquid phase.

c) Harker variation diagrams

Harker variation diagrams were plotted for the various rock suites in the study area. crystallization from basaltic liquids. Figure 4.

d) CIPW Norm Classification

The basaltic (lower and upper Elmenteita) samples contain no normative quartz but very high values of normative plagioclase and average normative orthoclase. This ranged between 52.4-62.1% and 5.2-22.3%, respectively. The normative diopside ranged from 10-19.5%, while the normative olivine values ranged from 4.5 to 12.2%. Normative ilmenite varied from 1.3 to 3.2%, and normative magnetite varied from 1.1-18%.

Normative nepheline values were generally low. Values ranging from 0.0 to 3.0% and 0.5 to 1.4% for normative nepheline and apatite, respectively, were also noted, with most samples containing no normative sodium silicate. Normative leucite was absent from all the basaltic samples, which is expected of all sub-alkaline bulk chemistry. The normative zircon ranged from 0.01 to 0.02%, while the normative chromite values were at 0.01%. All the other remaining normative minerals were absent or very low. These included acmite and calcite.

In the trachytic samples, normative quartz was noted. This ranged from 7.8% in sample 13 to 15.9-26.2% in the other samples. The samples also had relatively high values of normative plagioclase and normative orthoclase. This ranged between 22.3-42.3% and 27.7-32.6%, respectively. The normative diopside ranged from 1.8 to 4.6%, while the normative hypersthene values ranged from 5.8 to 10%. Normative acmite varied from 2.3 to 3.9%, while normative sodium silicate varied from 1.8 to 9.8%. Normative ilmenite was low and varied from 0.34-0.9%, while normative magnetite was very low (0.06%) and mostly absent. Normative apatite and zircon values were generally very low. Values ranging from 0.1 to 0.14 % and 0.0 to 0.1 % for normative apatite and zircon were noted, respectively. All the other remaining normative minerals were absent or very low. These included accessory minerals like nepheline, olivine, chromite and calcite.

In the rhyolitic samples, higher normative quartz was noted in comparison to the trachytic samples. This ranged between 30.0-33.1%. The samples also had relatively high values of normative plagioclase and normative orthoclase. This ranged between 14.5-24% and 26.0-28.2%, respectively. This lower plagioclase content in the rhyolites here (as compared to basalts and trachytes) is due to the low alumina deficit. The plagioclase effect usually plays a major role in the generation of peralkaline. The normative diopside was averagely low, ranging from 0.9 to 1.3%, though sample ES1 had 2.7% while the normative hypersthene values ranged from 7.1 to 9.7%. Normative acmite varied from 2.5 to 3.4%, while normative sodium silicate was averagely high,

varying from 5.8 to 11.1%. Normative ilmenite was averagely low and varied from 0.3-0.4%, while normative magnetite was very low (0.06%) and mostly absent. Normative apatite and zircon values were generally higher compared to basalts and trachytic suites. Values ranging from 0.02 to 0.08% and 0.18 to 0.24 % for normative apatite and zircon were noted, respectively. All the other remaining normative minerals were absent or very low. These included accessory minerals like nepheline, magnetite, olivine, chromite and calcite.

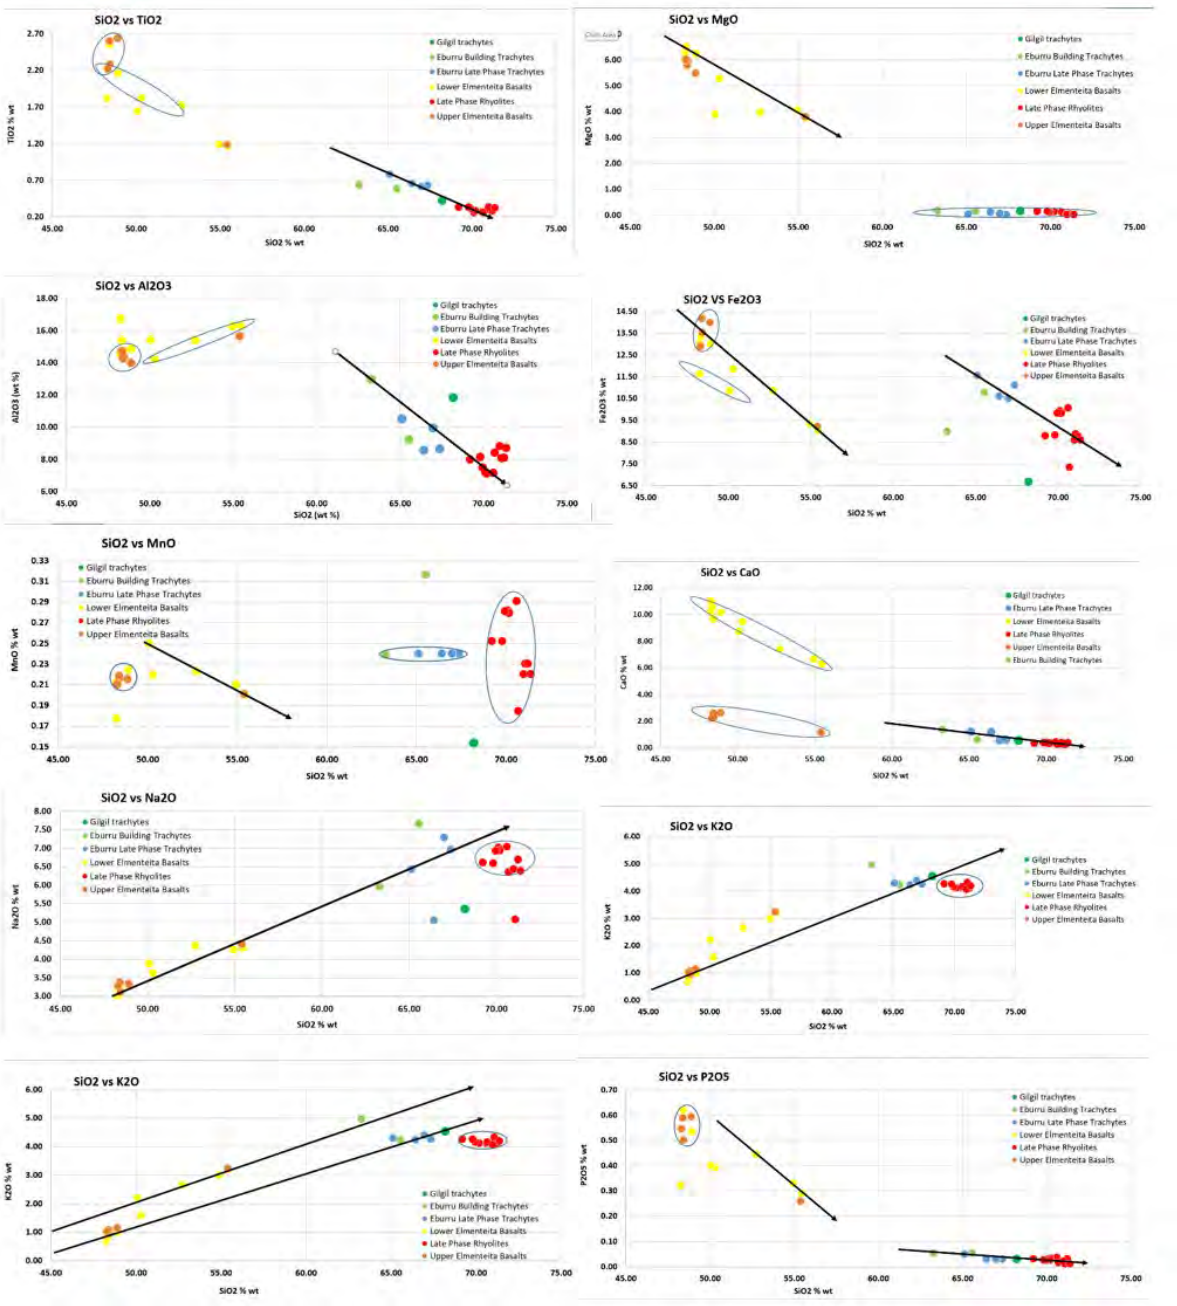

Figure 4: SiO2 vs Major Oxides variation diagram.

Generally, by CIPW classification, silicic rocks usually have normative quartz varying from the lower end trachytes through ignimbrites to the higher end rhyolites. The average quartz values are

1-4%, 17-21% and 22-30% for trachytes, ignimbrites and rhyolites, respectively. Silicic rocks also have averagely high values of plagioclase and orthoclase. For silicic rock as a whole, these ranges between 31-55% and 25-30%, respectively.

Most of the basalts show a good balance, with both olivine and hypersthene present, but not quartz (no tholeiite), whereas only 3 samples show the presence of nepheline, mostly as traces (ranging from 0.3-0.4%) with only one sample exceeding 1%, which confirm the transitional character of the basaltic magma source. Whereas olivine is always visible in thin sections under the microscope, orthopyroxene is not observed, which is classical in a basaltic environment (orthopyroxenes rather appear in plutonic environments). However, during the differentiation process, the magma progressively acquires a slight, then dominant, silica saturation in the end products.

Amphiboles are observed as phenocrysts in some intermediate lavas. They are not present in the normative analysis for the simple reason that the CIPW norm is based on “dry” mineral only – pyroxene in this case - and do not allow for amphibole (or mica) to occur. The amphiboles we observed frequently show signs of instability (mineral internally altered and rimmed with iron oxides) with the groundmass, indicating that these silica-deficient minerals formed at depth are not in equilibrium with the silica-saturated liquid containing them when emitted at the surface in more oxidizing and eventually “dryer” conditions, despite the fact that they have played a major role in the formation of silicic end products by fractionation of originally undersaturated magmas.

2.3.2 Trace Elements

The trace elements results obtained were plotted in variation diagrams while the multi elements (Rare Earth Elements) were normalized (chondrite normalized REE) and thereafter plotted for the study area to show the evolution chemistry.

a) Process Identification/Variation plots

Process identification plots (PIPs) were plotted to check on how the elements related to each other. PIPs are diagrams plotted of the ratio of two (2) incompatible elements against the abundance of the other. Incompatible elements are part of the trace elements. Figure 5 shows how these elements relate to each other.

b) Rare Earth Elements (REE)

Multi elements were normalized (chondrite normalized REE) and thereafter plotted for the study area to show the evolution chemistry, and this is illustrated in Figure 6.

One can observe a regular and parallel increase in REE elements with the evolution from basalt to rhyolites. From the diagram below, it is noted that there is a strong negative europium anomaly in trachyte and rhyolites due to the fractionation of feldspars. Barberi et al., (1975) described the negative Eu anomaly as resulting from the fractionation of alkali-feldspars since the element is incorporated in the lattice structure of the minerals.

Figure 5: SiO2 vs K2O variation diagram.

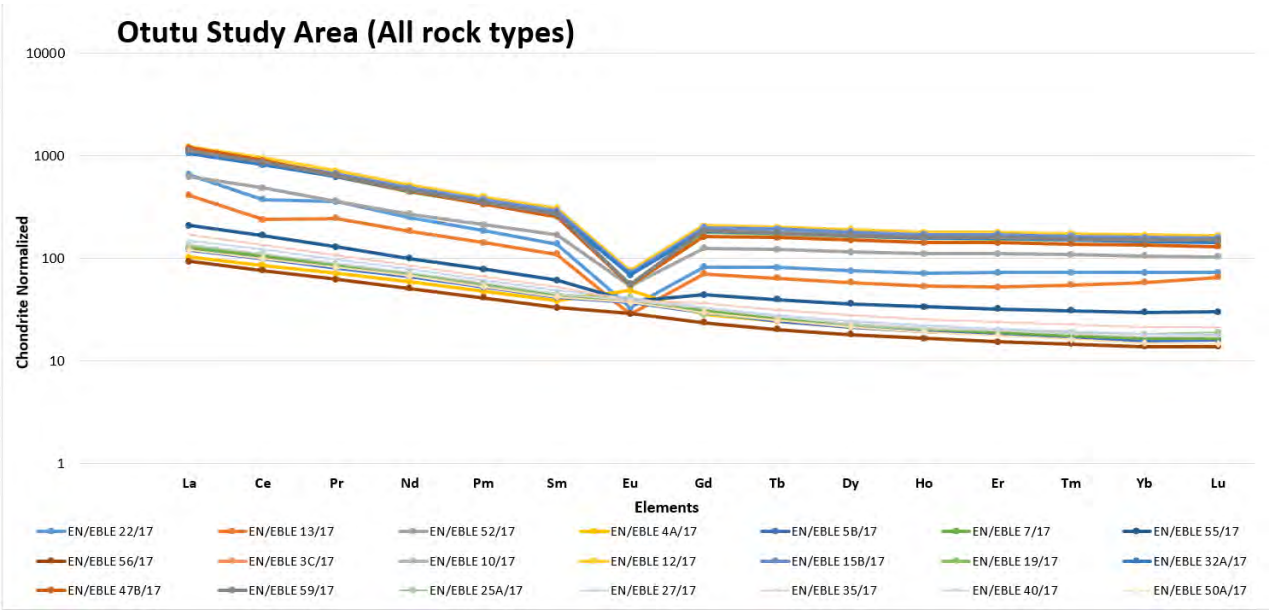

Figure 6: REE vs Chondrite normalized for all chemically analysed sampled rocks from the Otutu study area.

3. Conclusion

The Otutu rift study area is characterized by several volcano-structural features that include fissures, recent basaltic lava flows and shield structures. Important heat release along this rift axis is also noted all along the area. Steam vents are aligned along open fissures and faults synchronous and post-dating the volcanic events. Several hydrothermal zones are also noted resulting from fumarolic alteration. Though there are older or off-axis rock types that fall out of the fractionation line (the Gilgil Trachyte, the basalts sampled outside the rift axis and the Eburru rhyolites) but most rock types sampled within the rift axis of the study area still display a nice fractionation line. This clearly indicates the presence of a shallow steam-dominated reservoir underlying this rift axis. This reservoir is possibly heated by an underlying elongated magma chamber beneath it. The results also show that after the widespread trachyte emission that pre-dated the formation of the present rift, a variety of volcanic products were emitted. These happened during each of the successive steps of the rift segment development. The emission ranged from alkali-olivine basalts to pantellerites, with a few intermediate types. This means that, geothermally, the Otutu rift is not only fed by the fissural basalts originating from a deep-seated source but also from a shallow, elongated magma chamber that is along the rift axis.

Petrological investigations in this study allowed for the identification of the bimodal nature of the rocks in the area. The area has a large variety of both basic and acidic rocks. This variety of lava rocks ranged from alkali olivine basalts to mugearites, trachytes and pantelleritic obsidians, with a relative abundance of the later. Petrological analysis of the rocks and their interpretation shows that this evolution can simply be explained by the process of crystal fractionation occurring in the crust a few kilometres deep. It, therefore, appears that this linear volcano-tectonic context dominated by fissure eruptions along the rift axis allowed for this magma development. This could have occurred during the last few hundred thousand years. Successive magma chambers are interpreted as being elongated along the same axis with successive rejuvenations through basaltic magma injection from the relatively shallow underlying anomalous mantle.

Geochemical analysis carried on the selected fresh aphyric rock samples provided a complete view of the various kind of liquids emitted during the last million years along this active segment of the rift. The results showed that very dynamic magmatism had taken place that resulted in differentiation. This is evidenced by the different rock suites noted: basalts, trachytes and rhyolites. By use of trace elements, it is concluded that the magma sources for the various rock suites are at least three. This is due to the noted different elemental ratios noted in the plotted graphs. Incompatible elements ratios are less affected by FC than other element abundances. The ratios are usually similar in geochemical behavior, and rocks that are related by FC have a common/constant ratio. Therefore, the ratio of two incompatible elements in a magma will be more or less the same as that in the magma source.

The geological data collected in the field, the rock sample analysis, and the interpretation of the results in terms of geothermal implications have been included in a global geoscientific approach, thus allowing for a new conceptual model of the geothermal system in the rift segment to be proposed. As a result of the crystal fractionation and differentiation, this study alludes to presence of magma chambers below the study area. These results are thought to be of interest for the future development of the area, as well as – more generally – for the search for new geothermal resources along the East African Rift System away from the central volcanic units, i.e. along other active rifts segments, which represent much wider areas than the ones presently being targeted. Therefore, the possible heat source (s) in this type of environment should be investigated further and even confirmed by exploration drilling and exploited even if they differ in terms of size and shape with the central volcanoes.

4. Recommendations

The field work (rock-suites mapping), samples collection and analysis for major and trace element geochemistry provided only a limited insight into the petrogenesis of the Otutu rift. There is a need to undertake further studies in this area. The following studies are recommended: geochronological studies, a further detailed mineralogical study of a few key phases determining the major shifts in the fractionation process (e.g. how the amphibole pass from nepheline basalts to quartz trachytes and plagioclase pass from meta-aluminous to peralkaline liquids), close-knit geophysical surveys (preferably MT and magnetic surveys) to clearly map out the anomalies (thin, elongated heat sources), radiogenic isotope analysis, geochronological studies to evaluate not only the actual ages of the various rock series but also to quantify the periodicity of the magma injection and differentiation. This would go a long way in better understanding of this spreading axis in order to properly model the vertical dimensions of the rift segment and quantitatively define the whole geothermal conceptual model of this rift segment through the tectono-magmatic history.

ABSTRACT

Low and medium temperature hydrothermal reservoirs are differentiated from high-temperature geothermal reservoirs in several important ways: the predominant phase is liquid water, the reservoir temperature is usually less than 150 degrees Centigrade, the lithology is typically sedimentary rocks with primary pore space and permeability, and the pore space can be filled with other geofluids, including hydrocarbons. Most sedimentary systems are dominantly conduction-driven heat flow instead of convective.

In May 2022, a pilot geothermal energy plant at the Blackburn Field in northeast Nevada was installed to assess the integration of an Organic Rankine Cycle (ORC) engine with existing oil and gas facilities to generate electricity at an operating mature oil field.

The pilot project generated power as different process flow configurations were tested and the surface facilities integration of petroleum and geothermal resources were optimized to maximize power generation and minimize, or negate, operational interference with the oil and gas operator. The pilot project identified that thermal energy is lost in several processes between the reservoir and the ORC inlet at typical oil field flow rates creating forward opportunities for field optimization as project budgets allow. The project also validated the hypothesis of the geothermal operator that an intermediate flow loop is necessary to protect the heat exchanger in the ORC from the geofluids with residual petroleum compounds, high total dissolved solids content, and scaling tendencies.

1. Introduction

Physicists Richard Thomson, James Joule, and William Rankine theorized thermodynamic heat engines to transform thermal energy into mechanical work in the 1840’s and 1850’s (Smith, 1977).

Tabor and Bronicki (e.g., 1964) developed Organic Rankine Cycle (ORC) engines and opened the market for the use of ORC engines in heat waste power generation. ORC engines use a refrigerant with a boiling point below that of water to generate electricity for waste heat down to 65°C. Power generation at temperatures in the 65°-150°C range is of specific interest to well owners in sedimentary basins, particularly those in oil and gas where wells access similar reservoir temperatures (Johnson et al., 2020). Paired with geofluid flow rates that provide adequate thermal mass for power generation, the concept of geothermal power generation coproduced alongside oil and gas has been modeled and tested in several locations across the United States (e.g., ElectraTherm, 2012; Gosnold et al., 2017; Akhmadullin, 2017).

This paper discusses the results of the first phase of feasibility from a pilot project at the Blackburn oil and gas field in northeast Nevada. The location and history of the Blackburn field also prefaces the specific challenges and opportunities examined by the project in examining thermal energy loss throughout the geofluid gathering system and in optimizing the process flow of the fluids at the central facility to maximize power generation from both load and cumulative energy standpoints. The goals of the pilot project were to demonstrate the integration of geothermal power generation technology with an operating oil field. Specifically, the project identified the following goals:

- Document and monitor thermal energy loss across the geofluid gathering system
- Document and optimize the effect of oilfield central facility operations such as manifold flow gathering, separator, and pre-disposal water handling and storage on thermal energy loss
- Determine the optimal placement of geothermal power generation equipment within an oilfield
- Determine the feasibility of increasing power generation to 1 MW
- Plan for a specific scenario that increases power production and validates the 1 MW plan

2. Field Location & Selection

The Blackburn field is a conventional oil field located south of Carlin, Nevada, in Pine Valley, a narrow north-south oriented basin within the basin and range province of the western United States (Figure 1). This location was identified by Johnson et al. (2020) as having the ideal characteristics for piloting this type of operation.

The field was discovered in 1982 producing from a highly fractured dolomite at about 2440 meters depth (Scott and Chamberlain, 1988). The oil field is present because of the structural trapping of hydrocarbons. Over 2000 meters of Tertiary-aged volcanic deposits provide both an impermeable barrier to upward hydrocarbon migration and water flow creating in the Devonian-aged dolomite reservoir and artesian flow conditions with about 300 psi at surface. This pressure has been very consistent over the field's operations since 1982. The produced water has a total dissolved solids (TDS) content of about 2500 ppm. This low TDS value does not create mineralization or scaling issues for the oil and gas operator. The surface temperature at the well heads accessing the Devonian-aged Nevada Formation is about 116°C. Well log analysis and correction of bottom hole

temperature measuring during wireline logging of the wells in the 1980's and 1990's result in an estimated reservoir temperature of 138°C. The reservoir has zones with permeability as high as one Darcy.

The maturation of the field is a typical scenario for conventional oil and gas fields. The initial production was almost 100% oil with no gas in the early to mid-1980's. Total fluid production remained the same but the ratio of water to oil increased over time to its present number of just over 99% water to oil. In the early 2010's, atmospheric gas was pumped into parts of the field to create a gas cap in the reservoir and increase oil production by driving additional oil from its buoyancy-driven location at the very top of the reservoir to the perforations in some of the wells. This operation did not change the reservoir pressure of the field or the total fluids production volume but did increase the water to oil ratio temporarily.

3. Pilot Test Engineering

The pilot test generated electrical power from the approximately 4200 barrels per day (BPD) or 122.5 gallons per minute, of 116°C geofluid provided by the field operator. An ORC with a twin-screw induction generator and nameplate capacity 75 kW gross was used for power generation (Figure 2).

The geofluid production came from four wells: two wells in different fault blocks both penetrating the Nevada Formation and two wells penetrating the shallow Indian Wells formation. The two wells producing from the Nevada Formation provided the vast majority of the total production and the most thermal energy. These wells flowed naturally and were choked back by the oil and gas operator so that the central processing facilities at the field were not overwhelmed. The Indian Wells formation provided a few hundred barrels of oil and gas to the total fluid stream at temperatures around 90°C. The four individual flow lines joined at the central facility at manifold where the combined flow stream temperature was 107°C between the manifold and the inlet to the oil and water separators.

From the separators, oil is piped to holding tanks on one side of the central facility and water is piped to another tank in a different part of the pad. The separators flow water discontinuously to the water holding tank on a schedule known as a "dump schedule." One iteration of the pilot had the ORC and its heat conveyance sled directly downstream of the separators. The second iteration had the separators dump to a water tank and the ORCs were plumbed into the water tank for both inflow and outflow. The outcomes of those two plumbing configurations will be discussed in a later section.

The ORC as referred to in this paper is really two units: the ORC itself, which was configured with dry air-cooling fans, and a heat conveyance sled, which was the only direct point of contact between the produced geofluids and the geothermal power generation process. The direct point of contact was a plate-and-frame heat exchanger with gaskets selected for the separator dump pressures, geofluid chemistry, and the expected high temperature fluids. The heat exchanger was configured for a 5°C approach, meaning that the temperature conveyed to the ORC via the pipe loop was 5°C less than the input geofluid temperature. The intermediate pipe loop contained water in the warmer months and a mix of water and glycol for freeze production in the winter months.

4. Geothermal Pilot Outcomes & Learnings

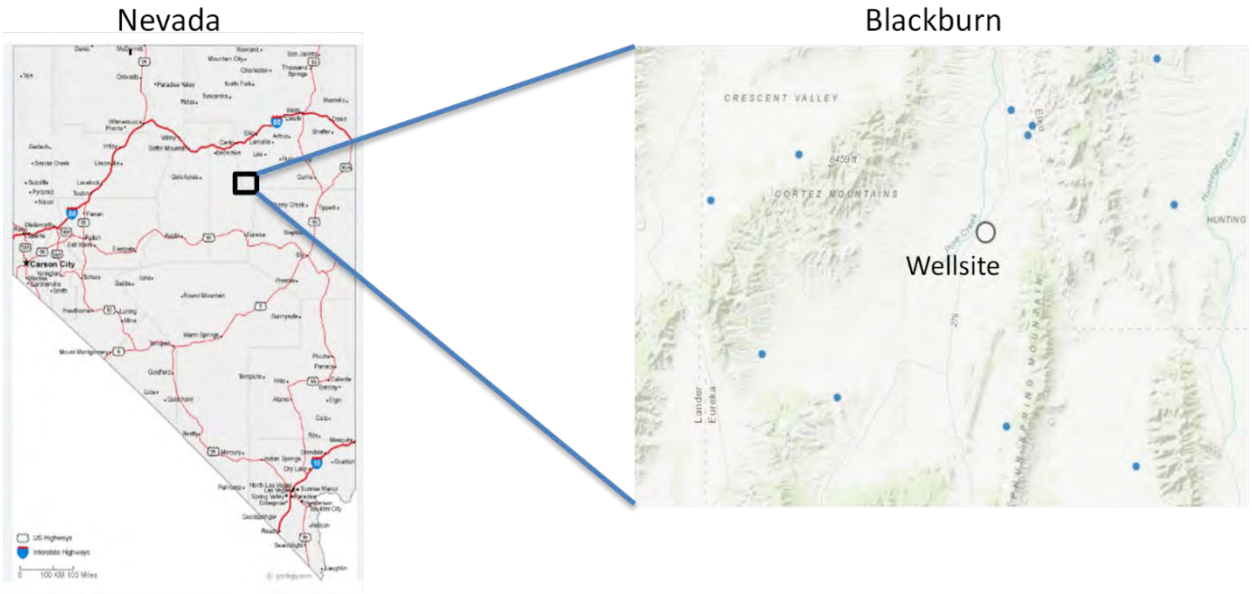

Figure 1 – Relative location of Blackburn field.

Figure 2 – Blackburn installed geothermal electricity generation equipment.

The geothermal pilot project commenced in May of 2022 and ran until March 2024 when the feasibility phase of the Wells of Opportunity project was completed. Simultaneous oil production and geothermal electricity generation was achieved throughout the project utilizing a fairly constant flow rate about 4200 BPD of produced water averaging between 93-104°C depending on where the take off point in the production stream was made. A custom and patent pending isolation heat exchanger (HXC) loop was engineered to protect the expensive ORC equipment from damage and contamination from the produced oil field waters. This HXC loop was run with a clean water and propylene glycol mixture to protect against freezing damage in colder times of the year. The entire system was remotely controlled and monitored through a 4G cellular network. In Figure 3 you can see the historical cumulative power production from a 75 kW nameplate capacity ORC from ElectraTherm. Of note is the slope of the line once continuous operations started in February 2023 versus the slope after October of that year. This lower power generation rate is due to re-piping the flow lines directly from the separator versus taking the output from the holding tank. The resulting average 11°C temperature drop is causing the lower power generation rate. The learning is that heat retention on surface is key to maximizing electricity output by placing the ORC equipment as close to the wellhead as possible if the necessary flow conditions can be attained by doing so.

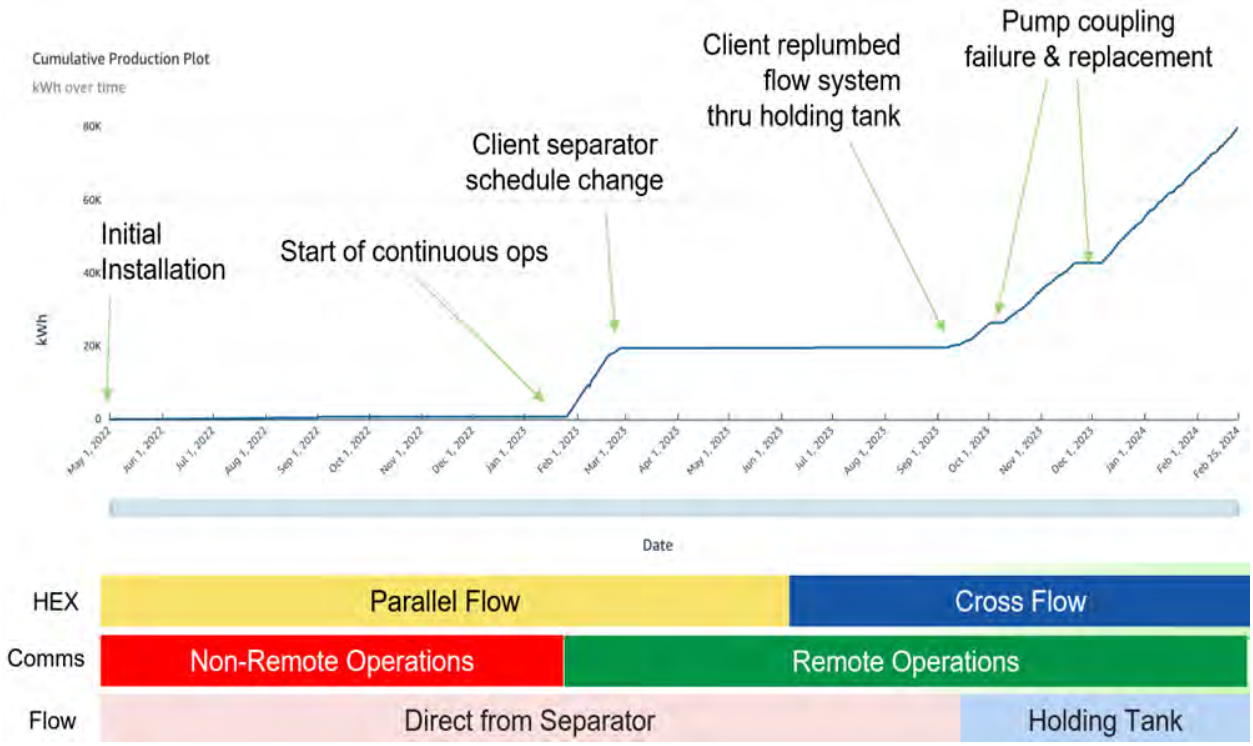

Figure 3 – Blackburn cumulative power production from feasibility phase.

Figure 4 demonstrates another important learning where the primary heat exchanger was modified from a parallel flow to a cross-flow orientation. As expected, the better heat transfer occurs when the HXC is plumbed in a cross-flow configuration. Contrary to many presentations, ORC's do in fact fluctuate in their power output when cooled using a dry air source. The geothermal heat source is almost constant from the organic heat flux within the earth and the gradual cooling of the reservoir at depth, but the mechanics of how the ORC works introduce sometimes substantial power output fluctuations. These changes cycle in both long term seasonal ambient temperature

changes from winter to summer seasons, but they also substantially fluctuate from hourly daytime and night-time ambient temperatures.

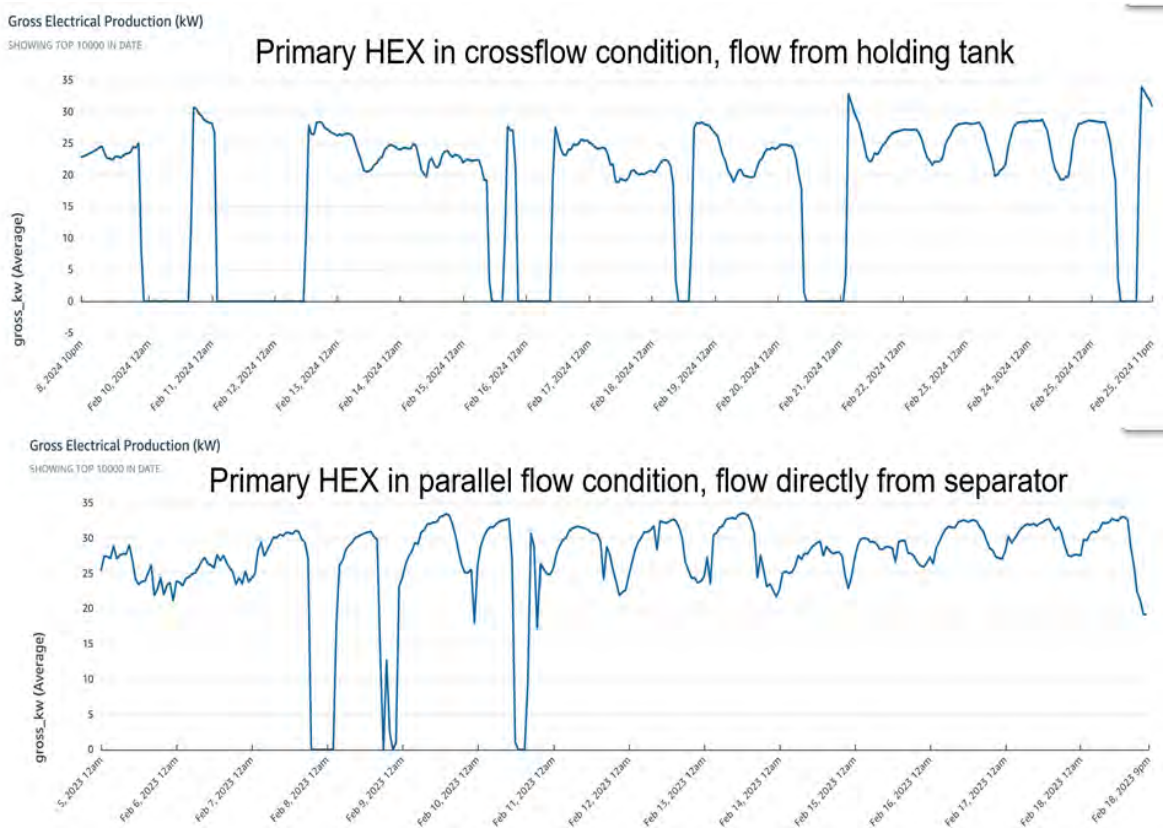

Figure 4 – Results of two simultaneous changes: HX plumbing from parallel to cross-flow, and change of heat source from separator to storage tank.

5. Effects of Ambient Temperature Variations on Modelled Output Power Generation

Using radiator cooling exploits the difference between the working fluid and ambient air temperatures to condense the working fluid to make it ready for the next power generation cycle. This is the most common cooling method utilized in ORC engines. This method has the convenience of allowing a modular and mobile solution for cooling and condensing the working fluid of the ORC. It has the disadvantage of high parasitic loads associated with the pumping and fan loads for the coolers. It also has the disadvantage of having strong seasonal and hourly variation in ambient temperatures. Figure 5, below, shows the seasonal variation in ambient temperature by month as well as the hourly temperature variation on a typical day. These variations cause ORC power output to also vary. Even with perfectly constant flow and hot water temperature, the ORC will have seasonal and hourly variation in power output for an air-cooled system. These variations need to be modeled on a case-by-case basis to accurately predict ORC system output throughout the day and over the course of months due to seasonal variation. In extreme cases the temperature swings can cause the ORC to shut down due to the fans no longer being able to cool and condense the working fluid. Output power can go to zero during the hottest portions of the day as shown in Figure 6. At higher latitudes the seasonal variation will be the dominant factor affecting ORC output variation. At lower latitudes, the hourly variation can often be the dominant factor affect

predicted ORC output variation. Each case needs to be modeled for reliable predictions of net power output from the ORC and the resulting project economics for the system.

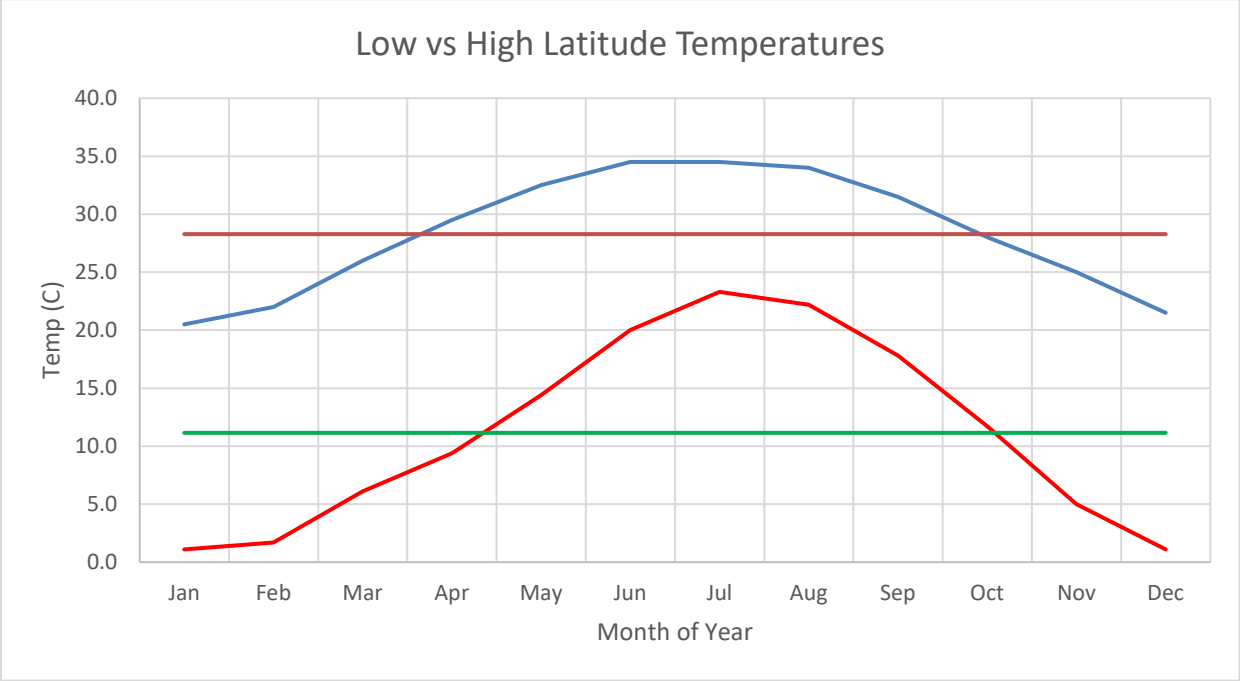

Figure 5 – Variation of seasonal and hourly temperatures at high and low latitudes.

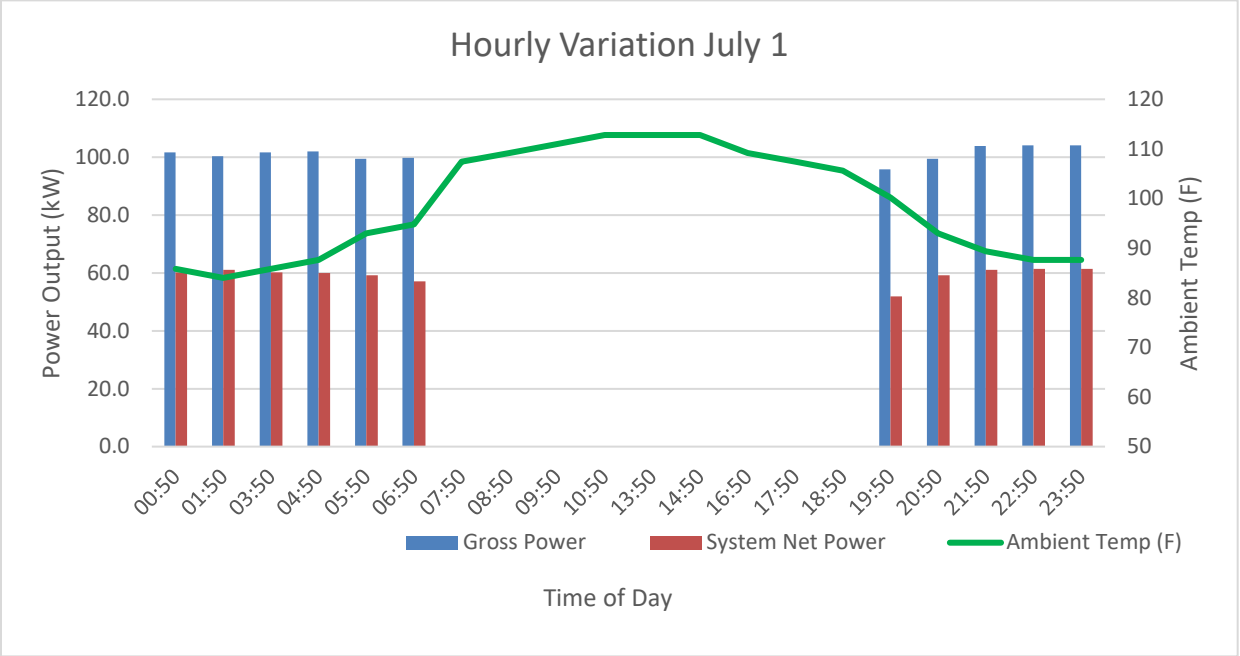

Figure 6 – Variation of seasonal and hourly temperatures at high and low latitudes.

6. Conclusions

Geothermal energy is one of the very best sources of non-carbon energy. The industry is in its infancy with many developments and improvements in store as it grows in the coming years. Virtually no forward-looking scenario of the growing energy demand is possible without a strong geothermal component as we look out 20, 30, or even 50 years into the future. The work force needs for the geothermal industry require skills and technologies from the oil and gas industry. It is reasonable to assume, much like in the case of cost reductions over time found in other renewable energy technologies, so too will geothermal energy development costs decline over time, especially in ORC design. With ORC's dependent upon ambient temperatures for air cooling of the working fluid, it is imperative to model both seasonal and hourly temperature variations to accurately forecast power output and project economics. The synergies gained by incorporating geothermal electricity generation capabilities to extract heat from existing oil and gas facilities is an obvious boost to lowering the hurdle rate for project economics. Generation near population centers also has the distinct advantage of being able to utilize the rejected ORC heat stream of slightly lower temperatures which are almost perfect for direct heating uses in communities or islanded industrial heating needs. As societal acceptance of these symbiotic approaches grows, and a much better full cycle use of the natural heat in the earth becomes commonplace, the future of geothermal in our future will be one of the most promising technologies and career paths over the next several decades.

Keywords

Flexible Geothermal Systems, Economic Modelling, huff-n-puff, EGS, Numerical Simulation, Sensitivity Analysis

ABSTRACT

Flexible energy resources are key for a reliable power supply in a decarbonized grid with a significant fraction of variable power source. Geothermal energy has always been an economic resource for baseload power and district heating. Recently, geothermal facilities have been expanding beyond baseload to supply flexible heat and electricity. Geothermal Energy can be harnessed through Enhanced Geothermal Systems (EGS). EGS involves creating an artificial reservoir by stimulating the natural permeability of hot rock formations beneath the Earth's surface. However, EGS may result in fast thermal depletion due to continuous fluid circulation. To slow down EGS thermal depletion due to continuous fluid circulation, we propose the Huff &Puff technique, which provides increased contact time between the injected working fluid and the hot geothermal rocks.

The primary objective of this work is to determine the technical and economic feasibility of harnessing geothermal energy from deep EGS using the huff-and-puff approach. To carry out these investigations, we use a 3-dimensional coupled thermo hydro mechanical numerical model to understand the system performance and the effect of different parameters on energy production. The outputs considered are wellhead temperature and production mass flow rates. Subsequently, we use a tool called FGEM, Flexible Geothermal Economics Modeling, to model the economics of EGS huff-n-puff systems.

The numerical simulation results show the feasibility of the huff-n-puff technique in EGS. The results from the economic modeling show that in the double well scenario, the Levelized Cost of Electricity (LCOE) for the huff-n-puff model is $0.40/KWh, slightly higher than the continuous model at $0.38/KWh. This is due to huff-n-puff's lower capacity factor from intermittent

production. However, huff-n-puff produces more cumulative water before thermal breakthrough, which occurs four times later than in the continuous model, supporting prolonged thermal storage feasibility. In contrast, the single well huff-n-puff model has a lower LCOE of $0.27/KWh, attributed to lower CAPEX and OPEX costs compared to the double well huff-n-puff model.

1. Introduction

Geothermal energy entails harnessing the heat from rocks beneath the Earth's surface to produce electricity (Barbier, 2002). In general, wells are drilled into the subsurface reservoir to extract hot fluids, with their application depending on the fluids' temperature and pressure: high-temperature fluids are primarily used for electricity generation, while low-temperature fluids are utilized for space heating and industrial processes (Barbier, 2002). Geothermal energy is unique among renewable energy sources because it is available continuously throughout the year, at any time of day, making it suitable for base load energy generation for both heat and power production (Agemar et al., 2014). Direct application of geothermal energy encompasses diverse uses like space heating and cooling, industrial processes, greenhouses, fish farming, and health spas. It relies on existing technology and basic engineering, utilizing both high- and low-temperature geothermal resources. The production cost for direct utilization varies but is often below US¢2/kWh (Fridleifsson, 2001). Despite statistics showing that geothermal energy contributes less to energy consumption than other low-carbon sources like solar, it offers several advantages that make it appealing for future energy development. These benefits include its consistency, significant untapped potential, widespread availability at depth, and a wide range of possible applications, especially where both power and heat are needed in varying proportions (Lund, 2000).

Despite these advantages, Michaelides (2016) reported that most of the world’s geothermal resources consist of low-temperature aquifers and hot dry rock resources, necessitating improved technologies for efficient power production from these sources. Additionally, a significant drawback is that these reservoirs can only be exploited for a limited time, until most of the contained fluid is extracted (Olasalo et al., 2016). These limitations have driven scientists to explore alternative solutions to mitigate the associated issues and ensure geothermal energy remains a viable and promising power source (Wong & Tan, 2015). The creation of artificial reservoirs has been proposed to decrease reliance on naturally occurring geothermal reservoirs. This alternative is known as "Enhanced Geothermal Systems" or EGS is an artificial reservoir constructed where the rock is hot, but there is insufficient fluid saturation and/or permeability in the rock (Okoroafor & Horne, 2024). Tester et al. (2006) led an interdisciplinary panel that defined EGS as "engineered reservoirs created to extract economical amounts of heat from geothermal resources with low permeability and/or porosity." For this assessment, this definition has been expanded to encompass all geothermal resources not currently in commercial production that require stimulation or enhancement (Breede et al., 2013).

One of the advantages of EGS over conventional geothermal reservoirs is that they can be harnessed in any location different from conventional hydrothermal geothermal locations. Despite being proposed as a viable solution, EGS still encounters significant challenges, such as requiring large contact time and contact area between the injected fluid and hot rock formations in continuous EGS operations (Okoroafor et al., 2022a). This drawback can result in slower heat transfer rates (Isaka et al., 2019). Advances in heat extraction strategies from geothermal rocks are crucial to meet increasing demand. Therefore, we consider the Huff & Puff technique as a possible

system for enhancing the contact time of injected working fluid with hot geothermal rocks and enabling higher cumulative heat extraction from the subsurface (Merzoug et al., 2023). In EGS, the Huff-n-Puff technique involves injecting a working fluid into wells, allowing it to soak for several days to enhance contact with hot rock formations. This process increases the fluid's temperature before resuming production, similar to its use in oil and gas recovery to optimize heat extraction (Isaka et al., 2019; Milad et al., 2021).

Assessing the feasibility of utilizing EGS with the huff-and-puff approach is essential for advancing and expanding this technique in future applications. Previous research on using the huff-and-puff technique in EGS is limited but promising. Recent studies on huff-and-puff EGS show advancements in thermal power extraction and optimization strategies, emphasizing factors like well spacing, fracture numbers, and operational parameters (Orzol et al., 2005; Tischner et al., 2010; Merzoug et al., 2023; Gudala et al., 2021 & Wu et al., 2023). Our study assessed the technical feasibility through numerical simulation, which replicated the subsurface EGS and implemented the Huff-n-Puff technique. In addition, the operational parameters are varied, and its impact is analyzed. This approach allowed for a comprehensive evaluation of the system's performance under varying conditions. The main parameter varied in this study is the number of wells drilled.

According to Lowry et al. (2014), the economic evaluation of EGS emphasizes that the Levelized Cost of Electricity (LCOE) is significantly influenced by pumping requirements. Therefore, determining economic feasibility is crucial for successful implementation alongside assessing technical feasibility. This dual evaluation ensures that EGS projects are both technically viable and economically sustainable. Thus, the primary objective of this work is to determine the feasibility of harnessing geothermal energy from EGS using the huff-and-puff approach both technically and economically.

Available software tools for evaluating geothermal power techno-economics include GETEM by Idaho National Lab, GEOPHIRES by NREL, and Hot Dry Rock economic by GTC Kappelmeyer GmbH. General-purpose tools such as PLEXOS, EnergyPLAN, GenX, and HOMER Energy are also utilized but are primarily designed for baseload geothermal projects and lack capabilities for modeling flexible geothermal operations (Aljubran & Horne, 2024). Hence, in our work for the economic feasibility analysis, we employed FGEM (Flexible Geothermal Economics Modeling), a specialized tool tailored for techno-economic assessments in flexible geothermal power generation. By applying FGEM, we conducted detailed economic modeling to optimize EGS Huff-n-Puff systems, ensuring that both technical and economic aspects were rigorously evaluated for feasibility.

2. Methodology

To determine the technical and economic feasibility of EGS huff-and-puff, we first used a 3-dimensional coupled thermo hydro mechanical (THM) numerical model to understand the system performance and the effect of different parameters on energy production. The outputs considered were wellhead temperature and production mass flow rates. The base case model had a top depth of 1200 meters and a reservoir temperature of 250°C with a single well used for both injection and production. We then compared the results of three different scenarios:

- **Single well Huff n Puff:** This strategy involves injecting fluid into the well and then allowing the well to rest before production.
- **Two well Huff n Puff:** Similar to the single well case, but here we have two wells, one for injection and one for production.
- **Two well continuous:** In this case, fluid constantly circulates between the two wells, continuously extracting heat.

For economics we used FGEM, Flexible Geothermal Economics Modeling, which is specifically designed for the techno-economic analysis of flexible geothermal power generation. We applied this tool to determine the economic viability of the huff-n-puff technique and further to optimize EGS huff-n-puff systems. The outputs from the FGEM tool include the Levelized Cost of Electricity (LCOE), Net Present Value (NPV), and payback period.

2.1 Numerical Model

The numerical model encompasses a reservoir with dimensions of 2000 feet in the x-direction, 300 feet in the y-direction, and 4000 feet in the z-direction. This model features a single horizontal well which is used as an injector and a producer. The base case scenario incorporates hydraulic fracturing by injecting slick water with a viscosity of 13.25 centipoise (cp) at surface temperature and 1.5 cp at reservoir temperature. This slick water carries a 100-mesh proppant and is injected at a rate of 80 barrels per minute (bpm). The fracturing schedule is divided into two phases: a fracturing phase and a production phase. In the base model, the fracturing phase lasts for 3.85 hours, followed by a shut-in period for the injection wells, amounting to a total of four days. Figure 1 illustrates the three-dimensional reservoir model, highlighting the fracture network and its distribution around the injection/production wells. The detailed model parameters and properties of the injected fluid are presented in Table 1. The reservoir model was assumed to be homogeneous with constant properties across the whole grid.

Table 1. Numerical model and injected fluid properties.

Parameter	Values
Model Parameters	
Model Size	2000*300 ft
Thickness	4000 ft
Reservoir Pressure	7250 psi
Reservoir Temperature	480 ^{o}F
Surface Temperature	60 ^{o}F
Well Depth	16400 ft
Heat transfer coefficient	9 BTU/(ft^2-hr)
Injected Fluid properties	
Fluid type	Water
Temperature	116 ^{o}F

The injection, soaking, and production schedule are detailed in Table 2. The injection and production scenarios are simulated under specific constraints. The rate constraint dictates that the maximum injection rate during the fracturing cycle is 80 barrels per minute (bpm), and during the injection cycle, it is 30 bpm. The wellhead pressure constraint stipulates that production must be maintained at a minimum pressure of 600 psi during both the fracturing and injection phases. This

wellhead pressure constraint effectively controls the bottomhole pressure and the wellhead production rate of the injected fluid. Following the establishment of the model as described, Huff 'n' Puff technique is implemented.

Table 2. Injection and Production Schedule

Phase	Process	Days
Fracturing cycle	Fracturing fluid injection	0.135
	Shut in	3.865
	Production	6
Huff n Puff Cycle 1	Injection Cycle – 1	10
	Soaking -1	5
	Production Cycle – 1	10
Huff n Puff Cycle 2	Injection Cycle – 1	10
	Soaking -1	5
	Production Cycle – 1	10

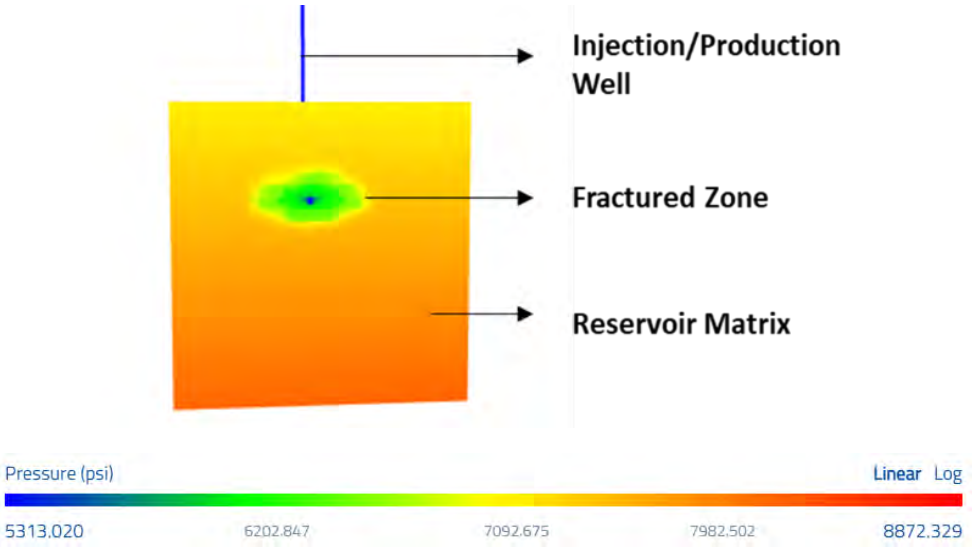

Figure 1: 3-Dimensional model showing the pressure after injection around the injection/production well

2.2 Numerical Model Validation

This study uses a coupled reservoir and fracture modelling simulator to replicate the subsurface enhanced geothermal system. To establish the suitability of the simulator for this study, we first validated the simulator results with already validated literature data. For the study validation, we used numerical simulation results from Okoroafor et al., 2022b. Fox et al., 2015 built a discretely fractured geothermal reservoir through a semi-analytical approach to study the effect of spatial aperture variations on EGS thermal performance. The model was developed by utilizing a hybrid method, including the finite element method for fracture to rock coupling and the boundary element method between the bulk rock. Okoroafor et al., 2022b modified and validated the work by Fox et al., 2021 for a square-shaped geothermal reservoir model to study the impact of fracture aperture anisotropy on EGS thermal performance using a commercial simulator (ECLIPSE E300).

In our validation study as a first step, we built the same reservoir model built by Okoroafor et al., 2022b and matched the bottomhole temperature from both models with a good degree of accuracy. The reservoir had a dimension of 50*50*45, grid cell counts of 112500, and a very thin fracture at a depth of 1295.5 m is considered. In the ECLIPSE model the fracture was initialized as a very thin layer with a thickness of 0.01 m. The temperature distribution in the fracture (X-Y) plane by Commercial simulator and Coupled fracturing Simulator is shown in Figure 2. Also, the graph showing the bottomhole temperature trend from commercial and coupled Hydraulic fracturing simulator is shown in Figure 3. The coupled Hydraulic fracturing simulator has the capability to integrate hydraulic fracturing and reservoir simulation into a single, unified model.

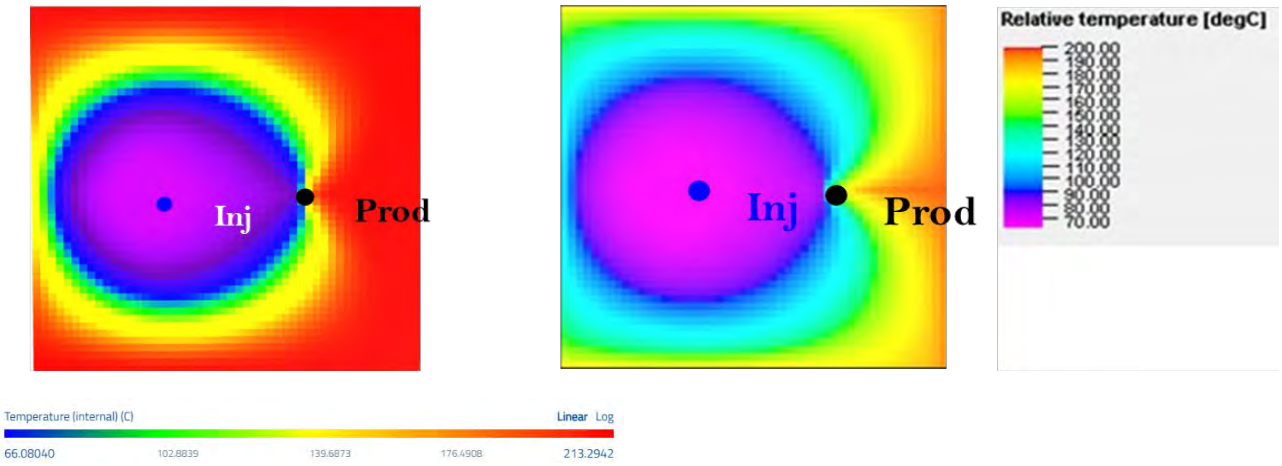

Figure 2: Temperature distribution in the fracture (X-Y) plane by Commercial simulator (right) and Coupled fracturing Simulator (left)

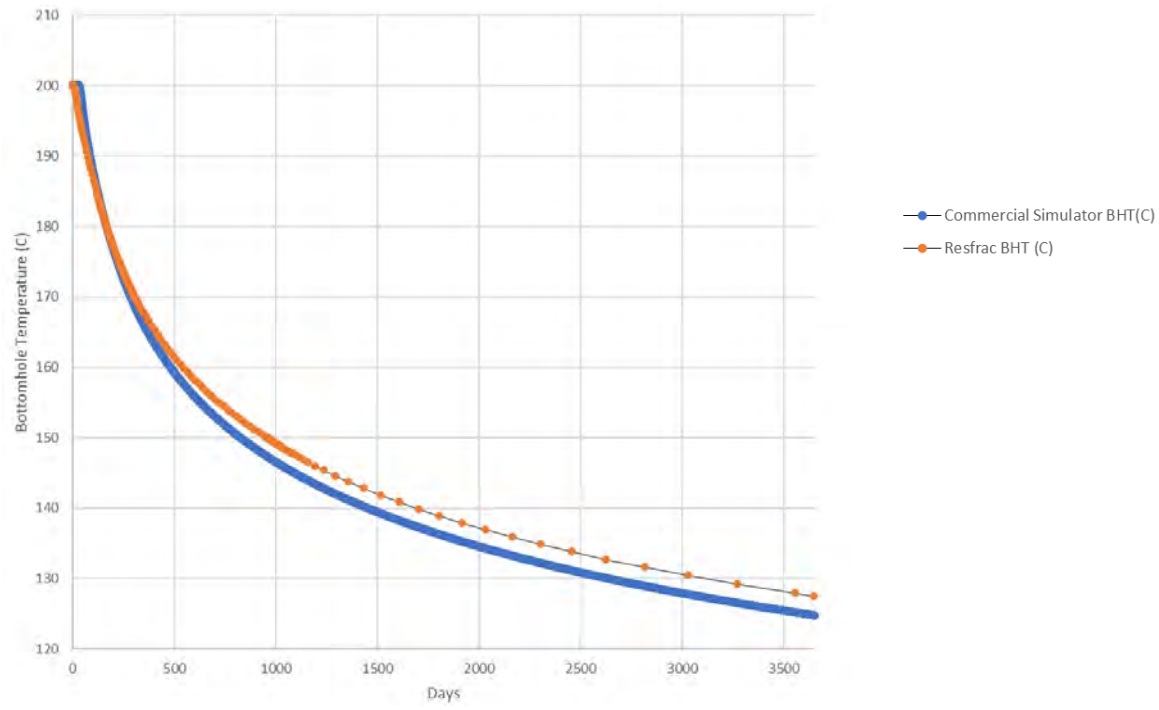

Figure 3: Graph showing the bottomhole temperature trend from commercial and coupled Hydraulic fracturing simulator

2.3 Sensitivity Analysis

After constructing and validating the numerical model, the optimal time of post-fracturing production is determined through a comprehensive sensitivity analysis. And in this study, for the injection, soaking and production schedule the values from Merzoug et al. (2023) and Sekar & Okoroafor (2024) were used. Studies have indicated that an optimal injection time of 10 days was most effective; five days were deemed too short to extract sufficient heat, while 15 days reduced injection and production rates due to storage volume saturation (Merzoug et al., 2023). Also, Sekar & Okoroafor (2024) determined the optimum soaking and production time to be 5 days and 10 days respectively. Subsequently, we compared the outcomes of single and double well huff-n-puff models to evaluate the technical feasibility of the huff-n-puff method in EGS.

2.4 Economic Feasibility Analysis through FGEM Flexible Geothermal Economic Modelling

After determining the technical and operational feasibility of the huff-n-puff technique, we used the open-source tool called FGEM (Aljubran & Horne, 2024). FGEM incorporates various parameters, including resource assessment, plant design, operational strategies, and market dynamics, to provide a comprehensive analysis of the economic viability of geothermal systems. FGEM requires three primary inputs: a configuration file in .json format, data files in .csv format, and a dispatch strategy implemented in Python code. These inputs collectively integrate detailed information on subsurface reservoir properties, power plant operations, and weather conditions. Table 3 presents the major input parameters used in the config. json configuration file for this case study. To accurately capture the dynamics of battery costs, weather patterns, wholesale energy prices users must provide the corresponding data files: battery.csv, weather.csv, wholesale.csv, and capacity.csv. These inputs regarding the reservoir, power plant and the weather are then validated and used to initiate the simulation run. Since our primary objective is to compare the continuous and Huff n Puff techniques for the double and single well type well configuration, we only changed the production temperature and mass flow rate while importing the data as a csv file (Aljubran & Horne, 2024).

2.4.1 Subsurface reservoir

FGEM seamlessly interfaces with numerical models like TOUGH2 and DARTS. It also allows for importing simulated reservoir outputs, such as wellhead temperature and mass flow rate stored in CSV files, to conduct comprehensive techno-economic evaluations (Aljubran & Horne, 2024). In our study, we will import our mass flow rates and wellhead temperature in the form of .csv files.

2.4.2 Weather

In this study for our economic modeling, we input one year of weather data and assume these patterns repeat annually over the project's lifetime.

2.4.3 Power Plant

The power plant component considers parameters like efficiency and reinjection water temperature, influenced by factors such as the power plant type (e.g., subcritical organic Rankine cycle (ORC) or single flash), entering geofluid temperature, and ambient conditions. Overall, this integrated approach with FGEM enables a thorough assessment of both the technical and economic

feasibility of implementing the huff-n-puff technique in EGS, leveraging detailed input parameters and sophisticated modeling capabilities.

Table 3. Major input parameters used in the config.json file for the double well case.

Metadata			
Initial Time	2024–01–01	State	Nevada
Economics			
Lifetime	25 $years$	Grid	130 $/kW
Discount	0.07	ITC	0.3
Inflation	0.02	TES	1434.53 $/m3
OPEX escalation	0.0	Battery	battery.csv
Downstream			
Plant type	Binary	Weather	weather.csv
PPC	12 MW	Wholesale	Wholesale.csv
CF	0.95	Capacity	Capacity.csv
Upstream			
Reservoir	Energy Decline	PRD count	1
Tr (0)	215 ◦ C	PRD-INJ ratio	1
Pr (0)	40 bars	Water loss	0%
Vr	5 km3	Pump efficiency	0.75
$Tsurf$	20 ◦ C	DSR	0.9
$Hwell$	1325 m	PI/II	20/20 kg/s/bar
$Dprd$	0.2159 m	$Dinj$	0.2159 m

Upon the end of the simulated project lifetime, records are stored, economics are computed, and various quantities are visualized. The visualized quantities include production temperature, mass flow rate and the net power generation (kWh) respectively. The outputs from the FGEM tool include the Levelized Cost of Electricity (LCOE), Net Present Value (NPV), and payback period.

3. Results and Discussions

We have conducted comprehensive simulations for single well huff-n-puff technique, focusing on their effectiveness in enhancing the temperature of the produced fluid through increased contact time of injected fluids. Initially, observations indicated that increased contact time could lead to higher temperatures in the produced fluid. By understanding the interplay between these parameters and their impact on the system's performance, we can ensure that the methods are not only technically sound but also ready for subsequent economic evaluation.

3.1 Determining the optimum post-fracturing production time

During the initial modeling phase, we observed that higher injection pressures result in greater vertical fracture propagation. On the other hand, reducing the injection pressure constraint led to model failure due to inadequate injection pressure, as illustrated in Figure 4. Prior to advancing the model development, we analyzed fracture propagation and discovered that a significant pressure decline post-fracturing mitigates the fracture propagation issue. Identifying the optimal production time post-fracturing is essential for managing fracture propagation and ensuring the required fluid injection volume. Sensitivity studies on the post-fracturing production period revealed that a production period of 6 days assists in pressure decline. This strategy stabilizes bottom hole pressure and effectively addresses fracture propagation challenges.

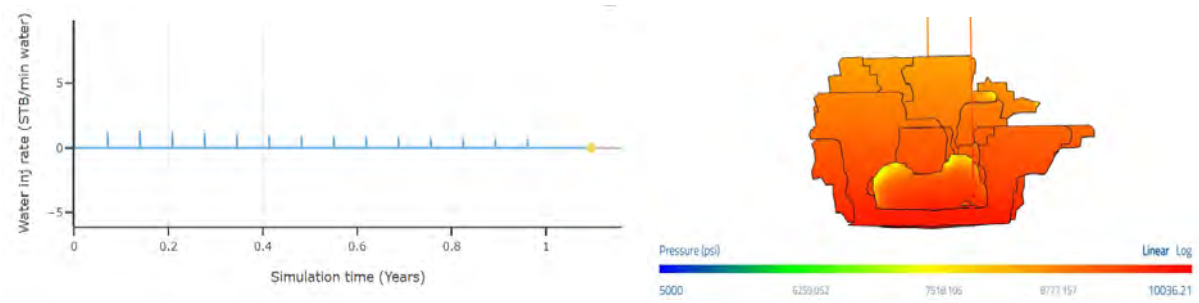

Figure 4: Figure showing the failed injection and higher fracture propagation issues

3.2 Determining the feasibility of single well Huff n Puff technique

Sekar and Okoroafor. (2024) compared the double well continuous and huff-n-puff long-term model and found that in the continuous model, the temperature declined from 475 to 375 ^{o}F and later it maintains the temperature around 375 ^{o}F for the next few years. But in the Huff n Puff case this decline is negligible. This is shown in Figure 5. These preliminary results prove the feasibility of huff-n-puff technique in EGS.

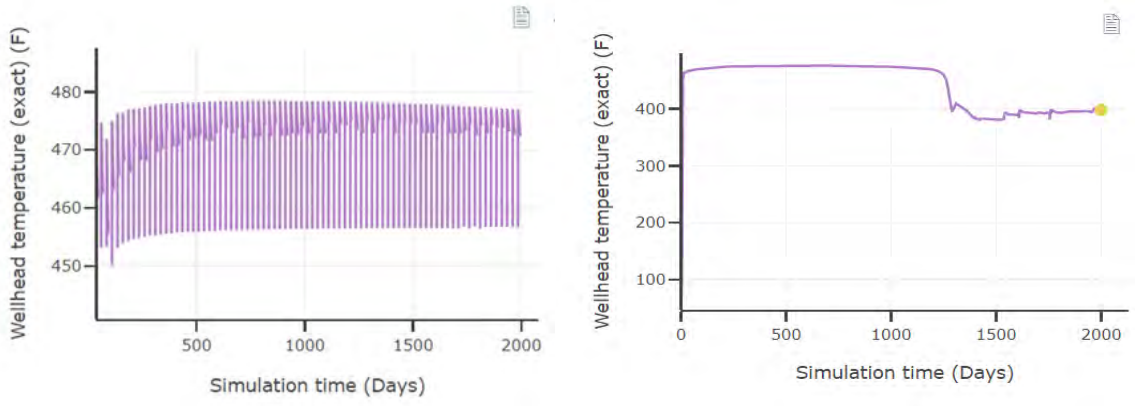

Figure 5: Comparison between the wellhead temperature of continuous (right) and Huff and Puff (left) Systems (Sekar & Okoroafor. 2024)

After simulating the single-well Huff n Puff models, we compared our results with the double-well huff-n-puff case by Sekar & Okoroafor (2024). The single well case shows a rapid decrease in the temperature and energy content (enthalpy) of the fluid coming out of the well (Figure 6). Also, our findings indicated that the average temperature values for the huff-n-puff technique in single wells is lower than that of double-well huff-n-puff. Even with a faster temperature decline, the CAPEX and OPEX values of single well case are anticipated to be less than that of the double well case. Thus, to demonstrate this fact and to identify the LCOE of the electricity generated, our next part of the study includes the economic analysis study using FGEM for all three cases, including the single and double well huff-n-puff models and double well continuous model.

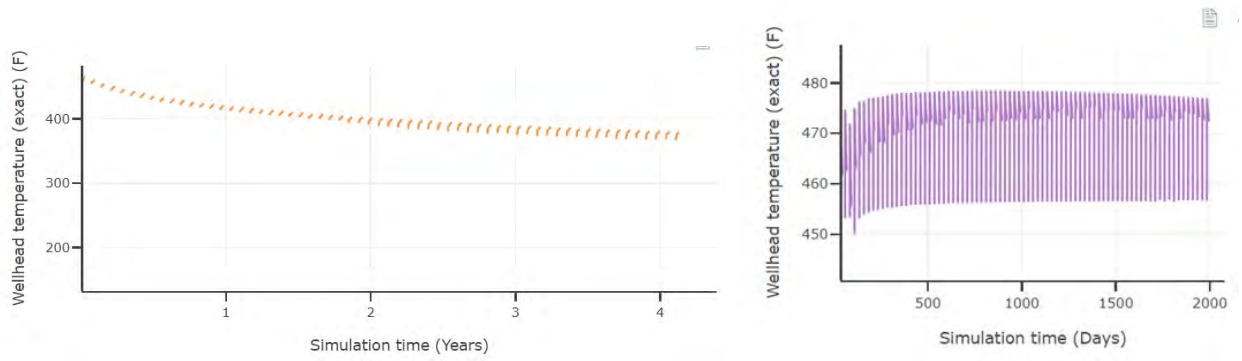

Figure 6: Comparison between the wellhead temperature of single well huff-n-puff (left) Systems and two well huff-n-puff (Sekar & Okoroafor. 2024) systems

3.3 Determining the economic feasibility of Huff n Puff technique

This study compares the double well continuous and huff-n-puff EGS models and the single well Huff-n-Puff model to determine the economic viability of the Huff-n-Puff technique and quantify its benefits over continuous extraction methods using a tool developed by Aljubran & Horne. (2024). We specifically demonstrate the application of FGEM (Flexible Geothermal Economics Modeling) to evaluate the techno-economic aspects of our simulated model, utilizing data from the Ormat Desert Peak II power plant located in Churchill County, Nevada. Post-economic modeling the wellhead temperature, thermal breakthrough time & LCOE for all three scenarios are tabulated in Table 4.

Table 4. Wellhead temperature, thermal breakthrough time & LCOE for different well count and injection scenarios.

Well Count & Injection Scenerio	Wellhead Temperature (°F) after 4 years	Thermal breakthrough time (days)	Levelized Cost of Electricity (dollars/KWh)
Double well continuous	375	1200	0.38
Double well huff-n-puff	475	4380	0.40
Single well huff-n-puff	390	1350	0.27

For the double well case, the Levelized Cost of Electricity (LCOE) for the Huff n Puff model (0.4 dollars/KWh) was higher than that of the continuous model (0.38 dollars/KWh). This slightly higher LCOE for the Huff n Puff technique is expected to be due to its intermittent production. Also, the single well huff and Puff showed an LCOE of 0.27 dollars/KWh. The low LCOE of single well huff-n-puff is anticipated to be due to the lower CAPEX cost for developing single well and the lower OPEX cost associated with it.

4. Conclusion

This study demonstrates the potential of the huff-n-puff technique to optimize energy extraction in EGS. The numerical simulation studies showed that the huff-n-puff approach showed superior heat extraction capabilities and maintained higher wellhead temperatures compared to continuous extraction, indicating its feasibility for sustainable geothermal energy production. Economic evaluations also highlighted the technique's viability, suggesting it could significantly improve the efficiency and longevity of EGS, thus contributing to a more reliable and flexible renewable energy

supply. The higher LCOE for the huff-n-puff technique is expected to be due to the lower capacity factor of huff-n-puff technique because of its intermittent production. Despite the slightly higher LCOE, the cumulative water produced before thermal breakthrough in the huff-n-puff technique was greater than in the continuous model. Additionally, the time for thermal breakthrough in the huff-n-puff model is four times longer than in the continuous model, ensuring the feasibility of prolonged thermal storage. The low LCOE of single well huff-n-puff is anticipated to be due to the lower CAPEX cost for developing single well and the lower OPEX cost associated with it. Economic modeling also proves the feasibility of huff-n-puff technique in EGS. Although this method may not supply continuous geothermal energy, it offers a viable option for heat storage and extended direct utilization. These insights represent a significant step towards the more efficient exploitation of geothermal resources, ultimately enhancing the overall energy recovery process in tight EGS reservoirs.
